We dedicate this book to our families:
To my wife, Susan Crisp; my children, Justin and Mary;
my parents, Robert and Sandy; and my brother, Thomas.
(SJB)
To my wife, Sherrie, and my son, Cameron.
(RGS)

Contributors

Nancy L. Anderson, DVM, PhD, ABUPC (Avian)
Director of Wildlife Services, Lindsay Wildlife Museum, Walnut Creek, California
Pet Rodents
Basic Husbandry and Medicine of Pet Reptiles

Francisco J. Alvarez, DVM
Chief Resident, Clinical Oncology Service, Veterinary Medical Teaching Hospital, Department of Veterinary Clinical Services, The Ohio State University, Columbus, Ohio
Respiratory Neoplasia

Laura J. Armbrust, DVM, Diplomate ACVR
Assistant Professor, Radiology, Clinical Sciences, Kansas State University College of Veterinary Medicine, Manhattan, Kansas
Radiographic and Ultrasonographic Techniques

Dennis N. Aron, DVM, Diplomate ACVS
Professor, Small Animal Surgery, Department of Small Animal Medicine, College of Veterinary Medicine, University of Georgia, Athens, Georgia
Luxation, Subluxation, and Shearing Injuries of the Tarsal Joint

Shane W. Bateman, DVM, DVSc, Diplomate ACVECC
Associate Professor-Clinical, Head of Emergency and Critical Care, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Emergency and Critical Care Techniques and Nutrition
Fluid Therapy for Dogs and Cats

Karin Muth Beale, DVM, Diplomate ACVD
Staff Dermatologist, Gulf Coast Veterinary Specialists, Houston, Texas
Dermatology Consultant, ANTECH Diagnostics, Irvine, California
Dermatophytosis

Richard M. Bednarski, DVM, MS, Diplomate ACVA
Associate Professor of Anesthesiology, Hospital Director, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Pain Management in the Surgical Patient

Jamie R. Bellah, DVM, Diplomate ACVS
Staff Surgeon, Affiliated Veterinary Specialists, Orange Park, Florida
Surgery of Intertriginous Dermatoses

Larry Berkwitt, DVM, Diplomate ACVIM
Chief of Staff, Internal Medicine, Veterinary Referral and Emergency Center, Norwalk, Connecticut
Diagnostic Methods in Respiratory Disease

Sonya V. Bettenay, BVSC (Hons), FACVSc (Dermatology), Diplomate ECVD
Dermatopathology, Laboklin, Munich, Germany
Skin Cytology and Biopsy

David S. Biller, DVM, Diplomate ACVR
Professor and Head of Radiology, Department of Clinical Sciences, College of Veterinary Medicine, Kansas State University, Manhattan, Kansas
Radiographic and Ultrasonographic Techniques

Stephen J. Birchard, DVM, MS, Diplomate ACVS
Associate Professor, Small Animal Surgery, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Diseases of the Thyroid Gland
Selected Skin Graft and Reconstructive Techniques
Surgery of the Liver and Biliary Tract
Diseases and Surgery of the Exocrine Pancreas
Peritonitis
Pleural Effusion
Principles of Thoracic Surgery

Dale E. Bjorling, DVM, MS Diplomate ACVS
Professor and Chair, Surgical Sciences, Affiliate Professor, Division of Urology, Department of Surgery, School of Veterinary Medicine, University of Wisconsin, Madison, Wisconsin
Surgery of the Kidney and Ureter
Surgery of the Urethra
Thoracic Trauma

Mark W. Bohling, DVM
Resident, Small Animal Surgery, Department of Clinical Sciences, Auburn University, Auburn, Alabama
Management of the Traumatic Wound by Primary Closure

John D. Bonagura, DVM, MS, Diplomate ACVIM (Internal Medicine, Cardiology)
Professor, Cardiology and Internal Medicine, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Cardiovascular Radiography
Cardiovascular Drugs
Heart Failure in Dogs
Syncope
Valvular Heart Disease
Cardiomyopathy
Pericardial Diseases
Vascular Diseases
Congenital Heart Disease
Respiratory Infections

Jennifer Bonczynski, DVM, Diplomate ACVS
Staff Surgeon, Department of Surgery, The Animal Medical Center, New York, New York
Pancreatic Beta Cell Neoplasia

Harry W. Boothe, DVM, MS
Professor, Small Animal Surgery, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, Alabama
Surgery for Otitis Media and Otitis Interna
Surgery of the Prostate Gland
Surgery of the Testes and Scrotum
Surgery of the Penis and Prepuce

Randy J. Boudrieau, DVM, Diplomate ACVS
Professor, Surgery, Clinical Sciences, Tufts University School of Veterinary Medicine, North Grafton, Massachusetts
Section Head, Small Animal Surgery, Henry & Lois Foster Hospital for Small Animals, North Grafton, Massachusetts
Delayed Union, Nonunion, and Malunion

Heather L. Bowles, DVM, Diplomate ABVP
Fallston Veterinary Clinic, Fallston, Maryland
Avian Reproductive Tract Disorders

Ronald M. Bright, DVM, MS, Diplomate ACVS
Affiliate Professor, Department of Clinical Sciences, College of Veterinary Medicine, Colorado State University
Staff Surgeon, Surgical Referral Services, Fort Collins, Colorado
Staff Surgeon, Veterinary Consultation Services, Inc., Knoxville, Tennessee
Surgery of the Esophagus
Diseases of the Stomach
Surgery of the Stomach
Surgery of the Intestines
Anorectal Surgery

Marjory B. Brooks, DVM, Diplomate ACVIM
Associate Director, Comparative Coagulation Laboratory, Animal Health Diagnostic Center, Population Medicine and Diagnostic Science, College of Veterinary Medicine, Cornell University
Ithaca, New York
Coagulation Diseases

Steven C. Budsberg, DVM, MS, Diplomate ACVS
Professor, Department of Small Animal Medicine and Surgery, University of Georgia, Athens, Georgia
Orthopedic Disorders of the Distal Extremities

C. Anthony Buffington, DVM, PhD, Diplomate ACVN
Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University, Columbus, Ohio
Emergency and Critical Care Techniques and Nutrition

Clay A. Calvert, DVM, Diplomate ACVIM
Professor, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, University of Georgia, Athens, Georgia
Heartworm Disease

Marcia A. Carothers, DVM, Diplomate ACVIM (Internal Medicine)
Staff Veterinarian, Akron Veterinary Referral and Emergency Center, Akron, Ohio
Respiratory Neoplasia

Sue Chen, DVM
Gulf Coast Veterinary Specialists, Houston, Texas
Avian Reproductive Tract Disorders
Rabbits

Dennis J. Chew, DVM, Diplomate ACVIM
Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University, Columbus, Ohio
Fluid Therapy for Dogs and Cats
Diseases of the Parathyroid Gland and Calcium Metabolism
Diseases of the Urinary Bladder

Lynette K. Cole, DVM, MS, Diplomate ACVD
Assistant Professor, Dermatology, College of Veterinary Medicine, Veterinary Teaching Hospital, The Ohio State University, Columbus, Ohio
Diseases of the Pinna
Otitis Media and Otitis Interna

Carmen M. H. Colitz, DVM, PhD, Diplomate ACVO
Assistant Professor, Ophthalmology, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Diseases of the Lacrimal System

Sarah Colombini Osborn, DVM, MS, Diplomate ACVD
Co-Owner, Dermatology, Gulf Coast Veterinary Dermatology & Allergy, Houston, Texas
Consultant, Dermatopathology/Dermatology, Antech Diagnostics, Phoenix, Arizona
Canine and Feline Demodicosis

Paul A. Cuddon, DVM, Diplomate ACVIM (Neurology)
Neurological Center for Animals, Lakewood, Colorado
Disorders of the Spinal Cord

Támara M. Costa-Gómez, DVM

Assistant Professor and Staff Oncologist, Iowa State University, Ames, Iowa
Soft Tissue Sarcomas and Mast Cell Tumors

David Grant, DVM, MS, Diplomate ACVIM (Small Animal Internal Medicine)
Clinical Instructor, Department of Small Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, Virginia
Diseases of the Kidney and Ureter

Thomas K. Graves, DVM, PhD, Diplomate ACVIM
Assistant Professor, Small Animal Medicine, Veterinary Clinical Medicine, University of Illinois, Urbana, Illinois
Diseases of the Testes and Scrotum
Diseases of the Penis and Prepuce
Diseases of the Ovaries and Uterus

Deborah S. Greco, DVM, PhD
Staff Internist and Endocrinologist, Department of Medicine, The Animal Medical Center, New York, New York
Diabetes Mellitus

Henry W. Green, III, DVM, Diplomate ACVIM (Cardiology)
Assistant Professor, Department of Veterinary Clinical Sciences, Purdue University School of Veterinary Medicine, West Lafayette, Indiana
Congenital Heart Disease

Tia B. Greenberg, DVM
Westminster Veterinary Group, Westminster, California
Avian Dermatology

Craig E. Griffin, DVM, Diplomate ACVD
Partner, Clinician, Animal Dermatology Clinic, San Diego and Garden Grove, California
Flea Allergy Dermatitis

Amy M. Grooters, DVM, Diplomate ACVIM
Associate Professor and Chief, Companion Animal Medicine, Veterinary Clinical Sciences, School of Veterinary Medicine, Louisiana State University, Baton Rouge, Louisiana
Deep Fungal Infections

Robert L. Hamlin, DVM, PhD, Diplomate ACVIM (Cardiology)
Professor, Veterinary Biosciences and Biomedical Engineering, The Ohio State University, Columbus, Ohio
Auscultation and Physical Diagnosis

Don J. Harris, DVM
Owner and Director, Avian and Exotic Animal Medical Center, Miami, Florida
Avian Infectious Diseases

Callum W. Hay, BVMS, Diplomate ACVS
President, Veterinary Surgical Services, Inc., Tampa, Florida
Osteomyelitis
Osteoarthritis
Immune-Mediated Arthritis

Cheryl S. Hedlund, DVM, MS, Diplomate ACVS
Professor, Surgery, Veterinary Clinical Sciences, School of Veterinary Medicine, Louisiana State University, Baton Rouge, Louisiana
Surgery of the Nasal Cavity and Sinuses

Karen Helton-Rhodes, DVM, Diplomate ACVD
Veterinary Referral Centre, Little Falls, New Jersey
Immune-Mediated Dermatoses

Andrew Hillier, BVSc
Associate Professor, Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Mycobacteriosis
Scabies, Notoedric Mange, and Cheyletiellosis
Atopic Dermatitis
Feline Symmetrical Alopecia

Cheryl Holloway, RVT
Animal Health Technician, College of Veterinary Medicine, The Ohio State University, Columbus, Ohio
Emergency and Critical Care Techniques and Nutrition

Robert V. Hitchinson, DVM
Co-director, Animal Clinic Northview, Inc., North Ridgeville, Ohio
Infertility and Breeding Disorders

John A. E. Hubbell, DVM, MS, Diplomate ACVA
Professor, Department of Veterinary Clinical Sciences, The College of Veterinary Medicine, The Ohio State University, Columbus, Ohio
Practical Methods of Anesthesia

Richard M. Jerram, BVSc, Diplomate ACVS
Specialist, Small Animal Surgery, Veterinary Specialist Group, Auckland, New Zealand
Fractures and Dislocations of the Mandible
Fractures of the Maxilla

Lynelle R. Johnson, DVM, PhD, Diplomate ACVIM (Small Animal Internal Medicine)
Assistant Professor, VM: Medicine & Epidemiology, University of California, Davis, California
Bronchopulmonary Disease

Susan E. Johnson, DVM, MS, Diplomate ACVIM (Internal Medicine)
Associate Professor, Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Diseases of the Esophagus and Disorders of Swallowing
Diseases of the Stomach
Diseases of the Intestines
Diseases of the Liver and Biliary Tract
Diseases and Surgery of the Exocrine Pancreas

Matthew S. Johnston, VMD, DABVP (Avian)
Assistant Professor, Zoological Medicine, Clinical Sciences, Colorado State University, Fort Collins, Colorado
Avian Respiratory System Disorders

Denise Jones, DVM, BS
Partner and Staff Veterinarian, Findlay Animal Hospital, Findlay, Ohio
History and Physical Examination

Nancy D. Kay, DVM, Diplomate ACVIM
Staff Internist, Animal Care Center of Sonoma County, Rohnert Park, California
Diseases of the Prostate Gland

Bruce W. Keene, DVM, MSc, Diplomate ACVIM (Cardiology)
Professor, Cardiology, Department of Clinical Sciences, North Carolina State University, Raleigh, North Carolina
Heart Failure in Dogs

Thomas J. Kern, DVM, Diplomate ACVO
Associate Professor, Ophthalmology, Department of Clinical Sciences, College of Veterinary Medicine Cornell University, Ithaca, New York
Diseases of the Cornea and Sclera

Peter P. Kintzer, DVM, Diplomate ACVIM
Staff Internist, Boston Rood Animal Hospital, Springfield, Massachusetts
Diseases of the Adrenal Gland

Susan E. Kirschner, DVM, Diplomate ACVO
Ophthalmologist, The Animal Eye Doctor, Beaverton, Oregon
Diseases of the Eyelid

William C. Kisseberth, DVM, PhD, Diplomate ACVIM
Assistant Professor, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Diseases of the Spleen

David W. Knapp, DVM, Diplomate ACVS
Staff Surgeon, Angell Animal Medical Center, Boston, Boston, Massachusetts
Management of the Open Wound

Shianne L. Koplitz, DVM, PhD Diplomate ACVIM (Cardiology)
Cardiology Resident, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Syncope

Michael P. Kowaleski, DVM, Diplomate ACVS
Assistant Professor, Small Animal Orthopedic Surgery, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio
Fractures and Dislocations of the Carpus
Osteochondrosis

Gail A. Kunkle, DVM, Diplomate ACVD
Professor, SACS-CVM, University of Florida, Gainesville, Florida
Necrotizing Skin Diseases

Kenneth W. Kwochka, DVM, Diplomate ACVD
Vice President for Research and Development, DVM Pharmaceuticals, Miami, Florida
Keratinization Defects

Mary Anna Labato, DVM, Diplomate ACVIM (Small Animal)
Clinical Associate Professor, Department of Clinical Sciences, Cummings School of Veterinary Medicine at Tufts University
Staff Veterinarian, Small Animal Medicine, Foster Hospital for Small Animals, North Grafton, Massachusetts
Disorders of Micturition

Linda B. Lehmkuhl, DVM, MS, Diplomate ACVIM (Cardiology)
Staff Cardiologist, Cardiology, Med Vet, Medical Center for Pets, Worthington, Ohio
Cardiomyopathy

Patricia J. Luttgen, DVM, MS, Diplomate ACVIM (Neurology)
Staff Neurologist, Neurological Center for Animals, Denver, Colorado
Disorders of the Spinal Cord

Preface

The world of small animal veterinary medicine continues to grow in scope and complexity. Practicing veterinarians and veterinary students are continuously bombarded with new information on the diagnosis and treatment of diseases affecting pet animals. Busy veterinarians have precious little time to keep up with current developments in the profession. We recognize that challenge, and thus we attempt to provide a comprehensive book that covers the commonly encountered disorders seen in small animal practice.

Although difficult to include all the pertinent material in a one-volume text, the semi-outline format used in the Manual allows our authors to be concise, yet thorough. As in the first two editions, we continue to make information user friendly by including many key points, condensing information into tables and bulleted lists, and illustrating procedures and surgical techniques with many simple line drawings. However, it is impossible to provide an exhaustive discussion of all small animal diseases in one book. Pathophysiology of disease, rare conditions, and infrequently used diagnostic and treatment methods are not included. Readers are directed to many well-written veterinary textbooks or journals that cover various subjects in greater detail than what we have space for in the Manual. But the Manual seems to have found a niche. From what countless practitioners and students have told us, it is a text that is not kept on a bookshelf gathering dust, but is open on a counter, desk, or exam table where it is almost constantly being used to update or review important clinical information. This is exactly how we hoped the book would be used.

Although we have stayed true to the book's original style, we have added some new authors, section editors, and chapters. New chapters include Pain Management, Vaccination Guidelines, Disorders of the Claw, Postoperative Physical Rehabilitation, and Syncope. Examples of other new areas covered in the third edition are: new emerging infectious diseases; skin cytology for diagnosis of skin disorders; an overview of current imaging techniques such as digital radiography, computed axial tomography, and magnetic resonance imaging; technique for laser declaw; indications for laparoscopic and thorascopic surgery; and a brief discussion of arthroscopic procedures for certain joint disorders. Additionally, all chapters, even if rewritten by the same author, have been thoroughly and meticulously revised and updated, and several new illustrations have been added. The Appendix of Drug Dosage Guidelines has also been updated and many new drugs included.

We are very grateful to all those who have contributed to the third edition of the Manual. The section editors and chapter authors have done an excellent job organizing and presenting information in their areas of expertise. They have correlated their own clinical experience with information available in the literature and have provided useful and practical information. We also wish to thank the faculty, residents, and students at The Ohio State University College of Veterinary Medicine for their support and advice on the preparation of this edition.

The Manual is the result of a tremendous amount of organizing, copyediting, proofreading, and attending to details. We are indebted to the staff at Elsevier for all their hard work, particularly Ms. Jolynn Gower, Managing Editor. Thanks also to Ms. Joy Moore, Senior Project Manager. We also thank Ms. Sarah Self, Production Editor and the staff at Graphic World Publishing Services. Finally, we appreciate the work of our very talented medical illustrator, Ms. Felecia Paras.

As we have indicated in both of the previous editions of the Manual, we are striving for continued improvement of our work. We welcome any comments or criticisms that will help make future editions an even more valuable part of the small animal clinicians' library.

Stephen J. Birchard, DVM, MS

Section 1

Patient Management

Stephen J. Birchard

Chapter 1

History and Physical Examination

Denise Jones

Veterinarians are faced with many diagnostic challenges on a daily basis. By far the most important diagnostic tool that veterinarians possess is their ability to obtain a complete history and perform a thorough physical examination. This information, when accurately interpreted, lays the foundation for a logical diagnostic and therapeutic plan. A systematic and thorough history and physical examination prevents unnecessary diagnostic testing and needless cost to the owner.

GENERAL HISTORY

Obtain both objective and subjective information when collecting the history.

- Objective data consist of the signalment, environment, diet, and medical history. For a patient's first visit, determine the length of ownership and the place of origin.
- Subjective data include a description of the primary complaint and a historical overview of the patient's general health. The owner often may not realize how a seemingly unimportant observation may be related to the primary problem. Tailor specific questions to the individual case.

Signalment

- The signalment consists of the patient's age, species, breed, and gender. Note whether the patient is intact or neutered. The patient's breed will sometimes become a key factor when formulating differential diagnoses. Congenital or hereditary disorders should be considered. For example, familial renal disease should be a primary differential for a young Shih Tzu presenting with polydipsia and polyuria. In other cases the disease process may not be congenital or hereditary, but it may be more prevalent in certain breeds than others. For example, a small-breed dog that presents with lameness that is localized to the hip is more likely to have avascular necrosis of the femoral head (Legg-Perthes disease) than hip dysplasia.
- Verify that previously recorded data are correct and up-to-date. For example, the patient may have been neutered since its last visit or the physical examination may indicate that the recorded age is questionable.

Environment

- Gather environmental information as a routine part of the patient's history. In many circumstances, where the pet is kept provides a vital clue in diagnosis.
- Determine whether the pet is free roaming or confined to a yard or house. If the patient is confined to a yard, ask the owner if the yard is fenced, if the pet is chained, and if an escape has been possible in the recent past. The free-roaming or recently escaped pet may have had access to toxins or have been

subject to trauma, which is less likely for an indoor pet. For example, in a dyspneic patient, diaphragmatic hernia ranks higher on the differential diagnosis list for a free-roaming pet than for a strictly indoor pet.
- Determine the geographic origin of the pet and any record of recent travels. This becomes paramount if the patient has been exposed to diseases endemic to certain regions but not prevalent in the current environment, such as systemic mycoses and vector-borne diseases.
- Determine the pet's water source. This may be important if the pet has access to contaminated outdoor water, toilet-bowl water treated with deodorants or cleansers, or if the pet has limited access to water.
- Question the owner if there has been any potential exposure to toxins such as antifreeze, pesticides, or insecticides if the patient's clinical presentation is indicative of intoxication. Exposure to houseplants or outdoor vegetation may also provide a clue. For a vomiting or anorexic patient, questions should include access to potential ingested foreign bodies.

Dietary History

- Always include dietary information in the routine database. Question the owner about the patient's appetite and noticeable weight gain or loss. Also note whether the owner watches the pet eat.
- Determine the following pertinent facts in the dietary history:
  - Type of diet (e.g., dry, moist, semimoist, or table food)
  - Brand name of food
  - Type of snacks
  - Method of feeding (i.e., free-choice or individual meals)
  - Amount

Preventive Health Care Status

- Evaluate the patient's preventive health care status. Review the patient's prior medical record.
- Record all previous vaccinations received and the dates of each. Avoid simply asking if the patient is current on vaccinations because many clients are unfamiliar with vaccination recommendations. Inform the client about what vaccinations are available as well as the indications and booster intervals for each (see Chapter 7).
- For a feline patient, discuss the subjects of feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV), including the dates and results of previous testing. Exposure to stray cats or cats known to be FeLV-positive or FIV-positive may also be relevant. History of previous cat fight wounds may warrant repeat testing for FIV. However, if the patient has been previously vaccinated for FIV, then further FIV testing will be invalid since the FIV test is an antibody test.
- For a canine patient, record heartworm test dates and results. If the patient is receiving heartworm preventive therapy, note the type, frequency, and dose (see Chapter 152).

Prior Medical History: Previous Illnesses and Surgeries

- Often the patient's prior or ongoing health problems play a role in its presenting ailment; therefore, review the information previously recorded in the medical record and discuss previous problems managed by other veterinarians.
- Record the dates of the previous illness or surgery, followed by a brief description of the problem, how it was managed, and the response to treatment.
- Discern the relevance of prior illnesses before obtaining extensive details; otherwise, the history may become unnecessarily lengthy and confusing.
- Specifically question the owner as to any medications the patient is currently or has recently been given. Over-the-counter products as well as prescription medications should be noted.

Primary Complaint

- Use the history to identify and localize the primary problem. Much of this information is subjective, based mostly on the owner's interpretation of the pet's clinical signs and behavior. Be aware that some owners are extremely observant of their pet and others are not. Prompt owners to describe the pet's behavior and clinical signs in their own words. An astute clinician collects all data and subjectively analyzes this information in context of an owner's perceptivity.
- Encourage the owner to describe the patient's problem from its onset so that a chronologic picture is obtained.
- Avoid leading questions that might result in a deceptive history. For example, ask if there has been any change in frequency of defecation. Do not ask if the patient is defecating more frequently than normal.
- Determine the last period of normalcy or the duration of the clinical signs. This will help determine how acute or chronic the problem may be and will guide the ranking of differential diagnoses. Some differentials are more likely for an acute problem; others are more likely for a chronic problem. For example, intestinal intussusception or an intestinal foreign body are likely differentials for a puppy presenting with an acute episode of persistent vomiting. A gastric foreign body or inflammatory bowel disease are more likely in a similar patient with chronic intermittent vomiting. The onset and severity of the illness influences how rapidly or aggressively the problem should be approached.

- Determine the progression of the clinical signs. Once again, this may help not only in formulating a list of differentials but also in developing a treatment plan. For example, a patient presenting with a history of seizures is managed more aggressively when the seizures are increasing in frequency and length than when they have been the same for months or years.
- Question the owner as to any intervening signs that might provide a clue to the most likely differential diagnosis. For example, a cat with chronic diarrhea and intermittent episodes of fever is considered a more likely candidate for infectious disease than for dietary intolerance.
- Attempt to further define and localize the problem. For example, characterize diarrhea as originating in the small or large bowel before proceeding to a diagnostic or therapeutic plan. Ask questions regarding frequency, appearance (color and consistency), and presence or absence of straining to help localize this problem. Specific questions oriented by body systems follow in the next section.
- Determine treatments and response. For example, a dog presenting with pruritus unresponsive to previous treatment with corticosteroids is a more likely candidate for food allergy dermatitis than for atopy. Record what medication was given, the dose, the duration of treatment, and the level of response observed.

HISTORY ORIENTED BY BODY SYSTEMS

For a complete history, include a system-by-system review of the patient's general health. This can be accomplished by the experienced clinician as the physical examination is performed. The novice may prefer to obtain the entire history before proceeding with the physical examination. Develop a consistent and systematic method. One method is to begin with questions concerning the patient's head and proceed caudally, as demonstrated in the following text. It is left to the clinician's discretion as to how in-depth the client is questioned about systems that do not appear to affect the primary complaint. Apply the general principles described in the previous section in the approach to all body systems (e.g., onset and duration).

Eyes

- Ask if any ocular discharge has been noted. If so, describe the discharge (serous, mucoid, or mucopurulent) and determine if it has been unilateral or bilateral.
- Determine if ocular pain or discomfort is present as indicated by blepharospasm, face rubbing or pawing, or photophobia. These signs may be seen with anterior uveitis, glaucoma, corneal ulcerations, or foreign bodies.
- Ask about ocular redness, swelling, and asymmetry.
- Ask if the owner has noticed a color change in the pet's eye. This change can occur with anterior uveitis and iriditis, in which hyphema may be present or the iridial color may be altered. A localized pigment change in the iris may occur with an iris cyst or melanoma.
- Ask the owner if their pet seems to be experiencing any loss of vision. If there is an apparent problem, does it seem to be affected by daylight or darkness? Also ask if decreased vision appears to be a unilateral or bilateral problem. See also Section 10.

Head, Neck, Ears, Nose, and Oral Cavity

- Record any history of swelling or asymmetry of the head and neck region.
- Inquire about head shaking, ear scratching, and otic discharge or odor that may indicate the possibility of otitis or a foreign body in the ear. Determine if any loss of hearing has been evident.
- Ask if any nasal discharge has been present. Note the character of any nasal discharge (serous, mucoid, mucopurulent, or hemorrhagic) and whether it has been unilateral or bilateral. Note any history of sneezing, nose rubbing, nasal asymmetry, or stridor.
- Request information relating to the oral cavity, such as odor, difficulty eating or drinking, abnormal swellings involving the gingiva or tongue, and changes in gingival pigmentation. Ask if there has been any change in the patient's ability to vocalize. The patient's voice can be affected either by a mass in the laryngeal region or by laryngeal paralysis.

Cardiopulmonary System

- Ask if cough, exercise intolerance, weakness, or fainting have been observed. These may indicate cardiopulmonary disease.

▼ ***Key Point*** Attempt to differentiate syncope from seizures based on the owner's description of the event.

- Syncope is a transient loss of consciousness that may be precipitated by exercise in patients with underlying cardiac disease (see Chapter 148). During a syncopal episode the patient usually demonstrates very little motor movement. The episode typically lasts less than a minute, and usually the patient returns to normal within a short period of time. Seizures vary greatly in severity. They are often preceded by a preictal phase during which the patient may be anxious or disoriented. The actual seizure usually involves a loss of consciousness and active motor activity such as tonic-clonic limb movements and rapid jaw movements. The postictal phase may last from minutes to days. The patient may be either overly agitated or depressed during this time. Seizure disorders are discussed in Chapter 127.

- Characterize coughing as productive or nonproductive, moist or dry, and harsh or honking. Some owners may confuse a productive cough with vomiting; therefore, ask whether abdominal heaving occurs prior to the production of fluid or foam or whether coughing and gagging are more typical. Yellow or green fluid is indicative of vomitus. The circumstances surrounding the cough are often relevant. For example, cough associated with tracheal collapse is often elicited with excitement or pulling on the patient's collar. Coughing secondary to congestive heart failure may be exacerbated with the pet in a sternal position. Is the pet routinely exposed to cigarette smoke? This can play a role in chronic bronchitis or feline asthma.
- Determine if dyspnea has been observed. It may be difficult for an owner to differentiate between heavy panting and true dyspnea. Ask if the pet is breathing the same during the exam as it was at home. Also inquire if the pet seems reluctant to exercise or lie down, as would be expected with most dyspneic animals. Open-mouth breathing for a cat is always considered abnormal except when it is excessively stressed. See also Chapter 142.

Digestive System

Most problems related to the digestive system are clinically manifested as anorexia, regurgitation, vomiting, diarrhea, constipation, weight loss, or a combination of these. Determine which clinical sign is being exhibited, because the owner may incorrectly interpret what is observed. For example, owners often assume that their pet is constipated if it is observed straining to defecate, when diarrhea may be the actual cause. Ask specific questions to differentiate between vomiting and regurgitating. Regurgitation is characterized as a passive ejection of ingested material from the esophagus. It typically occurs soon after a meal is eaten. The regurgitated material is usually undigested and tubular in form. Vomiting frequently involves an abdominal heave movement or retching. Time of vomiting in relation to eating should be noted and is variable depending on the underlying disorder. Vomitus is not tubular in form and may consist of froth, fluid, yellow-green bile, food, or ingested foreign material. Include the following specific information in approaching a digestive system problem:

- Review dietary history, as previously described. Specifically ask about treats or access to garbage.
- Record environmental history, as previously described.
  - Has there been any exposure to toxins, drugs, or plants?
  - Are there any toys or other foreign objects that the pet may have ingested?
- Note vaccination status.
- Ask how the patient's appetite has been and how it compares with its normal appetite.
- Has any vomiting been noted (onset, frequency, progression)?
  - Has the owner actually observed the pet vomiting? In a multi-pet household, verify that it is the presenting patient that is actually vomiting.
  - Does the pet exhibit any retching or abdominal heaving when "vomiting"?
  - How frequently is the pet vomiting?
  - What is the relationship of vomiting to eating, if any?
  - What is produced when the pet vomits? Describe the vomitus—digested or undigested food, fluid, foam, and color. Green or yellow fluid is typical of bile.
- Has the owner witnessed the patient defecating, and are there any abnormalities?
  - How long since the last observed bowel movement?
  - Has any diarrhea been observed (onset, progression)?
  - Has the stool been persistently loose?
  - How frequently does the animal defecate?
  - What volume of stool is typically produced? Small amounts of stool produced frequently are indicative of large bowel disease, and larger amounts of stool produced less frequently are more typical of small bowel disease.
  - What is the color and consistency of the stool (formed but soft, cow patty–like, watery)?
  - What is the consistency of the last stool produced?
  - Is there any blood or mucus present? (These are indicative of large bowel disorders.)
  - Does the animal strain while defecating? Straining is typical of diseases localized to the colon, rectum, or anus.
  - Does the owner witness all eliminations (i.e., is the pet walked on a leash, does it have access to a fenced yard. or does it roam free)? Consider that owners may not be fully aware of what their pet is eliminating.

See also Section 6.

Urinary System

Often, the owner complaint may be that the pet is urinating excessively. The following questions help distinguish whether excessive urination is due to polyuria or pollakiuria:

- Has there been any change in the quantity of water that the pet consumes?
- Are there other pets in the household that have access to the same water source?
- Is the pet urinating inside the house (i.e., having "accidents")?

- Are these urinations observed? (The owner should verify that this is the pet having the accidents versus another pet in the household.)
- Does the owner know if the accidents occur while the animal is awake or asleep? If the owner has not observed the act, there may be other clues to pursue. Where has the owner found the accidents (where the pet sleeps, next to a door, etc.)? A patient that is experiencing urinary incontinence may be dribbling urine while resting in its sleeping area. Dogs that are well house-trained may urinate close to an outside door if they are unable to hold their urine until allowed access to the outside yard. Another clue to urinary incontinence is the presence of urine on the pet's perineal region or rear legs.
- Does the animal seem to be consciously aware of the act, or does the animal dribble urine without seeming to be aware?

- Has there been any change in frequency of urination? If the patient is urinating frequent small amounts (pollakiuria), then differentials should include lower urinary tract disorders such as cystitis, urolithiasis, and neoplasia.
- Does the animal appear to strain while urinating? (This is typical of lower urinary tract disease.)
- What quantity of urine is produced? Larger quantities of urine are indicative of polyuria, which occurs with a large number of underlying metabolic disorders (renal disease, liver disease, diabetes, mellitus, diabetes insipidus, hyperadrenocorticism, hypercalcemia, etc.).
- Has the owner noticed any blood in the urine? If so, is it before, during, or after urination? Bleeding only at the beginning of urination is more likely to be from the urethra. Hematuria present throughout the urination is most typical of bleeding of renal origin. Blood seen at the end of urination usually originates from the urinary bladder. Remember to consider the genital system as a potential source for the blood, as with prostatic disease or vaginal masses.

See also Section 7.

Genital System

Females

- Verify if the patient is intact or spayed.
- Note any vulvar discharge and describe the amount, consistency, color, and odor. This type of discharge may be valid for spayed pets as well as intact ones.
- If the patient is intact, ask the following questions:
  - When did the owner last observe a heat cycle for the patient? Was it a normal cycle? How long did it last?
  - Have the heat cycles been at regular intervals?
  - Has the pet been intentionally bred or is there any possibility of an accidental breeding? Is there any previous history of pregnancy? If so, were there any complications (e.g., dystocia, abortions, mastitis, metritis, etc.)?
  - If there is a history of successful pregnancy, how many puppies were whelped?
  - Has the patient been tested for brucellosis? When? Was the mate previously tested?

Males

- Verify if the patient is intact or neutered.
- Has the patient exhibited any evidence of difficulty urinating or defecating?
- Has any preputial or penile discharge been noted? (Describe the amount, consistency, color, and odor.)
- The following questions apply to intact males:
  - Has the patient been used for breeding? If so, when was he last bred? Was there any difficulty in breeding?
  - Were any litters sired? If so, how many puppies were in each litter?
  - Has the patient been tested for brucellosis? When? Was the mate previously tested?

See also Section 7.

Swelling or Masses

Ask if any abnormal masses or swellings have been observed that have not been previously mentioned. Note the location, how long the mass or swelling has been present, and any change in appearance, character, or size. If the patient has not been examined in your practice before, ask if the mass has been previously sampled by either a fine needle aspirate or a surgical biopsy. Obtain a fine needle aspirate from masses that have not been previously investigated.

▼ ***Key Point*** Perform diagnostics on masses that are changing rapidly since there is a higher incidence of malignancy associated with these.

Skin

An accurate and detailed history is essential for successful management of dermatologic problems. Remember that some systemic disease processes may manifest themselves in cutaneous changes, such as hyperadrenocorticism or systemic lupus erythematosus (SLE). Some clinicians prefer to have the owner fill out a standardized dermatologic history form prior to specific questioning. Include the following questions on such a form, or directly ask the owner:

- Has any hair loss been observed? Did hair loss involve the undercoat or the main coat?
- Is there evidence of pruritus (scratching, biting, or licking)?
- Where does the pet seem to be most pruritic? Many atopic and food-allergic patients may rub their faces

and lick their feet excessively. Flea-allergic patients predominantly chew the dorsal tail-base region.
  - If the pet is pruritic, how severe is it? Have the owner grade the degree of pruritus on a scale of 1 to 10, with 10 being the most severe. This helps subsequent evaluation of treatment response.
  - Is the skin problem continuous or seasonal? If seasonal, then determine when the pet is most severely affected.
  - Has the owner noticed fleas? What flea products have been used? Has the pet been on monthly preventive treatment? If so, which product?
  - What type of bedding does the pet use?
  - Is there any exposure to feathers?
  - What type of carpet is in the house (wool, synthetic, cotton)?
  - What is the diet? What treats are given?
  - Are there any indoor plants?
  - Is the pruritus worse indoors or outdoors?
  - Is there any exposure to tobacco smoke?
  - Has the pet ever had any drug reactions? (describe)
- Describe odors, pigment changes, or texture changes of the skin or hair coat.
- Does the pet have any dandruff? If so, what areas are involved?
- How often is the patient groomed (clipped, brushed, combed)?
- How often is the patient bathed? When was the pet last bathed, and what products were used?
- Are there other pets in the household? Has the pet been exposed to other animals outside of the household? Did any of these animals exhibit signs of skin disease?
- Do any members of the household have skin problems?
- Do any of the pet's close relatives have a history of skin problems?
- Has there been any previous treatment? When was the pet last treated? What was the name of the drug, the dose, the route of administration, and the frequency of treatment? What level of response was noted?

See also Section 5.

Musculoskeletal System

- History relating to the musculoskeletal system generally focuses on lameness or discomfort.
- Remember to correlate the age and breed of the individual to the lameness observed. There are numerous examples in which the signalment may provide a clue to the underlying disorder. Many musculoskeletal disorders occur predominantly in young, large-breed dogs. These include but are not limited to osteochondritis dissecans, ununited anconeal process, panosteitis, and hypertrophic osteodystrophy. Middle-aged to older large-breed patients are more at risk for neoplasia such as osteosarcoma. Small-breed individuals have a higher tendency toward medial patellar luxation and avascular necrosis of the femoral head.
- When lameness has been observed, discern if the patient has been bearing weight on the affected leg. Determine if lameness has been previously observed in this limb or other limbs. For example, panosteitis is often considered a shifting leg lameness. Ask if there are any other signs of illness in addition to the lameness. The lameness may be a manifestation of systemic disease such as SLE or Lyme disease. Has the owner noticed any swelling or masses associated with the affected limb?
- Is the lameness intermittent, progressive, or static? Is the lameness worse before or after exercise? Arthritic patients often "warm out" of their lameness.
- Question owner in regard to routine daily activity such as running, jumping, hunting, jumping on and off furniture, etc. Has the pet engaged in any activities out of the ordinary lately? These patients are more at risk for traumatic injuries such as a cranial cruciate ligament tear or a ruptured intervertebral disc.
- Ascertain any possibility of trauma that could have resulted in a fracture. In some cases, the owner may have witnessed the traumatic incident. In others, the patient may have been unsupervised during the time in question. Specifically ask if the patient was confined to the house or a fenced area. If the animal was free roaming and unobserved, determine how long it was unsupervised to help assess the possibility of a traumatic incident.
- Determine if the owner has observed loss of muscle mass, asymmetry of the limbs, or swollen joints.
- Ask if the patient has demonstrated any difficulty rising, climbing stairs, or descending stairs. These problems are frequently noted in patients with hip dysplasia, intervertebral disc disease, or neurologic diseases such as degenerative myelopathy.
- In regions endemic for Lyme disease, ask if any ticks have been observed on the pet. Check vaccination status regarding Lyme disease. In nonendemic areas, obtain a travel history.

See also Section 8.

Nervous System

Many questions related to the nervous system may have been previously asked while taking the history of the other body systems. Once again, consider the age and breed to help provide clues to the differential diagnoses. Small-breed dogs are more commonly seen with portosystemic shunts and may present with neurologic signs. Hypoglycemia and congenital diseases are prime differentials for seizuring puppies. Epilepsy typically has an onset in young adults. For seizures with an onset during middle age or geriatric years, consider metabolic disease or neoplasia. Diseases of the central nervous

system (CNS) may be reflected by abnormalities in other systems (e.g., blindness, hearing loss, or urinary incontinence). With a presenting complaint of rear limb "weakness," differentiate between disorders of the musculoskeletal system and those of the nervous system with the history and physical examination. Consider the following points in regard to the nervous system:

- Verify vaccination history for distemper and rabies.
- Focus on obtaining a good environmental history, such exposure to toxins or plants. Is there any possibility of a traumatic accident resulting in head trauma or spinal injury?
- Ask if any behavioral changes, such as aggression or dementia, have been observed. If these signs are present, are they intermittent or persistent?
- Is there any evidence of pain when the patient is touched or picked up? Does the pet cry or yelp when it moves? These signs can occur in a patient with intervertebral disc protrusion.
- Record any history of seizures, including their duration and the time interval between them. Obtain a description of the seizure.
- If behavioral changes or seizures have been observed, ask if there is any relationship between when the pet eats and when these signs occur. Neurologic signs may be exacerbated postprandially in patients with a portosystemic shunt.
- Ask if there has been any evidence of weakness in the patient. If present, is the weakness generalized or localized (i.e., to one side of the body, in the forelegs, or to the rear)? Determine if any abnormalities in posture or ambulation have been observed, such as the pet's tendency to fall to one side, to circle to one side, to knuckle over, or to drag its toes. Be sure to note the acuteness of onset and the progression of the neurological signs.

See also Section 9.

PHYSICAL EXAMINATION: GENERAL OBSERVATION

- To begin the physical examination, watch the patient as it enters the room.
- Continue the visual evaluation of the patient while the history is collected. Observe the general body condition and any abnormalities in behavior, attitude, posture, ambulation, and respiratory pattern. During this time, the patient may be placed on the examination table or allowed to roam the examination room.
- During the general observation of the patient, evaluate its body condition. Several body condition scoring systems have been developed to aid in assessing the amount of body fat present in the individual dog or cat. The most commonly used systems utilize either a 5- or 9-point scale. I prefer the 5-point scale, where score 1 correlates to an emaciated body condition and score 5 indicates a grossly obese state. Score 3 is considered an ideal weight for the patient. Those body conditions that fall between two scores are assigned a half score. For example, a patient that is just over its ideal weight would be scored as 3.5. Refer to Tables 1-1 and 1-2 for details of body condition scoring in dogs and cats, respectively. Record the patient's body condition score (BCS) in the patient's record each visit.
- If the collection of the history and the physical exam result in a vague, poorly defined illness, consider hospitalizing the patient for observation. Sometimes owners may find it difficult to accurately describe the pet's behavior or clinical signs. Also, some patient's may mask their depression or pain when they initially arrive in a new environment. A nervous patient should be reevaluated once it has adjusted to the hospital surroundings. Occasionally, animals become more agitated the longer they are away from their owner. Finally, many disease processes become more evident with time, so the physical should be repeated on any undiagnosed or hospitalized patient.

Table 1-1. BODY CONDITION SCORING FOR DOGS

Score	Body Condition	Parameters Evaluated
1	Emaciated	Skeletal in appearance with no obvious body fat and minimal muscle mass. Boney prominences visible.
2	Thin	Ribs slightly visible and easily palpable. Prominent waist and abdominal tuck from side and dorsal views.
3	Ideal	Ribs not visible but palpable with only a slight fat covering. Abdominal tuck present from side view, and waist present from dorsal view. Smooth contour over tail base.
4	Overweight	Difficult to palpate ribs because of moderate fat layer. Loss of abdominal tuck from side view, and wide waist from dorsal view. Thickening over tail base.
5	Obese	Excessive fat cover over entire body. Ribs extremely difficult to palpate. No waist present from dorsal view. Fat skin folds droop from caudal abdomen on side view. Thick fat roll at tail base.

Table 1-2. BODY CONDITION SCORING FOR CATS

Score	Body Condition	Parameters Evaluated
1	Emaciated	Skeletal in appearance in the shorthaired cat. Boney protrusion of the wing of ilia and lumbar vertebra.
2	Thin	Ribs easily palpable with only slight fat covering. Waist prominent caudal to ribs. Minimal abdominal fat present.
3	Ideal	Uniform distribution of body fat. Ribs palpable but not prominent. Slight waist present caudal to ribs. Minimal abdominal fat pad present ventrally.
4	Overweight	Ribs difficult to palpate. Loss of visible waist and some abdominal distention present. Moderate abdominal fat pad present ventrally.
5	Obese	Ribs not palpable. Excessive fat deposits generalized but especially noted in abdominal region.

PHYSICAL EXAMINATION: VITAL SIGNS

Initially, record the vital signs and current body weight of every patient.

Body Temperature

- Obtain the rectal temperature early in the course of the examination to help avoid an elevation of temperature that may result from anxiety or excitement. If you are unsure whether the elevated temperature is the result of environmental factors, then consider hospitalizing the patient to recheck the body temperature in a few hours. In emergency situations, attend to hypothermia or hyperthermia early in the course of the examination.
- Normal rectal temperature for dogs range from 99.5°F to 102.5°F. For cats the range is 100.5°F to 102.5°F.
- Note any blood or melena that is evident on the thermometer.

Pulse and Heart Rate

- Record the pulse rate and evaluate the pulse quality.
- Normal heart rate values (beats per minute) are as follows:
  - Large dogs—60 to 100 bpm
  - Medium-size dogs—80 to 120 bpm
  - Small dogs—90 to 140 bpm
  - Domestic cats—140 to 250 bpm
- Determine if arrhythmias or pulse deficits are present.

Capillary Refill Time

- Lift up the upper lip, press on the buccal mucous membranes, and determine how long it takes for the membranes to resume normal pink color (normal is <2 seconds).

Respiratory Rate

- Evaluate the respiratory pattern as the rate is taken.
- The normal respiratory rate for dogs is 10 to 30 breaths per minute. For domestic cats the normal rate is 20 to 30 breaths per minute.
- If moderate or severe dyspnea is present, observe caution in continuing with the remainder of the examination. The additional stress of restraint and examination may result in life-threatening respiratory compromise. Administer oxygen therapy followed by a rapid oral examination and thoracic auscultation to help determine the source of the dyspnea and the appropriate emergency therapy. After stabilizing respiratory function, continue with the remainder of the physical examination.

Hydration

- Note if the eyes appear sunken or if the third eyelids are protruding bilaterally. This can be seen in a markedly dehydrated patient.
- Note if the mucous membranes are dry or tacky, as is typical of a moderately dehydrated patient.
- Evaluate skin turgor by gently lifting the skin over the dorsal thorax. Geriatric or cachectic patients may appear to be dehydrated based on their skin turgor alone because of the loss of the skin's natural elasticity.

PHYSICAL EXAMINATION: BODY SYSTEMS

The physical examination should follow the same logical pattern as the history. A consistent approach is taken so that no part of the examination is overlooked. For example, analyze one body system at a time, starting with the patient's head and proceeding caudally. Look at each body system as a piece of the puzzle. Attempt to link the results of the entire history and physical exam so that multisystemic disorders will not be overlooked. Additionally, your evaluation of one body system may affect what you recommend for an unrelated problem for another body system. Consider the whole patient when you formulate your diagnostic and therapeutic plans.

Head

- Examine the head carefully for evidence of asymmetry or localized swellings. Palpation is necessary to assess the nature of any swelling or mass (firm or fluctuant, mobile or attached).
- Evaluate the posture of the head and neck. Ventriflexion may be observed in cats with hypokalemia, chronic organophosphate toxicity, thiamine deficiency, and polymyopathies. Reluctance to move the head may be noticed in a dog with cervical intervertebral disc protrusion.

Eyes

The ocular exam often provides information that relates to systemic disorders. Systemic infections may manifest themselves through retinal lesions (FeLV, toxoplasmosis, fungal infections, etc.) or as anterior uveitis (FeLV, feline infectious peritonitis, ehrlichiosis, etc.).

- Determine if abnormalities are present unilaterally or bilaterally. If only one eye is affected, examine the normal eye first.
- Note evidence of pain such as blepharospasm, photophobia, and pawing or rubbing at the eye(s).
- Observe the size and symmetry of the eyes. Congenital microphthalmia or acquired phthisis bulbi results in a smaller-than-normal eye, whereas chronic glaucoma results in a larger-than-normal eye.
- Examine the position of the eyes for evidence of enophthalmos, exophthalmos, or strabismus. Enophthalmos may be secondary to microphthalmia, loss of the orbital fat pad (e.g., cachexia), Horner syndrome, dehydration, or acute ocular pain (e.g., anterior uveitis). Exophthalmos may be due to space-occupying lesions of the orbit (neoplasia, abscess, or cellulitis), buphthalmos (glaucoma), myositis, or breed predisposition.
- Note ocular discharge and characterize it as serous, mucoid, or mucopurulent.
- Note any swelling or masses involving the eyelids. Evaluate the eyelids for entropion and ectropion. Carefully examine the palpebral margins under magnification for evidence of distichiasis. Magnification may be necessary to identify distichia.
- Evaluate the conjunctiva for hyperemia, chemosis, pallor, or jaundice of the underlying sclera. The superior conjunctiva is more reliable for evaluating hyperemia than the inferior conjunctiva, which may normally appear somewhat hyperemic over the surface of the third eyelid. Note any abnormal pigmentation or masses involving the sclera or conjunctiva.
- Protrusion of the third eyelid may be a reflection of enophthalmos or Haw syndrome in cats. Haw syndrome is a bilateral protrusion of the third eyelids that may be seen in feline patients with gastrointestinal disease or parasites. Note any masses associated with the nictitans or prolapse of the gland of the nictitans. Apply gentle pressure to the superior globe to aid in exposing the nictitans. Apply topical anesthesia and grasp the third eyelid gently with forceps so that the posterior surface of the third eyelid can be examined for foreign bodies or follicular hyperplasia.
- Examine the cornea for cloudiness, pigmentation, vascularization, or obvious defects.
- Evaluate the anterior chamber for aqueous flare, hypopyon, hyphema, or abnormal masses. If a slit lamp is not available, use a magnifying lens and a penlight to produce a narrow beam of light so that subtle aqueous flare can be detected when the anterior chamber is viewed from the lateral aspect.
- Evaluate pupil size and symmetry and direct and consensual pupillary light reflexes. A darkened room aids in this examination. Persistent pupillary membranes may also be identified.
- Evaluate the iris for pigmentary changes, hyperemia, roughening, swelling, or synechia. Any of these changes can be seen with anterior uveitis. Tumors or cysts may occasionally occur on the iris. Melanoma of the iris may initially present as patchy pigmentation in the iris. Ask the owner when the color change was first noticed.
- Evaluate the lens via direct or indirect ophthalmoscopy for the presence of lenticular sclerosis, cataracts, or displacement of the lens.
- If a "red eye" is found during the exam, perform a Schirmer tear test, a fluorescein stain, and a measurement of intraocular pressure. Perform the Schirmer tear test prior to the other tests since eye drops used in the subsequent tests can affect results. A Tonopen is a valuable tool for easily measuring intraocular pressure.
- For a complete fundic examination, dilate the pupil with a short-acting topical mydriatic. Evaluate the fundus for vascularity, areas of hemorrhage, pigmentary changes, chorioretinal dysplasia or hypoplasia, and retinal detachment. Evaluate the optic disc for color, size, vascularity, fissures or colobomas, and abnormal masses. Practice and experience are the keys to retinal examinations.
- Evaluate vision by dropping a cotton ball in front of the patient or by rolling a cotton ball across the table or floor. Alternatively, create an obstacle course to discern if the patient has the visual ability to negotiate barriers. Compare the patient's performance in full-light versus low-light settings. Evaluate the menace response. Young puppies and kittens (<6 weeks of age) normally do not respond appropriately to menace.

See also Section 10.

Oral Cavity

- Perform a thorough oral examination if the patient's demeanor allows (Fig. 1-1). If this examination is indicated but the patient is uncooperative or aggressive, sedation (see Chapters 2 and 64) may be necessary. Sedation also allows the clinician to perform a more thorough oral exam in any patient presenting with clinical signs suggestive of oral cavity disease (i.e., ptyalism, halitosis, bleeding, or oral pain).
- Always carefully evaluate the mucous membranes for color, moisture, and capillary refill time to assess the hydration status. Hyperemia, congestion, cyanosis, jaundice, pallor, or petechiae can provide vital diagnostic clues to the underlying disorder.
- Note gingival masses, ulcerations, inflammation, or pigmentary changes.
- Examine the teeth for calculus or exudate at the gingival margin. Digital pressure applied to the gingiva may aid in expressing exudate when a tooth root abscess is suspected. Note any fractured teeth, and look for evidence of pulp exposure. Slab fractures of the upper fourth premolar may be difficult to identify. Be suspicious of a fracture if a significant amount of calculus has accumulated on the surface of this tooth compared to the surrounding teeth and the contralateral carnassial tooth.
- Examine the tongue for evidence of trauma or masses when unexplained oral hemorrhage has been observed.

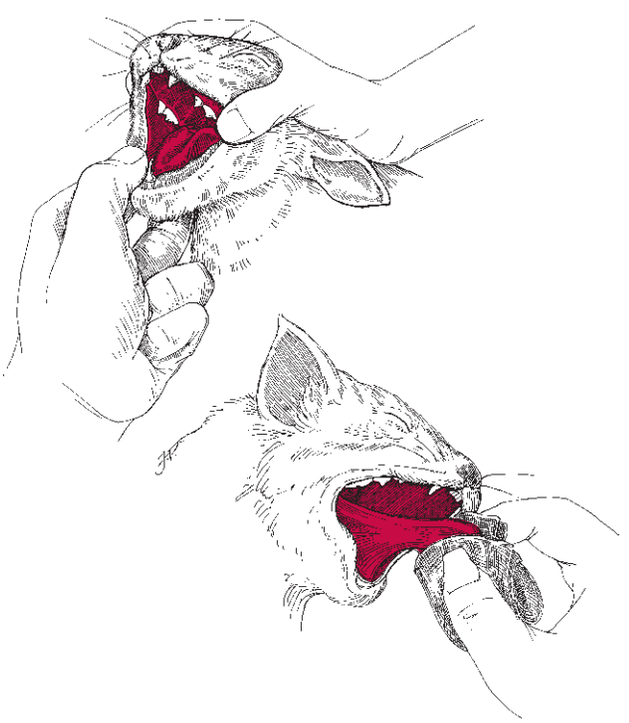

Figure 1-1. Oral examination of the feline mouth and tongue.

▼ ***Key Point*** In the feline patient that presents for vomiting, examine the sublingual area for evidence of a linear foreign body.

- Use one of the following two methods:
  - Open the patient's mouth and, with the middle finger of the hand depressing the mandible, apply pressure between the mandibular rami from the ventral aspect. In this manner, the tongue is elevated so that the sublingual surface can be seen (see Fig. 1-1, *top*).
  - Occasionally, a linear foreign body can be overlooked with the first method. The sublingual tissue can overlap a thin string that has been drawn taut so that it is not seen. In this case, the second method is to grasp the tongue with a gauze sponge and pull the tongue out and laterally so that the string can be seen more completely (see Fig. 1-1, *bottom*). Sedation may be required for this in some patients.
- Examine the hard palate in the neonate for clefts. Evaluate the soft palate (if possible) for defects or masses.
- Examine the pharyngeal region for asymmetry, masses, or foreign bodies or for evidence of inflammation or trauma. Examine the tonsils for enlargement or masses. Depress the caudal aspect of the tongue to see the caudal pharynx. Once again, sedation may be necessary for a thorough exam.
- In the cat, if pharyngeal polyps are a differential diagnosis based on the history, examine the soft palate for evidence of bulging. For a more complete exam, sedate the patient to look under the soft palate.

See also Chapter 64.

Nose

- Examine the nose for asymmetry or swelling. If a mass or swelling is present, palpate it carefully to determine whether it is firm or fluctuant. Evaluate brachycephalic breeds for stenotic nares.
- Note evidence of nasal discharge. Examine the nares closely to determine if the discharge is unilateral or bilateral. Characterize it as serous, mucoid, mucopurulent, or hemorrhagic. It may be beneficial to gently swab the external nares to detect a subtle discharge.
- If either nasal swelling or discharge is present, evaluate the patency of each nostril. Several techniques can be utilized to aid in this evaluation. Occluding one nostril at a time and listening for stertorous breathing may help identify a partially obstructed passageway. Another technique is wiping the examination table with an alcohol swab and positioning the patient's nose close to the table to observe condensation of the patient's breath on the surface. An alternative method is placing a wisp of cotton in

front of each nostril and observing movement from air flow

See also Chapter 160.

Ears

- Inspect both the external and inner surfaces of the pinna for skin lesions, hair loss, erythema, or swelling.
- Examine the external ear canals for erythema, discharge, and odor before an otoscopic examination. Palpate the ear canal cartilages for calcification, masses, pain, or other abnormalities.
- An otoscopic exam is invaluable in assessing an ear-related problem.
- Otoscopic technique requires practice to be successful. Sedation of the pet may be required if the patient is painful or aggressive.
- Lift the pinna and gently place the otoscopic cone in the vertical canal from a dorsal approach and direct it ventrally (Fig. 1-2). As the otoscope is guided deeper into the vertical canal, pull the pinna and otoscope horizontally to bring the horizontal ear canal and tympanic membrane into view.

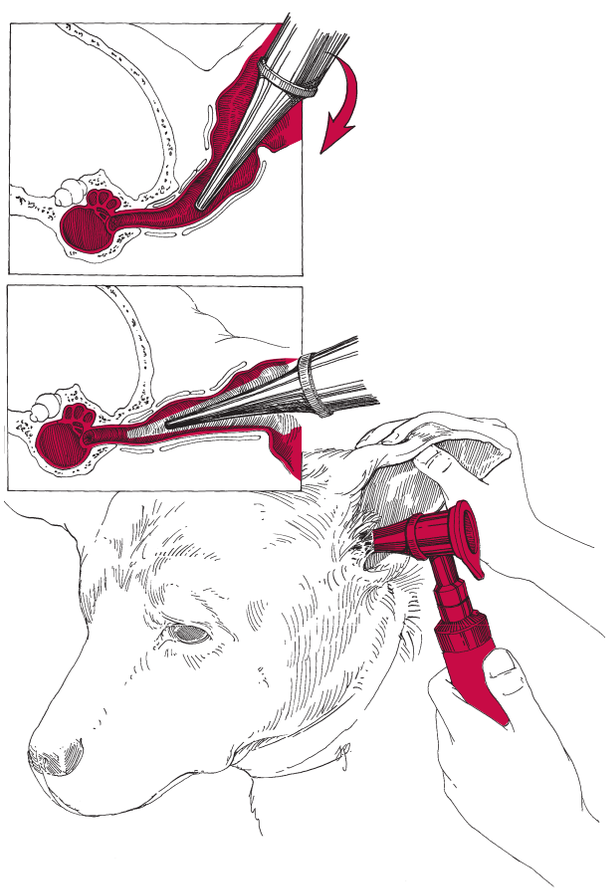

Figure 1-2. Otoscopic examination.

- Examine both the horizontal and vertical canals for stenosis, masses, foreign bodies, discharges, and parasites (ear mites and ticks). Assess the tympanic membrane for rupture or evidence of otitis media (erythema or protrusion).

See also Chapters 58 to 60.

Neck

- Palpate the paratracheal area from the larynx to the thoracic inlet.
  - In middle-aged to older cats, this palpation is especially important because of the high incidence of hyperthyroidism caused by thyroid adenomas. The normal thyroid is not palpable.
  - Stand behind the cat with it standing or sitting, extend the neck, and point the nose upward. Place your thumb and forefinger on each side of the trachea. Starting at the larynx, slide them down the length of the trachea using gentle pressure. The typical thyroid nodule will "pop" as your thumb and forefinger slip over the caudal pole (Fig. 1-3*A*).
  - Alternatively, palpate each side individually. Turn the patient's head slightly to one side and place your forefinger between the trachea and the adjacent muscles on the opposite side (Fig. 1-3*B*). Once again, start at the larynx and slide your finger down to the thoracic inlet. Turn the patient's head to the opposite side and repeat the procedure on the second side. Repeated palpation may be necessary to detect subtle nodules.
  - In dogs, palpation may detect a thyroid tumor.

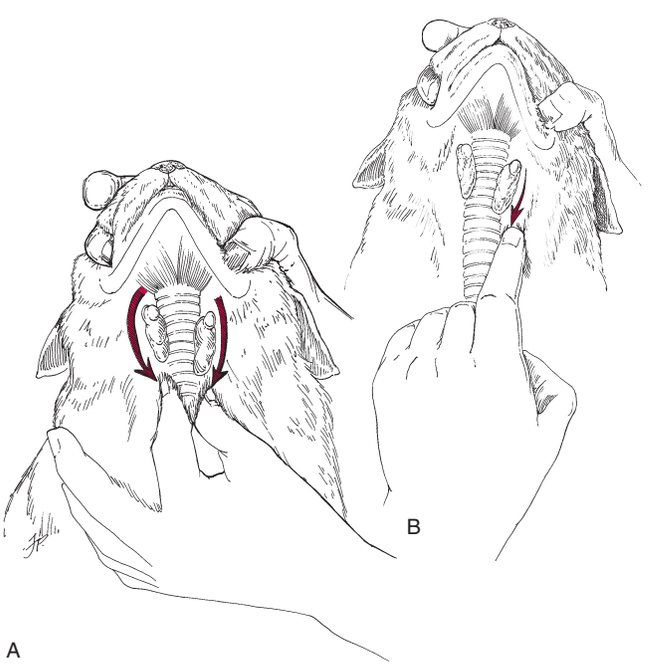

Figure 1-3. *A,* Paratracheal palpation of the thyroid. *B,* The alternative, palpation of each side of the thyroid gland individually.

- Palpate the trachea for collapse, soft cartilage, or flattening.
- Attempt to elicit a cough by gently encircling the trachea with one hand and applying pressure on the tracheal muscle dorsally. If a cough is produced by this method, it suggests tracheal collapse or tracheobronchitis. Conduct this part of the examination after the thorax has been auscultated because it may induce paroxysms of coughing.
- Evaluate the jugular veins for distention. A jugular pulse extending more than one third of the way up the neck is indicative of right-sided heart disease. It may be necessary to moisten this area with alcohol or to clip the hair to aid in visualization of the jugular vein.

Lymph Nodes and Subcutaneous Masses

- Palpate all external lymph nodes (Fig. 1-4). Generalized lymphadenopathy usually indicates a systemic disease (systemic fungal infection, immune-mediated disease, or neoplasia), whereas local lymph node enlargement usually indicates a localized tumor or a regional infection. If enlarged lymph nodes are present, use calipers to measure and record the size of the affected node or nodes. This information is helpful in monitoring the patient's response to treatment (antibiotics or chemotherapy).
- The mandibular lymph nodes are located at the angle of the mandible, slightly cranial and ventral to the parotid and submaxillary salivary glands. The nodes are generally smooth and ovoid in contrast to the irregular texture of the salivary glands. Practice distinguishing these lymph nodes from salivary glands.
- The superficial cervical or prescapular lymph nodes can usually be palpated just in front of the cranial border of the scapula. Grasp them by palpating beneath the scapular border. They may be more difficult to palpate in the obese or heavily muscled patient.
- The axillary lymph nodes are not always palpable because of their disc-like shape and the surrounding musculature.
- The superficial inguinal lymph nodes are located at the junction of the abdominal wall and the medial thigh and may be difficult to palpate in the obese patient.
- The popliteal lymph nodes are usually palpable caudal to the stifle joint. The surrounding subcutaneous fat may make these nodes seem larger than their actual size, especially in cats.
- Palpate the trunk and extremities for abnormal masses or swelling. When a mass is found, note the location, size, and consistency. Use calipers to accurately measure the size of the mass. Determine which tissues are involved (dermal, epidermal, subcutaneous, underlying tissue, etc.). Note whether the mass is freely movable or attached to the underlying muscle, fascia, or bone.

Thorax

- As previously described, evaluate the respiratory rate, rhythm, and effort.

Palpation

- Palpate the thorax for evidence of fractured ribs, congenital malformations (pectus excavatum), subcutaneous emphysema, and masses. Palpate the areas

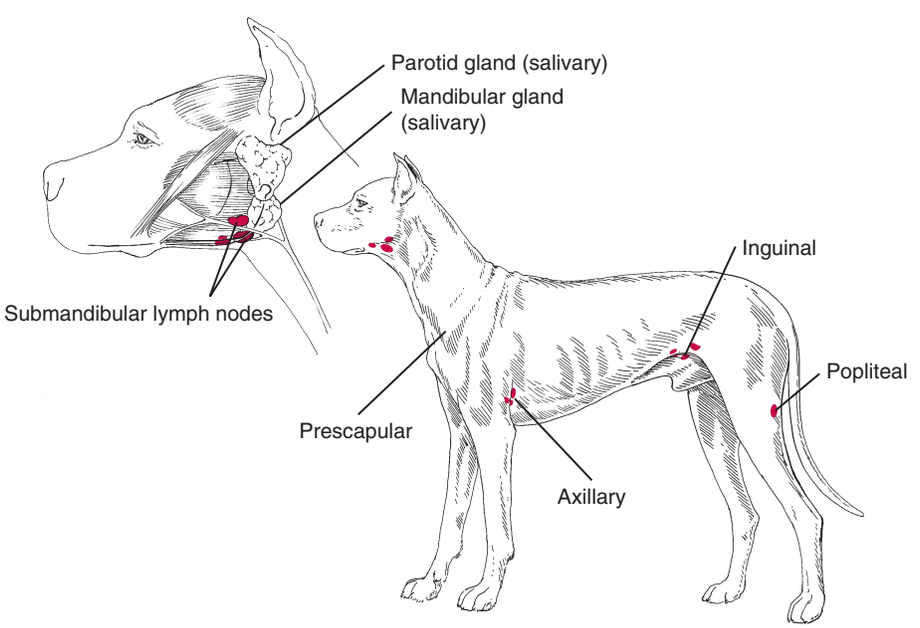

Figure 1-4. Commonly palpated lymph nodes.

between the fourth and sixth intercostal spaces on either side of the thorax for the point of maximum intensity (PMI) of the heartbeat and for cardiac thrills.
- Attempt to compress the cranial thorax in cats to help identify the presence of a mediastinal mass. In a normal feline, the cranial thorax is easily compressible.

Auscultation

- Perform auscultation in a quiet room with a calm patient. Have the patient standing during the examination so that the heart is in its normal position. Evaluate the heart independently from the lungs.
- Disregard sounds that are artifacts. These sounds include rumbles secondary to shivering and crackles created by the stethoscope rubbing against the hair. Close the patient's mouth for short periods of time to reduce upper respiratory noise. An additional technique is to apply moderate pressure on either side of the chest to help decrease motion caused by panting or shivering.
- Auscultate the heart initially over the PMI and identify the first and second heart sounds. Characterize the cardiac rhythm. Sinus arrhythmia is considered normal and is typified by increased cardiac rate during inspiration and decreased rate during expiration. Evaluate the femoral pulses for quality and deficits while auscultating the heart. Note split heart sounds, murmurs, and clicks. Auscultate all cardiac valve areas, because some murmurs are localized, such as the mitral, aortic, and pulmonic on the left hemithorax and the tricuspid on the right (see also Chapter 142).
- Note muffled heart sounds that may be due to obesity, pleural effusion, pericardial effusion, thoracic mass, or diaphragmatic hernia.
- Pulmonary auscultation requires practice and persistence. Normal bronchovesicular sounds may be increased, decreased, or normal. They may be intensified in the nervous or tachypneic patient. These sounds are heard equally on both sides of the chest. Abnormally quiet or dull areas are suggestive of pleural effusion, pneumothorax, thoracic mass, and pulmonary consolidation. Crackles are abnormal discontinuous sounds resulting from popping open of small airways or air moving through airway secretions. Wheezes are abnormal continuous, musical sounds resulting from passage of air through narrowed or partially obstructed airways.

Percussion

- Percussion is a technique for evaluating the resonance (pitch and tone) of sound produced by a series of quick taps of uniform force at various points on the chest wall using a finger or a percussion hammer.
- Increased resonance (tympany) is indicative of pneumothorax, and decreased resonance (dull sounding) suggests pleural effusion, a diaphragmatic hernia, a large pulmonary mass, or an area of consolidation.

See also Chapter 142.

Abdomen

- Examine the external appearance of the abdomen for distention or asymmetry. If distention is apparent, perform percussion to help determine if it is a result of peritoneal effusion, air (gastric dilatation or volvulus), obesity, or a mass.
- Palpate the abdomen systematically proceeding in a cranial-to-caudal direction with the animal standing. Palpate the trunk superficially for evidence of skin masses or hernias. In puppies and kittens, check for evidence of umbilical or inguinal hernias. To palpate abdominal organs, apply firm but gentle pressure. In small animals, use a one-handed technique. With larger patients, two hands are needed, one on each side of the abdomen (Fig. 1-5). If the patient is nervous or tense, try to get the patient to relax by talking reassuringly and stroking its belly or sides just prior to palpation. Start again in a cranial-to-caudal direction just as you did with the superficial palpation. Use a systematic method to attempt to identify each organ.

Stomach

- Palpate the cranial abdomen for evidence of gastric distention (see also Chapter 67). The normal stomach is rarely palpable. Tympany indicates gastric dilatation or volvulus. Diagnosis and treatment should be pursued aggressively. Overeating may result in a doughy or fluid-filled stomach in the left side of the cranial abdomen.

Liver

- The liver may be difficult to palpate in the normal patient (see also Chapter 71). The caudal edges are barely palpable, smooth, and well defined. Hepatomegaly results in a liver that extends past the costal arch. The edges may be rounded rather than sharp. Palpation with the animal in lateral recumbency or standing on its hind legs may be helpful.

Spleen

- The spleen is located in the mid-abdomen and may not always be palpable (see also Chapter 25). If splenomegaly is present, it is usually palpable. Determine if the spleen is irregular or if a palpable mass is present. Use gentle palpation on mid-abdominal masses. It is possible to rupture a splenic or hepatic hematoma or hemangiosarcoma.

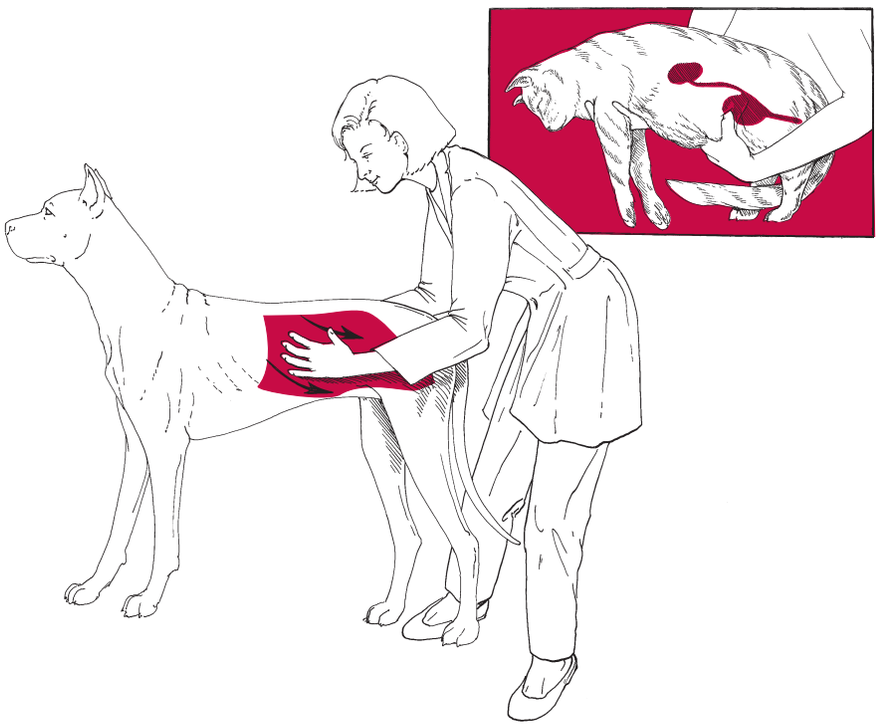

Figure 1-5. Perform abdominal palpation with two hands or with one hand *(inset)*.

Intestines and Mesenteric Lymph Nodes

- Other organs in the mid-abdomen include the mesenteric lymph nodes and intestines. The mesenteric lymph nodes are not usually palpable unless markedly enlarged, as with lymphoma. Occasionally, mesenteric lymph nodes are palpable in cats with inflammatory bowel disease.
- Palpate the thickness of the bowel wall and evaluate for the presence of gas, fluid, foreign bodies, or masses (see also Chapter 69). Plication and clumping of the intestines may sometimes be palpated in patients with a linear intestinal foreign body. Note if palpably abnormal sections of the bowel appear painful. Palpation of an intestinal foreign body frequently produces a painful response.
- Palpate the colon in the dorsal-caudal abdomen, and note the presence of feces. To determine whether the palpable structure is feces or a mass, apply gentle pressure to test for deformability of the stool. Evaluate quantity and consistency of the feces to aid in the diagnosis of constipation.

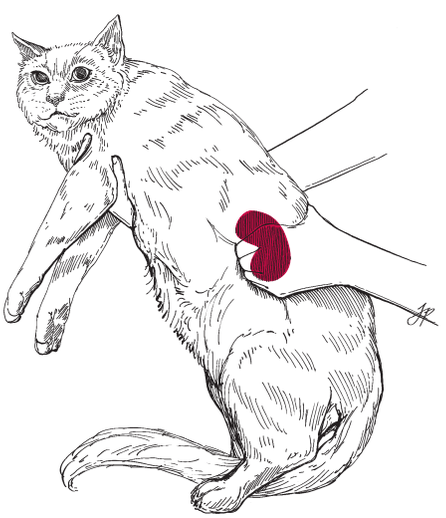

Figure 1-6. Renal palpation in the cat.

Kidneys

- The kidneys can be palpated in the feline patient in the dorsal region of the abdomen. The right kidney tends to be further cranial than the left and may be obscured by the caudal rib cage. Elevate the cat's thorax with one hand while palpating with the other. This maneuver allows the kidneys to fall into a palpable position (Fig. 1-6). Palpate both kidneys and compare them for size, shape, firmness, and surface irregularities. The left kidney is especially movable. Do not mistake it for a mid-abdominal mass. The kidneys are not as readily palpable in the dog unless the patient is young or thin. The caudal and lateral aspects may be palpable in other patients. Kidney palpation will also be discussed in Chapter 77.

Urinary Bladder

- If the urinary bladder is moderately or markedly distended, it can usually be palpated in the ventral-caudal abdomen (see also Chapter 79). The patient does not usually resist palpation of the normal bladder. Assess size, turgidity, and thickness of the bladder wall. The normal urinary bladder is thin walled. Careful palpation may reveal cystic calculi. A painful, firm distended urinary bladder indicates urethral obstruction.

Uterus

- The normal uterus usually cannot be palpated (see also Chapter 90). If it is markedly enlarged, because of pyometra or late pregnancy, the uterus is found in the mid- to-ventral abdomen, often extending from the diaphragm to the pelvic inlet. The uterus often is tubular in shape with pyometra or late pregnancy. In mid-gestation, the individual fetuses may be palpated. In the pregnant cat, these fetuses may feel similar to the urinary bladder but will usually be present in multiple numbers and feel slightly thicker walled than the bladder.

Prostate

- The prostate in intact male dogs can occasionally be palpated in the caudal abdomen ventral to the colon and caudal to the urinary bladder (see also Chapter 84). If found in this location, evaluate the prostate for size, shape, and surface irregularities.

External Genitalia

- In the female patient, palpate the mammary glands carefully for masses. If the history indicates a possibility of pregnancy or pseudopregnancy, gently express the nipples for signs of discharge or milk. In the nursing bitch or queen, examine the mammary glands for abnormal swelling, firmness, or heat, as seen with mastitis or abscessed glands.
- In the female patient, examine the vulva for conformational abnormalities, swelling, or discharge. Determine the color, consistency, and odor of the discharge. Examine the vulvar mucous membranes for evidence of jaundice, cyanosis, petechiae, or ulceration for clues of systemic disease. In dystocia or when a vaginal discharge is present, a vaginal examination is indicated. Vaginoscopy may be required to rule out the presence of vaginal masses.
- In the male canine, examine the prepuce and penis. Retract the preputial sheath caudal to the bulb so that the entire penis can be examined for any signs of trauma or masses. Inspect the penis for jaundice, cyanosis, petechiae, ulceration, or masses. Examine the tip of the feline penis for evidence of obstruction (discoloration or the presence of plug material) if indicated by the history.
- In the male intact patient, palpate both testicles for symmetry, firmness, and irregularity. If both testicles are not present in the scrotum, examine the inguinal region for the presence of a retained testicle and palpate the abdomen for masses.

See also Section 7.

Rectal Examination

- A rectal examination often provides valuable information during a physical examination.
- During a rectal examination, palpate the sublumbar lymph nodes in the dorsal aspect of the pelvic canal. Enlargement is usually suggestive of metastatic neoplasia.
- Note the symmetry of the pelvis and the presence of palpable fractures during the rectal examination. This is always indicated in a trauma victim. Evaluate abnormal masses in the pelvic canal for size, position, and consistency.
- During the rectal examination, evaluate the perineal and perianal regions for hernias or abnormal masses.
- Evaluate the anal sacs for evidence of infection, distention, or masses.
- Examine any fecal material obtained for amount, consistency, color, and presence of blood or mucus. Note the presence of foreign material such as bone fragments, gravel, cloth, or plastic.
- Perform a rectal examination in all mature male dogs to evaluate the prostate. The normal prostate is bilobed (characterized by the presence of the median raphe), symmetric, smooth, and nonpainful. If the prostate is enlarged, it may extend slightly over the brim of the pelvis or fall into the abdomen, as previously described for the palpation of the caudal abdomen.
- In female dogs, abnormal masses associated with the uterus or urethra may occasionally be detected on rectal palpation.

Skin

- Inspect the general appearance of the haircoat for luster, fullness, and areas of hair loss. Note symmetric alopecia as seen with endocrinopathies, such as hyperadrenocorticism, hypothyroidism, or sex hormone imbalances. Inspect areas of alopecia for broken hairs as seen with pruritic or psychogenic conditions. Check for erythema as will be seen in allergic or inflammatory conditions.
- When approaching a pet with a dermatologic problem, examine all areas of the body. Location of skin lesions often aids in the diagnosis. For example, localized demodicosis causes patches of alopecia involving the head and forelegs. Sarcoptic mange typically causes scaling and partial alopecia of the pinnae, elbows, and hocks. Do not overlook the interdigital areas and the foot pads. Examine mucocuta-

neous junctions (lips, anus, vulva, preputial orifice, etc.) for evidence of an immune-mediated disease.
- Identify all skin lesions and categorize them as primary or secondary. Primary lesions include papules, pustules, nodules, wheals, macules, and vesicles. Common secondary lesions are scales, crusts, ulcers, excoriations, lichenifications, hyperpigmentations, and hyperkeratoses.
- Note evidence of external parasites. Large flakes and scales in a pruritic patient may indicate *Cheyletiella* infestation. If fleas are not seen, search the patient for flea dirt, especially in the tail-head region. A flea comb is often helpful in discovering small amounts of flea dirt. Repetitive combing may be necessary to find small amounts of flea dirt in the flea allergy dermatitis patient. While combing the patient, you can educate the owner regarding flea control.

See also Section 5.

Musculoskeletal System

- Initially evaluate the musculoskeletal system by observing for lameness while the patient is in motion both at a walk and at a trot. Observe the patient's posture with special attention to head carriage, head bobbing, arching of the back, or stilted gait. For forelimb lameness, an obvious downward bobbing of the head will be present as the sound leg makes contact with the ground.
- A complete musculoskeletal examination is not necessary unless evidence of lameness or pain is noted in the history or on initial observation of the patient.
- Gently manipulate the patient's head dorsally, ventrally, and to either side to look for evidence of pain or resistance. Palpate the vertebral column for signs of a pain response. Pressure applied to either side of the dorsal spinal process of each vertebra may be necessary to elicit pain (see Chapters 100, 128).
- If lameness is present, examine the affected limb systematically to localize the area involved. First, examine the foot for evidence of traumatized or abnormal toenails or nail beds. Evaluate each interdigital area for erythema, swelling, or draining tracts, which may be indicative of a foreign body. Palpate each toe individually and note swelling or pain.
- Palpation proceeds proximally. Evaluate each long bone for pain, swelling, abnormal masses, or palpable fractures.
- Evaluate each joint for evidence of effusion, soft-tissue swelling, crepitation, or pain with flexion and extension.
- In examining the stifle, note the position of the patella in extension and flexion. If the patella is in its normal location, attempt to luxate it medially and laterally. Extension of the stifle usually aids in mobilizing the patella. Manipulate the stifle for evidence of a cranial drawer sign that indicates an anterior cruciate ligament tear (see Chapter 110).
- Evaluate each coxofemoral joint range of motion and evidence of pain. Test for a positive Ortolani sign to evaluate for hip laxity if the patient's breed is at risk for hip dysplasia (see Chapter 108 for more details).
- If difficulty arises in localizing the lameness, always compare the results of palpation and manipulation of the affected limb with those on the contralateral limb.

Nervous System

As with the musculoskeletal system, a complete neurologic examination is not necessary unless specifically indicated by the history or the general physical examination. The details of the neurologic examination are discussed in Chapter 125. A brief overview of the basic procedures for the localization of lesions is provided here.

- Observe mental status and behavior as previously described.
- Evaluate the gait and posture while the patient is walking and standing. Pay particular attention to strength, symmetry, and coordination.
- Always perform a complete cranial nerve examination when evaluating neurologic problems (see Chapters 125 and 126). This includes checking for a menace response, palpebral reflex, and pupillary light flexes. Note pupillary symmetry and ocular positioning. Facial sensation can be tested by lightly touching the nasal mucosa with a hemostat. The presence of a gag reflex should have been noted during the oral exam.
- Evaluate and compare postural reactions in all limbs, including proprioception, "wheelbarrowing," hopping, extensor postural thrust, and placing reactions.
- Evaluate and compare spinal reflexes with the calm patient in lateral recumbency. Important segmental reflexes include the triceps, biceps, patellar, and cranial tibial reflexes, as well as the flexor (withdrawal) reflexes of the thoracic and pelvic limbs. Evaluate the panniculus reflex by needle stimulation of the thoracic or lumbar skin (see Chapter 125).
- Evaluation of some parts of the neurologic examination is subjective. If you are unsure how the patient responded to a particular test, then repeat the test in question and compare the results. If the patient is hospitalized, the exam will need to be repeated at regular intervals to evaluate progression of the disease and response to treatment.

Chapter 2

Practical Methods of Anesthesia

John A. E. Hubbell

Anesthesia is an integral part of the practice of companion animal medicine. In addition to surgical applications, some form of anesthesia may be required for a wide variety of procedures, such as radiography, endoscopy, cerebrospinal fluid collection, and bone marrow aspiration.

▼ ***Key Point*** The keys to successful anesthesia include (1) an understanding of what is "normal" in the various species; (2) a working knowledge of the pharmacology of anesthetic drugs; and (3) a systematic evaluation and reevaluation of the patient's status (monitoring) during the period of anesthesia.

The understanding of what is "normal" comes with experience. Several excellent texts describe the pharmacology of anesthetic drugs (see "Supplemental Reading" at the end of this chapter). Monitoring is a matter of establishing a routine and maintaining the discipline to adhere to the routine. This chapter suggests some basic anesthetic techniques and protocols that can be used successfully in small animal practice.

GENERAL PRINCIPLES

Preoperative Assessment (Table 2-1)

- A history of vomiting or a recent meal is an indication for postponing surgery or using techniques that produce rapid induction, allowing rapid endotracheal intubation that minimizes the potential for aspiration of gastric contents.
  - On an elective basis, withhold food 6 to 8 hours before the administration of anesthetic drugs.
  - Do not withhold water.
  - Potential problems discovered from the history include exercise intolerance or cough, as an indicator of cardiorespiratory dysfunction; polyuria or polydipsia, as an indicator of endocrine or renal dysfunction; or any other recent change in the animal's physical status.
- Perform a physical examination with emphasis on the cardiovascular and respiratory systems (Table 2-2 provides normal values).
  - Evaluate traumatized patients more extensively because of the potential for blood loss, cardiac arrhythmias (ventricular tachycardia), and thoracic trauma (pneumothorax).
  - Evaluate abnormalities discovered after auscultation, percussion, palpation, and examination of mucous membranes with ancillary tests, such as thoracic radiography and electrocardiography.
  - The pertinent abnormalities associated with various metabolic diseases are discussed in the appropriate chapters of this text.
- Weigh the animal. Estimate the lean body weight if the animal is obese to more accurately calculate correct anesthetic drug doses.
- Determine packed cell volume and total plasma protein to establish a baseline for reference if hemorrhage occurs. Check renal function with blood urea nitrogen (BUN) or creatinine concentrations in older (>7 years) animals. Increases in BUN or creatinine values may dictate a more careful perianesthetic fluid management to prevent further renal dysfunction (see Table 2-2).

Intravenous Catheterization

Place an IV catheter before induction of anesthesia to provide a convenient pathway for the administration of drugs, to allow fluid or blood administration if required, and to ensure access to the vascular space if an emergency occurs.

Endotracheal Intubation

A patent airway is essential to any anesthetic protocol.

- Place a cuffed endotracheal tube in the trachea soon after induction of anesthesia.
- Alternatively, use drugs that maintain the swallowing reflex (ketamine or tiletamine/zolazepam).
- Clean, thoroughly rinse, and dry endotracheal tubes between uses. Sterilization of endotracheal tubes between uses is not necessary on a routine basis. Use chemical sterilization or discard the tube if a known pathogen is present. Glutaraldehyde is a safe disinfectant if the tubes are thoroughly rinsed following sterilization.
- See Table 2-3 for the suggested range of sizes of endotracheal tubes for dogs and cats.

Table 2-1. PREANESTHETIC CHECKLIST

History and Physical Examination
Age
Body weight
Temperature
Auscultation
Respiratory rate
Pulse rate, rhythm, and strength
Hydration, mucous membrane color, and capillary refill time
Mentation
Current medication history
Cardiopulmonary, renal, and nervous system disease history

Laboratory Data
Packed cell volume
Total plasma protein
Blood urea nitrogen, creatinine, or serum dipstick analysis (Azostick) if less than 7 years
Other tests optional, dependent on primary disease

Drugs
Appropriate anesthetic drugs
Sufficient oxygen supply
Emergency drugs
- Atropine or glycopyrrolate
- Lidocaine
- Epinephrine
- Sodium bicarbonate
- Intravenous fluids
- Dopamine
- Doxapram

Equipment
Syringes, needles, and catheters
Leak-tested anesthetic machine
Cuffed endotracheal tubes
Optional monitoring equipment
- Electrocardiogram
- Blood pressure monitor (pulse detector)
- Stethoscope
- Pulse oximeter

PRODUCING A TRACTABLE ANIMAL

Many procedures, such as radiography and cystocentesis, do not require complete anesthesia. In these instances, the combination of appropriate sedation and physical restraint can facilitate the completion of the procedure with minimal stress to the patient and minimal drug-induced cardiopulmonary depression. The choice of drugs is based on species, the patient's temperament, physical status, the veterinarian's familiarity with the drug, and the intended purpose. The agents that follow are employed as components of many anesthetic protocols.

The doses of drugs alone and in combination are listed in Table 2-4 (dogs) and Table 2-5 (cats).

Tranquilizers

Acepromazine

- A potent phenothiazine tranquilizer that produces sedation in the dog. It also has antiemetic and antiarrhythmic properties.

Table 2-3. APPROXIMATE ENDOTRACHEAL TUBE SIZES

	Weight (kg)	Cuffed Tube Diameter (mm)
Dogs	3–7	3.0–5.0
	7–15	5.0–7.5
	15–30	7.5–9.5
	>30	9.5–12.0
Cats		2.5–4.0

Table 2-2. NORMAL VALUES

	Dogs Awake	Anesthetized (If Different)	Cats Awake	Anesthetized (If Different)
Temperature (°F)	99.5–102.5		100.0–102.5	
Heart rate (bpm)	70–180	60–180	145–200	100–200
Respiratory rate (breaths/minute)	20–40	8–20	20–40	10–30
Capillary refill time (sec)	<1.5		<1.5	
Packed cell volume (%)	35–54		27–46	
Total plasma protein (g/100 ml)	5.7–7.3		6.3–8.3	
Total leukocytes (6,000–17,000/µl)	6–18		6–20	
Albumin (g/100 ml)	2.1–3.6		2.3–3.6	
Sodium (mEq/L)	140–155		149–162	
Potassium (mEq/L)	3.8–5.3		3.6–5.4	
Chloride (mEq/L)	105–121		105–135	
Calcium (mg/100 ml)	8.8–11.3		8.3–11.3	
Creatinine (mg/100 ml)	0.3–1.3		0.8–1.8	
Blood urea nitrogen (mg/100 ml)	8–25		15–35	
Arterial pH	7.30–7.43		7.27–7.40	
Arterial pCO_2 (mm Hg)	30–49		35–49	
Arterial pO_2 (mm Hg)	91–97	90–500 (>50% inspired O_2)	91–97	100–500 (>50% inspired O_2)
Arterial HCO_3 (mEq/L)	18–22		18–25	
Arterial base excess (mEq/L)	–3 to +3		–5 to +1.5	
CO_2 combining power (mEq/L)	15–25		16–30	

Table 2-4. ANESTHETIC DRUGS AND DOSES IN DOGS

Drug	Intravenous Dose (mg/kg)	Intramuscular or Subcutaneous Dose (mg/kg)

Ketamine/acepromazine	2–5/0.05–0.10	5–10/0.1–0.2
Ketamine/xylazine	1–5/0.1–0.8	5–10/0.3–1.5
Ketamine/diazepam (50:50)	1 ml/10 kg	NR

*NR, not recommended.

- Not an analgesic itself, but it may potentiate other drugs that are analgesics.
- Produces hypotension through an α-adrenergic blockade, particularly in large doses.
- Potentiates hypothermia.
- Epinephrine reversal (i.e., hypotension after epinephrine administration) can occur.
- Calms excitable dogs. Aggressive dogs or cats may not become tractable. Combine with opioids or cycloheximides to produce the desired effect (see Tables 2-4 and 2-5).
- Avoid in animals with epilepsy, shock, bleeding disorders (inhibition of platelet function), or liver disease.
- Reduce the dose or choose another agent in stressed or older animals because effects may be exaggerated. Cats are calmed but usually still resist restraint.

Xylazine

- An α_2-adrenergic agonist that produces sedation with muscle relaxation and analgesia.
- Produces an obtunded state from which the patient is difficult to arouse.
- Produces analgesia for minor procedures. Is not usually sufficient for surgery.
- Produces profound cardiopulmonary depression, including bradycardia, first- and second-degree atrioventricular blockade, catecholamine sensitization, and decreased respiratory rate.
- Combine with an anticholinergic (atropine or glycopyrrolate), particularly if large doses are administered.
- Do not use in patients with preexisting cardiac, liver, or kidney disease or with shock.
- Reverse effects with yohimbine, tolazoline, or atipamezole (see "Recovery and Reversal" for doses).
- Vomiting occurs in approximately 25% of dogs and 50% of cats.
- See Tables 2-4 and 2-5 for doses.

Medetomidine

- An α_2-adrenergic agonist that produces sedation with muscle relaxation and analgesia (see Tables 2-4 and 2-5 for doses).
- Similar to but approximately 100 times more potent than xylazine with a longer duration of action.
- Produces analgesia for minor procedures. Combine with ketamine or opioids to enhance analgesia.
- Produces dose-dependent cardiopulmonary depression including bradycardia, decreased arterial blood pressure, and slowing of respiratory rate.

Table 2-5. ANESTHETIC DRUGS AND DOSES IN CATS

Drug	Intravenous Dose (mg/kg)	Intramuscular or Subcutaneous Dose (mg/kg)
Anticholinergic		
Atropine	0.02–0.04	0.02–0.04

Acepromazine/butorphanol	0.05–0.07/0.07–0.15	0.1–0.2/0.1–0.2
Ketamine/acepromazine	4–8/0.05–0.10	7–15/0.1–0.2
Ketamine/xylazine	4–8/0.1–0.8	7–15/0.3–1.5
Ketamine/diazepam (50:50)	1 ml/10 kg	NR

*Higher doses can be associated with nervousness and excitement.
†NR, not recommended.

- Combine with an anticholinergic (atropine or glycopyrrolate), particularly if large doses are administered.
- Do not use in patients with preexisting cardiac or kidney disease or with shock.
- Reverse effects with yohimbine, tolazoline, or atipamezole (see "Recovery and Reversal" for doses).
- Vomiting, diuresis, and muscle jerking may occur.

Diazepam and Midazolam

- Benzodiazepine derivatives that produce mild sedation in dogs and cats. Neither is effective in calming an excited patient when used alone. Both are anticonvulsants.
- Use to enhance tractability in depressed patients or in combination with other agents (primarily opioids).
- Administer diazepam IM or slowly IV with caution. The drug is solubilized in a propylene glycol base that can produce bradycardia and hypotension.
- Administer water-soluble midazolam IV, SC, or IM.
- Use in patients with cardiorespiratory compromise or another metabolic disease. Both agents produce minimal cardiopulmonary side effects and provide muscle relaxation.
- Use both drugs as premedicants to parenteral or inhalation anesthesia.
- Occasionally, paradoxical responses occur, including disorientation and aggression.
- Diazepam can be given as an appetite stimulant in cats.
- See Tables 2-4 and 2-5 for doses and suggested combinations.

Analgesic Drugs (see also Chapter 6)

Nonsteroidal Anti-inflammatory Drugs

- Use nonsteroidal anti-inflammatory drugs (NSAIDs) for acute and chronic pain associated with inflammation. They reduce pain by inhibiting prostaglandin formation and through central effects.
- Potentiate the action of other analgesics.
- Use NSAIDs orally or by injection to provide analgesia, antipyresis, and as an anti-inflammatory in the perioperative period and for chronic pain. Analgesia produced is equivalent to opioids for some types of pain.
- NSAIDs can cause gastrointestinal injury and renal damage.
- See Table 2-6 for doses.

Table 2-6. NONSTEROIDAL ANTI-INFLAMMATORY DRUG USE IN DOGS

Nonsteroidal Anti-inflammatory Drug	Dosage
Carprofen	2 mg/kg twice daily or 4 mg/kg once daily orally (injectable 4 mg/kg SC once daily)
Deracoxib	3–4 mg/kg once daily orally for 7 days
Etodolac	10–15 mg/kg once daily orally
Ketoprofen	2.2 mg/kg IV, SC, or IM for dogs and cats, single dose
Meloxicam	0.1 mg/kg (0.2 mg/kg loading dose) once daily, SC, PO (cats: if given SC, dose of 0.3 mg/kg is used one time only)
Phenylbutazone	40 mg/kg daily in three divided doses for 2 days then reduce
Tepoxalin	10 mg/kg once daily orally

Opioids

- Use in dogs and cats to augment the effects of sedatives and tranquilizers and to provide analgesia.
- Minimal or no sedation is produced when administered alone, except for morphine and meperidine. Use in combination with tranquilizers or sedatives.
- Use lower doses in cats compared with dogs (see Tables 2-4 and 2-5), because higher doses have the potential to cause excitement and disorientation.
- Morphine, oxymorphone, fentanyl, hydromorphone, and meperidine are opioid agonist drugs frequently used in small animal practice. Regulations require rigorous recordkeeping and security.
- Vagal tone is increased (bradycardia), and respiration is depressed.
- Sensations of touch or vision are not diminished. Sensitivity to sound may be increased.
- May cause vomiting and defecation.
- Reverse agonists and agonist-antagonists with naloxone. Partial reversal of the respiratory and central nervous system (CNS) depressant effects of agonists can be accomplished with agonist-antagonists (e.g., butorphanol), which reverse the deleterious effects of the agonists and provide the animal with some analgesia.

Fentanyl

- Fentanyl can be administered transdermally using a patch developed for human use. Time from patch application until full effect is 2 to 6 hours in cats and 12 to 24 hours in dogs.
- The skin must be clipped (or shaved) to facilitate absorption, but absorption varies considerably. Duration of action may be as long as 5 days. Prevent ingestion by the animal or humans.

Other Opioids

- Butorphanol, nalbuphine, and buprenorphine are opioid agonist-antagonist or partial agonist drugs. This classification means that these compounds produce analgesia but have less addictive potential.
- Degree of analgesia may be sufficient for mild to moderate pain but not for severe pain.

Dissociative Anesthetics

Ketamine and Tiletamine/Zolazepam

- Ketamine and tiletamine/zolazepam (Telazol, Ft. Dodge Animal Health, Ft. Dodge, Iowa) produce a unique form of sedation or anesthesia that has been called dissociative anesthesia.
- These maintain swallowing and ocular reflexes, increase muscle tone, and produce amnesia, superficial analgesia, and catatonia.
- They stimulate the cardiovascular system, resulting in increased heart rate and arterial blood pressure.
- They produce an apneustic (breath-holding) respiratory pattern. The intensity is dose related.
- Use low doses of ketamine (up to 6 mg/kg IM) in the cat to produce an obtunded state with malleable rigidity of the limbs, dilated pupils, and hypersalivation. Higher doses (14–20 mg/kg IM) have been used, but analgesia is not an appropriate level for visceral surgery. Using ketamine with other drugs (xylazine, medetomidine, diazepam, or midazolam) is a better approach in both dogs and cats. Do not give ketamine alone in the dog because of resultant muscle rigidity and seizure activity. See Tables 2-4 and 2-5 for doses.
- Use tiletamine/zolazepam (Telazol) to produce a state similar to that of ketamine with the addition of muscle relaxation. The drug is approved for IM use in both the dog and the cat. At low doses (2–4 mg/kg IM) it provides helpful restraint in both the dog and the cat. It is also used in small doses IV (0.5–1.5 mg/kg) in a manner similar to ketamine/diazepam for induction and short-duration restraint (see Tables 2-4 and 2-5 for doses).

INJECTABLE DRUGS FOR SHORT-TERM ANESTHESIA

A variety of injectable drugs and drug combinations can be used for short-term anesthesia or restraint in dogs (Table 2-7) and cats (Table 2-8). Many of these combinations employ the drugs previously described. Prior administration or coadministration of sedatives or

Table 2-7. SUGGESTED ANESTHETIC PROTOCOLS FOR DOGS

Patient (Agent)	Dose	Comments
Healthy (Elective Procedure)		
Acepromazine	0.02 mg/kg SC or IM	Total dose not to exceed 4 mg
Thiopental	6–10 mg/kg IV	Give 6 mg/kg initially, increase in 2 mg/kg increments
Isoflurane* (or)	0.5%–3.5%, inhaled	Adjust to anesthetic depth
Sevoflurane*	2.0%–4.5%, inhaled	Adjust to anesthetic depth
Aged Patient		
Intravenous fluids		
Ketamine/diazepam (50:50) (or)	1 ml/10 kg IV	Short duration of action
Propofol	2–4 mg/kg IV	
Isoflurane* (or)	0.5%–3.5%, inhaled	
Sevoflurane*	2.0%–4.5%, inhaled	
Patient in Pain		
Intravenous fluids		
Acepromazine	0.01–0.02 mg/kg IM	Can be mixed with oxymorphone
Oxymorphone	0.05–0.02 mg/kg IM	Watch for bradycardia
Thiopental	4–8 mg/kg IV	Dose is reduced after premedicant; start with 4 mg/kg
Isoflurane* (or)	0.5%–3.5%, inhaled	
Sevoflurane*	2.0%–4.5%, inhaled	
Critical Patient		
Intravenous fluids		
Diazepam and	0.02 mg/kg IV	Give slowly
Propofol (or)	2–4 mg/kg IV	Give to effect
Ketamine/diazepam (50:50)	1 ml/10 kg IV	
Isoflurane* (or)	0.5%–3.5%, inhaled	
Sevoflurane*	2.0%–4.5%, inhaled	

*Concentration required depends on fresh gas flow rate. The lower the flow rate, the higher the concentration required.

Table 2-8. SUGGESTED ANESTHETIC PROTOCOLS FOR CATS

Patient (Agent)	Dose	Comments
Healthy (Elective Procedure)		
Acepromazine (with)	0.01–0.02 mg/kg SC or IM	Mix acepromazine with ketamine; add opioid for analgesia
Ketamine (and)	4–8 mg/kg IM	
Thiopental (or)	5–10 mg/kg IV	Give to effect
Tiletamine/zolazepam (with)	3–5 mg/kg IM	Tiletamine/zolazepam may be sufficient for intubation
Thiopental	3–7 mg/kg IV	
Isoflurane* (or)	0.5%–3.5%, inhaled	
Sevoflurane*	2.0%–4.5%, inhaled	
Aged or Renally Compromised Patient		
Intravenous fluids	0.05 mg/kg IM	
Midazolam with oxymorphone	0.1–0.2 mg/kg IM	Drugs can be mixed
Ketamine (or)	1–2 mg/kg IV	
Thiopental (or)	3–7 mg/kg IV	
Propofol	2–4 mg/kg	Give slowly to effect
Isoflurane* (or)	0.5%–3.5%, inhaled	
Sevoflurane*	2.0%–4.5%, inhaled	
Critical Patient		
Intravenous fluids		
Ketamine/diazepam (50:50)	0.5 ml/5 kg IV	Administer slowly
Isoflurane* (or)	0.5%–3.5%, inhaled	
Sevoflurane*	2.0%–4.5%, inhaled	

*Use a non-rebreathing anesthetic system (Bain or Ayres T-piece).

tranquilizers with drugs that produce anesthesia allows a reduction in the dose of the anesthetic drug. Anesthetic drugs tend to produce more depression of cardiopulmonary function than do sedatives or tranquilizers; thus the patient benefits from the decreased dose. Thiobarbiturates are the primary addition to the list of drugs already discussed. Other drugs, such as etomidate and propofol, offer potential advantages, such as fewer cardiopulmonary effects and lack of cumulative effects, but are expensive. Although endotracheal intubation is not required for the delivery of injectable anesthetic drugs, patients can benefit from intubation for protection of the airway and for oxygen supplementation.

Thiobarbiturates (Thiopental)

- Sedative or hypnotic agents that produce short-term IV anesthesia.
- Barbiturates produce CNS depression that ranges from drowsiness to coma.
- Not good analgesics at subhypnotic doses. When doses are increased to produce unconsciousness, anesthesia is produced.
- Cause respiratory depression and some arterial blood pressure depression.
- Sensitize the heart to catecholamine-induced arrhythmias. Ventricular bigeminy is often noted but resolves without treatment.
- Duration of effect is primarily determined by redistribution away from the brain into muscle and lean body tissues. Level and duration of anesthesia produced by a given dose depends on what other drugs have been administered, the rate of administration, and the level of awareness of the animal at the time of administration.
- Use with caution in patients with preexisting cardiovascular disease, hypotension, or shock.

▼ ***Key Point*** Do not use thiobarbiturates in greyhounds or other sighthounds because of prolonged elimination.

- Administer to effect, beginning with doses in the range of 4 to 6 mg/kg, increasing in 2 mg/kg increments. Onset of action is within 30 seconds.
- Can be mixed 50:50 (volume to volume) with propofol to allow a reduction in the dose of both drugs as a way to reduce cost. Can cause sloughing of tissues if administered perivascularly.
- Use for induction to inhalation anesthesia. Compatible with all agents previously described. Reduce the dose by approximately half if sedatives or tranquilizers are given prior to administration.
- Duration of action is prolonged by hypoproteinemia and acidosis. Administer IV fluids to shorten duration by promoting diuresis, and administer $NaHCO_3$ (2 mEq/kg) to shorten duration by alkalinizing the urine.

Propofol

- A phenolic compound that produces hypnosis similar to thiopental.
- Depresses hemodynamics comparable to thiobarbiturates, but does not sensitize the myocardium to epinephrine-induced arrhythmias.
- Depresses respiration. Administer slowly IV over a 30- to 60-second period to minimize the potential for apnea.
- Use with analgesics for painful procedures. Anesthesia can be maintained using propofol as a continuous IV infusion (0.4–0.8 mg/kg/min).
- Noncumulative, so recovery following multiple doses or an infusion occurs within the same time frame as that following a single dose.
- Relatively insoluble. Supports microbial growth if contaminated. Discard unused drug.
- Useful for induction of anesthesia in sighthounds and patients requiring cesarean section. Useful in compromised patients because of the lack of residual effects.

Ketamine Mixtures

Use ketamine in combination with sedatives and tranquilizers to provide short-term injectable anesthesia.

Ketamine/Diazepam

- Administer ketamine with diazepam in a 50:50 (volume-to-volume) mixture at a dose of 1 ml/10 kg IV. Give for brief periods (5–10 minutes) of restraint. Provides enough analgesia for minor surgical procedures. Readminister as needed to effect.
- Works well in depressed or geriatric patients. May not be effective in young, excited, or aggressive animals. Produces moderate muscle relaxation, cardiopulmonary support, and increased salivation. Ocular and swallowing reflexes are maintained, but orotracheal intubation can be accomplished.

Ketamine/Acepromazine

- Use ketamine with acepromazine to produce a quieter recovery than that with ketamine/diazepam but less muscle relaxation. Usually produces enough anesthesia for minor peripheral surgery, but visceral analgesia is not sufficient for abdominal surgery.

Ketamine/Xylazine and Ketamine/Medetomidine

- These combinations produce muscle relaxation, sedation, and analgesia that are improved over other combinations.
- Bradycardia and depression of cardiac contractility and respiration occur. Coadminister an anticholinergic. Use in young animals with good cardiopulmonary reserve. Avoid in animals with preexisting

cardiovascular disease, particularly those with cardiac conduction abnormalities.
- The combination of medetomidine (60–80 μg/kg), butorphanol (0.2 mg/kg), and ketamine (5 mg/kg) administered IM is a useful preanesthetic in cats that is sufficient for some surgery and is easily augmented with inhalants.

Tiletamine/Zolazepam

- Use IV or IM to produce anesthesia.
- Produces muscle relaxation and support of hemodynamics, but also produces respiratory depression.
- Maintains oropharyngeal reflexes. Recovery is prolonged with increasing doses. Recovery is usually uneventful in the cat but may be stormy in the dog.
- Administer low doses of acepromazine to quiet a difficult recovery.

Etomidate

- A nonbarbiturate hypnotic that can be used for short-term IV anesthesia.
- Produces a hypnotic state with little cardiovascular effect.
- Etomidate is expensive. Limit to patients with significant cardiovascular and respiratory disease.
- Recovery can be stormy, with vomiting and muscle tremors. Premedicate the animal with sedatives or tranquilizers to minimize these effects.

Anticholinergics

- Used to reduce salivation, block vagal inhibition of the heart, and quiet the digestive tract if indicated.
- Not innocuous. Respiratory dead space is increased (bronchodilation). Ventricular arrhythmias are more likely to occur.
- Use if bradycardia occurs or is likely to occur.
- Not routinely indicated in anesthesia. Myocardial oxygen consumption is increased owing to tachycardia. Secretions become more viscous.
- Glycopyrrolate is more potent and has a longer duration of action than atropine. It does not cross the placental or blood-brain barrier.
- Give IM, SC, or IV when expediency is important. Atropine dose is 0.02 to 0.04 mg/kg. Glycopyrrolate dose is 0.01 mg/kg.

ANESTHESIA FOR MAJOR PROCEDURES

Anesthesia for major procedures, requiring optimal hypnosis, analgesia, and muscle relaxation for relatively long periods, usually incorporates the inhalant anesthetics (see Tables 2-7 and 2-8). Although inhalant drugs can be given as the sole source of anesthesia, injectable drugs are usually given to facilitate induction and endotracheal intubation. The injectable drugs and drug combinations previously described, with the possible exception of ketamine/xylazine combinations, can be used to induce anesthesia. Ketamine/xylazine combinations produce significant cardiopulmonary depression that can be extreme when inhalant anesthetic drugs are added.

Inhalant Anesthetics

- Inhalant anesthetics have several advantages, including the coadministration of oxygen, the ease with which anesthesia depth is changed, and the fact that recovery does not depend on metabolism. The agents are primarily eliminated by exhalation. Administer via breathing circuits, with circle anesthetic systems being the most common.

Equipment

Circle Anesthetic Systems

- A carbon dioxide absorber removes carbon dioxide from the exhaled gas.
- Exhaled gas is rebreathed, making the system an economic one.
- Use 4 to 7 ml/kg/min as the minimum fresh gas flow rate for oxygen. This rate matches the animal's metabolic need for oxygen. Increase the fresh gas flow rate for oxygen to 10 to 20 ml/kg/min if nitrous oxide is given. Add the nitrous oxide flow to the oxygen flow rate. The pop-off valve in the circle system needs to be open to vent the excess gas at this flow rate.

Non-rebreathing Anesthetic Systems

- Bain and Modified Jackson Rees (Hudson RCI; Temecula, California) (SurgiVet; Waukesha, Wisconsin).
- Use for patients less than 2 to 4 kg, because less resistance to respiration is produced.
- Use a fresh gas flow of 1.5 times the minute ventilation (approximately 150 ml/kg/min). Fresh gas flow rates are higher because the fresh gas removes carbon dioxide from the system.

Scavenging Equipment

▼ ***Key Point*** Use of inhalation anesthetics mandates the removal of expired and waste gases from the operating room environment.

- Exhaust waste gases using suction systems or vent them to the outside via a hole in an exterior wall.
- Directing gases to the floor is insufficient.
- Use activated charcoal canisters as alternatives to absorb halogenated compounds. This is not effective for nitrous oxide.

Isoflurane

- Halogenated ether that produces anesthesia when inhaled in concentrations of 1.0% to 3.0%.
- Produces very rapid induction and recovery; relatively insoluble in blood.
- Maximal attainable concentration at room temperature is 30%.
- Use in precision out-of-the-circle vaporizers.
- Produces dose-dependent cardiopulmonary depression. Adequate ventilation is usually maintained. Ventricular arrhythmias are not enhanced.
- Use in patients with metabolic disease, in geriatric patients, and in patients prone to cardiac arrhythmias.
- Is minimally metabolized (<1%).

Sevoflurane

- Newest inhalant anesthetic approved for use in animals.
- Cardiopulmonary effects similar to isoflurane.
- Very insoluble in blood, and similar to nitrous oxide in speed of induction and recovery.
- Inoffensive odor is useful for masking.
- Administer at concentrations of 5% of induction followed by maintenance at 2.5% to 3.5%.
- Use in a precision out-of-the-circle vaporizer.
- Is minimally metabolized (3%). Do not used with desiccated carbon dioxide absorbent because of fire hazard.

Nitrous Oxide

- A nonirritant gas that produces some analgesia when inhaled in concentrations of 50% to 70%.
- Cannot produce anesthesia when administered alone. Can reduce the required concentration of the other, more potent, gases (e.g., isoflurane) by approximately one third when coadministered.
- Recovery can be complicated by diffusion hypoxia. Oxygen should be supplemented for 3 to 5 minutes after cessation of nitrous oxide administration.
- Total fresh gas flow rate must be increased if nitrous oxide is given.
- Not employed widely in veterinary practice because of its limited potency and potential problems with hypoxia.

▼ ***Key Point*** Do not use nitrous oxide in patients with pneumothorax, gastric torsion, or intestinal obstruction because it will diffuse into closed gas spaces and enlarge them.

Adjuncts to Inhalant Anesthesia

- Inhalant anesthetics may be too depressant for some patients.
- Intravenous opioids such as fentanyl (0.002–0.006 mg/kg IV) can be administered to augment analgesia with little cardiopulmonary effect.
- The combination of morphine, lidocaine, and ketamine can be used to supplement analgesia and reduce the requirement for inhalant anesthetics. Add 15 ml of 2% lidocaine (300 mg), 0.6 ml ketamine (60 mg), and 1.6 ml morphine (24 mg) to 1 L balanced electrolyte solution. Administer the combination at the standard rate (10 ml/kg/hour IV).

LOCAL ANESTHESIA AND ANALGESIA

- Local anesthetics (lidocaine, mepivacaine, bupivacaine, ropivacaine, etc.) produce complete analgesia with few cardiopulmonary effects.
- Local anesthesia can be used alone for some minor surgery, such as skin mass removal.
- Use local anesthetics in combination with other techniques prior to surgery to prevent pain "wind-up," allowing for better postoperative pain relief.
- Block the digital nerves at the level of the carpus prior to performing surgery of the paw, such as declawing cats.
- Epidural injection of local anesthetics or opioids (morphine) is used to produce analgesia for surgery of the rear limbs and caudal abdomen.

MONITORING THE ANESTHETIZED PATIENT

Monitoring is the cornerstone of safe anesthetic practice. Because irreversible CNS changes can occur within 4 or 5 minutes of cardiac arrest, a convenient monitoring interval of 5 minutes is appropriate. The skills needed in basic monitoring of anesthetized patients parallel those needed for performing a physical examination.

Anesthetic Record

- Prompts the anesthetist to evaluate the patient at regular intervals. Serves as a legal document.
- Contains the following information, at minimum:
  - Summary of preoperative physical examination
  - Purpose of anesthesia
  - Drugs administered, including dose, route, and time
  - Regular recording of heart or pulse rate and respiratory rate

Heart Rate

- Measured by auscultation using an esophageal stethoscope (Mallinckrodt), precordial stethoscope, or Doppler flow probe.
- Palpate a peripheral pulse to determine heart rate and provide additional subjective information concerning the strength of cardiac contraction. Feel the pulse on the ventral side of the tongue (lingual

pulse). Alternatively, use the femoral pulse if the animal's head is covered.
- Administer anticholinergics (atropine or glycopyrrolate) if the heart rate falls to less than 60 bpm in dogs and 90 bpm in cats.
- Evaluate the patient for hypotension or anesthetic plane that is too light if the heart rate is greater than 150 bpm in dogs or greater than 180 bpm in cats.
- Evaluate patients with irregular heartbeats or heartbeats of variable intensity with an electrocardiogram for abnormal cardiac rhythms.

Respiratory Rate

- Measure respiratory rate by watching the movements of the thoracic wall or the rebreathing bag of the anesthetic machine.
  - Most anesthetics are respiratory depressants.
  - Increases in rate or depth of respirations or panting usually indicate a plane of anesthesia that is too light.
  - Check the anesthetic depth in patients with irregular respirations; this can be a sign of excessive medullary depression. An apneustic pattern is expected after ketamine or tiletamine administration.

Capillary Refill Time and Mucous Membrane Color

- Gives further information on homeostasis.
- Capillary refill time should be less than 1.5 to 2 seconds.
- May be altered by the anesthetic agent chosen.

Other Monitoring Parameters

- Assess jaw tone to determine the degree of muscle relaxation present. This is an index of anesthetic depth.
  - Gently push the jaws apart and note the resistance to movement.
  - Dissociative agents do not produce muscle relaxation.
- Pinch a toe and look for a withdrawal response to check the depth of anesthesia prior to incision.

Monitoring Equipment

A wide variety of instruments are available to aid in monitoring patients.

Stethoscope

- Use esophageal stethoscopes (Mallinckrodt) to hear heart and respiratory sounds. Amplified stethoscopes are also available.

Electrocardiogram

- Use an electrocardiogram (ECG) to measure heart rate and to determine if cardiac arrhythmias are present.
- The ECG does not always ensure that the heart is beating or producing effective cardiac output.

Pulse and Blood Pressure Monitors

- Use Doppler flow probes (Parks Electronics; Aloha, Oregon) to detect peripheral pulses. Place the probe over a peripheral artery. An audible signal is created as pulses of blood pass under the probe and the sound waves emitted by the Doppler probe are altered. Place an occlusive cuff proximal to the Doppler probe to obtain an estimate of systolic arterial blood pressure. This monitor is reliable as a pulse detector but unreliable as an estimator of blood pressure. It can be used to follow trends. Use cuff widths approximately 30% of the circumferences of the extremity.
- Oscillometric units (Dinamap, Critikon; Tampa Bay, Florida) can record heart rate and estimate systolic, mean, and diastolic blood pressures. The units inflate an occlusive cuff and slowly release pressure. Characteristic pressure fluctuations during deflation are used to estimate blood pressure. These monitors are expensive and tend to lose accuracy as blood pressure falls. Use cuff widths approximately 30% of the circumference of the extremity.
- Dorsal pedal artery can be catheterized with an over-the-needle catheter to directly measure arterial blood pressures. Connect an aneroid manometer to the catheter as a simple way to determine the mean arterial blood pressure. Use a pressure transducer to make more definitive measurements.

Pulse Oximetry

- Detects pulses and uses reflectance or absorbance of light to estimate hemoglobin saturation.
- Pulse oximeters do not assure adequacy of ventilation, only adequacy of oxygenation.
- Most units also display pulse rate.
- Values should be in excess of 90%.
- Probes are usually placed on the tongue.
- Reposition the probe periodically as needed to maintain signal.

Blood Gas Analysis

- More definitive monitoring of respiratory and metabolic integrity is accomplished by measuring arterial pH and blood gas values.

See Chapter 5 for the characterization and treatment of acid-base disorders.

Table 2-9. ANTAGONISTS USED TO REVERSE ANESTHESIA

Benzodiazepine (Diazepam, Midazolam, Lorazepam) Antagonists	
Flumazenil	0.01–0.02 mg/kg IV
α_2-Adrenergic (Xylazine, Medetomidine) Antagonists	
Yohimbine	0.1–0.4 mg/kg IV
Tolazoline	0.5–2.0 mg/kg IV
Atipamezole	0.2–0.4 mg/kg IV
Narcotic Analgesic (Opioid) Antagonist	
Naloxone	0.003–0.010 mg/kg IV or IM

RECOVERY AND REVERSAL

Watch the patient after anesthesia until it can remain in sternal recumbency without being assisted.

- If reversible drugs have been given, the administration of antagonists speeds recovery (Table 2-9). Do not administer an antagonist indiscriminately.
- Doxapram (1–5 mg/kg) is a nonspecific stimulant of respiration and the CNS. Doxapram can be given to cause arousal in an emergency, but it can also produce undesirable excitement.
- Animals recovering from anesthesia may go through a period of emergence delirium. This period apparently results from a rapid return to consciousness with disorientation. The animal may or may not be in pain. Many animals respond to a reassuring voice and petting. Provide analgesia, sedation, or both for animals that do not respond to these actions.
- Check the animal's temperature. Most animals lose body heat during anesthesia.
- Some animals do not return to consciousness until body temperature is restored to 95°F to 97°F (35°C to 36.1°C).
- Warm animals by placing them on recirculating, warm-water heating pad; by providing radiant heat from a lamp; or by using a forced-air blanket.
- Take care to not burn the patient, particularly when heating lamps are used.
- Oxygen use increases dramatically with shivering. Monitor the patient, and provide oxygen if necessary.
- Leave the endotracheal tube in place until the animal regains the oropharyngeal reflexes (i.e., begins to swallow). Give oxygen if necessary.
- Remove IV catheters, if no longer necessary, after the patient is rewarmed and conscious. Postoperative hypotension can occur, particularly if the patient does not rapidly return to consciousness.
- Monitor the patient periodically until it can stand unassisted.

Chapter 3

Emergency and Critical Care Techniques and Nutrition

Shane W. Bateman / C. Anthony Buffington / Cheryl Holloway

This chapter describes commonly used techniques in emergency and critical care medicine. See appropriate chapters for information about diseases that require critical care.

INTRAVENOUS CATHETERIZATION BY CUTDOWN

Indications

▼ ***Key Point*** Venous access is required in every emergency situation.

Perform venous cutdown when percutaneous venous catheterization has been unsuccessful after one or two attempts (depending on the urgency with which access is required). Nonurgent venous cutdown can also be performed when numerous percutaneous catheterization attempts have resulted in severe peripheral hematoma formation or thrombophlebitis.

Contraindications

Relative contraindications include severe hemostatic dysfunction. However, occasionally such patients require IV catheterization, necessitating an easily compressible location as the best choice for a cutdown procedure.

Objective

Obtain vascular access for administration of fluid and drugs.

Equipment

- Local anesthetic
- Scalpel handle and #10 or #15 blade
- Iris scissors (very small sharp/sharp)
- Thumb forceps
- Curved mosquito hemostat
- Suitable size IV catheter (e.g., Surflo catheter, Terumo Medical Corp.)
- Needle holders, tissue forceps
- Monofilament skin suture appropriate to patient
- Skin staples (optional)

Technique

1. When the patient is semicomatose or moribund, local anesthesia is not required. Otherwise, infiltrate small amounts of local anesthetic into the aseptically prepared skin site.
2. In general, the lateral saphenous (canine) or medial saphenous (feline) are easier to approach than the cephalic veins. Jugular cutdown can also be performed with the same technique, but the vein is deeper and may be more troublesome for inexperienced surgeons to find.
3. After aseptic skin preparation and use of aseptic technique, identify the vessel. In many situations the vessel may not be visible even when occluded, so the anatomy of the vessel is important to understand.
4. Place the scalpel blade gently on the skin over the vessel and, without cutting the skin but maintaining skin contact with the blade, pull the skin laterally to the vessel (Fig. 3-1).
5. Incise approximately 1 to 1.5 inches parallel to the vessel.
6. Allow the skin to retract back into place over the vessel.
7. The bluish hue of the vessel should be obvious if the incision was made in a correct location. Move the skin to attempt to identify the vessel if it is not immediately obvious. To differentiate the vessel from underlying muscle bellies, the vessel should blanch with minimal digital pressure; muscle bellies will not.
8. Hold the iris scissors with the thumb and index finger in the finger rings with the tips of the scissors pointing across the palm of your hand, not extending out from the fingers. This allows the shaft of the scissors to be perpendicular to the patient and the vessel.
9. Place the tips of the scissors as close to the vessel wall as possible, apply gentle pressure to the tissue,

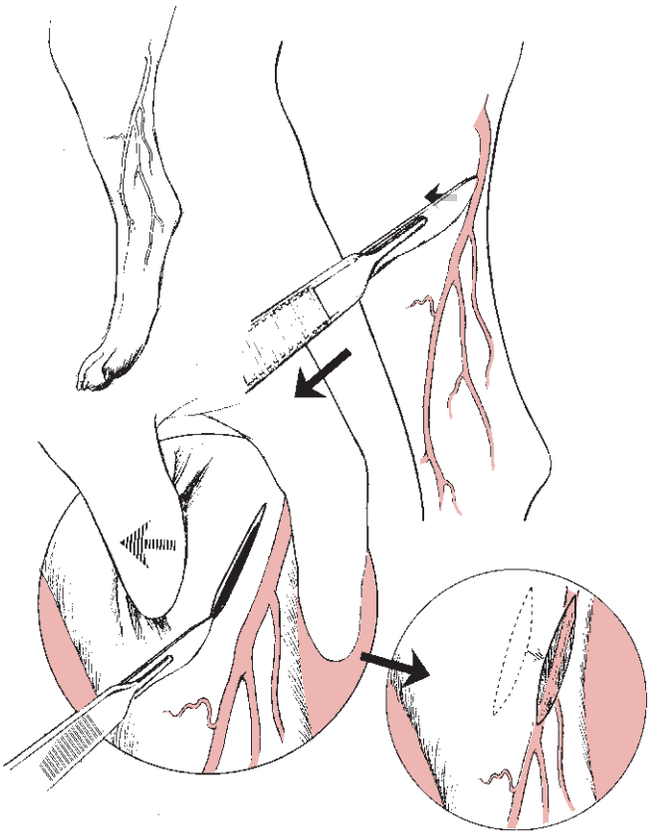

Figure 3-1. Position of scalpel and skin for skin incision.

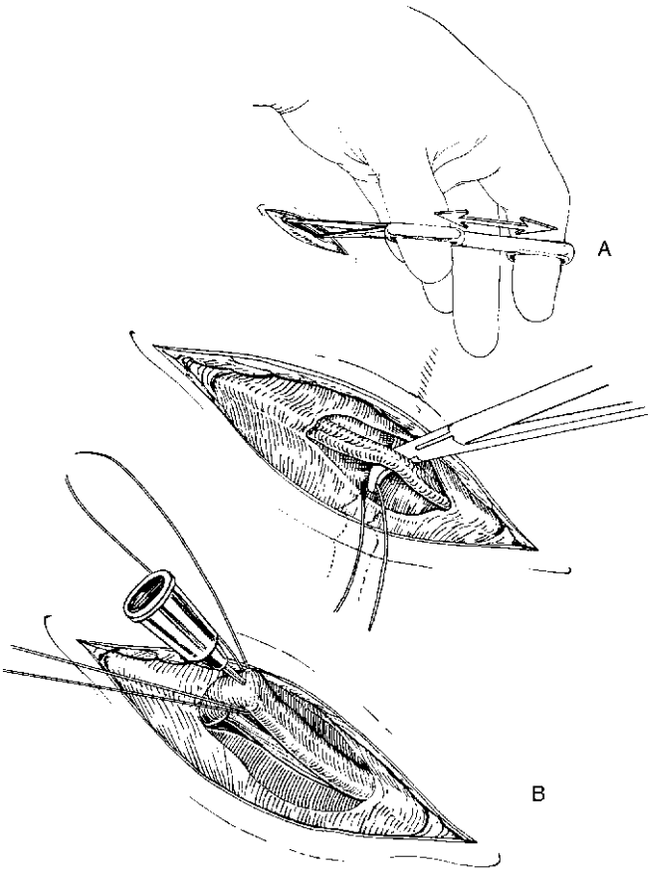

Figure 3-2. *A,* Blunt dissection of the vessel using sharp/sharp scissors. *B,* Catheterization of vessel using stay sutrue.

and extend the blades maximally, bluntly dissecting the fascia from the vessel wall (Fig. 3-2*A*).

10. Repeat this procedure on both sides of the vessel wall until the vessel is freed from its fascial attachments and the mosquito hemostat can be placed under the vessel. Take care not to place the tips of the blades on the vessel itself. In addition, if small side branches of the vessel are present, choose a more proximal or distal location.
11. Pull a loop of suture ventrally underneath the vessel to exteriorize and serve as a manipulator to allow positioning of the vessel for catheterization.
12. Examine the vessel for remnants of fascia. It is easy to catheterize one of these fascial planes by mistake and think that you are in the vessel lumen. Strip the vessel of any remaining fascia by gently using one arm of the Adson thumb forceps.
13. Catheterize the vessel using the suture as a handle to manipulate the vessel into an appropriate position (Fig. 3-2*B*).
14. It is easy to puncture both sides of the vessel wall, so prior to advancing the catheter, verify that the metal of the stylet cannot be seen underneath or beside the vessel wall by gently moving the catheter.
15. Flush the IV catheter to confirm successful catheterization.
16. Remove the loop of suture, connect IV fluids to the catheter, suture or staple the skin with the catheter exiting from the suture line, and secure the catheter to the skin with the normal taping method.

INTRAOSSEOUS ACCESS FOR FLUID ADMINISTRATION

Indications

Intraosseous access is typically utilized only in neonatal or pediatric patients because of the small size of their peripheral vessels.

Contraindications

▼ ***Key Point*** Do not use intraosseous access where severe tissue trauma exists or in areas of potentially infectious dermatitis.

Equipment

- Local anesthetic
- 22- to 20-gauge, 1- to 1.5-inch spinal needle (with stylet)
- Commercial intraosseous catheter (optional)

Technique

1. Aseptically prepare the skin over the appropriate site. In general, the intertrochanteric fossa or the tibial crest is the easiest site to gain access (Fig. 3-3).
2. Infuse a small quantity of local anesthetic into the periosteum and the skin surrounding the site. Be cautious that the volume administered is not in the toxic range for the size of the animal. Lidocaine can be diluted to 1% to prevent toxicity if necessary.
3. Using aseptic technique, identify the site of needle insertion into the appropriate long bone (femur or tibia) and palpate firmly to identify the appropriate direction and angle of needle advancement. Direct the needle as straight as possible down the marrow cavity of the shaft of the long bone.
4. Advance the needle using gentle but steady forward pressure as you slowly twirl the shaft of the needle back and forth.
5. Once the needle is firmly seated into the bone, remove the stylet and attempt to aspirate through the needle. Ability to aspirate bloody fluid (bone marrow) generally indicates successful placement. If awake, animals will often object to aspiration as they would for bone marrow aspiration.
6. Gently flush the needle with isotonic fluid and gently palpate around the long bone for accumulation of fluid. If fluid accumulates outside the bone, then the needle has penetrated the cortex and must be repositioned into the marrow cavity.
7. If successfully placed, attach the IV line to the needle (a luer lock tip assists in prevention of accidental disconnection). Carefully bandage the limb and exposed needle to minimize movement.

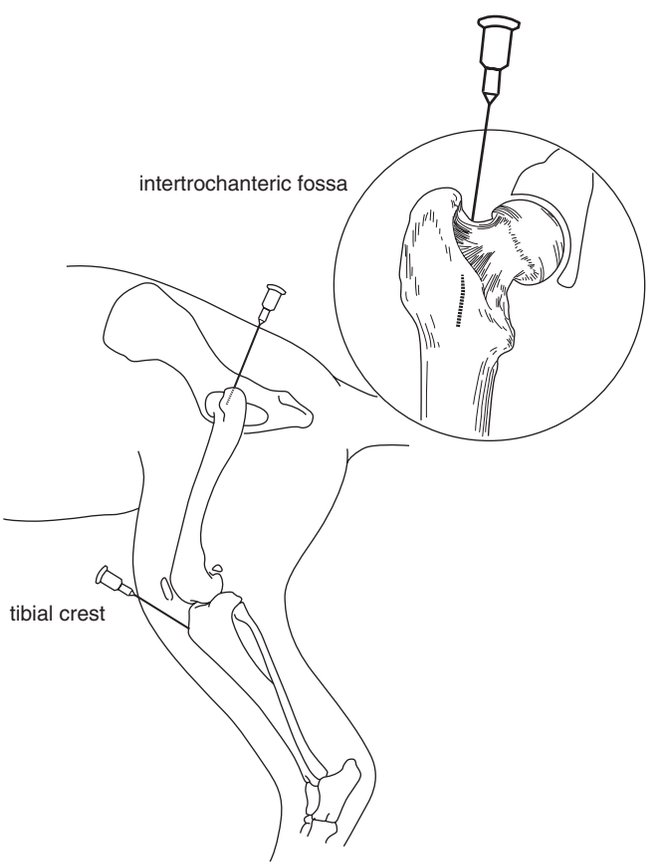

Figure 3-3. Anatomic locations for intraosseous access.

Complications

Poor needle placement can result in inappropriate needle tip placement into the cortex or outside the cortex. Repositioning of the needle usually results in success. Patients that are moving vigorously or traumatizing the needle may shift the tip to an inappropriate location, allowing fluid accumulation in the subcutaneous tissue. Regular monitoring of the limb and needle are warranted to detect this complication.

ARTERIAL SAMPLING FOR BLOOD GAS ANALYSIS

Indications

Collection of an arterial blood sample is often helpful in assessing respiratory function and effective gas exchange. Analysis of a blood gas for acid-base status is more meaningful when venous blood is utilized.

Contraindications

Presence of a severe coagulopathy is a relative contraindication. In general, with firm direct pressure for prolonged periods, significant blood loss is not a concern. The sample is most easily obtained when the patient is in lateral recumbency; thus observe patients with respiratory compromise carefully for worsening of respiratory distress during the procedure and give supplemental oxygen as required.

Objectives

- Obtain arterial blood for blood gas analysis
- Prevent hemorrhage

Equipment

Use either of the following:

- Dry heparin blood gas syringe
- A heparinized regular syringe

Technique

1. If no commercially available dry heparin blood gas syringes are available, heparinize a regular syringe by withdrawing liquid heparin into the syringe so that the insides of the syringe barrel are in contact with the heparin. Depress the syringe plunger to extrude the liquid heparin out of the needle. A small quantity of liquid heparin should remain in the syringe hub. Place a new needle onto the syringe prior to puncturing the skin.
2. The two most commonly utilized sites for arterial sampling are the femoral artery medial to the femur in the inguinal region (Fig. 3-4*A*) and the dorsal metatarsal artery medial to midline and distal to the tarsus joint (Fig. 3-4*B*).
3. Hold the tips of the index and middle fingers of the nondominant hand perpendicular to the artery but parallel to the long axis of the patient and gently palpate the region until the pulsation of the artery can be felt underneath both finger tips. Excessive pressure will often occlude the artery and prevent successful palpation of the pulsation.
4. Gently stabilize the artery and skin between the fingers of the nondominant hand.

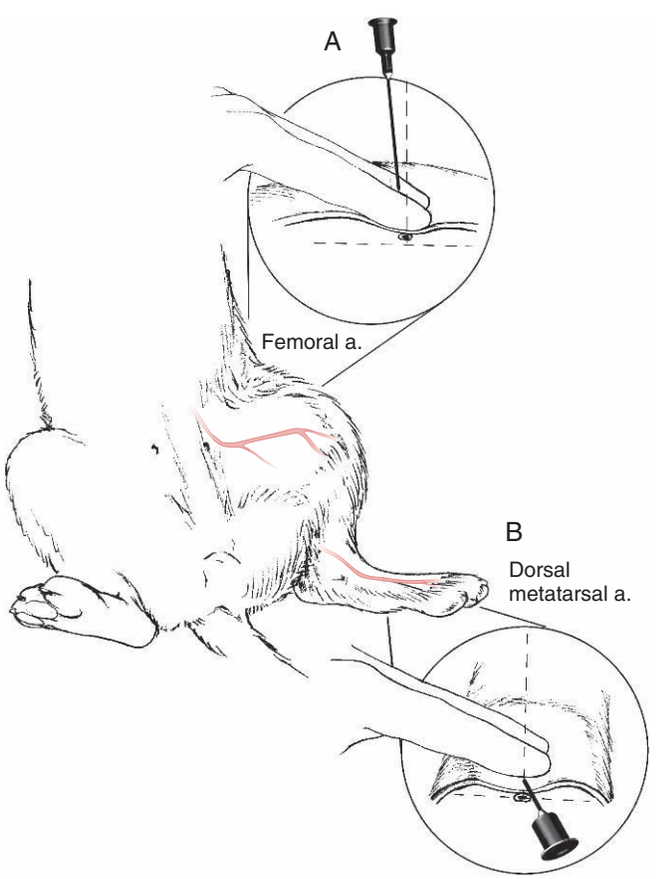

Figure 3-4. *A,* Femoral artery puncture. *B,* Dorsal metatarsal artery puncture.

5. Hold the sampling syringe with the dominant hand. Place the needle between the fingers over the artery and advance slowly at an acute angle (45 degrees or greater for the dorsal metatarsal artery, slightly less than 90 degrees for the femoral artery).
6. Observe the hub of the needle carefully for a blood flashback to "jump" into the hub. Frequently, pulsations can be observed if the patient's blood pressure is high enough. Self-filling blood gas syringes should fill rapidly if the pressure is normal. Withdraw the sample volume if a conventional syringe is being utilized. Slow flashbacks, lack of observable pulsations, color of the blood sample, slow filling of self-filling syringes, and the blood gas results may all indicate that the sample is venous or mixed rather than a pure arterial sample.
7. Place gentle but firm pressure over the sampling site for 3 to 5 minutes, then observe for an additional 30 to 60 seconds to ensure that the puncture site has sealed to prevent hematoma formation.

Complications

Hematoma formation is infrequent and can be prevented by applying pressure for an appropriate duration. Avoid accidental puncture of the nerve that courses parallel to the artery; puncture can cause a painful reaction.

NASAL CATHETER PLACEMENT

Indications

Patients require supplemental oxygen or enteral feeding.

Contraindications

- Patients with severe deforming facial trauma
- Brachycephalic breeds with respiratory distress
- Severe thrombocytopenia or other coagulopathy
- Severe or protracted vomiting (if placing a feeding tube)

Objectives

- Provide oxygen therapy using a nasal catheter
- Provide nutritional supplementation using a nasogastric tube

Equipment

- Nasal oxygen cannula or nasoesophageal or nasogastric feeding tubes
- Topical ophthalmic local anesthetic
- Tape
- Needle holders and tissue forceps
- Monofilament skin suture appropriate to the patient
- Skin staples

Technique

1. Install several drops of local anesthetic into the nostril with the patient's head tipped up slightly; allow several minutes to reach peak effect.
2. Premeasure the catheter to (a) the last rib for nasogastric tube, (b) the base of the heart for nasoesophageal tube, or (c) the junction of the zygomatic arch and the cranial edge of the ramus of the mandible for nasal oxygen.
3. Restrain the patient with the head tipped slightly up and place the tip of the catheter gently into the nostril.
4. Use the thumb of the nondominant hand to push gently up on the nasal philtrum. With the index finger of the same hand, gently squeeze against the thumb from the top of the nasal planum (Fig. 3-5).
5. Advance the catheter quickly and gently, forcing the tube in a ventral and medial direction into the ventral meatus. The patient will often retract away from you, so release your advancing fingers immediately after you have advanced the tube. This is a similar motion to holding and throwing a dart.
6. Advance the catheter with repetitive motions until the premeasured catheter length has been inserted. If placing a nasal oxygen cannula, advance the tube past the nasopharynx if possible to confirm placement into the ventral meatus, then pull back to the premeasured length. Tubes that will not advance past the nasopharynx may be in the dorsal meatus and should be repositioned.
7. Place a small length of tape to the dry tube where it exits the nostril.
8. Place a simple interrupted suture at the ventromedial corner of the nostril. Place a finger trap suture pattern over the tape on the tube to secure the tube to the nostril (Fig. 3-6*A–D*). Tie multiple knots to complete the finger trap.
9. Place a second simple interrupted suture to the ventrolateral corner of the nostril at the mucocutaneous junction using the remaining ends of the suture to further secure the tube from accidental removal (Fig. 3-6*C*).
10. Use skin staples to attach the end of the tube to the patient's face, generally either on the side of the face or up the center of the face between the eyes and to the top of the head (Fig. 3-6*D*).
11. Verify feeding tube placement with radiographs or capnographic confirmation.

Complications

Occasionally the tube will not advance past the nasopharynx (even through the ventral meatus) because of anatomical conformation in individual animals. In such patients, pass the tube through the opposite nasal passage. In addition, feeding tubes may be inadvertently passed into the trachea and airway, especially in sedated, anesthetized, or obtunded patients. Confirm placement using radiography or capnography. Feeding tubes can also be vomited back up the esophagus and chewed off by the patient, so closely observe patients with nasal feeding tubes.

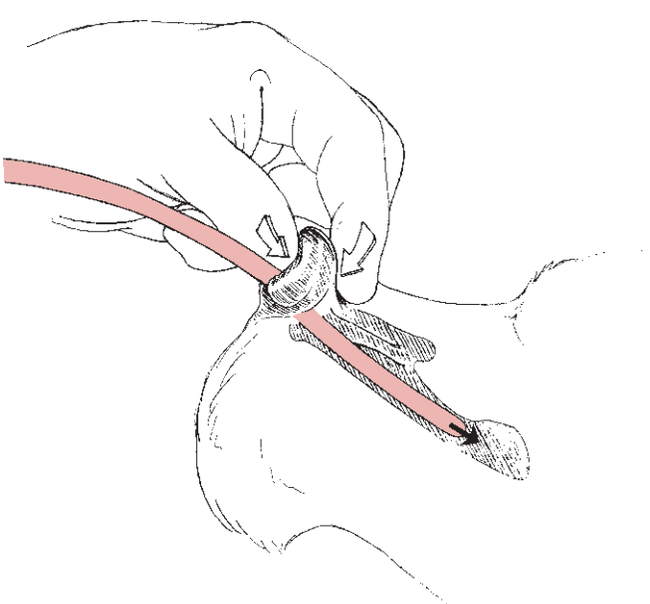

Figure 3-5. Positioning for placement of nasal catheter.

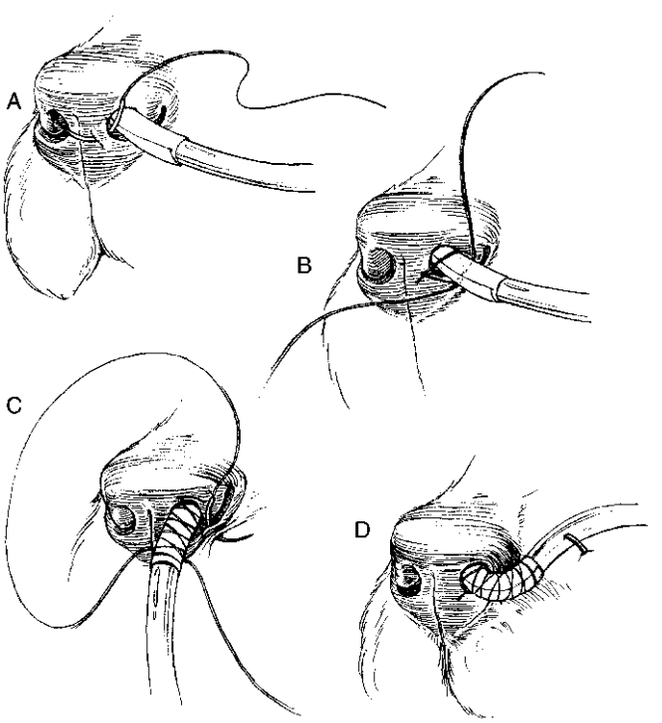

Figure 3-6. Finger trap suture pattern.

EMERGENCY TEMPORARY TRACHEOSTOMY

Indications

Patient has life-threatening upper airway obstruction (proximal to the cervical trachea) and cannot be intubated with an endotracheal tube.

Contraindications

Airway obstruction distal to the site of tracheostomy. Severe coagulopathy is a relative contraindication, but this can be treated with transfusion component support and direct pressure.

Objectives

- Establish a patent airway
- Maintain the patent airway by frequently cleaning or replacing the tracheostomy tube

Equipment

- Scalpel handle and #10 or #15 blade
- Mayo scissors
- Large, curved Kelly or Carmalt hemostat
- Tracheostomy tube
- Monofilament suture material appropriate to patient

Technique

1. Position the patient in dorsal recumbency with the head extended slightly off and over the edge of the table or with the neck over a rolled towel or sandbag.
2. Make one attempt to insert a large over-the-needle peripheral IV catheter into the trachea at the base of the neck close to the thoracic inlet to provide oxygen to the patient while final preparations are made.
3. Rapidly clip and aseptically prepared the skin.
4. The patient will need rapid IV anesthesia for the procedure unless it is moribund.
5. Incise the skin from the larynx to the thoracic inlet.
6. Bluntly force the closed tips of Mayo scissors into the first tissue plane, open and insert one tip into the tissue plane created, then incise the tissue plane to each end of the incision. Attempt to use the sharp edges of the scissors to cut by advancing with the blades open rather than "scissoring" through the tissue.
7. Incise the sternohyoideus muscles (strap muscles) in a similar way, exposing the trachea.
8. Identify the neurovascular bundle on each side and bluntly insert a hemostat through the fascia dorsal to the trachea, allowing it to be elevated into the surgical incision.
9. Do not damage the vessels overlying the trachea.
10. Depending on the experience and skill of the surgeon, two approaches to incising the trachea are possible:
    a. If the surgeon feels comfortable and excellent surgical precision is possible, incise the trachea transversely "between" two rings in the mid cervical trachea (Fig. 3-7). Extend the incision over the ventral two thirds of the circumference of the trachea. Do not incise into the dorsal tracheal membrane.
    b. Alternatively, if the surgeon is less comfortable and a lesser degree of surgical precision is likely, incise longitudinally "through" several rings (Fig. 3-8). Holding the scalpel upside down and gripping the blade carefully to allow only 10 to 15 mm of blade to be exposed, incise approximately four tracheal rings beginning with ring 3 and continuing through ring 6 distal to the larynx.
11. Direct oxygen toward the incision.

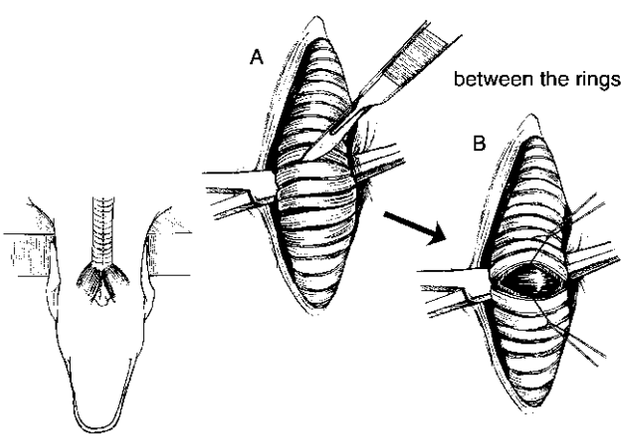

Figure 3-7. Between-the-rings tracheostomy with stay suture placement.

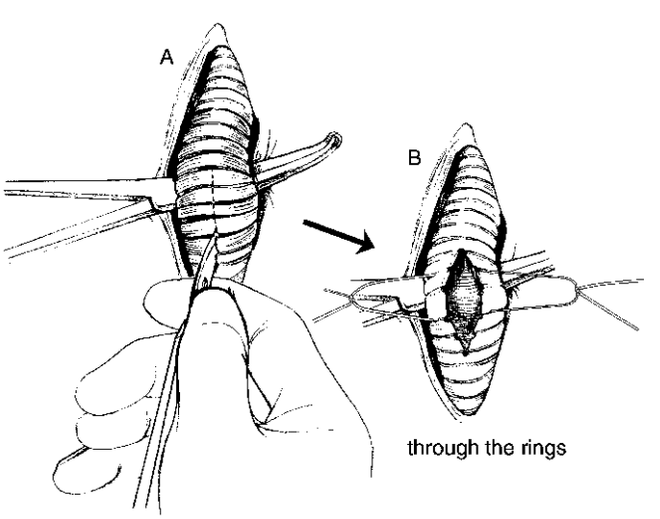

Figure 3-8. Through-the-rings tracheostomy with stay suture placement.

12. Place stay sutures (3-0 or 4-0 silk) in the edges of the tracheal incision. If a transverse incision was made, place stay sutures in the ventral-most aspect of the trachea and around the first proximal and first distal ring. If a longitudinal incision was made, place stay sutures around two adjacent rings, approximately 3 to 5 mm from the tracheal incision and encompassing 2 tracheal rings on both sides of the incision. Leave the suture ends long.
13. Insert the tracheostomy tube into the trachea. Several types of specialized tracheostomy tubes are commercially available. Each has advantages and disadvantages. A simple tracheostomy tube can also be easily constructed from an endotracheal tube (Fig. 3-9).
14. The most critical aspect of tube placement is the size and fit of the tube. If the tube exerts circumferential pressure on the tracheal mucosal, then significant pressure necrosis, scarring, or fibrotic web formation are more likely to occur as a complications. Choose a tube that fits loosely in the trachea with no major points of mucosal pressure. Do not inflate the cuff unless positive pressure ventilation is required.
15. Suture the skin edges to allow easy access to the tracheal incision when the tube needs to be changed.

Postoperative Care and Complications

- Clean or replace the tube as necessary to maintain patency.
- Clean the "dirty tube" and allow it to soak in an appropriate and safe antimicrobial solution, then rinse carefully with sterile saline prior to the next tube exchange.
- Do not apply suction to the tube.
- Keep the animal well hydrated.
- Protect the skin around the tube with petrolatum (Vaseline).

If possible, use tracheostomy heat and moisture exchange devices (HME) to maintain airway humidification and thus decrease viscosity of secretions. These devices add a small amount of increased resistance that contributes to the work of breathing. In patients with marginal muscle strength, this may be significant and lead to a vicious cycle of hyperthermia and increased work of breathing.

Monitor the patient's temperature regularly. Routine administration of saline into the tracheostomy site is not recommended. A poorly fitting tube and inappropriate inflation of the cuff are the most common cause of fibrosis and web formation as a long-term complication.

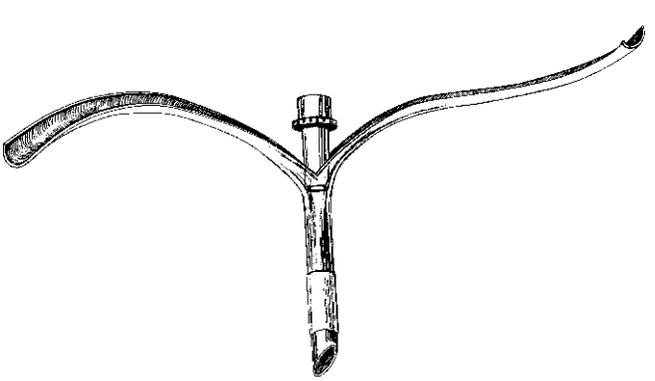

Figure 3-9. Tracheostomy tube construction from endotracheal tube.

ABDOMINOCENTESIS

Indications

Physical examination or radiographic evaluation indicates moderate quantities of peritoneal effusion, and cytological or chemical analysis of the fluid will assist in the diagnostic process.

Contraindications

Severe coagulopathy is a relative contraindication depending on the value or benefit of obtaining a fluid sample. Relative contraindications to use of a blind technique include a large abdominal mass; significant organomegaly, particularly of a vascular organ such as the spleen, liver, or kidney; or distension of a hollow viscus such as bowel or uterus. Consider ultrasonographic guidance if available.

Objectives

- Aseptically obtain fluid from the abdominal cavity for analysis and culture
- Avoid trauma to abdominal organs

Equipment

- 22- to 20-gauge, 1- to 1.5-inch needle and syringe appropriate to patient size (e.g., 3- to 12-ml syringe)

Technique

1. If possible, allow the patient to stand or be positioned in sternal recumbency to allow access to the most dependent site on the abdomen. Alternatively, place the patient in left lateral or dorsal recumbency.
2. The goal of the patient position and of the location and direction of the abdominocentesis attempt is to avoid the spleen, thus preventing hemorrhage that will contaminate the sample.
3. Clip and aseptically prepare the skin. Local anesthetic can be infiltrated if desired.
4. Advance the needle and syringe through the skin and withdraw the plunger of the syringe to create a small amount of negative pressure in the syringe prior to advancing the needle into the peritoneal cavity and away from the presumed location of the spleen.

5. In sternally recumbent or standing patients, frequently productive sites are caudal to the spleen, on or slightly to the right side of midline, with the needle directed toward the cranial aspect of the bladder. In left laterally recumbent patients, frequently productive sites are slightly caudal to the umbilicus, on or slightly to the right of midline, with the needle directed toward the cranial aspect of the bladder and slightly toward the dependent or left side of the patient. If these areas are unproductive, attempt a second site just cranial to the umbilicus, on or slightly to the right of midline, with the needle directed perpendicular to the long axis of the patient or at a 20° to 30° angle (needle tip toward the cranial aspect of the patient). In dorsal recumbency, frequently productive sites are caudal to the umbilicus, on or slightly to the right of midline, with the needle directed toward the cranial aspect of the bladder. If this attempt is unproductive, attempt a second site just cranial to the umbilicus, to the right of midline, with the needle directed perpendicular to the spine.
6. In general, extremely gentle aspiration of the syringe may yield a larger sample size and prevent clogging of the needle with omentum.

Complications

Complications are minimal. Inadvertent splenic aspiration may occur, but unless the patient has a bleeding tendency, this is unlikely to create a problem except for contamination of the sample with blood or potential contribution to an erroneous diagnosis of hemoabdomen.

TENCKHOFF PERITONEAL DIALYSIS CATHETER PLACEMENT

Indications

Tenckhoff peritoneal dialysis catheter placement is ideal for short-term (24 to 48 hours) access to the peritoneal cavity. This may be useful for treating patients with acute intoxication with drugs or chemicals that can be effectively removed by peritoneal dialysis; for core warming or cooling of patients with severe hypothermia or hyperthermia, respectively; for short-term management of uremia in unstable uroabdomen patients; or for performing diagnostic peritoneal lavage (DPL).

Contraindications

Relative contraindications to use of the blind technique for placement include large abdominal masses; significant organomegaly, particularly of a vascular organ such as the spleen, liver, or kidney; or distension of a hollow viscus such as bowel or uterus.

Objectives

- Obtain abdominal fluid or perform DPL
- Perform peritoneal dialysis
- Avoid organ damage
- Avoid subcutaneous leakage of fluid

Equipment

- Local anesthetic
- Scalpel blade (#11 or #15)
- Needle holders and thumb tissue forceps
- Monofilament skin suture appropriate to the size of the patient
- Tenckhoff peritoneal catheter (numerous commercially available kits, e.g., Sherwood Davis & Geck)
- Connecting adapters and fluid lines to maintain a closed ingress-egress system

Technique

1. Place the patient in left lateral recumbency and aseptically prepare a wide area around the abdominal entry site. Infiltrate the site with local anesthetic. Drape the area appropriately and perform the procedure aseptically.
2. The site of entry is just cranial to the umbilicus and slightly to the right of midline.
3. Make a small stab incision through the skin and the external fascial plane of the external rectus abdominus muscle large enough to just accommodate the diameter of the catheter.
4. Several types of catheter kits are available for purchase with differing methods and equipment for actual placement of the catheter through the abdominal wall. Follow the instructions with the kit or modify them to allow placement of the catheter into the peritoneal cavity. Kits using the peel-away introducer or Seldinger (over the wire) technique generally have a lower risk of injury to internal organs.
5. Position the catheter tip near the pelvic canal. Secure the catheter to the patient using the finger trap suture method (see Fig. 3-8).

▼ ***Key Point*** Use aseptic technique and ensure that the system remains closed.

Complications

Minor hemorrhage may be expected for a short time after placement. Ongoing evidence of hemorrhage into the draining fluid indicates more significant hemorrhage. Frequently, the omentum may occlude the openings of the catheter and prevent appropriate drainage. In patients with a thin or compliant body wall or poor body condition, gently palpate the catheter inside the peritoneal cavity and gently strip the omentum from the catheter tip if necessary. Introduction of infection into the peritoneal cavity may have devastating conse-

quences and requires vigilant attention to the care and maintenance of the drainage system.

THORACOCENTESIS

Indications

Perform diagnostic thoracocentesis on all patients that present with symptoms of pleural space disease (rapid shallow breathing, respiratory distress, symmetrical or asymmetrical dullness, or absence of lung sounds on auscultation) as described in Chapter 142. Patients with significant respiratory distress that are unsuitable candidates for radiographic evaluation may also benefit from diagnostic thoracocentesis.

Contraindications

Patients with long-standing chronic effusions (particularly cats with chylous effusion) may be at a higher risk for development of fibrosing (restrictive) pleuritis. Inadvertent needle contact with, and subsequent laceration of, the diseased pleura in this syndrome can produce significant and life-threatening pneumothorax. Exercise extreme caution in using sharp instruments to drain thoracic fluid in such patients.

Objectives

- Evacuate fluid or air from the pleural space
- Avoid iatrogenic pneumothorax or trauma to the lungs, heart, and intercostal blood vessels

Equipment

- 19- or 22-gauge butterfly catheter, 18- to 22-gauge over-the-needle intravenous catheter, 18- to 22-gauge, 1- to 1.5-inch needle, or metal stylet from 18- to 22-gauge over-the-needle catheter with catheter removed
- IV extension set
- Three-way stopcock
- Syringe

Technique

1. Clip hair from the site and aseptically prepare the skin. Many patients will tolerate the procedure without instillation of local anesthetic and often resent the injection of local anesthetic more than the procedure.
2. The site of thoracocentesis will depend on whether air or fluid is suspected to be causing respiratory distress. If fluid is suspected, select a ventral location in intercostal spaces 3 to 7 approximately one third of the distance between the costochondral junction and the sternum. If air is suspected, select a dorsal location in intercostal spaces 5 to 9 at the junction of the dorsal one third and ventral two thirds of the chest wall.
3. Choose a needle or catheter of sufficient size and length appropriate to the situation and patient. Ensure that the three-way stopcock is closed to the atmosphere.
4. Advance the sharp point of the needle or stylet through the skin, then place a small amount of negative pressure on the syringe. Advance the needle tip cautiously until a slight "pop" through the parietal pleura is felt, which ideally is accompanied by productive aspiration of air or fluid from the pleural space.
5. Use one of the following methods:
   a. If using a rigid metal device, attempt to reposition the needle or stylet tip into the intercostal space (parallel to the ribs with the bevel facing into the chest) so that as the pleural cavity is drained and the lung expands closer to the chest wall, there is less likelihood that the lung will be lacerated by the needle tip (Fig. 3-10*A*).
   b. Alternatively, advance the needle under the cranial rib and flatten the needle against the caudal rib (perpendicular to the ribs with the bevel facing into the chest). This method should cause the cranial rib to be pushed gently from the chest, again protecting the tip of the needle and preventing laceration of the lung parenchyma (Fig. 3-10*B*).
   c. In a third method, grasp the rigid shaft of the needle or stylet between the index finger and the thumb such that only the tip of the needle or stylet is within the pleural cavity. Guard the needle or stylet firmly to prevent inadvertent advancement into the thoracic cavity. As soon as a "scratching" or "scraping" sensation is detected on the needle, immediately withdraw it to prevent inadvertent laceration of the lung (Fig. 3-10*C*).
6. Gently reposition the needle or stylet or withdraw it if there is lack of continuing production of fluid or air from further attempts at aspiration.
7. Drain as much as possible from the pleural cavity using the three-way stopcock, syringe, and collection basin (a second thoracocentesis may be required on the contralateral chest wall in some cases).

Complications

Patients with chronic fluid accumulations, especially with significant quantities of fibrin, may have significant compartmentalization of fluid that is difficult to remove with routine thoracocentesis. Ultrasound-guided attempts may be more successful in collecting fluid from such patients; alternatively, consider a chest drain (see the next section). Inadvertent laceration of lung parenchyma resulting in pneumothorax is rare (except in fibrosing pleuritis patients) and can be managed with chest drain placement and intermittent or continuous suction. Laceration of a coronary artery is an extremely rare complication and likely only if the position of

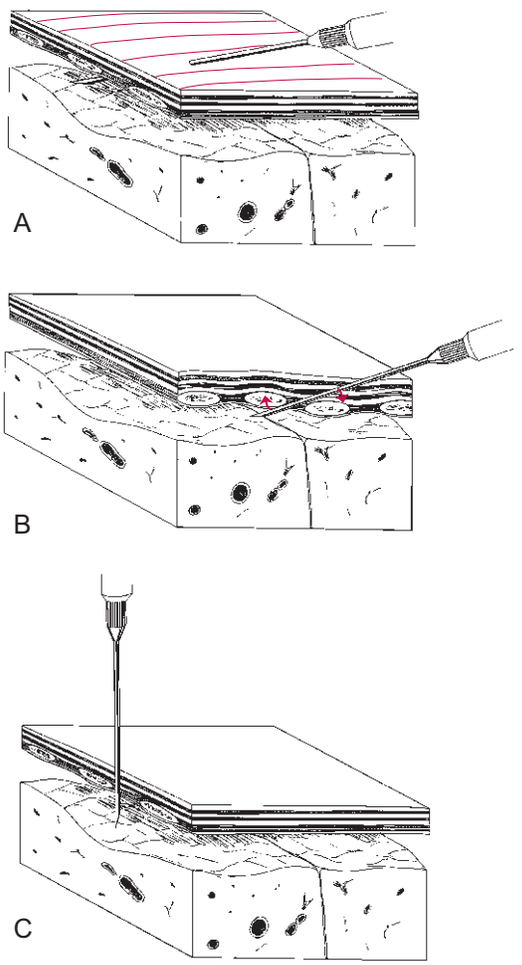

Figure 3-10. *A,* Needle position for parallel intercostal approach to thoracocentesis. *B,* Needle position for perpendicular intercostal approach to thoracocentesis. *C,* Needle position for subpleural approach to thoracocentesis.

the heart is significantly deviated within the thoracic cavity.

THORACIC CATHETER OR TUBE PLACEMENT

Indications

Consider placing a thoracic catheter or tube in patients with large volumes of air or fluid production that are not reasonably and effectively drained with intermittent thoracocentesis.

Contraindications

Significant coagulopathy is a relative contraindication for this procedure. Severe trauma or instability of the chest wall at the proposed site is a contraindication to nonsurgical placement of the catheter or tube.

Objectives

- Aseptically place an indwelling thoracic drain tube without causing iatrogenic trauma to thoracic viscera
- Minimize iatrogenic pneumothorax
- Place the tube so that it effectively drains pleural air or fluid

Equipment

- Scalpel handle with #10 or #15 blade
- Adson Thumb forceps
- Mayo scissors
- Needle holders
- Curved Kelly or Carmalt hemostat appropriate to the size of the patient and tube
- Chest catheter or tube of appropriate size (two thirds of the intercostal space) (Argyle trocar catheter or red rubber feeding tube)
- Monofilament skin suture material appropriate to patient (i.e., 3-0 to 0)

Technique

1. Use either general anesthesia or heavy sedation with local anesthesia and intercostal nerve blocks.
2. Pull the patient's lateral chest wall skin cranially as far as comfortably possible.
3. Clip the hair and aseptically prepare the skin from the 5th to the 12th intercostal space. Use local anesthetic to infiltrate into the 7th or 8th intercostal space at the junction of the dorsal one third and ventral two thirds of the lateral body wall.
4. Incise the skin at the 10th intercostal space. Make the incision approximately 5 mm longer than the diameter of the tube being placed.
5. Using thumb forceps and sharply incise the subcutaneous and latissimus dorsi muscle tissue. Do not use excessive blunt dissection so that you have a tight seal around the tube.
6. Clamp the thoracostomy tube tip 3 to 5 mm behind the tips of the Kelly or Carmalt hemostat (Fig. 3-11*A*). Ensure that the open end of the tube is clamped or plugged with a collection device. Alternatively, use an Argyle trocar catheter.
7. Premeasure the tube from the intercostal entry site (seventh or eighth intercostal space) to the point where the elbow naturally overlies the sternum.
8. Place the clamped tube into the deepest part of the incision, ensuring that the hemostat is curved toward the elbow and the tips are in the intercostal space and not over a rib.
9. Stand at the patient's back and grasp the shaft of the tube or hemostat with the nondominant hand, allowing one finger's width between the patient and the bottom of the nondominant hand. Form a fist over the finger rings of the hemostat (or trocar catheter) with the dominant hand (Fig. 3-11*B*).

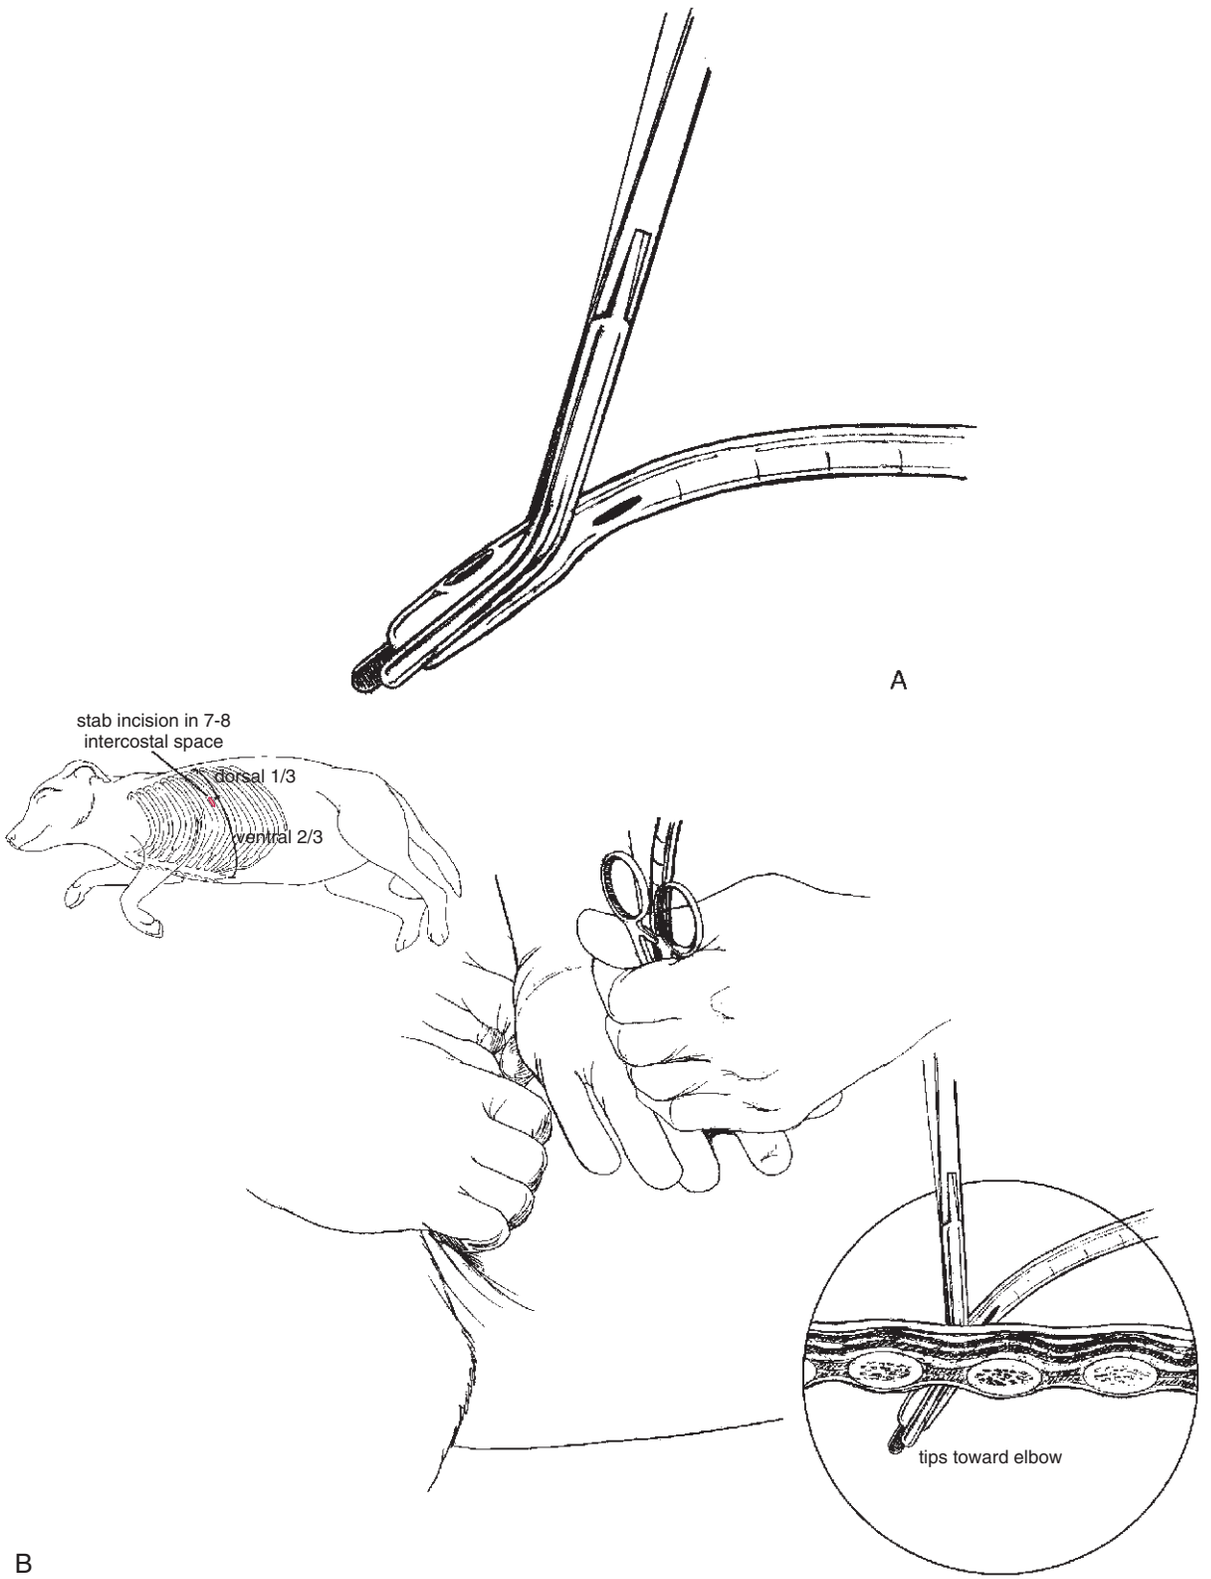

Figure 3-11. *A,* Position of thoracic tube in Kelly or Carmalt forceps. *B,* Technique for placement of thoracic tube.

10. Place the tube into the chest cavity at the seventh or eighth intercostal space with a sharp, quick, and forceful motion.
11. Open the hemostat and slide the tube gently into the chest cavity while the hemostat is removed.
12. After inserting the tube to the premeasured length, release the skin to slide caudally, forming a "tunnel" over the tube as it exits the chest wall.
13. Place a purse-string suture in the skin around the tube. Leave both suture ends of approximately equal length.
14. Place a finger trap suture pattern to secure the tube to the skin (see Fig. 3-6). Also, if desired to prevent leakage around the subcutaneous portion of the tube, place a simple interrupted suture around the tube between its entry site in the skin and where it enters the thorax.
15. Cover the skin-tube interface with copious amounts of antibiotic ointment and bandage it into place.

Postoperative Care and Complications

- Use an Elizabethan collar if necessary to prevent tube damage.
- Change the chest bandage every other day or more often if necessary. Check tube position during bandage changes.
- Frequently check tube connection devices for leaks.
- A small amount of subcutaneous air or fluid ventral to the tube entry site may occur. However, consider replacing the tube in a new site if large amounts of fluid or air drain to the subcutaneous space.
- Obtain thoracic radiographs if necessary to check tube position. Reposition the tube if necessary.
- Pull the chest tube when minimal fluid or air is drained. The chest tube can create 1 to 2 ml/kg/24 hours of pleural fluid.
- Remove sutures and pull the tube quickly and smoothly from the chest. Submit the tube tip for culture if indicated.
- Apply antibiotic ointment and bandage the incision.

FEEDING TUBE PLACEMENT

Nasal Feeding Tubes (Nasoesophageal, Nasogastric)

See "Nasal Catheter Placement" in this chapter.

Esophagostomy Tube Placement

Indications

Enteral tube feeding is required for long-term home feeding in patients with good gastric motility and when longer anesthetic periods or expense precludes the use of a percutaneous endoscopically placed gastrostomy tube (PEG tube).

Contraindications

Contraindications for esophagostomy tube placement include megaesophagus or localized infection at the desired tube insertion site. Coagulopathy is a relative contraindication. Consider severity of the hemostatic dysfunction and the urgency of nutritional support.

Objectives

- Provide nutritional supplementation using an esophageal catheter
- Avoid excessive trauma to the esophagus

Equipment

- Scalpel handle with #15 or #11 blade
- Large curved Kelly or Carmalt hemostat
- Appropriate red rubber feeding tube (size 14 Fr or larger)
- Monofilament skin suture appropriate to the patient

Technique

1. Commercially available customized esophagostomy kits are available. If using a kit, follow the instructions for placement that accompany the kit.
2. Anesthetize the patient and place in right lateral recumbency with an endotracheal tube in place.
3. Premeasure the tube to ensure that the tip of the tube is in the distal esophagus (from the entry site to the eighth rib).
4. Clip and aseptically prepare the skin over the left neck caudal to the ramus of the mandible.
5. Insert a curved hemostat into the mouth with the curve pointed laterally. Use a mouth gag to facilitate hemostat placement if necessary. Advance the hemostat into the esophagus and palpate the tips of the hemostat on the left lateral neck.
6. Place the tips of the hemostats to the level of the second to third cervical vertebral body and as far dorsal from the jugular vein (furrow) as possible. Push outward or upward to "tent" the skin of the neck.
7. Have an assistant's index finger and thumb grasp the tips of the hemostat and gently push down to stretch the skin over the tips of the hemostat to hold it firmly in place and prevent it from moving (Fig. 3-12).
8. Have the assistant make a stab incision directly over the tips of the forceps, making contact with the metal tips with the scalpel blade. Do not remove the blade until the tips of the hemostat penetrate the incision. The goal is to gently use the scalpel to enlarge the incision only until it permits exit

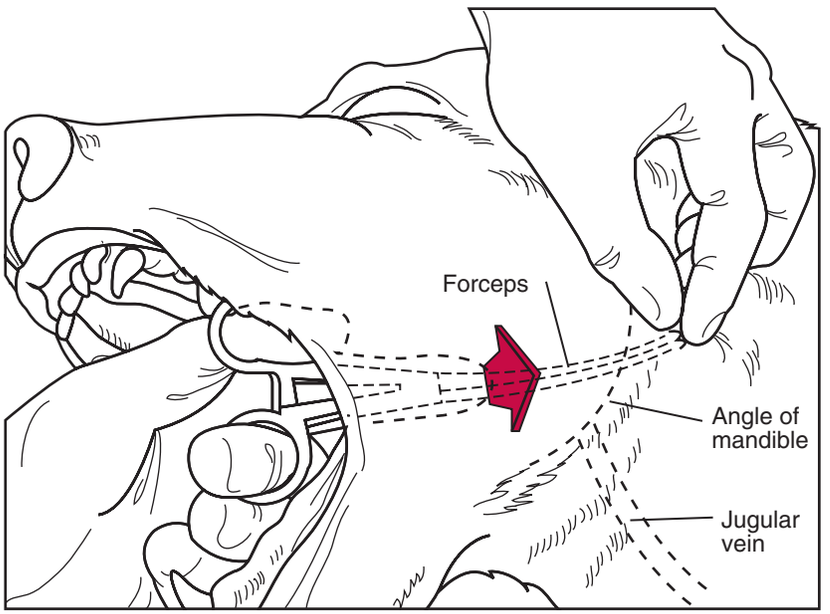

Figure 3-12. Technique for esophagostomy tube placement.

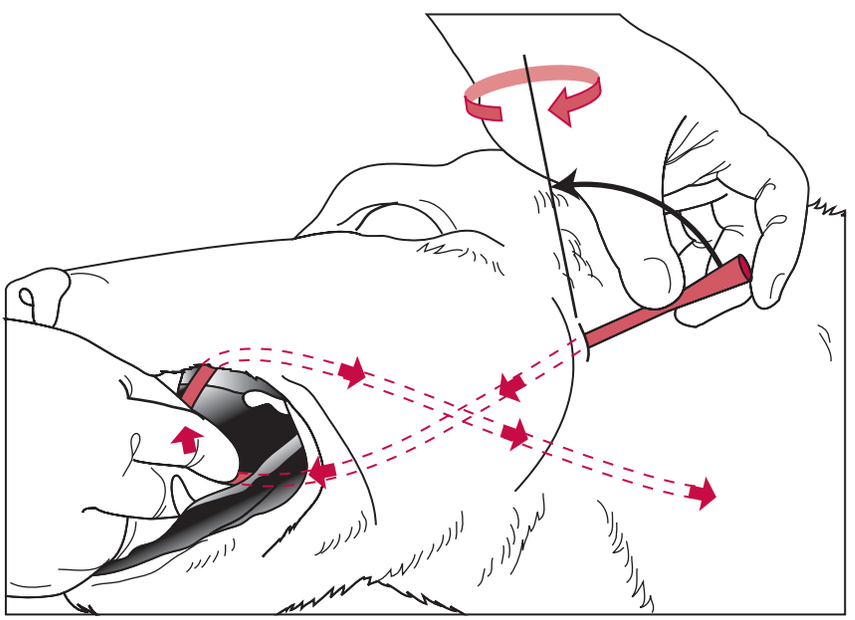

Figure 3-13. Positioning of tube after placement of esophagostomy tube.

of the hemostat. A large or ragged incision is not desirable.

9. Push the hemostat tips outward through the stab incision. If resistance is felt, the blade of the scalpel can be "wiggled" slightly to allow the hemostat to penetrate.
10. Open the jaws of the hemostat, place the distal tip of the feeding tube parallel to the tips, and clamp it into place.
11. Pull the tube through the mouth to the appropriate length and remove the clamp.
12. Direct the end of the tube down the esophagus and advance the tube as far as possible (Fig. 3-13).
13. Gently pull out the tube exiting the neck, and twist while attempting to advance the tube in place into the patient's pharynx. The tube should straighten and "unkink." If correct and unkinked placement has been achieved, the tube can be advanced and withdrawn smoothly from the esophageal incision with little resistance.
14. Suture the tube to the skin using the finger trap suture pattern (see Fig. 3-6).

15. Verify correct tube placement using a portable capnograph (no visible waveform and end-tidal carbon dioxide measured at 0 mmHg) or with lateral and ventrodorsal radiographic views of the thorax before feeding.

Postoperative Care and Complications

- Keep the incision clean and covered with a light bandage or stockinette.
- See the nutrition section of this chapter for supplementation guidelines.
- If the tips of the hemostats remain slightly open during creation of the stab incision, a strip of esophageal mucosa may get trapped between the jaws of the hemostats. When the tube is being pulled into the esophagus from the skin, the strip of tissue will make it difficult to pull the tube back into the esophagus until the tissue breaks or the tube dislodges from the hemostats.
  - Ensure that the hemostat tips are not opened until they are completely free from the skin-esophageal incision.
- If the tube will not straighten or unkink during insertion of the tube down the esophagus, do the following:
  - Ensure that the tube tip is in the esophagus and not the trachea.
  - Gently withdraw the tube from the neck incision and continue twisting.
  - Realize that the tube is not large enough, so it has insufficient tensile strength or memory to straighten or unkink (ensure that the tube is at least 14 Fr).
- If the jugular vein is lacerated, take the following steps:
  - Apply direct pressure to the wound for several minutes to prevent blood loss.
  - Extend the incision and isolate the jugular vein, then ligate it above and below the laceration, sacrificing the vessel.

Percutaneous Endoscopically Placed Gastrostomy Tube

Indications

- Consider a PEG tube for any patient for which long-term (weeks to months) nutritional support is warranted. It is generally the feeding tube of choice for long-term nutritional support when an endoscope is available to assist in placement.
- Use a PEG tube to bypass the oral cavity and esophagus.

Contraindications

Infection at the site of insertion is a contraindication. Coagulopathy is a relative contraindication. Consider the severity of the hemostatic dysfunction and the urgency of nutritional support in the decision. Placement of the tube described later in this section is also a relative contraindication in large-breed (especially deep-chested) dogs because of the increased risk of inadvertent tube removal from the stomach, resulting from excessive tension between the paracostal placement site and the stomach wall. Consider placement of a customized tube with a large, nonremovable inner flange for these patients. Removal of such tubes must also occur using an endoscope and cannot be accomplished percutaneously. The presence of neoplasia or severe disease of the stomach wall increases the risk of leakage and peritonitis and is a relative contraindication.

Objectives

- Allow nutritional supplementation bypassing the oral cavity and esophagus
- Provide a leakage-free, chronic, indwelling gastric tube

Equipment

- Gastrointestinal (GI) endoscope
- Endoscopic grasping forceps
- Bard urologic catheter (18- to 24-Fr Pezzer mushroom-tip model)
- Sovereign over-the-needle IV catheter (14 gauge)
- Three-way stopcock and adapters
- Vetafil suture, size 2-0 (3–5 feet depending on patient size)
- #11 blade
- 20-gauge, 1-inch needle
- Scissors
- Hemostats
- Stockinette (cut to fit for “sweater”)

Technique

1. Prepare the Pezzer catheter by removing the flared end and cutting the flared end into two pieces of approximately equal length. Make a long axis stab incision in the center of each piece large enough to accommodate the diameter of the Pezzer catheter. Advance the hemostats through the stab incision of one piece and pull the catheter through. Advance this “inner flange” piece down to the mushroom tip. Some clinicians prefer to snip off the nipple-shaped tip of the Pezzer catheter to reduce occlusion of the tube with food particles. Cut the shaft of the opposite end of the catheter at an approximately 60 degree angle to leave a tapered tip.
2. Place the anesthetized animal in right lateral recumbency, and clip and aseptically prepare a 10- to 14-cm^2 area of the skin just caudal to the costal arch.
3. Insert an endoscope and distend the stomach with air. Gently palpate the distended stomach from the abdominal wall just caudal to the last rib using an extended finger. Observe using the endoscope to

ensure that the proposed exit site is positioned in the body of the stomach away from the pylorus.
4. Quickly and forcefully insert the Sovereign IV catheter percutaneously into the distended stomach and observe using the endoscope. Withdraw the needle, leaving the catheter in place (Fig. 3-14*A*).
5. Thread Vetafil suture material through the catheter into the stomach.
6. Using endoscopic grasping forceps, grasp the Vetafil suture and withdraw the entire endoscope, along with the luminal end of the suture, out through the mouth. Ensure the end of the suture exiting the body wall does not enter the stomach accidentally (Fig. 3-14*B*).
7. Withdraw the Sovereign IV catheter from the body wall. Place a hemostat on the body wall end of the suture to prevent inadvertent pull-through into the stomach (Fig. 3-14*C*).
8. Insert the luminal end of the suture through the narrow end of the Sovereign IV catheter and advance the catheter toward the patient's mouth (Fig. 3-14*D*).
9. Secure the pointed tip of the Pezzer catheter to the luminal suture end using a horizontal mattress suture.

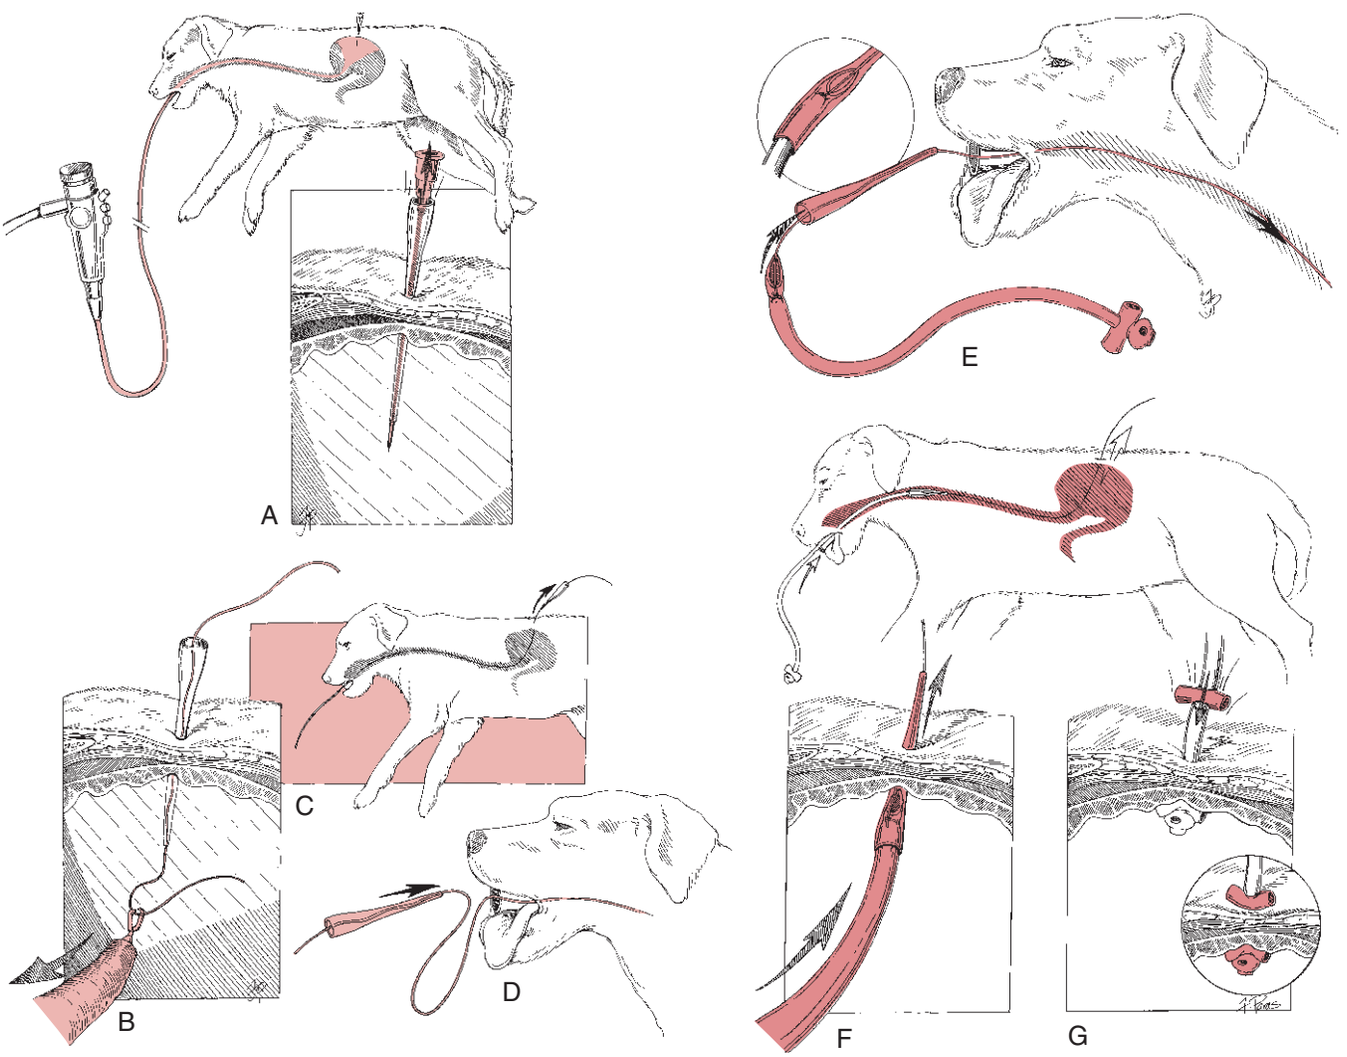

Figure 3-14. Placement of percutaneous endoscopic gastrostomy (PEG) tube. *A,* Over-the-needle catheter is placed through the skin and into the air-distended stomach; *B,* suture threaded through the catheter is grasped by endoscopic forceps and pulled out through the mouth *(C); D,* over-the-needle catheter is threaded onto the suture, which is tied to the gastrostomy tube. (*E*) and subsequently pulled into the stomach and out the gastric and body wall. The flange at the end of the gastrostomy tube should press snugly against the gastric mucosa. See text for *F* and *G.*

10. Slide the Sovereign IV catheter back down the suture toward the Pezzer catheter and firmly seat the pointed tip and suture knot (if possible) into the large flared end of the catheter (Fig. 3-14*E*).
11. Lubricate the IV catheter and the gastrostomy tube.
12. Pull the percutaneous end of the suture until the IV catheter tip is through the skin surface. Frequently, the skin will need to be incised a few millimeters (cautiously using a #11 blade). Place firm downward pressure around the exit site and pull the gastrostomy tube out through the body wall until the mushroom tip and inner flange are positioned against the gastric mucosa and the stomach is pulled up against the body wall. Pull the tube out gently and observe the position of the mushroom tip using the endoscope to ensure correct placement (Fig. 3-14*F*).
13. Slide the "outer flange" over the external end of the Pezzer catheter to ensure a snug fit to the patient's body wall. Secure the tube into place (Fig. 3-14*G*).
14. Wrap a small piece of tape circumferentially around the tube at the junction of the tube and the outer edge of the outer flange to identify ideal positioning and serve as a method for detecting inadvertent flange movement or slippage.
15. Remove the pointed tip of the catheter and the suture material with scissors and place the three-way stopcock into the tube tip. Alternatively, place a small, graduated Christmas tree adapter in the tube tip. Place a cap on all openings of the stopcock or Christmas tree adapter.
16. Cut a 4 × 4 gauze sponge on the folded edge and tuck around the feeding tube-skin interface.
17. Cut a sufficient length of stockinette and pull one end through so that both cut ends are together. Cut holes near the folded end of the stockinette for the patient's front legs and place the stockinette to protect the tube site. Tuck the free end of the tube under the stockinette to prevent inadvertent removal.
18. Small amounts of water can generally be administered through the tube immediately, but delay feeding 12 to 24 hours to allow an appropriate fibrin seal to form around the insertion site.

Postoperative Care and Tube Removal

- Cleanse the skin-tube interface using saline- or water-moistened gauzes once daily.
- Prevent damage to the tube by covering it with a light bandage or stockinette.
- When the tube is no longer required, it can be removed in one of two ways:
  - Cut the tube close to the patient's body wall and push the mushroom tip gently into the stomach using the wooden end of a cotton-tip applicator. Let the mushroom tip pass through the GI tract; if there is concern regarding obstruction because of the tip, retrieve it endoscopically.
  - Alternatively, remove the tube percutaneously by grasping and pulling the mushroom tip through the body wall while applying firm downward pressure to stabilize the body wall. A blunt stylet (e.g., cotton-tip applicator) can be placed inside the tube against the nipple tip to stretch the mushroom tip, making it easier to remove. The inner flange slides off the mushroom tip and passes out the GI tract.
  - Once a strong seal has developed between the stomach and the body wall (at least 2–3 weeks), the Pezzer mushroom catheter can be replaced by any of a variety of low-profile or "button" gastrostomy tubes. These are placed percutaneously into the stoma immediately following extraction of the original Pezzer tube.

Complications

- The opening in the inner or outer flange may be too small and may cause severe constriction of the tube and obstruction to feeding. Observe the tension on the catheter walls when the inner and outer flanges are placed to prevent this complication.
- Inadvertent tube removal from the stomach wall can result in leakage and peritonitis. Stomach wall integrity because of disease and excessive tension on the stomach wall in large-breed dogs because of deep-chested conformation may contribute to this complication. Use caution when placing a tube in a gastric site suspected to have infiltrative disease. Consider alternative tubes for large-breed deep-chested dogs. Inadvertent removal of the tube from the body wall by the patient or by snagging on another object is not a concern if the tube has been in place 10 to 14 days or more to allow fibrous seal or stoma formation. Tube replacement can occur through the same stoma if it is still patent, or a low profile tube (button tube) can be considered.
- Tube obstruction with food can also be a complication. In general, mechanical removal or an attempt to advance the obstruction forward with a narrow diameter stylet is preferable to the use of chemical dissolution methods.

NUTRITIONAL MANAGEMENT OF THE CRITICAL CARE PATIENT

The goal of nutritional support of critical care patients is to get them from the intensive care unit to the ward and then out of the ward to eating their own food at home as efficiently as possible. Until this goal can be achieved, the next best thing is for the patient to eat its own food in the hospital. Encourage feeding of usual and favorite foods whenever possible. Animals, particularly cats, offered novel foods may not eat them and may

develop learned aversions if the food is associated with illness-related nausea or other negative sensations. Encourage owners of hospitalized patients to provide whatever food is typically offered at home and to feed the pet during hospitalization (many pets eat more willingly for their owners than for strangers) when possible. In some cases, however, patients cannot eat by themselves and need more invasive approaches to nutrition support.

Nutritional Assessment

- If malnutrition is not present initially, reevaluate the patient periodically during hospitalization to ensure that malnutrition does not develop secondary to an ongoing disease process, administered drugs or treatments, persistent inability to eat, or inadvertent food deprivation.
- Nutritional support is part of the primary therapy for malnourished patients and when voluntary food intake is impossible for prolonged periods.

▼ ***Key Point*** Do not begin nutritional support until the initial goals of fluid therapy—rehydration, electrolyte replacement, and normalization of acid-base status—have been achieved.

- The steps of nutritional assessment include a history (including a complete diet history), a physical examination, and an evaluation of any supporting laboratory data. Increased risk for malnutrition is suggested by a recent history of one or more of the following clinical situations:
  - Greater than 10% weight loss
  - Decreased food intake
  - Increased nutrient needs because of trauma or surgery
  - Increased nutrient losses resulting from vomiting, diarrhea, or burns
  - Acute exacerbation of a chronic disease problem
- Obtain a diet history to determine the quality and appropriateness of the diet fed and the total daily intake of food. Ask if corticosteroids, cancer chemotherapeutic agents, antibiotics, diuretics, or other drugs that may adversely affect nutritional homeostasis have been administered recently.
- Perform a thorough physical examination, including assigning a body condition score (BCS) (Fig. 3-15).
- Underweight animals lose subcutaneous fat and experience muscle wasting. Patients in a moderate or overweight body condition also may be tissue depleted but may not appear so because of an "overcoat" of fat. This situation occurs when muscle tissue is broken down more quickly than is adipose tissue. Affected patients usually can be recognized by a poor haircoat; easily pluckable hair; thin, dry skin; and abnormal prominence of the bones of the head.
- Use a muscle condition score (MCS) (Fig. 3-16) to quantify the assessment. Structural impediments to eating also may be identified during the examination.
- Hypoalbuminemia, lymphopenia, and anemia are nonspecific laboratory findings that can be associated with severe malnutrition. Decreased resistance to the passage of a needle for blood collection because of loss of skin collagen also is a reasonably sensitive indicator of peripheral protein depletion.
- Assess a serum biochemical profile to provide important information regarding visceral organ function, which may influence the composition of the diet or the route of administration. For example, evidence of significant abnormalities of liver or kidney function could indicate the need for protein restriction, and severe pancreatitis could necessitate parenteral administration of nutrients.

Routes of Nutrient Delivery

Oral Feeding

- Oral feeding is the safest, least expensive, most beneficial physiologically, and most convenient method of feeding; thus, use oral feeding whenever possible.
- Try nursing techniques to improve food intake (often referred to as "coax-feeding") before proceeding to more invasive methods.
- Attempt hand-feeding, petting or stroking, vocally reassuring the animal, offering food when the animal is outside of the cage (during a walk outside or in a quiet area of the hospital), warming the food to body temperature to enhance aroma, or offering a favorite food.
- When new diets must be introduced to hospitalized patients, offer 15 to 30 g of the food initially. If resistance is observed, remove all food and attempt again in 1 to 2 hours. If no intake is observed within another 1 to 2 hours, or if the food hardens, remove it immediately and offer a different food.
- If the diet is intended for long-term patient management, offering it after the patient is home and feels better improves the probability of long-term acceptance and success.
- If attempts to restore food consumption fail, try force-feeding using a syringe for 1 to 2 days. Force-feeding provides some nutrition, but the inconvenience and the stress imposed on the patient during feeding limit its usefulness.
- A feeding tube also may be passed through the mouth into the stomach for each feeding. Passing an orogastric tube is relatively simple; limited restraint and the opening of the animal's mouth just enough to introduce the tube minimize the patient's opposition to this procedure.

Enteral Routes

- If the patient is too debilitated to tolerate repeated tube feedings, or if nutritional support is required for

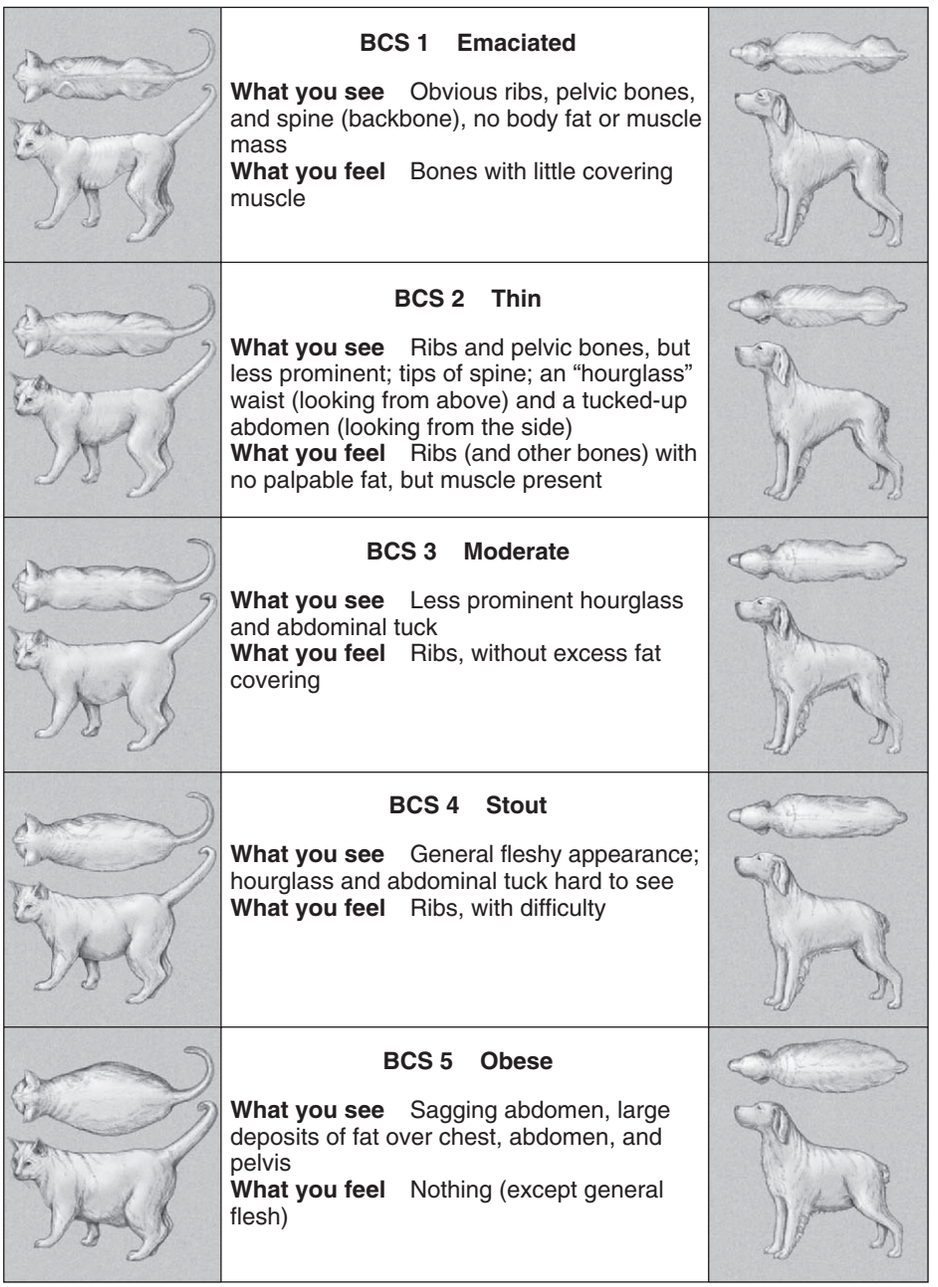

Figure 3-15. Body condition scoring. (Buffington CAT, et al: Manual of Veterinary Dietetics. St. Louis: WB Saunders, 2004.)

more than 2 days, place either a nasogastric or a nasoesophageal tube (see the technique described in "Nasal Catheter Placement"). Tube placement is simple, does not require anesthesia or sedation, and allows provision of fluid and nutrients for days to weeks.

- If a nasal tube cannot be placed, or if a prolonged course of feeding is anticipated, place an esophagostomy tube in patients that have a functional GI tract and no history of vomiting or regurgitation (see "Esophagostomy Tube Placement").
- When access proximal to the stomach is not available in patients with normal GI function, place a gastrostomy feeding tube. Surgical gastrostomies are the safest but the most expensive and difficult to place. Alternatively, a feeding tube can be placed using an endoscope or a blind placement device (see "Percutaneous Endoscopically Placed Gastrostomy Tube"). Gastrostomy tubes can be maintained in patients for months with good nursing care.
- Rarely, a needle catheter jejunostomy or gastrojejunostomy may be necessary when gastric atony, gas-

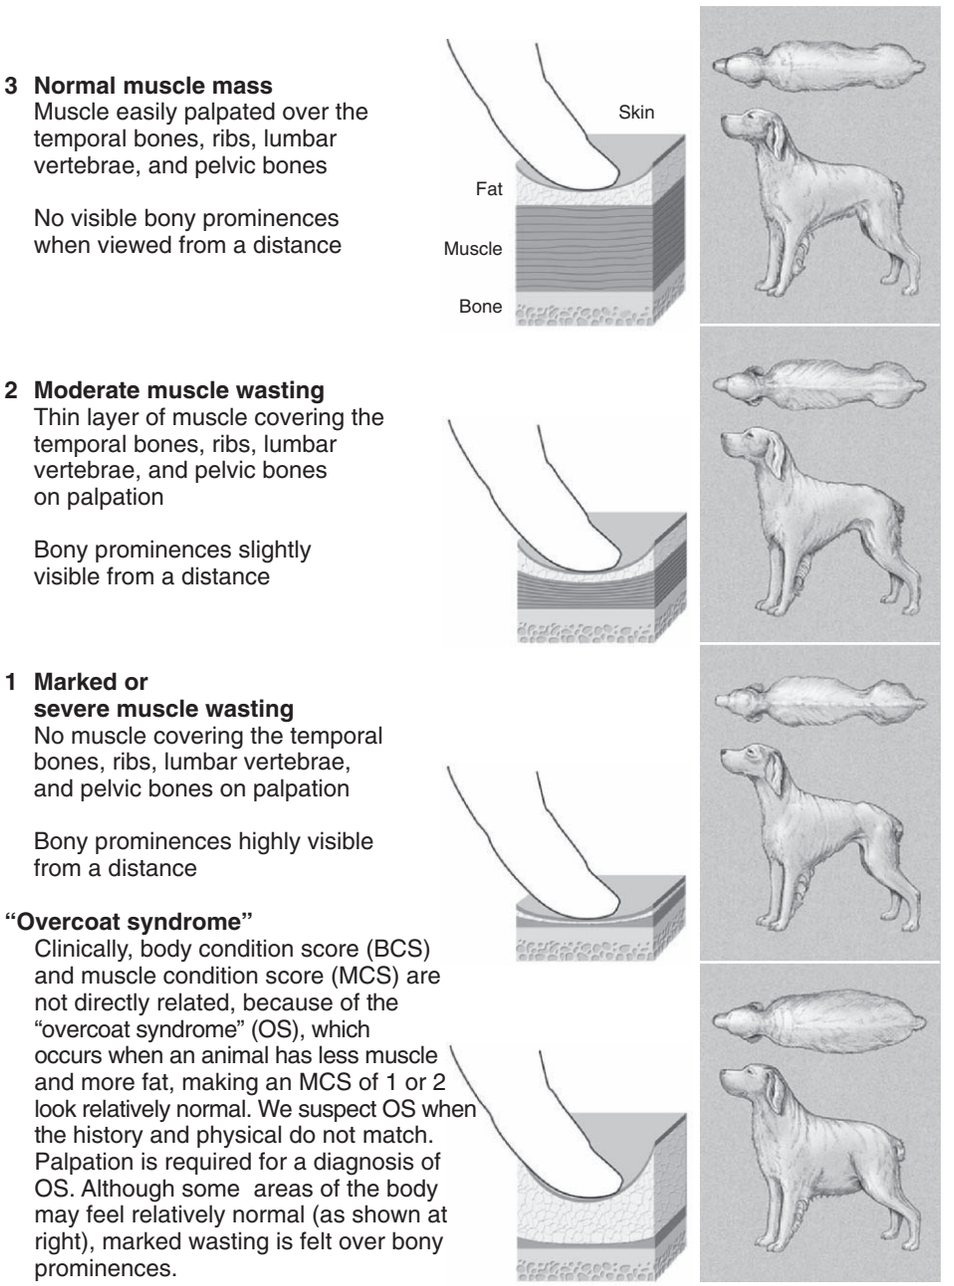

Figure 3-16. Muscle condition scoring. (Buffington CAT, et al: Manual of Veterinary Dietetics. St. Louis: WB Saunders, 2004.)

troduodenal obstruction, neoplasia, regurgitation, or vomiting prevent feeding using more proximal sites. Jejunostomy tubes are typically placed at surgery. Patients requiring extensive surgical procedures of the stomach, duodenum, pancreas, or hepatobiliary system also can be fed in the immediate postoperative period through these tubes.

- Small feeding tubes also can be threaded into the jejunum through a surgically placed gastrostomy tube at the time of surgery if the patient is not expected to eat orally for a prolonged period. Patients can be fed immediately postoperatively using the jejunal tube, which can be removed from the gastrostomy tube to permit gastrostomy feeding once motility returns to the stomach.

Nutrient Needs

Calories

Provide hospitalized patients with their basal energy needs. Graphs of the basal energy needs of dogs and cats over a range of body weights are presented in

Figure 3-17. These graphs were constructed using the following equation: *97 kcal × kg of body weight$^{0.655}$ per day.* Use the exponential equation for patients weighing less than 2 kg or more than 50 kg. For animals weighing between 2 and 50 kg, a linear equation such as *(30 × kg body weight) + 70 = kcal/day* can be used.

These estimates are conservative and may be lower than the energy needs of some patients during the course of their disease. They are only initial guidelines, also intended to avoid adverse consequences of overfeeding. Provide slightly less food than needed to avoid the potential for overfeeding. The estimated energy needs of a patient can be converted to food needs by assuming that many canned foods contain approximately 1 kcal/g and that many dry foods contain approximately 350 kcal/8 oz. If more accurate values are needed, consult the pet food's manufacturer.

Protein

- In patients with no disease-related limitations on protein intake, 7 to 10 g of protein per 100 kcal of energy is usually adequate.
- Patients with advanced liver and kidney disease require careful use of limited amounts of high-quality protein, probably in the range of 2 g (in dogs) to 3 g (in cats) of a high-quality protein per kilogram of body weight per day.
- Monitor animals consuming these amounts or less for signs of protein depletion.

Minerals and Vitamins

In addition to energy and protein, provide vitamin and mineral intake near the National Research Council requirements for growth in the absence of a specific contraindication.

Diet Selection

- Choose an appropriate diet for the disease-related nutrient modifications required.
- Secondary factors include both size and location of the feeding tube.
- Liquid diets specifically formulated for veterinary use (e.g., CliniCare; Abbott Laboratories) are available and may be fed through a tube of any size. To maximize success and minimize the risk of clogged tubes, feed only liquid diets through tubes smaller than 12 Fr. Feed veterinary or commercial canned pet foods that have been processed in a blender (with water added as needed) through tubes larger than 12 Fr. Tables of veterinary foods are available in the *Manual of Veterinary Dietetics* (see "Supplemental Reading") and at www.nssvet.org.

Feeding

- Provide food or water soon after the patient recovers from anesthesia.
- Estimate and deliver fluids and nutrients in four to six feedings over a 24-hour period.
- Give small volumes distributed over several meals during the first 24 to 48 hours of feeding to avoid overdistention of the stomach, vomiting, or regurgitation.
- In severely ill patients, use slow, constant administration rates to help minimize incidents of diarrhea and cramping and to maximize absorption of the nutrients. Hang small volumes of liquid diet (approximately a 12-hour supply) in fluid therapy bags or burettes for gravity-assisted constant-rate infusion to minimize the possibility of "overdosing" patients with the feeding solution during continuous feeding.

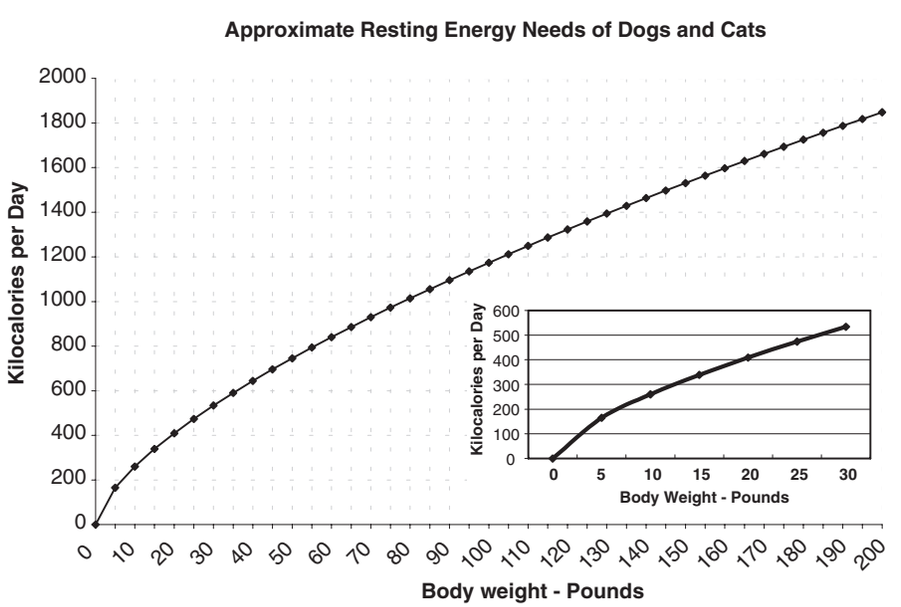

Figure 3-17. Basal energy requirements of dogs and cats.

- Flush tubes with water before and after each feeding to avoid occlusion with food or mucus.
- Diarrhea (usually small amounts of soft, pasty feces) can occur in enterally fed patients. It is generally more of a nuisance than a threat to the patient and usually results from rapid gastric emptying caused by overly rapid administration of a bolus meal. Reduce the feeding rate and feed diets that contain fiber or higher concentrations of fat (>50% of total kcal) to delay gastric emptying.

Parenteral Nutrition

- Parenteral nutrition (PN), or intravenous feeding, allows the provision of short-term metabolic and immune system support to animals with severe GI disease or pancreatitis. Because PN therapy is relatively expensive and is associated with more complications than feeding through the GI tract, use enteral feeding whenever the GI tract can tolerate it. PN is also not indicated when the patient's prognosis is hopeless.
- The high osmolality of PN solutions requires the use of a central venous catheter inserted in the external jugular vein or placed in a peripheral catheter and advanced into a central vein. Proper insertion and maintenance of the PN catheter is one of the keys to successful PN therapy. Use aseptic technique when placing the intravenous catheter. If well cared for, central vein catheters may be used for prolonged periods. Do not remove the catheter unless a specific indication for removal exists.

▼ ***Key Point*** Once a catheter is placed and designated for PN therapy, do not use it for other purposes, such as drawing blood samples, administering medications, or measuring central venous pressure.

Adverse drug-nutrient reactions and clogged catheters are serious potential complications of these practices.

Glucose Content

- Formulate glucose-based PN solutions based on the patient's estimated nutrient needs. The most commonly used PN solution for patients at Ohio State University contains 17.5% glucose. Glucose-based PN solutions are filterable, bacteriostatic because of the high osmolality, relatively easy to prepare, and relatively inexpensive. On the other hand, their hyperosmolality necessitates central venous access, and thrombophlebitis may result if solutions are infused at high rates into small veins.
- Hyperglycemia, usually less than 600 mg/dl, is also more common with glucose-based solutions than with lipid-based solutions. This has minimal pathophysiologic significance but needs to be monitored and controlled with insulin therapy as needed (see "Glucose Monitoring").

Calorie and Protein Content

Estimate energy needs of PN patients as previously described. Attempt administration of nutrients at rates exceeding resting energy needs only after the initial goal has proved tolerable for the animal. Provide 2.5 g of protein per kilogram of body weight. Restrict protein intake to approximately 2 g/kg/day in animals with severely compromised liver or kidney function.

Minerals and Vitamin Content

The macromineral portion of the solution is provided by an amino acid-electrolyte solution. Zinc, copper, manganese, and chromium, as well as water-soluble vitamins, are routinely added to PN solutions. The essential fatty acids, fat-soluble vitamins, and minerals necessary for prolonged PN therapy do not appear to be necessary for the short-term PN more typically provided to veterinary patients.

Apparatus and Delivery

- The apparatus required for PN administration includes the solution, the solution container, an administration set, a 0.22-µm filter, a dedicated central venous catheter, and, preferably, an infusion pump.
- Provide PN at a rate intended to meet resting energy needs by the end of the first 24 hours, then advance to slightly higher rates of intake, if necessary, over the next 24 to 48 hours as patient tolerance allows.

Glucose Monitoring

- During the initiation phase, measure blood glucose every 4 to 6 hours until stable. Once goals are reached, monitor the patient as described subsequently. At the end of therapy, wean the patient from the solution over 4 to 24 hours as tolerance permits by progressively halving of the infusion rate to avoid hypoglycemia, particularly if insulin has been infused. If the patient is able to eat, offer food and record the food intake. As soon as signs of appetite are observed, decrease the PN administration rate to approximately half the previous rate to encourage the animal to begin eating on its own.

▼ ***Key Point*** The most important monitoring parameter for patients receiving glucose-based PN is blood glucose, which is monitored closely during initiation of therapy.

- Treat patients when blood glucose concentrations exceed 250 mg/dl with intramuscular administration of 0.25 U of regular insulin per kilogram of body weight every 4 to 6 hours as necessary. Insulin therapy

is not commonly required for dogs, although consider it for cats during the first 36 hours to control hyperglycemia. Diabetic animals placed on PN often require continuous infusions of higher-than-expected quantities of insulin to control their blood glucose concentration effectively. When insulin is used, caution must be exercised with regard to the central venous catheter, which is presumed to be in place continually. If insulin is given and then vascular access is lost, give a 5% glucose infusion through a peripheral vein immediately to prevent severe rebound hypoglycemia.

Complications of PN

The most common PN-related complications are mechanical, technical, and related to glucose abnormalities. Use a strict protocol for prevention, diagnosis, and treatment of sepsis. PN-related infections occur only rarely.

Returning to Normal Food Intake

- In general, discontinue assisted feeding when patients begin eating a quantity of food that contains at least half of their calculated daily energy needs. Ideally, the weaning process should take place gradually over at least a day or two before the feeding tube is removed or PN administration stopped.

Chapter 4

Radiographic and Ultrasonographic Techniques

David S. Biller / Laura J. Armbrust

The purpose of the radiograph is to provide a lasting record of maximum information. The sequence of the major operations involved in transforming the altered morphology and tissue density within a diseased animal into a two-dimensional, black-and-white radiograph and then reaching a diagnosis is complex and includes the following steps: (1) making a properly exposed and positioned radiograph; (2) recording the x-ray picture with the assistance of accessory equipment; (3) reviewing radiographs in proper conditions and in a systematic and detailed manner; (4) recognizing lesions—therefore [requiring] a knowledge of normal radiographic anatomy and its variation by age, species, and breed and the ability to recognize and understand artifacts; and (5) evaluating radiographic abnormalities with respect to clinical and laboratory findings.

Dr. Peter Suter

X-RAY MACHINE

Milliampere-Second and Kilovolt Peak

- *mA (milliampere) × seconds (time) = mAs (milliampere-second),* which affects the degree of blackness (density) of the radiograph with no effect on contrast. A direct relationship exists between mA and radiographic density. Time and mA both influence the number of x-rays produced but have no effect on the penetrating ability of the beam. To quickly check the adequacy of the mAs on a film, hold the film up to room light and place a white sheet of paper about 1 inch behind the film. Place a finger between the film and the paper. If the finger can be readily seen through the film in the black area (the most exposed), increase the mAs.
- *kVp (kilovolt peak)* is the only machine factor that influences radiographic contrast and has some control over the amount of radiographic density (blackness). The contrast can be expressed as being low, which means that there are many shades of gray (long scale) between the extremes of black and white. The term *high contrast* means that there are few shades of gray (short scale). Lowering the kVp increases the contrast, and raising the kVp reduces the contrast.
- To adjust the technique to alter film contrast while maintaining the same radiographic density, consider the following:
  - The mAs and the kVp have to be in balance.
  - As the mAs increases, the kVp must decrease.
  - As the kVp increases, the mAs must decrease.
  - Doubling radiographic density requires doubling the mAs or increasing the kVp by 10% in the 40- to 100-kVp range or 15% in the 100-kVp or greater range.

Recommendations

- The *300-mA machine* may have adjustable mA stations of 25, 50, 100, 200, and 300 and two (1 and 2 mm or smaller) focal spots.
- An ideal kVp range is 40 to 120 and is adjustable in 1 or 2 kVp per step.
- A *timing device* is necessary to control the duration of an x-ray exposure. Modern x-ray machines have electronic timers with ranges that can control motion in the patient and prevent blurring. With a timed exposure of $^{1}/_{120}$ second, all significant motion is stopped.
- The *line voltage compensator* is automatic or manual.
- The *tube stand* moves along the full length of the table and has an adjustable height from 0 to 60 inches (152 cm). The tube is able to rotate 90 degrees around the vertical axis and 180 degrees around the horizontal axis.
- The *table* is 5 to 6 feet in length with a top that has floating motion in four directions.
- The *collimator* decreases scatter radiation and human and patient exposure as it increases film quality. Always leave a clear margin of collimation on every film. The collimator is lighted and has a centering mark. A high-quality, dial-adjustable, multileaf lead shutter collimator is highly recommended.
- *Filters* have the primary function of reducing patient radiation dose by removing scatter radiation and increasing (mean beam energy) quality. Most x-ray equipment has inherent filtration equal to 1.5- to

2.0-mm aluminum. Increased film quality can be obtained by adding an additional 2.0-mm aluminum filtration. Total filtration must be at least 2.5-mm aluminum.

- *Grids* consist of a flat plate with a series of lead foil strips separated by transparent spacers. They are made in various sizes and improve the diagnostic quality of radiographs by absorbing the greater part of the scatter radiation. Position grids between the patient and the cassette, usually under the table. Use only for body parts thicker than 10 cm. The reciprocating grid (Potter-Bucky diaphragm) includes a mechanism that moves the grid during exposure to eliminate grid lines from the radiograph. This grid is optional equipment but recommended for the best-quality radiographs.
  - Grids can be classified in three ways: the lead content (g/cm^2), the number of lines per inch, and the ratio of lead strip height to the space between the lead strips. In general, high-ratio grids absorb scatter better but are more expensive. More lines per inch give better quality, because the lead strips are narrower and therefore lines become less prominent; however, they cost more. The most common grid is an 8:1 with 103 lines per inch.
  - The higher the grid ratio, the more critical the x-ray tube alignment. Always stay within the focal zone of the grid. This is usually written on the grid and is 36 to 42 inches (90–105 cm) in most instances.
- *Exposure switches* include the two-position exposure switch on the console and the two-position exposure foot switch, with a cord of sufficient length.
- *High-frequency x-ray machines* have a few advantages over single-phase x-ray machines. A 150-mA high-frequency generator can produce a quantity of x-rays equal to that of a 300-mA, single-phase x-ray machine. Many of the units use 110 volts. They are reliable, with less downtime than single-phase machines. Their cost, at present, is greater than that of single-phase machines but most likely will decrease in the future.
- For a list of x-ray machine manufacturers, see Table 4-1.

ACCESSORY RADIOGRAPHIC EQUIPMENT

Intensifying Screens

The screen is a suspension of phosphor crystals in a binder. The phosphor in the screen converts x-ray photons into visible light, to which the film is more sensitive. A latent image is created by exposure of the film to this light. This technique reduces x-ray exposure to the patient by at least 10 times and the time of x-ray exposure, thus decreasing the chance of blurring.

- Screen speed depends on the thickness of the phosphor layer, the size of phosphor crystals, and the efficiency of phosphor crystals at absorbing x-rays and converting them to light.
- Screen classification varies because each company has a slightly different system for labeling screen speed. Resolution ability of the screen is inversely related to speed. Increased speed gives decreased resolution. Have a technique chart available for each screen speed. Par speed is the starting point for comparison of screens. High speed has a speed 2 times that of par speed. Ultraspeed is 4 times par speed. High detail speed is half that of par speed.
- Types of Screens
  - Calcium tungstate screens reduce the amount of radiation necessary to expose film by 10 times com-

pared with film exposed without a screen. They are also less expensive than rare-earth screens. Calcium tungstate emits a broad spectrum of light in the ultraviolet and blue range.
  - Rare-earth screens are more expensive than calcium tungstate screens. The light emitted is in the ultraviolet, green, or blue range. The major advantage of rare-earth over calcium tungstate screens is that rare-earth screens are fast, because of a more efficient production of light. Therefore, they decrease the production of scatter, the exposure time, the radiation dose, the chance of motion and subsequent blurring, and the wear and tear on the x-ray tube.
- System speed is the speed of film and screen in combination. It is not an additive system. A very low system speed results when screens and films with different color spectrum sensitivities are put together. Ask the film dealer what system speed you have with your particular screens and film. The higher the system speed number, the more sensitive the system and the less radiation necessary to make an exposure. System speeds can vary from 50 to 3200 and higher. The higher the system speed number, the less radiation to the patient and to personnel within the room; however, the lower the system speed number, the better the resolution qualities. When you know the system speed, changing the technique chart is simpler. If the system speed doubles, change the mAs on the technique chart by half. If the system speed decreases by 50%, double the mAs on the technique chart.
- Exposure time

▼ ***Key Point*** Always use the shortest exposure times possible to eliminate blurring.

  - For thoracic radiographs, exposure times of $\frac{1}{60}$ second or shorter stop the effects of respiratory and heart motion.
  - For abdominal radiographs, employ exposure times of $\frac{1}{40}$ second or shorter to eliminate gastrointestinal motion.
  - For extremity radiographs, exposure times of $\frac{1}{20}$ second or shorter eliminate the effects of patient motion.
- Rare-earth screens have a system speed that allows the shortest exposure times possible to eliminate motion problems and to lower radiation exposure to patient and personnel. In general, when using a 300-mA machine and a 400 to 800 speed system, with an 8:1 grid, good-quality radiographs are attainable even for large-breed dogs. In a feline practice, a slower system, such as a 100 to 250 speed system, provides excellent quality. As the crystal size gets larger, the system gets faster but resolution is reduced.
- Clean screens with the product recommended by the manufacturer on a regular schedule (monthly) and whenever debris is noted on the radiographs.

Film

Radiographic film provides a permanent record containing the maximum amount of diagnostic information.

- Film is made of a light-sensitive emulsion, composed of gelatin and silver halide with other ingredients attached to a plastic (polyester) base. The silver halides are sensitive to light and change when exposed to light to produce a latent image. The process of developing changes silver ions into black silver, thus producing the radiographic image. Fixer removes all unexposed silver from the film. The emulsion may be attached to one or both sides of the base. X-ray film may be most sensitive to direct x-ray exposure (nonscreen film) or to blue, green, or ultraviolet light.
- Films vary in their contrast. Some films appear more black and white after exposure and development. Use the film that is recommended by your screen manufacturer to match the spectrum of light produced by your screens. Choose a film that results in the contrast range most pleasing to you. Use a film that gives you a system speed that results in quality radiographs. Make sure to match film, screens, and processing chemicals.
- Film must be sensitive to the type of light emitted by the screens in use. Film speed determines the amount of light required to produce an image on the radiograph. Fast film has large crystals (silver halide), requires less exposure, and produces a grainy image. Slow film has small crystals, requires greater exposure, and produces a sharper image.
- Screen film is manufactured with crystals that are sensitive to fluorescent light. Nonscreen film is a direct exposure–type film and is manufactured to be sensitive to x-rays. Nonscreen film requires 10 to 25 times more radiation than screen film.
- Film is available in both metric and nonmetric measurements. The most common sizes used in small animal practice are 8×10 inches, 10×12 inches, and 14×17 inches.
- X-ray film is sensitive not only to light and x-ray photons but also to humidity, chemicals, and physical stress. Film is stored on end to reduce pressure on the face of the film. High humidity causes film fogging, and low humidity causes film static; therefore, between 30% and 40% humidity is appropriate for film storage. Storage temperature should not exceed 50°F to 70°F (10°C to 21.1°C). Store the film away from developing chemicals and ionizing radiation. Do not put pressure on the film when loading or unloading film.
- Film and screen companies are provided in Table 4-2.

Cassettes

Cassettes are used primarily to contain and protect film. Two basic types are available: rigid cassettes that contain both the film and the screen and cardboard cassettes that hold nonscreen film.

- Rigid cassettes protect both screens and film from physical damage and film from exposure to light. The cassette provides snug contact between the film and the screens. The front of the cassette is usually a rigid plastic, aluminum, or other substance that absorbs relatively few x-ray photons. Usually, a small rectangle in the corner of the cassette shields the film from x-rays to allow an unexposed area for film identification. The back of the cassette is lined with lead to absorb backscatter radiation. The back of the cassette is also equipped with latches to provide a lightproof seal.
- Cassettes for a nonscreen film only protect the film from light exposure. They are usually made from cardboard.
- Cassettes are numbered. When defects are noted on a radiograph, they can be traced to the correct cassette. Dropping a cassette causes warping and results in poor film-screen contact and a distorted radiographic image.

Miscellaneous Accessories

- Use the screen cleaner that is recommended by your screen manufacturer.
- Use safety devices (lead aprons, lead gloves, glasses, and lead thyroid shield) when personnel are required in the x-ray room for patient positioning.
- Film markers consist of right and left lead film markers, Mitchell markers (for horizontal radiographs), and time markers (for upper gastrointestinal and intravenous urography radiographs).
- A device capable of measuring body-part thickness and determining the kVp for exposure is needed.
- Positioning devices include sponge wedges, sandbags, Plexiglas or foam trough, rope, tape, and agents for chemical restraint to avoid human exposure associated with hand-holding whenever possible.
- Film filing envelopes are needed.
- Contrast media are required (see "Contrast Studies" and Table 4-6).
- Monitoring devices (film badges) for employees and room monitoring, a film viewer (at least one double bank), and a hot light (high-intensity light) are needed.
- Radiographic accessory companies are listed in Table 4-3.

CHECKING X-RAY MACHINE ACCURACY

Milliampere Station Check

- Use an aluminum step wedge to check mA station (setting) accuracy. Use the step wedge to determine if your mA stations are linear. It cannot determine if all your mA stations are off by the same amount. A step wedge (see Table 4-3 for sources) gives a general idea about the mA stations. A step wedge is inexpensive ($100) and easy to use. Place the step wedge on a loaded cassette; make many separate exposures of the step wedge, changing the mA but always having the same mAs and kVp. If you cannot keep the same mAs throughout all mA stations, do as many as possible at one mAs setting then go back and check the rest at another mAs.

Example

25 mA	$^1/_{10}$ second	2.5 mAs	70 kVp
50 mA	$^1/_{20}$ second	2.5 mAs	70 kVp
100 mA	$^1/_{40}$ second	2.5 mAs	70 kVp
300 mA	$^1/_{120}$ second	2.5 mAs	70 kVp
100 mA	$^1/_{60}$ second	1.7 mAs	70 kVp
200 mA	$^1/_{120}$ second	1.7 mAs	70 kVp

Compare the densities of all exposures. They should be the same for all mA stations taken at the same mAs. An exposure that varies from the average shows that there is a problem with that mA station. This test

Wolf X-ray Corp.	420 Hempstead Turnpike West Hempstead, NY 11552	800-356-9729	www.wolfxray.com

does not tell you if all mA stations are accurate, but it does tell you if a particular station has a problem.

- A digital, electronic mA-checking device is the most accurate way to compare your mA stations.

Kilovolt Peak Check

▼ ***Key Point*** The only accurate way to check the kVp is the Wisconsin test cassette ($1300; see Table 4-3 for sources).

- The Wisconsin test cassette has many kVp settings listed on the front of the cassette. Under each of these settings is a certain amount of material to attenuate the beam. After exposure and processing, this film provides information to determine if the kVp settings are accurate.
- Another less accurate way to obtain a general check of kVp accuracy is to vary mAs and kVp. Go through all kVp settings, employing density-changing factors to keep the densities the same throughout all these exposures.

Example

100 mAs at 50 kVp	3.1 mAs at 81 kVp
50 mAs at 55 kVp	1.5 mAs at 90 kVp
25 mAs at 61 kVp	0.8 mAs at 99 kVp
12.5 mAs at 67 kVp	0.4 mAs at 108 kVp
6.2 mAs at 74 kVp	0.2 mAs at 124 kVp

If your mA stations and kVp settings are working correctly, each exposure has the same density but a different contrast range. Remember to employ density-changing factors when necessary.

Exposure Timer Check (Single-Phase Machine)

Use a spinning-top test tool. It can be purchased from the same company as the machine (see Table 4-1) or from an accessory company (see Table 4-3). This tool is inexpensive ($50) and easy to use. It is a flat metal spinning top with a hole in one side. The top is set on a loaded cassette and spun. Take an exposure at $^1/_{120}$ second. Move the top to another corner of the film, spin again, and expose at $^1/_{60}$ second. This maneuver is repeated at $^1/_{40}$ and $^1/_{30}$ second. At $^1/_{120}$ second, only one dot should be seen; at $^1/_{60}$, two dots; at $^1/_{40}$, three dots; and at $^1/_{30}$, four dots. If more or less dots are on the film than expected, the timer is not accurate.

Line Voltage

Line voltage is the amount of current coming into the machine. The amount of current may vary, depending on electrical wiring, consistency of voltage in the area, and usage of current on the same circuit in the particular practice. Almost all machines used for small animals have a line voltage-check device. Some have a meter and a dial to adjust line voltage and do not permit exposure until the voltage is manually adjusted. Other machines have an automatic line voltage adjustment.

Almost all equipment in small animal practice uses 120 volts (i.e., right out of the socket).

FILM PROCESSING

Manual Processing

Film developing is a chemical process and therefore depends on both time and temperature.

Advantages and Disadvantages

- Advantages
  - Less expensive setup costs than those of an automatic processor.
  - No special electrical or structural changes are necessary for the darkroom.
- Disadvantages
  - Valuable technician time to develop films and maintain chemical baths (i.e., increased labor costs).
  - Quality is not consistent, due to human error, compared with automatic processors.
  - Longer time to prepare diagnostic films compared with automatic processors.

Accessories

- Developing tanks
- Two stirring paddles
- Two thermometers
- Film developing hangers of different sizes
- Chemicals
- Adjustable mixing valve for measuring water temperature
- Timer
- Dust-free drying cabinet or area

Darkroom Safelight

Darkroom safelights must produce enough illumination in the darkroom so that a person can see to process radiographic film (load and unload cassettes) without unwanted density (fog) to the film. Safelights utilize a wavelength of light different from that to which the film is sensitive. A Wratten 6B filter is adequate for blue-sensitive film. A GBX-2 filter is employed with green-sensitive or both green- and blue-sensitive films. Usually, 15-watt bulbs are used with safelights. The safelight is about 4 feet from the film-handling area. No system is 100% safe; therefore, expose the film no longer than necessary.

Radiograph Labeling

- A radiograph is a legal document and must therefore have permanent labeling. On the label, include the hospital or veterinarian's name, the date the radiograph was taken, and the owner's name or the animal's file number. Label the radiograph with right or left, dorsoventral or ventrodorsal (DV/VD), a time marker on contrast studies, and a Mitchell marker when a horizontal beam is used. Basic types of permanent marking systems are available:
  - Lead letters and numbers in a holder with the hospital or veterinarian's name, placed on the cassette during exposure.
  - Radiopaque marking tape (lead-impregnated tape). Information may be written on the tape, and the tape is placed on the cassette before exposure.
  - A darkroom printer transfers data from a card to the corner of the x-ray film that was shielded from radiation during exposure. This system requires cassettes with special windows. The film is removed from the cassette, and the corner of the film where it was blocked from light exposure is imprinted by exposing the patient information on a 5 × 7-inch card onto the film.

Silver Recovery

Recover silver from fixer solutions by either manual or automatic systems. Fixer solutions may be sold to companies for silver recovery. Alternatively, you may purchase a system (metallic replacement process, electrolytic recovery, or chemical precipitation) for silver recovery in your practice. Exposed developed and undeveloped film may also be sold for silver recovery. Usually, the supplier of the x-ray films or processing solutions can be consulted to determine if silver recovery is feasible and who to contact.

Procedure for Manual Film Processing

- Check temperatures, turn off room lights, use safelights, and agitate (mix) solutions well.
- Place the film on development hangers, making sure all four corners are attached.
- Set and start time depending on the temperature in the developing tank.
- Place the hanger with the film into the developing tank. Rap hard against the tank wall to dislodge air bubbles. Agitate by pulling film out of the developer, and let the developer drain to one lower corner. Return film to the developer. Repeat agitation every minute. Manufacturers recommend a specific temperature for the developed solution that they produce, usually 68°F (20°C). Adjust for change in temperature (increased temperature, decreased time, and vice versa). The chemical manufacturer can provide a time-temperature development chart.

Example

60°F (15.5°C) 8.5 minutes
65°F (18.3°C) 6.0 minutes
68°F (20.0°C) 5.0 minutes
70°F (21.1°C) 4.5 minutes
75°F (23.8°C) 3.5 minutes

- At the end of the developing time, remove the hanger from the developer and drain over the rinse tank. Agitate film in rinse water for 30 seconds.
- Place the hanger with film in fixer at the end of the developing time.
- Set the timer. Fixer time equals twice the development time.
- Agitate film every 2 to 3 minutes while in the fixer.
- At the end of fixation time, remove film from fixer and drain.
- Place the hanger in wash water at the end of fixer time.
- Agitate after 2 to 3 minutes.
- Wash for 15 to 30 minutes, depending on water flow and temperature in wash tank.
- Provide no less than four water changes per hour in the wash tank.
- At the end of the wash, remove from water and drain.
- Place film in a drier cabinet or hang up to dry.

Automatic Processing

- Processors are a good investment for most veterinary practices. New, small, tabletop models are priced from $3500. Most of these processors develop an excellent quality film in 90 to 210 seconds. They can use cold water for processing; therefore, no special needs exist for plumbing. They are also easy to maintain.

▼ ***Key Point*** If your small animal practice is processing 7 to 10 films a day, consider an automatic processor.

- Advantages
  - Highly repeatable results
  - Short waiting time for diagnostic films
  - Ability to process large quantity of films quickly and accurately
  - Good quality control
  - Smaller darkroom necessary
- Disadvantages
  - Machine is expensive.
  - Darkroom structural changes are expensive.
  - Needs daily and weekly maintenance.
  - Repairs can be expensive.
- Equipment includes processor, safelight, water for processing, chemicals, sponges to clean rollers of processor, and processor cleaning solution.
- Tabletop film processors are easy to install (no special plumbing or wiring). Different models process films as fast as 90 seconds or as long as $3\frac{1}{2}$ minutes. Most are made for easy care and cleaning. They are relatively inexpensive (from $3000 to $7000).
- Large, hard-wired, 90-second film processors need special plumbing and electrical wiring, but they are able to process many films. They need special cleaning and repairs and are expensive ($15,000–$25,000).
- The more a processor is used, the fewer problems it will have. It is made to be used on a 24-hour basis. Chemical buildup on rollers can cause film artifacts. Rollers age and crack if oxidized chemicals are left on them.
- Clean processors often.
  - All processors need cleaning daily when not in use. Take out the rollers and wash them down with a sponge and water. Dry and replace the rollers. Clean the chemical tanks. Once a month, clean with processor cleaning solution. Cleaning a processor takes about 15 minutes a day but saves in wasted film and time.
- Consider purchasing a processor with a standby mechanism. This function helps conserve water, energy, and chemicals.
- Automatic processor companies are listed in Table 4-4.

Darkroom

Recommendations

- Darkroom location: Locate the darkroom close to water and drains for plumbing purposes, and close to radiographic area to reduce unnecessary walking and to increase efficiency.
- Darkroom layout (Figs. 4-1 and 4-2): Darkrooms do not have to take up much room but are at least 6 × 8 feet. Many darkrooms are located where a bathroom might have been. This eliminates the process of bringing in new plumbing and electrical outlets. Try to include a sink for cleanup and processor maintenance. Keep wet and dry areas separate to eliminate contamination of screens and unexposed film by chemicals. Always have good ventilation to keep heat, humidity, and chemical fumes from destroying film and to reduce exposure of personnel to chemical fumes. Paint all walls white to reflect light from the safelights and for a brighter working environment. Use an adequate number and type of safelights. Make sure all safelights are 40 inches from the working area to prevent film fogging.

TECHNIQUE CHARTS

- Have a working knowledge of equipment (tube rating charts and anode cooling curves). A constant focal film distance is recommended. The same film, screens, and darkroom technique are used, as described previously.
- The technique chart is set up to take radiographs of normal animals. Different animals may have the same lateral thoracic measurement but different body types (obese, emaciated, etc.). The emaciated animal may be overexposed with the technique from the chart; therefore, you will need to decrease the exposure (kVp). The obese animal may be underexposed following the chart technique; therefore, you will have to increase the exposure (kVp).
  - The technique may need to be increased (2–30%) for numerous reasons (e.g., obesity, pregnancy, ascites, pleural effusion, or disease processes that increase lung opacity, such as pneumonia and atelectasis) and for positive-contrast studies.
  - The technique may need to be decreased (2–30%) for numerous reasons, including emaciation, pneumothorax, emphysema, gastric dilatation, and volvulus.

▼ ***Key Point*** Always select the shortest possible exposure times. This entails choosing the highest mA value to achieve the shortest exposure times.

Technique Chart (with Grid) (Fig. 4-3)

Thorax with Grid

1. Use a dog of average size and body condition for all measurements.
2 Take a lateral measurement across the chest at the widest point.
3. Find that measurement on your technique chart.
4. Underneath this lateral measurement, set your kVp at 95—a value in the middle of the ideal kVp parameters for a thorax.
5. Fill out your chart according to the kVp per centimeter increments.
6. Once the kVp values have been assigned, take three chest films at different mAs values. You may begin with 0.8, 1.6, and 3.2 mAs for a rare-earth system and 5, 10, and 20 mAs for calcium tungstate, for example. Select the mAs value at 95 kVp that provides you with the best technique.

Abdomen with Grid

1. Follow the first three steps under "Thorax with Grid."
2. Set your kVp at 85.
3. Fill out the chart according to the kVp per cm increments.
4. Double the mAs value used in the thorax technique.

Spine with Grid

1. Follow the first three steps under "Thorax with Grid."
2. Set your kVp at 65.
3. Fill out the chart according to the kVp per cm increments.
4. Set the mAs value 4 times that used for the abdomen. This setting also works for femur, humerus, shoulder, and pelvis.

Technique Chart (Tabletop without Grid) (Fig. 4-4)

Thorax, Abdomen, and Spine

1. On the grid chart for thorax, abdomen, and spine, find the last kVp setting for 11 cm.
2. Decrease the kVp as the thickness decreases. For example, if 74 kVp is at 11 cm, use 72 kVp at 10 cm, 70 kVp at 9 cm, and so forth.
3. Adjust the mAs by reducing to half (possibly more depending on the type of grid) the mAs value for the base techniques for the thorax, abdomen, and spine. If films are still overexposed, reduce the mAs by half again.

Extremity

1. Measure a normal dog carpus. The average is 4 to 5 cm.
2. Underneath that measurement, set your kVp at 60 (a value in the middle of your ideal kVp parameters for extremities).

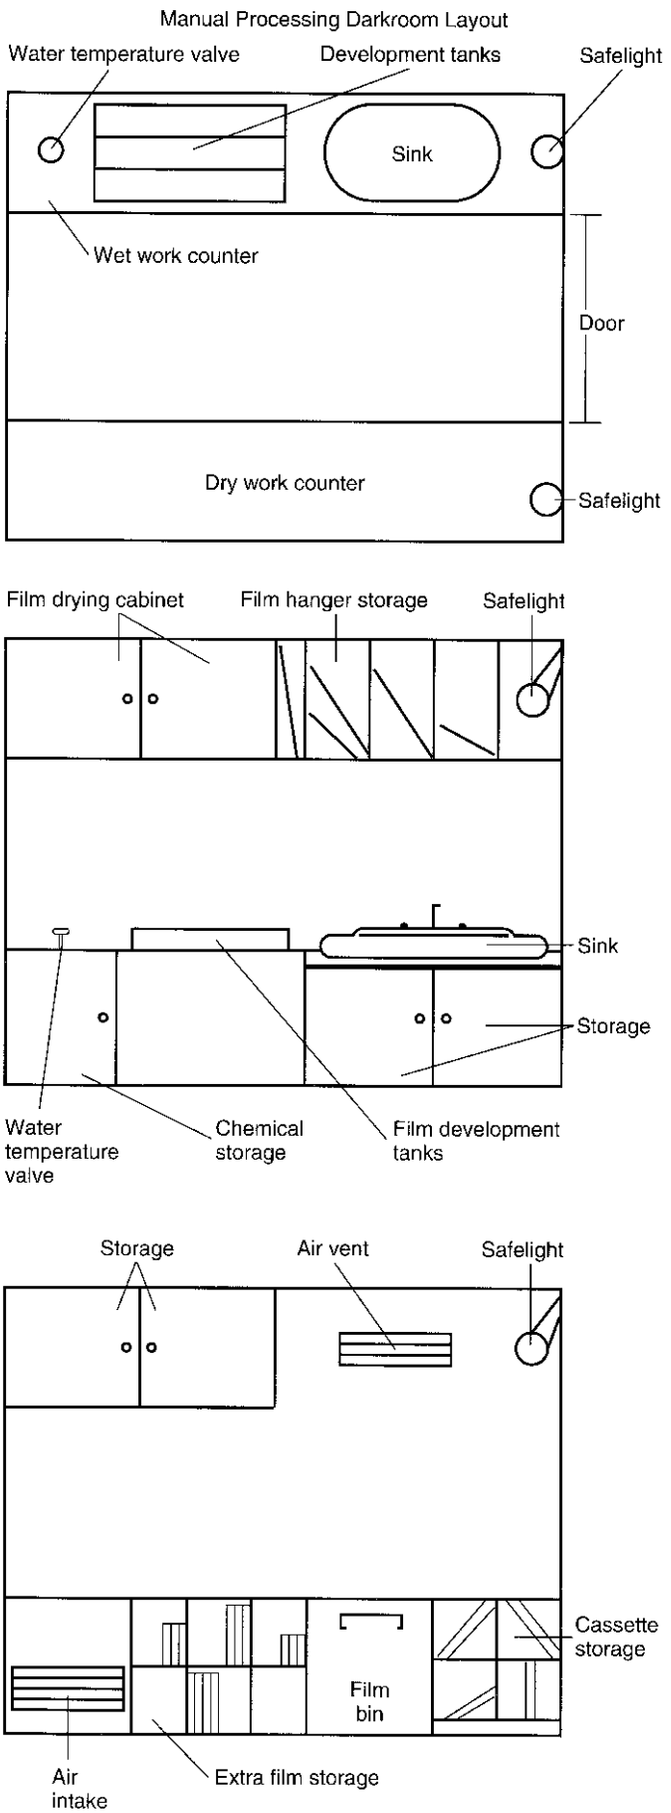

Figure 4-1. Floor plan for a darkroom using manual (wet tank) processing.

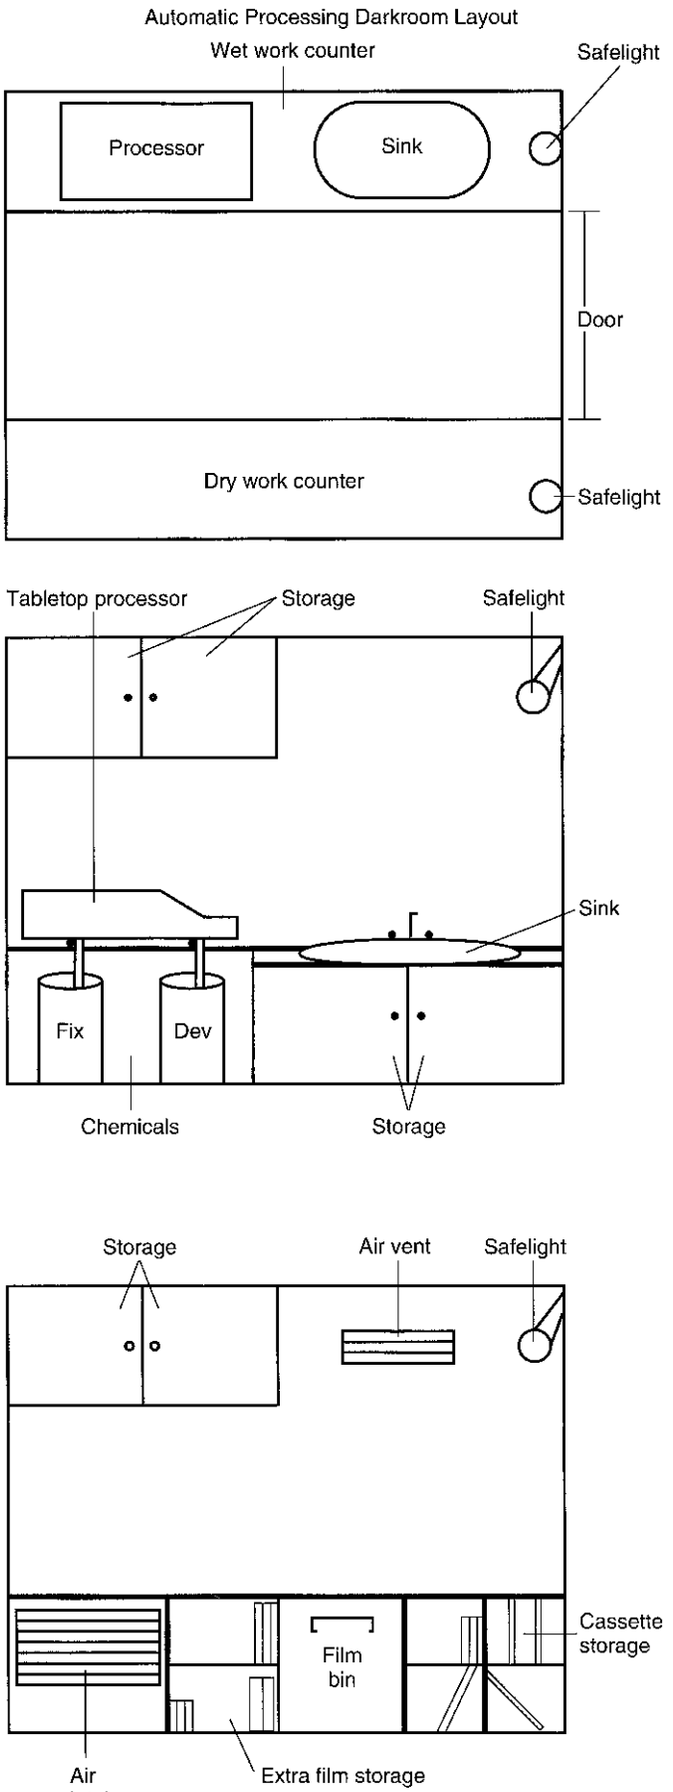

Figure 4-2. Floor plan for a darkroom using automatic processing.

Making a Technique Chart (Grid)

	1	2	3	4	5	6	7	8	9	10	cm
Abdomen ___ mAs											kVp

	1	2	3	4	5	6	7	8	9	10	cm
Spine, Skull, Pelvis ___ mAs											kVp

	1	2	3	4	5	6	7	8	9	10	cm
Extremities ___ mAs											kVp

Figure 4-4. Technique chart. For tabletop exposures, take the Buckey grid technique and reduce the mAs by 50% to 75%. Continue kVp down from Buckey chart.

3. Fill out the chart, according to the kVp per cm increments.
4. Take films at three different mAs values (0.8, 1.6, and 3.2 with rare earth; 5, 10, and 20 with calcium tungstate). Continue selecting the mAs values until an appropriate exposure has been made. Your tabletop extremity chart is now complete. Employ this chart for all extremities distal to and including the elbow and stifle.

Nonscreen Film Technique Chart

- For the nonscreen film technique chart, the mAs in your technique chart may vary up or down from the example shown in Figure 4-5.

COMPUTED RADIOGRAPHY

Computed radiography (CR) is an indirect digital imaging technology in which a plate (which looks similar to a cassette but is filmless) is used to record the image. A reader is required to extract the data, which is converted to a digital image and viewed on a computer screen. CR utilizes standard x-ray machines. Components of CR include both the hardware described previously and the software (for display, storage, and archiving). New technique charts must be developed when switching from a traditional film-screen system to CR. CR software allows image manipulation that can adjust for exposure and contrast. Images can also be drawn, and measurements can be taken.

▼ ***Key Point*** The ability of the viewer to appreciate the image quality provided by CR depends on the quality of the computer monitor.

Advantages

- A digital image is generated (these can easily be sent to specialists if needed).
- Existing radiography equipment can be used.
- Excellent image quality.
- Initially less expensive than digital radiography.
- Film, processor, and darkroom can be eliminated.

Disadvantages

- Still have to use an imaging plate
- Need to purchase new plates and a reader
- Need to have computers and a software package to integrate with medical records

DIGITAL RADIOGRAPHY

Direct digital radiography (DR) uses specialized x-ray equipment that has a digital imaging sensor. Once the image is transferred to the computer system, image analysis and storage are similar to those previously listed for CR.

Advantages

- A digital image is generated (these can easily be sent to specialists if needed).
- Excellent image quality.
- Film, processor, and darkroom can be eliminated.

Disadvantages

- Currently more expensive than CR systems (cannot be used with existing x-ray equipment).
- Few current systems allow horizontal beam radiography.
- Need to have computers and a software package to integrate with medical records.

POSITIONING AND TECHNIQUE

Measuring for Radiographic Studies

- Measure all animals standing.
- Measurements for the thorax, abdomen, and thoracolumbar spine are all taken at the same location on the animal. Observe the animal from above, taking the lateral measurement from the widest point across the ribs. The DV/VD measurement is made at the same point. The widest point is usually at the thoracolumbar junction.
- Measure the pelvis across the wings of the ilium. This is a very accessible area to measure, giving highly repeatable results. The same measurement is used for both the lateral and the VD.
- Measure extremities at the widest point.
- Make sure all personnel measure all areas at the same point; otherwise, the technique will vary from one study to the next.

Nasal, Dental, and High Detail Studies

1	2	3	4	5	6	7	8	9	10	11	cm
50	100	125	150	200	250	300	350	400	450	500	mAs

Figure 4-5. Technique chart to use with nonscreen film. Use a lateral measurement across the skull to set technique. Always use 50 kVp for the best contrast.

Thorax

Obtain thoracic films at full inspiration. Include from the thoracic inlet to behind the diaphragm. In a large dog, this may take two radiographs for both lateral and DV/VD views. Short exposure times of $^1/_{60}$ second or less decrease motion artifact from cardiac and respiratory motion. A high-kVp, low-mAs technique increases latitude (increased shades of gray).

- For the lateral (right or left) measurement, elevate the sternum to the same plane as the spine. Pull the animal's legs cranially to reduce soft tissue over the cranial thorax. Include the sternum, and take the radiograph during peak inspiration (Fig. 4-6).
- For the DV/VD view, the sternum is superimposed over the spine. Center the beam at the caudal border of the scapula; center the beam on the spine. Take the radiograph during peak inspiration. VD radiographs are preferable to DV for evaluation of the accessory lung lobe and the caudal mediastinum. DV radiographs are preferred if evaluation of the caudal pulmonary vessels is important. The dog's disposition, clinical status (e.g., heart failure, pulmonary edema, or pleural effusion), or position of previous radiographs help choose between VD and DV thoracic radiographs (Fig. 4-7). A Plexiglas or foam trough is useful for positioning for the VD view (add 10% kVp to your technique when using a trough).
- Take both right and left lateral views of the thorax with a DV/VD view to evaluate for pulmonary metastases or focal disease.

Abdomen

Withhold food for at least 12 hours for optimal abdominal radiographs. Encourage the animal to defecate and urinate before being radiographed. Radiographs include the diaphragm to the coxofemoral joints. For large-breed dogs, this may require two 14 × 17-inch films for both the lateral and DV/VD views. Use a $^1/_{40}$-second or less exposure time to reduce motion; use a kVp in the 70 to 90 range for maximum latitude.

- For a lateral (right or left) radiograph, pull the legs caudally but not enough to stretch the abdominal musculature taut. Place the edge of the cassette 1 to 2 inches cranial to the xiphoid and at the coxofemoral joint (palpate for the greater trochanter). Take the radiograph at peak expiration (Fig. 4-8).
- The DV/VD is the same as that for the lateral abdomen (Fig. 4-9). A Plexiglas or foam trough is useful for positioning for the VD view (add 10% kVp to your technique when using a trough).
- A horizontal beam radiograph can be used to check for free abdominal air. Place the animal in left lateral recumbency for 10 minutes before radiography. Air is demonstrated around the right liver lobes. The technique is similar to the vertical beam technique in that distance remains at 40 inches. Remember to reduce the mAs if a grid is not used.
- In compression radiography, a wooden spoon can be used to compress the abdomen for separation of

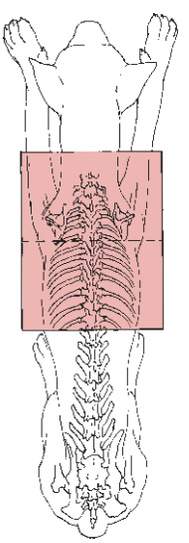

Figure 4-7. Positioning for dorsoventral or ventrodorsal thoracic radiograph.

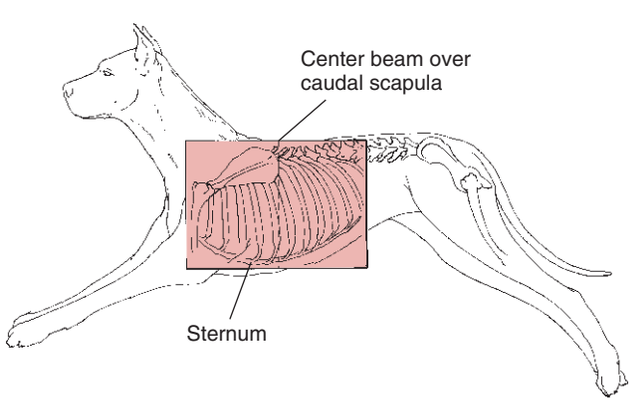

Figure 4-6. Positioning for lateral thoracic radiograph.

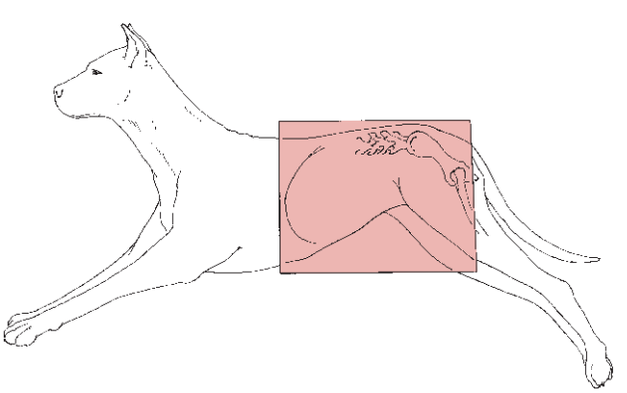

Figure 4-8. Positioning for lateral abdominal radiograph.

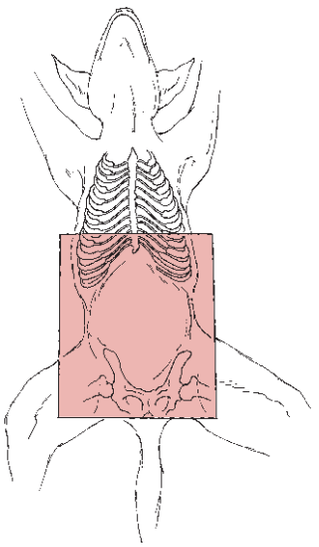

Figure 4-9. Positioning for ventrodorsal abdominal radiograph.

structures. The spoon can separate the colon from the urinary bladder to demonstrate the uterus, for example. Remember to reduce the kVp, because you are decreasing the thickness of the tissue being radiographed.

Extremities

For radiography of the extremities, the animal needs a clean, dry haircoat. Remove splints and bandages if possible. Place the limb to be radiographed closest to the film. Employ a high-mAs, low-kVp (50–70) technique to produce high-contrast radiographs. Collimate closely. Use tabletop (nongrid) techniques on parts less than 10 cm thick. Administer anesthesia or tranquilizers whenever needed. Use positioning devices. Measure the part to be radiographed over the thickest area. If the part thickness varies greatly, two exposures (e.g., lateral pelvis and femur) may be necessary. In the case of moderate variation, choose the greater measurement to set the exposure and "hot light" the slightly overexposed areas when reading the film. When long bones are being radiographed, include the joints proximal and distal.

▼ ***Key Point*** Radiograph the opposite limb for comparison to determine normal from abnormal.

Scapula and Shoulder Joint

Caudocranial

The animal is in dorsal recumbency, with the sternum rotated away from the side being radiographed. The leg is fully extended. Center the x-ray beam at the mid-scapula. For the shoulder joint, center the beam at the point of flexion for the joint.

Mediolateral (ML)

The animal is in lateral recumbency, with the down side to be radiographed. Extend the leg about 45 degrees from the vertebral column. Flex the opposite leg and place it over the thorax. Pull the head and neck back so that the cervical spine and trachea are not overlapping the joint space.

Humerus

Caudocranial

The animal is in dorsal recumbency, with the legs extended. Rotate the sternum away from the side being radiographed. Center the x-ray beam at the mid-humerus. The radiograph includes both the shoulder and the elbow joints.

Mediolateral

Place the animal in a position similar to that for the ML view of the scapula and the shoulder joint. Center the x-ray beam at the mid-humerus. The radiograph includes both the shoulder and the elbow joints.

Elbow Joint

Craniocaudal

The animal is in sternal recumbency, with the elbow joint in full extension. If the elbow cannot be completely extended, angle the x-ray beam 10 degrees to 20 degrees, craniodistal to caudoproximal.

Mediolateral

The animal is in lateral recumbency, with the elbow slightly flexed. Pull the opposite leg caudally. Center the beam on the palpable medial epicondyle. The elbow is in extreme flexion if identification of the anconeal process is of importance.

Craniolateral-Caudomedial Oblique

This aids in imaging of the lateral aspect of the medial coronoid.

Antebrachium

Craniocaudal

Place the animal in sternal recumbency. Extend the leg and position the elbow for a true craniocaudal projection. The film includes both elbow and carpus.

Mediolateral

The animal is in lateral recumbency, with the leg in the neutral position. Move the opposite limb caudally; center the beam on the midshaft radius. It may be easier to obtain the radiograph if the elbow is slightly flexed. Include the elbow and carpal joint on the film.

Carpus or Metacarpus

Dorsopalmar

By convention, positional terms change from cranial and caudal to dorsal and palmar distal to the radius. Place the animal in sternal recumbency, with the extremity extended. Allow the elbow to abduct slightly so that the carpus is in true dorsopalmar (DP) view. Center the x-ray beam on the carpus or metacarpus.

Mediolateral

Place the animal in lateral recumbency, with the affected leg down. Slightly flex the carpus; center the x-ray beam on the carpus. A lateral view of the metacarpus is often unrewarding.

Oblique Views

Place the animal in sternal recumbency, with the carpus/metacarpus in DP. Rotate the extremity 45 degrees in both directions for the two oblique views (dorsolateral to palmar medial oblique and dorsomedial to palmar lateral oblique).

Digits

Dorsopalmar

Place the paw flat against the cassette.

Mediolateral

Place the animal in lateral recumbency. Pull the specific digit to be examined dorsally with tape.

Oblique Views

Place the animal in sternal recumbency, with the carpus/metacarpus in DP. Rotate the extremity 45 degrees in both directions for the two oblique views (dorsolateral to palmar medial oblique and dorsomedial to palmar lateral oblique). Cotton can be placed between the digits to help with separation.

Pelvis

Tranquilization may be necessary for routine VD and lateral radiographs. General anesthesia is recommended for Orthopedic Foundation for Animals (OFA) or Penn-Hip radiographs.

Ventrodorsal Extended Hip

The animal is in dorsal recumbency, with the legs extended. The pelvis is straight; the femurs are parallel and as close to the cassette as possible. Patellae are superimposed over the distal femurs. Center the x-ray beam on the hip joints. Include the stifles on the radiographs. Legs are the same distance apart as the acetabula.

Lateral

The animal is in lateral recumbency, with the dependent leg pulled cranially. Elevate the nondependent leg with a foam block parallel to the tabletop.

Lateral Oblique

Place the animal in lateral recumbency. Place a foam wedge to elevate the pelvis approximately 20 degrees. Push the upper leg proximally to rotate.

Ventrodorsal Flexed Hip (Frog-Leg Position)

Place the animal in dorsal recumbency, and flex and abduct the femurs so that the stifles are lateral to the abdomen. Place the femurs at an angle of 45 degrees to the spine.

Femur

Craniocaudal

Place the animal in dorsal recumbency or in the erect sitting position, with the leg extended. Center the x-ray beam at mid-femur. Include the hip and stifle on the radiograph. Measure at the proximal femur.

Mediolateral

Place the animal in lateral recumbency with the leg to be examined on the cassette. Abduct the opposite leg and rotate out of the x-ray beam's path. Center the x-ray beam at mid-femur. Include the hip and stifle on the film.

Stifle

Caudocranial

Place the animal in ventral recumbency with the leg to be examined pulled caudally into maximum extension. In large dogs, angle the x-ray beam 15 degrees caudodistal to cranioproximal. Center the x-ray beam at the joint space.

Mediolateral

Position the animal as for the mediolateral femur view, with the x-ray beam centered on the joint space. Usually, the tarsus is away from the cassette, so you need to place a foam wedge under the hip and femur.

Tibia and Fibula

Caudocranial

Position the animal as for the caudocranial stifle view. The x-ray beam remains vertical and centered at the mid-tibia. Include stifle and tarsus on the film.

Mediolateral

Place the animal in lateral recumbency with the tibia and fibula included on the film.

Tarsus

Dorsoplantar

Place the animal in dorsal recumbency. Extend the leg, and center the x-ray beam at the proximal intertarsal joint.

Mediolateral

Place the patient in lateral recumbency. Slightly flex the tarsocrural joint. Center the x-ray beam at the proximal intertarsal joint.

Oblique Views

Dorsolateral to palmar medial oblique and dorsomedial to palmar lateral oblique. Position the animal in dorsal recumbency, then rotate 45 degrees in each direction (lateral and medial) for the two oblique views.

Metatarsus and Digits

Position the animal as for the metacarpus and digits of the forelimbs.

Spinal Positioning and Technique: General Principles

- Materials needed include sandbags, foam wedges, markers (right and left), and a Plexiglas trough to aid in positioning the animal without anyone in the room.
- Use general anesthesia or heavy sedation in all but the most subdued animals. Exceptions are suspected fracture, congenital malformation with instability, and other diseases in which the animal's condition or protective mechanisms that have maintained stability will be compromised.
- Short-scale, high-contrast (high-mAs, low-kVp) technique provides good detail. Use a grid and collimate to include only the spine.
- At least two radiographic views of the area of interest are needed: lateral and VD.
- In the average-size dog, five vertebral segments can be adequately evaluated per film. Because of the divergence of the x-ray beam, all areas of interest have to be centered to evaluate intervertebral disc spaces.

▼ ***Key Point*** Poor patient positioning and poor radiographic quality commonly occur when animals are not anesthetized or heavily sedated for spinal films. Many radiographic lesions can be obscured by poor technique. Conversely, a normal structure can be falsely identified as a lesion.

- Ideal spinal survey studies are listed in Table 4-5.

Cervical Spine

Measure at the caudal cervical spine for all views.

Lateral View

For radiography, the spine must be parallel to the cassette. In many cases, support the center of the neck with radiolucent positioning blocks (sponges). Place the head in a normal position (neither flexed nor extended) relative to the neck. The head must be lateral because it controls the position of the proximal neck. Pull the front legs back over the thorax to allow thinning of the tissues over the caudal neck. The thorax must be in the accurate lateral position because it controls the position of the caudal neck. Extending the entire neck may help open up the caudal cervical disc spaces. Include both occipital and cervicothoracic areas on the radiograph.

Ventrodorsal View

The spine is not parallel to the cassette because of the anatomic variation between the head and the thorax. The spine inclines away from the cassette at the thorax. Place the head in normal position (hard palate and dorsal nose at a 60 degree angle to the cassette). If the head is in a true VD position, an undesirable arch is pro-

Table 4-5. SPINAL SURVEY STUDIES

Study	Centering—Lateral	Centering—Ventrodorsal

Lumbar spine	L3-4	L3-4
Lumbosacral spine	LS LS flexion LS extension	 LS
Post-trauma	Center on area of suspected lesion	Cross-table (horizontal beam); center on area of suspected lesion

duced in the cervical spine. The midplane of the head and thorax must be perpendicular to the cassette. Tilting the x-ray tube ventrocaudal to dorsocranial approximately 10 to 20 degrees permits imaging of the intervertebral disc spaces.

Thoracolumbar Spine

Lateral View

The midplane of the entire body must be parallel to the cassette. Most animals must have the sternum elevated for good lateral views of the spine. Pull the front legs cranially and the rear legs caudally to straighten the spine. Extending the entire neck may help open up the cranial thoracic disc spaces.

Ventrodorsal View

The midplane of the entire spine must be perpendicular to the cassette. When the dorsal spines are prominent, as in thin animals, radiolucent positioning blocks may be beneficial. The body may be held by placing tension on the legs.

Skull Radiography

- General anesthesia or deep tranquilization of the patient is essential, if not specifically contraindicated by the patient's physical condition, to obtain radiographs of good diagnostic quality.

▼ ***Key Point*** The lack of proper patient restraint is the most common cause of skull radiographs of nondiagnostic quality.

- The highest-resolution (detail) radiographic image of the skull is produced with a nonscreen film or an ultradetail film-screen combination. Nonscreen film necessitates a 10- to 20-fold increase in the mAs compared with film in par speed screen cassettes.
- The positioning of the patient and the number of projections needed for a complete study depend upon the area of the skull being evaluated. A minimum of two views is necessary.

Routine Skull

Lateral and DV views are used.

Nasal Cavity and Paranasal Sinuses

Lateral and DV occlusal (Fig. 4-10), VD open mouth (extraoral film) (Fig. 4-11), frontal (primary beam parallel to the hard palate) (Fig. 4-12), and lateral oblique (right and left) (Fig. 4-13) are used to evaluate small frontal sinuses.

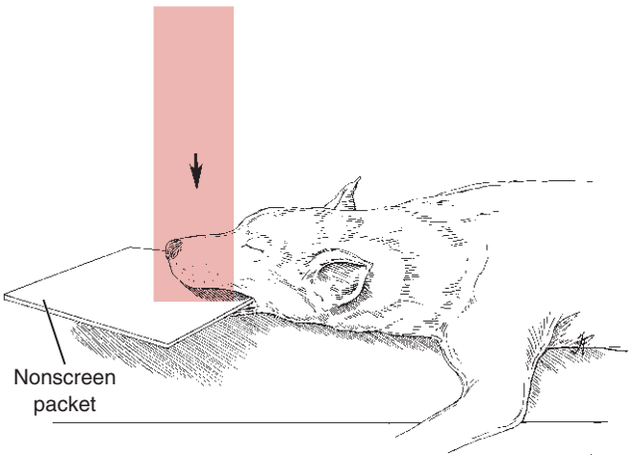

Figure 4-10. Positioning for dorsoventral occlusal (intraoral) radiograph of the skull.

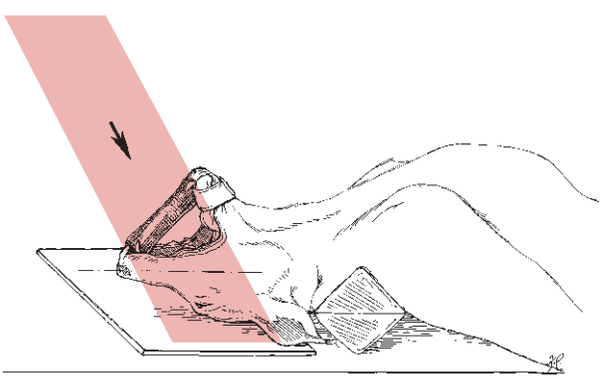

Figure 4-11. Positioning for the ventrodorsal (20° to 30° tube angle), open-mouth view of the skull.

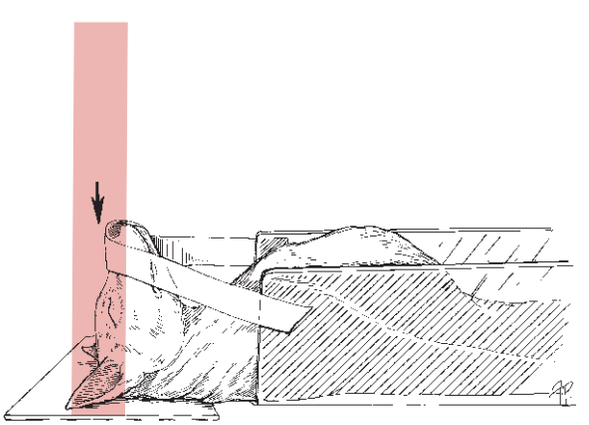

Figure 4-12. Positioning for the rostrocaudal (frontal) view of the skull.

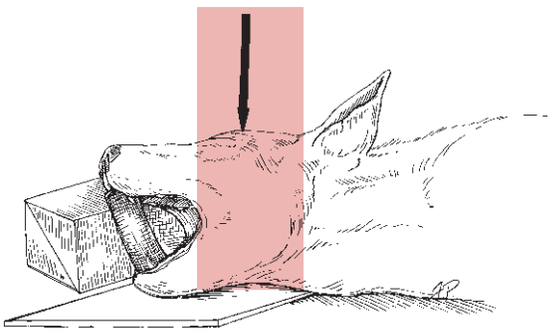

Figure 4-13. Positioning for the open-mouth lateral oblique (20° to 30°) view of the frontal sinuses.

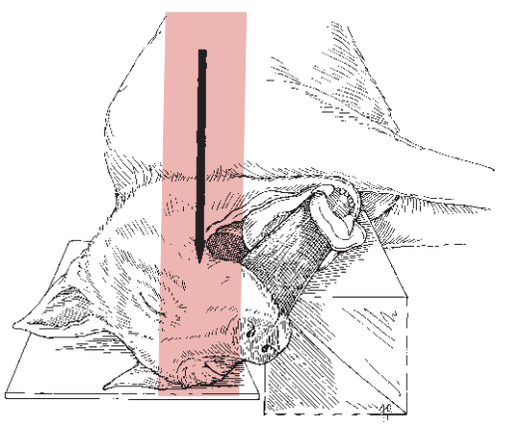

Figure 4-14. Positioning for the open-mouth lateral oblique (20° to 30°) view of the maxilla.

Dental Arches

- Maxillary: Right and left lateral obliques (20–30 degrees) (Fig. 4-14), VD open mouth (extraoral film), and DV occlusal.
- Mandibular: Right and left lateral obliques (20–30 degrees), open mouth (Fig. 4-15), and VD occlusal (Fig. 4-16).

Bisecting Angle Technique

Project the central beam perpendicular to an imaginary plane that bisects the angle formed by the long axis of the tooth (or teeth) and the plane of the film (Fig. 4-17).

Tympanic Bullae (Middle Ears)

DV, open mouth frontal. The primary beam bisects the angle of the opened temporomandibular joint (TMJ) (Fig. 4-18); right and left lateral obliques (30 × 30 degrees) (Fig. 4-19). Palpate the jugular processes; when these processes are oblique, the bullae will also be properly oblique.

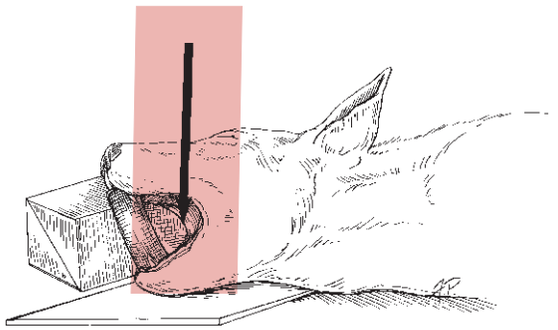

Figure 4-15. Positioning for the open-mouth lateral oblique (20° to 30°) view of the mandible.

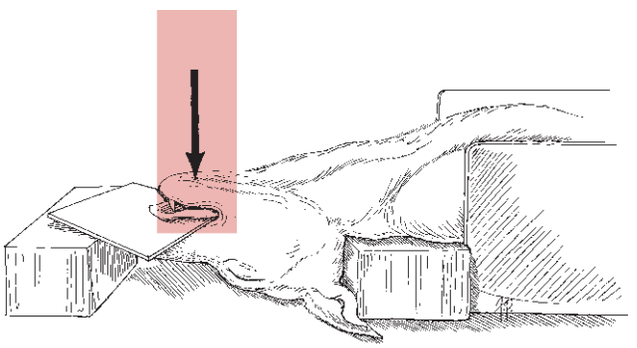

Figure 4-16. Positioning for the ventrodorsal occlusal (intraoral) view of the mandible.

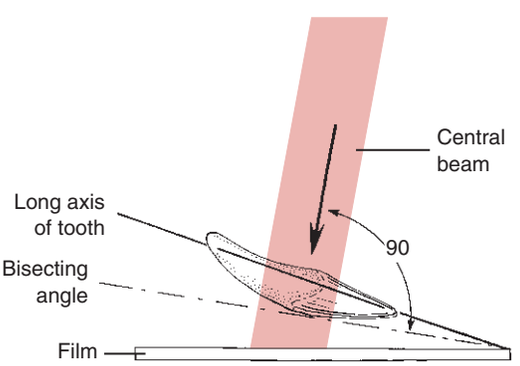

Figure 4-17. Bisecting angle technique for radiographing the teeth.

Foramen Magnum

Rostrodorsal-caudoventral oblique (fronto-occipital). The central beam passes between the eyes and exits through the foramen magnum (Fig. 4-20).

Temporomandibular Joint

DV, open mouth frontal (see Fig. 4-18). The primary beam bisects the angle of the opened temporomandibular joint; right and left lateral obliques (20–30 degrees) (see Fig. 4-13).

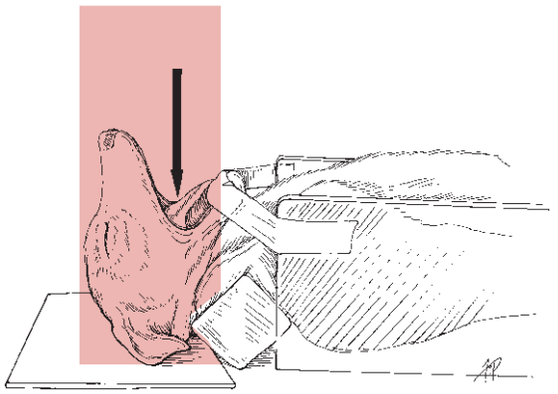

Figure 4-18. Positioning for the open-mouth rostrocaudal (basilar) view of tympanic bullae.

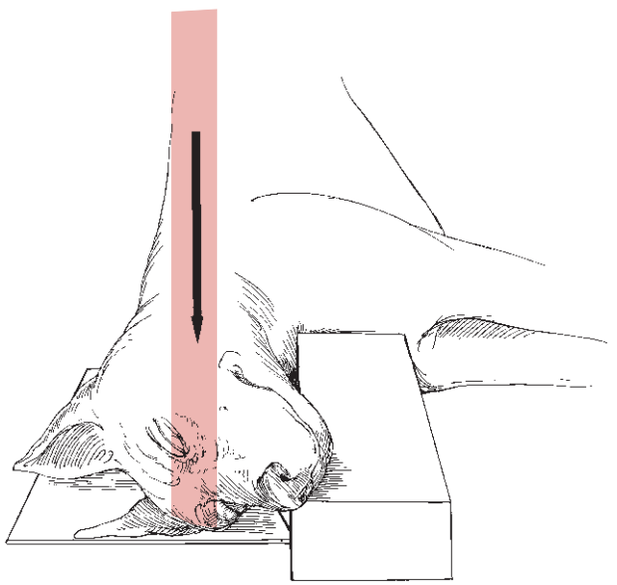

Figure 4-19. Positioning for the lateral oblique (30° nose elevated, then 30° oblique) view of tympanic bullae.

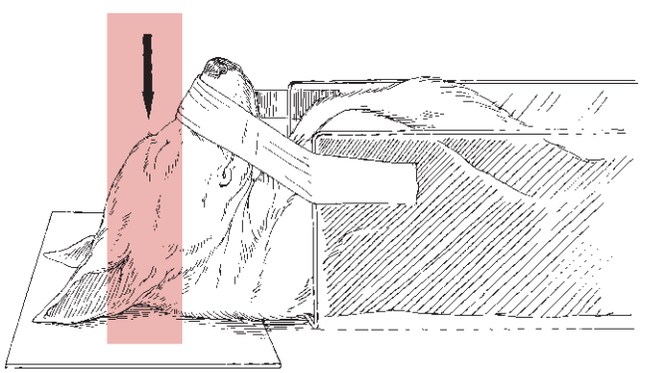

Figure 4-20. Positioning for the rostrodorsal-caudoventral (fronto-occipital) view of the skull.

Mandible

DV, lateral, and lateral oblique (right and left).

Maxilla

DV occlusal, VD open mouth, lateral, and lateral oblique (right and left).

Zygomatic Bone and Orbit

DV, lateral, and lateral oblique (right and left); frontal; and VD open mouth.

CONTRAST STUDIES

Contrast Medium

- Positive-contrast medium: iodine (ionic, nonionic), barium (liquid, paste) (Table 4-6)
- Negative-contrast medium: room air, carbon dioxide, nitrous oxide

Excretory Urogram (Intravenous Pyelogram, Intravenous Urogram)

- A well-prepared animal is important for this contrast study (excretory urogram[EU], intravenous pyelogram, and intravenous urogram are synonymous terms). Withhold food for 12 to 24 hours. Give enemas the night before and at least 2 hours before the study. Determine renal function (blood urea nitrogen and serum creatinine) before initiating the study.

▼ ***Key Point*** Always take scout films before performing contrast studies of the urinary tract.

- The primary contraindication in animals is dehydration. Contrast medium is hypertonic and will compromise an already unstable patient. Make sure the patient is properly hydrated before EU. Other contraindications in people include diabetes mellitus, multiple myeloma, heart failure, and known hypersensitivity to the contrast medium.
- Use a water-soluble, iodinated ionic contrast media (Renografin, Conray, Hypaque, Renovist, etc.). Dose is 2 ml/kg intravenously (approximately 300–400 mg/ml of iodine), not to exceed 90 ml or 35 g of iodine. For animals with impaired renal function, the dose may need to be doubled (4 ml/kg). Place an indwelling catheter to help avoid perivascular injections and to allow intravenous access if complications occur. Give the bolus as fast as possible.
- Increase radiographic technique (mAs) 5% to 10% over scout films. Keep the kVp approximately 70 to produce better differentiation between the kidney and the contrast medium.

Table 4-6. RADIOGRAPHIC CONTRAST AGENTS

Type of Contrast Agent	Brand Names	Manufacturers
Barium products	Intropaste (barium paste)	Lafayette Pharmacal (Lafayette, IN)
	Barosperse (barium suspension)	Mallinckrodt (St. Louis, MO)
	Novopaque (barium suspension)	Lafayette Pharmacal (Lafayette, IN)
	E-Z-ML- 196 (barium suspension)	E-Z-EM (Westbury, NY)
Iodinated gastrointestinal contrast agent	Gastrografin	Bracco Diagnostics (New Brunswick, NJ)
	Omnipaque (iohexol)	Amersham Health (Piscataway, NJ)
Iodinated contrast agent	Renografin 60 or 76	Bracco Diagnostics (New Brunswick, NJ)
	Hypaque-76	Amersham Health (Piscataway, NJ)
	Conray 30 or 400	Mallinckrodt (St. Louis, MO)
Myelographic contrast agent	Omnipaque (iohexol)	Amersham Health (Piscataway, NJ)
	Isovue (iopamidol)	Bracco Diagnostics (New Brunswick, NJ)

Technique

1. Immediate postinjection VD film demonstrates nephrographic phase.
2. VD and lateral films at 5 minutes.
3. In some cases, if there is poor filling of the renal pelvis, between 10 and 20 minutes following contrast administration place an abdominal wrap between the bladder and the kidney to compress the ureters, causing the pelvis and diverticula of the kidney to completely distend for better evaluation. This is contraindicated in cases of severely diseased bladder walls or mass lesions, in which it may cause rupture.
4. VD and lateral films at 15 minutes for evaluation of the pyelographic stage.
5. VD and lateral films at 30 minutes.
6. Remove the compression wrap and take lateral and VD radiographs.
7. Modify this technique as needed for the suspected disease entity. For example, to evaluate for ectopic ureters, take oblique films off lateral at the bladder trigone between 15 and 20 minutes. A pneumocystogram may also be helpful for identifying the distal ureters and vesicoureteral junctions.
   - Complications include perivascular injection, which can be treated by instilling saline into tissues to dilute; nausea or vomiting; adverse systemic (anaphylactoid) reaction; and contrast-induced renal failure. The study may be nondiagnostic when the kidneys become bright (contrast enhanced) and remain that way, but there is no opacification of the collecting system, ureters, or bladder. Be careful in VD positioning to avoid aspiration.

Cystography

- Contrast medium: For negative contrast, use nitrous oxide, room air, or carbon dioxide; for positive contrast, use a water-soluble iodinated ionic contrast medium (not barium).
- Catheters: Foley, tom cat, male dog, or metal female catheters
- Sterile lubricant gel
- Three-way stopcock
- Contrast studies
  - Negative-contrast cystogram (pneumocystogram)
  - Positive-contrast cystogram (technique of choice for identifying urinary bladder location and tears)
  - Double-contrast cystogram (superior for demonstrating lesions involving the urinary bladder wall and intraluminal filling defects)

Technique (Double Contrast)

1. Withhold food for 12 to 24 hours.
2. Administer warm-water cleansing enemas the night before and 3 to 4 hours before the procedure if needed.
3. Sedation or tranquilization may be necessary for catheterization, especially in cats and female dogs.
4. A small amount of 2% lidocaine (2–5 ml) infused into the urinary bladder before the contrast agent may reduce urinary bladder spasm.
5. Place the catheter tip within the bladder neck.
6. Empty the urinary bladder.
7. Infuse the positive-contrast medium (1–3 ml in cats and dogs <25 pounds; 4 to 6 ml in dogs >25 pounds), rotate the patient, and massage the bladder to distribute the contrast medium and coat the entire mucosal surface.
8. Slowly infuse negative-contrast material (approximately 10 ml/kg, but range is extremely variable). Complete distention is desirable and can be judged by palpation, back pressure felt on syringe plunger, or reflux of gas around catheter.
9. Take a lateral, two lateral obliques, and a VD radiograph to examine the bladder full on double-contrast cystograms.
10. Evacuate contrast material from the bladder after the study.

Technique (Positive Contrast)

- Increase exposure technique by 10% for a positive-contrast study.
- Only lateral and VD views are necessary for positive-contrast cystograms.

- Use the technique described previously for catheter placement.
- Administer 3 to 5 ml/kg of positive-contrast medium.

Complications

- Fatal air embolism (rare cases). An increased risk exists with ulcerative or erosive cystitis. Carbon dioxide is more soluble than room air in blood and thus less likely to cause this problem. Air embolism occurs immediately after the administration of negative-contrast medium. Place the animal in left lateral recumbency, and lower the head to maintain normal blood circulation through the heart. The air is trapped in the right ventricle.
- Iatrogenic trauma (hematuria or rupture) and infection (bacterial contamination or cystitis).

Urethrography

- Retrograde positive-contrast study of the urethra using iodine.
- Equipment includes catheter (Foley, metal, male dog), sterile gel, lidocaine, and water-soluble iodinated contrast medium.

Technique

1. Evacuate the colon with an enema, if needed, before the study; take scout films before the study to evaluate technique and preparation.
2. Pass a urinary catheter into the distal urethra. Inflate the balloon if a Foley catheter is used (in distal urethra for female dogs or cats and proximal to the os penis in male dogs when possible).
3. Administer 2 to 5 ml of 2% lidocaine before injecting contrast material to reduce urethral spasm.
4. Position male dogs with their legs drawn cranially.
5. Administer 10 to 20 ml of contrast medium for male dogs and 5 to 10 ml for female dogs and cats. Inject as a bolus and take radiographs during the last few milliliters of injection.
6. A lateral radiograph may be sufficient, but subsequent lateral and VD oblique views may be helpful.

Complications

- Iatrogenic trauma and bacterial contamination

Esophagography

Technique

1. Take survey cervical and thoracic radiographs.
2. Position the animal in lateral recumbency.
3. Administer contrast medium (see Table 4-6) (barium sulfate suspension, Esophotrast, barium burger) slowly into the buccal pouch.
4. Dose is variable (5–20 ml); use enough to induce swallowing and coat esophagus.
5. Obtain radiographs following swallows. The lateral view is most informative; additional views can be taken if needed. Follow-up radiographs may be helpful if a bolus of contrast material is retained within the esophagus.

Complications

- Aspiration.
- Leakage of barium into mediastinum. Low osmolality, nonionic iodinated contrast medium (iohexol) may be indicated if perforation is suspected.

Gastrography

▼ ***Key Point*** Before contrast studies of the gastrointestinal tract, discontinue all drugs that may influence motility.

Technique

1. Fast patient 12 to 24 hours before the study.
2. Give cleansing enema the night before and 3 to 4 hours before the study, especially if complete upper gastrointestinal study is to be done.
3. Take plain films before the study. Then pass a stomach tube for administration of contrast medium.
4. Obtain negative-contrast gastrogram (pneumogastrogram) by administering 6 to 16 ml of room air per kilogram of body weight using a stomach tube. Immediately take four views (right and left lateral, VD, and DV). This is often valuable in the diagnosis of radiolucent foreign bodies.
5. Obtain positive-contrast gastrogram using barium (suspension, 30% weight-to-volume) at a dose of 6 to 12 ml/kg (see Table 4-6). Administer through a stomach tube, and take films immediately (right and left lateral, VD, and DV). Use this procedure to document gastric displacement, certain gastric foreign bodies, and gastric perforation. Barium begins leaving the stomach within 5 to 15 minutes. The stomach is emptied by 30 to 60 minutes in cats and 1 to 2 hours in dogs.
6. A double-contrast gastrogram can be done as a separate study or during an upper gastrointestinal study. Give barium, 60% weight-to-volume at a dose of 1.5 to 3 ml/kg, and insufflate with room air at 10 ml/kg. Immediately take DV, VD, and right and left lateral films. This study is indicated in cases of suspected gastric wall and mucosal lesions.

Upper Gastrointestinal Study

- Preparation requires a 12- to 24-hour fast and an enema the night before and 3 to 4 hours before the study.
- Use barium suspension, 30% to 60% weight-to-volume, for routine studies (see Table 4-6). Dose is 8 to 16 ml/kg.
- Use iodinated contrast (ionic and nonionic) agents (see Table 4-6) with suspected perforation for quick determination of small intestine patency and location

and when endoscopy is planned immediately following the contrast study.
- For restraint in canines use acepromazine, and in felines use ketamine/acepromazine preparations. See Chapter 2 for doses. These sedatives have less effect on motility than do many others.

Technique

1. Take survey radiographs (right lateral and VD).
2. Immediately after administration of barium, take right and left lateral and DV and VD views. Obtain right lateral and VD radiographs at 15, 30, and 60 minutes. Be consistent unless a lesion is identified that is better evaluated by repositioning the animal. Then, proceed at hourly intervals until the contrast material reaches the colon.
3. Modify this protocol for each individual depending on the suspected disease entity or the lesions visualized during the procedure.
4. Expected transit time to the colon is 3 to 4 hours for dogs and 1 hour for cats.

Complications

- Aspiration of barium with or without gastric contents.
- Leakage of barium indicates a gastrointestinal (GI) perforation, which is a surgical emergency. Barium itself induces a chemical peritonitis that may make treatment of GI perforation more difficult.

▼ ***Key Point*** Whenever GI perforation is suspected, use nonionic iodinated contrast medium (e.g., iohexol) instead of barium.

Myelography

- Myelography is the radiographic evaluation of the spinal cord by injection of a positive-contrast agent into the subarachnoid space.
- Indications
  - To evaluate transverse myelopathy
  - To determine nature, location, and extent of a lesion prior to surgery
  - To identify multiple lesions when one lesion might be masked by another and therefore not detected clinically
- Contraindications
  - Diffuse myelopathy that is not amenable to surgery
  - Meningitis, which may be aggravated by contrast medium
  - Not indicated when survey radiographs and clinical signs are adequate for diagnosis
- Contrast medium (see Table 4-6)
  - Dose for cisternal tap: Cervical study (0.2–0.3 ml/kg); thoracolumbar study (0.45 ml/kg)
  - Dose for lumbar tap: Cervical study (0.45 ml/kg); thoracolumbar study (0.3 ml/kg)

▼ ***Key Point*** Always obtain survey spinal radiographs before myelography.

Basic Technique

1. Animals must be under general anesthesia.
2. Perform sterile preparation of the puncture site.
3. Collect and analyze cerebrospinal fluid (CSF) if deemed necessary.

Cisternal Tap Procedure

1. Position the animal in lateral recumbency.
2. Place the nose parallel to the tabletop and perpendicular to the spine.
3. Use a 20- or 22-gauge, 1.5- to 2.5-inch spinal needle with the bevel directed caudally.
4. Insert the needle on the dorsal midline between the occipital protuberance and the wings of the atlas.
5. Direct the needle toward the mandible.
6. If the needle hits bone, move the needle cranially or caudally until it falls into the atlanto-occipital (AO) space.
7. Remove the stylet and check for CSF flow often while advancing the needle.
8. Inject contrast material slowly after seeing CSF in the needle. Prior to injection, collect a specimen if CSF for later analysis is indicated.
9. Elevate the head for 5 minutes before taking radiographs.
10. Take lateral and VD radiographs (also VD oblique if necessary). Remove the endotracheal tube, if necessary, for the VD radiograph.

Lumbar Tap Procedure

1. Position the animal in lateral or sternal recumbency, and flex the rear legs to help open the interarcuate spaces.
2. Use a 20- or 22-gauge, 1.5- to 3.5-inch spinal needle.
3. Insert the needle through the L5-6 interarcuate space for small dogs and cats and L4-5 for large dogs. Place the needle on the dorsal midline just lateral to the dorsal spinous processes of L6 at a 50 to 60 degree angle in a cranioventral direction toward the interarcuate space at L5-6. In cats, insert the needle off the cranial edge of the L6 dorsal spinous process perpendicular to the long axis of the spine. Direct the needle ventrally through the interarcuate space.
4. Inject in either the dorsal or the ventral subarachnoid space. Always check for CSF flow before injection; however, it is not always obtained. Increase the likelihood of obtaining CSF by elevating the head and shoulders before placing the needle.
5. Perform a small test injection (0.25–0.50 ml) followed by a radiograph to check needle placement.
6. Slowly inject total dose. Take radiograph views based on localization determined by neurologic examination.

Complications

- Seizures (incidence is reduced with new contrast agents, e.g., iohexol)
- Exacerbation of clinical signs
- Hyperesthesia
- Apnea during injection
- Epidural injection will not negatively affect the health of the animal but negatively affects the quality of the myelogram.
- Central canal filling occurs when the needle is placed through the center of the cord. It usually appears thin on radiograph and sharply defined in the normal animal.

Interpretation

Lesions are divided into three categories (Fig. 4-21):

1. Extradural, characterized by
   a. Displacement of the spinal cord
   b. Narrowing or compression of the subarachnoid space
   c. Deviation of the subarachnoid space
   d. Spinal cord may appear wide on opposite view
2. Intradural extramedullary, characterized by
   a. Filling defect within the subarachnoid space ("golf tee" sign)
   b. Possibly associated extradural or intramedullary component
3. Intramedullary, characterized by
   a. Spinal cord widening in all views

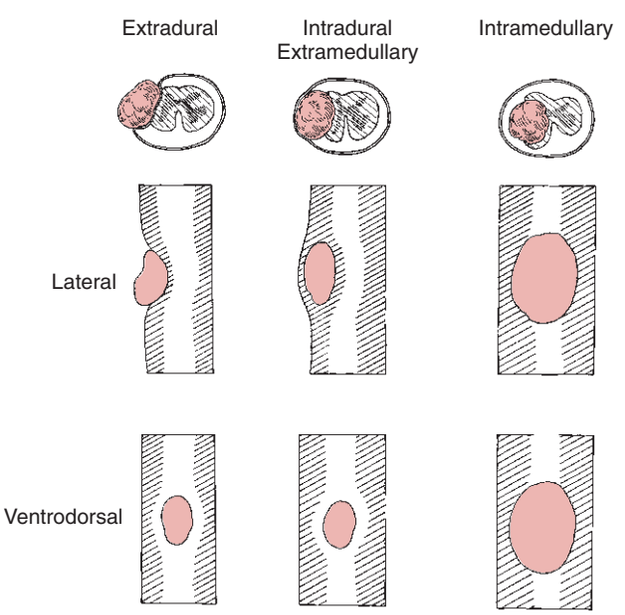

Figure 4-21. Radiographic patterns of myelographic lesions.

RADIATION SAFETY

Basic Radiation Safety

The objectives of radiation safety are to obtain the maximum amount of diagnostic information while keeping the radiation exposure to personnel and animals to a minimum.

▼ ***Key Point*** The responsibility for radiation safety lies solely with the owners of the practice.

Radiation protection in veterinary medicine is the subject of the National Council on Radiation Protection and Measurements (NCRP) Report No. 36, titled *Radiation Protection in Veterinary Medicine*. This report specifically outlines when radiation protection surveys are made. The report makes recommendations concerning tube housing, aluminum filtration, collimation types, and centering devices. A special section discusses radiography with portable and mobile diagnostic equipment. All practices need a copy of this report. Other NCRP reports that may be pertinent are No. 116, which discusses protection devices and provides recommendations for the maximum permissible dose (MPD); No. 107, which explains the concept of ALARA (as low as reasonably achievable) for medical and dental personnel; and No. 35, which discusses dental applications of diagnostic radiology.

The MPD was established to keep the radiation exposure of workers below a level at which adverse effects might be observed during a lifetime and to minimize the incidence of genetic effects in the entire population. The MPD does not apply to animal patients, to radiation emitted from natural background sources, or to radiation therapy. The actual risk to an individual exposed to MPD is small, but the risk is directly proportional to the received dose. Therefore, radiation exposure must be kept as low as possible. Radiation can cause both tissue and genetic damage. The effects of radiation can be demonstrated in a short time, or they can be cumulative and not observed for a long time.

Federal regulations regarding use of x-ray equipment and radiation protection are published in the Code of Federal Regulations, available at university and public libraries. Individual states publish radiation control regulations that are reprinted from the state codes. These regulations include information concerning the licensing of x-ray machines, the licensing fee, and the procedure to be followed in obtaining licensing. The goal in diagnostic radiology is to obtain radiographs with minimum exposure to both patient and personnel.

Maximum Permissible Dose

The MPD is currently 5 rem per year.

▼ ***Key Point*** Be familiar with federal, state, and local regulations regarding use of x-ray equipment and radiation safety.

Reducing Exposure

Three methods reduce radiation exposure: (1) increased distance between the individual and the radiation source, (2) decreased duration of exposure, and (3) protective barriers between the individual and the radiation source.

- Limiting radiation exposure
  - Limit the number of individuals within the room where the procedure is taking place. Use positioning devices, such as sandbags, sponges, tape, and Plexiglas or foam trough. Use chemical restraint whenever possible.

▼ ***Key Point*** When you must be present within the radiographic room during film taking, always wear protective clothing.

  - Protective lead apparel includes apron, gloves, thyroid shield, and protective goggles. Lead apparel is usually 0.5-mm lead equivalent. Hang aprons up to prevent the lead from cracking. Store gloves so that liners can dry. Check all protective clothing at least twice a year for cracks and tears. Place the items on a film cassette and radiograph them at an exposure of approximately 85 kVp.

▼ ***Key Point*** Never permit any portion of the body to be within the primary beam, even if covered with protective clothing.

  - Never hand-hold any x-ray tube. All x-ray tubes leak radiation from the housing.
  - Use a shielding device whenever possible to protect all or part of your body. Lead glass may be part of this shield so that you may continue to see the patient.
- When using a horizontal x-ray beam, never position any part of your body behind the cassette.
- Use collimation. An unexposed border on the radiograph demonstrates that the primary beam did not exceed the size of the cassette (film). This practice helps reduce scatter radiation by decreasing the interaction between the primary beam and the tissue, therefore increasing radiographic quality. Check the collimator light for accuracy; replace the bulb as needed.
- Use fast film, fast rare-earth screens, and high-kVp techniques to lower the exposure factors and the amount of radiation produced.
- Use a 2.0-mm aluminum filter installed at the tube housing port to remove the softer (less energetic) radiation portion of the x-ray beam. This aids in the reduction of scatter radiation and exposure to the patient.
- Individuals within the room should always stand as far from the radiation source as possible. If you double the distance from the source of radiation, you decrease your exposure level by a factor of 4 (inverse square law).
- All personnel working with radiation are required to wear a film badge or some other method of monitoring the amount of exposure if they have the potential to receive greater than $^1/_4$ MPD. Remember that wearing the device does not protect the individual, but it serves as a reminder of working in a potentially hazardous environment. For a monitoring device to be most helpful in determining exposure to radiation, wear it consistently in the same location on the body outside the apron at the neck. Film badges register when exposed to heat, light, water, or pressure. They can be purchased through companies listed in Table 4-7.

▼ ***Key Point*** Never permit anyone under the age of 18 or a pregnant woman in the room during a diagnostic procedure.

- Rotate personnel, thus reducing the amount of exposure to each person.
- Do not direct the x-ray beam into adjacent rooms that may be occupied.
- Use a gonadal shield for the patient.
- Always plan radiographic procedures (e.g., proper position and technique), thus reducing the number of films needed, which ultimately reduces the exposure to patient and personnel.

Clinic Construction

- Check with your state's health department (radiation protection division) for the latest laws on radiation safety and clinic construction.
- Register your x-ray machine with the state.
- Many states are now conducting "surprise spot checks" of x-ray machines and radiographic records. Maintain film and technique logs for complete records (Figs. 4-22 and 4-23).
- If constructing a new clinic, a drawing of the layout must be sent to the state radiation protection department. This drawing indicates the location of the x-ray machine and demonstrates how the space in the room where the x-ray machine is located will be used. The use of the adjoining rooms and an estimate of the degree of traffic in these areas are determined. The radiation safety department then sends a computerized layout of wall, ceiling, and floor materials to be used in certain areas of your clinic.

RADIOGRAPHIC INTERPRETATION

Radiology is a valuable adjunctive diagnostic tool. Do not interpret radiographs without considering the history, clinical signs, physical examination findings, and laboratory data. Radiographic signs are rarely pathognomonic; therefore, a specific diagnosis is seldom possible.

History + Physical exam + Lab findings + Radiographs = Differential list

From the differential list, additional tests can be done to help formulate a definitive diagnosis.

- Successful interpretation of radiographs depends on many factors.

▼ ***Key Point*** The most important factor in the successful interpretation of radiographs is the quality of the radiographs being examined.

- At least two views at right angles to each other are needed. The use of right or left lateral radiographs is based on the preference of the individual reading the radiographs. The same holds true for VD and DV views, but be consistent.
- Maximize viewing conditions.
- Dark, quiet room.
- At least two view boxes to evaluate two views simultaneously.
- Always place the film on the view boxes such that the anatomic structures are in the same position and direction: DV/VD radiograph with the animal's right to your left; lateral radiograph with the head to your left.
- Have a shielded, high-intensity (hot) lamp available.
- Read films slowly and thoroughly.
- Always have radiology and anatomy texts nearby.
- Evaluate the radiographs using a systematic approach. Evaluate the entire film before concentrating on obvious lesions.
- Use an area method, evaluating the radiograph either peripheral to center or center to peripheral.
- Use an organ system method. Evaluate all parts of a system before examining the next system.

Radiology Log and Film Inventory

Date	Client Name	Type of Study Performed	Film Size and Number of Films			
			8×10	10×12 24×30	11×14 30×35	14×17 35×43

Figure 4-22. Film usage and inventory log.

Radiology Technique Log

Date	Exam	Patient Thickness	Views Taken	mAs	kVp	Tabletop/ Grid	Film size	Screen	Notes

Figure 4-23. Radiology technique log.

- However you choose to evaluate films, be consistent from case to case.
- Knowledge of normal radiographic anatomy is essential.

Radiographic Signs

- *Radiopacity:* Various radiographic opacities are caused by the differential absorption of x-rays. The opacity of surrounding material also influences the observed opacity of a structure. The five radiopacities in decreasing order (white to black) are those of metal, bone, soft tissue (fluid), fat, and gas. Metal is the only one that is not a biologic opacity.
- *Geometry:* Size, shape, position, margination, and number.
- *Function:* Excretion (intravenous urography), motility (upper gastrointestinal), patency, and integrity. Evaluation of function often requires contrast medium and multiple films.

COMPUTED TOMOGRAPHY

Computed tomography (CT) is a cross-sectional imaging technique that allows identification of structures without the superimposition present with radiographs. Like radiographs, CT uses x-rays to produce an image. There are many different types of CT machines, but all produce a thin fan of x-rays that are directed through the patient and strike a row of radiation detectors. The amount of radiation going through a specific part of the patient, and therefore reaching the detector, is related to the density of the body part. Based on numerous views of each part and the image density of different areas, a computer is used with various algorithms to form a cross-sectional, gray-scale image.

Similar to radiographs, when looking at a CT: bone = white, air = black, fat = dark gray, and soft tissues/fluid = various shades of gray. Once the image has been acquired, post-processing parameters can be adjusted to optimize viewing of certain areas (i.e., bone, soft tissue, lung, and brain). Thus, the term *soft-tissue* or *bone window* is commonly used when evaluating CT images. Often, the same study is viewed in multiple windows for a complete evaluation. For example, a CT of the thorax would need to be viewed in a soft-tissue window (for the mediastinum), a lung window (for the pulmonary parenchyma), and a bone window (for the ribs and spine). The adjustment in a bone versus a soft-tissue window is made by changing the window width and window level. The window width defines how many shades of gray are seen over a given density of tissue (providing a long or short scale of contrast). The window level is the midpoint of the window width.

CT studies are normally performed with slices in the transverse (axial) plane through the area of interest. This information can then be used to reformat the area

of interest into a different plane (sagittal, coronal, or oblique), therefore maximizing interpretation. Common areas to use CT in veterinary medicine are the nasal cavity, middle ears, skull (bone changes or trauma), skeletal (elbows and spine), thorax, abdomen, and areas of neoplasia (for surgical or radiation planning). Magnetic resonance imaging (MRI) is considered best for soft-tissue structures, particularly the brain and spinal cord.

Advantages

- The cross-sectional image is provided without superimposition of structures, allowing more accurate detection and assessment of the extent of disease.
- CT is considered better than MRI for evaluation of bone abnormalities (MRI is best for soft tissue).

Disadvantages

- Higher cost compared with radiographs (less expensive than MRI).
- The animal must not move during the CT study, so the patient must undergo general anesthesia in most cases.

MAGNETIC RESONANCE IMAGING

MRI is a cross-sectional imaging technique that is considered excellent for imaging soft tissues. CT is still considered the best cross-sectional imaging modality when assessment of bone is required. MRI utilizes a magnetic field, radiofrequency (RF) waves, and the hydrogen protons in the patient for creation of the images. The equipment consists of a magnet, receiving coils, and hardware and software of the control station.

MRI technology utilizes a magnet to polarize hydrogen atoms in the tissues and monitor the summation of the spinning energies within living cells. When a patient is put in a strong magnet, some of the atoms become aligned with the magnetic field. If an RF pulse is sent into the patient, the vector direction of the hydrogen protons can be changed. As the atoms realign themselves with the magnetic field, they give off an RF pulse that can be detected by the receiver coil. The amount of RF signal given off and the time at which it is released are characteristic for certain tissues. This information is again processed by a computer to provide a cross-sectional image with various shades of gray. The shade of gray of a certain tissue depends on the acquisition parameters. In other words, fluid may be dark gray in one acquisition and bright white in a different acquisition. *Cortical bone and air will always be black with MRI.* The images can be acquired in any plane without reformatting.

There are different types of magnets, ranging from low- to mid- to high-field units. The unit strength is termed the *Tesla.* Low-field magnets are less than 0.5 Tesla, mid-field magnets are 0.5 to 1 Tesla, and high-field magnets are more than 1 Tesla. Although all types of magnets are utilized, the cost of the machine and the time needed to acquire the image depend on field strength. In general, high-field magnets are more expensive, but images are acquired more quickly than from low-field units.

Images are acquired using different pulse sequences (imaging acquisition parameters). These different sequences are used because the signal intensity (appearance of the image) will vary depending on primarily the water, fat, and mineral content of the area being imaged. Typical sequences are termed T1-weighted, T2-weighted, and proton density. There are a variety of fat saturation techniques and variations in the sequences that are also utilized. Contrast material is generally given to patients and the T1-weighted sequences are repeated. The contrast material is a ferromagnetic substance that enhances signal intensity on T1-weighted sequences.

Advantage

- MRI is useful for areas that cannot be evaluated by more conventional methods (radiographs or ultrasound) such as the central nervous system, particularly the brain.

Disadvantage

- Limited access
- High cost

ULTRASOUND

Ultrasound is rapidly becoming an accepted imaging modality in small animal practice. New and used equipment is available at reasonable prices, and usefulness has increased to include ophthalmic, cardiac, abdominal, and reproductive disease diagnosis. It is a safe, noninvasive diagnostic technique that provides information about the internal architecture of organs within the abdomen and thorax. Functional information can also be obtained with echocardiography. Ultrasound is not meant to replace diagnostic radiography but to complement it. Ultrasound is operator dependent. The quality of the image and the information gained are directly related to the ability of the person doing the study.

Equipment

The major components of the diagnostic ultrasound imaging system are pulser, transducer, receiver, memory, and display. Electrical pulses are produced by the pulser, and these drive the transducer. The transducer produces ultrasound pulses for each electrical

pulse it receives. The transducer also produces electrical pulses for each ultrasound pulse (reflection) it receives from tissues. The electrical pulses go to the receiver, where they are converted to information that the memory can utilize. Information from the memory drives the display, which produces an image.

Suppliers of ultrasound equipment are listed in Table 4-8.

Machines

- Questions to consider before purchasing or leasing ultrasound equipment:
- What kind of scanning will I be doing (e.g., heart, abdomen, real-time, B-mode, or M-mode)?
  - How large or small are my patients?
  - Is someone in the practice willing to accept primary responsibility for learning and doing the procedures?
  - How much money can I invest?
- There are multiple types of transducers
  - A linear array scanner produces a rectangular image and can be used to evaluate broad areas, where no bony or gas-filled structures interfere. These scanners are usually less expensive. The major drawback is the transducer contact zone, which makes intercostal and subcostal (heart, liver, biliary tract, and right kidney) imaging difficult.
  - A sector scanner produces a pie-shaped image. A smaller contact zone is used, which makes intercostal and subcostal imaging less difficult.
  - Mechanical: In a mechanical (sector) scanner, the sound wave is focused a certain distance from the transducer (focal point). The sound wave is within focus for some distance on both sides of the focal point (focal zone). Resolution is best within this fixed focal zone. The scanner contains moving parts.
  - Electronic: These are linear or sector scanners with no moving parts; therefore, they are more durable than mechanical scanners. The beam is formed by adding together many small beams from an array of small crystals. The scanner has variable (dynamic) focusing. The focal zone therefore can be placed anywhere in the image depth.
- Image display
  - M-mode (motion-mode): Documents motion, especially that of the heart (echocardiography). A thin ultrasound beam is directed into the heart, is reflected back, and then is shown on the screen as numerous moving lines. Motion is indicated along the side, and time is shown along the bottom of the screen.
  - B-mode (brightness-mode): Echoes are displayed as dots. The brightness of the dot changes with the amplitude of reflection. The larger the reflection, the brighter the dot—no reflection, black dot. The location of the dot corresponds to the location of the reflector in the body.
  - Real time: The image is continually updated during the entire examination. This permits direct observation of moving structures (e.g., heart or bowel peristalsis).

- New versus used equipment
  - New equipment purchase is ideal because some companies offer training (in-house or continuing education course) and a year-long warranty with service and parts (in-house service or another unit is made available while your unit is serviced by the company). Manufacturer-reconditioned units may provide a year-long or shorter warranty. The major disadvantage of new equipment obviously is the higher cost.
  - A great deal of used equipment is available with the advent of newer technology. Older, used, outdated equipment is being replaced with new equipment based on new technology. The price of old equipment is very attractive, sometimes as low as $1000. Although initial cost is low, some significant expense may be required, including service, maintenance, transducers, and accessories. If the appropriate frequency transducers do not come with the unit (often only 2- and 3-MHz transducers come with units that were used on human patients), the cost can increase 3 to 4 times to purchase 5- and 7.5-MHz transducers.

Transducers

- Transducers are available in a variety of frequencies (2–15 MHz). Low-frequency transducers provide greater depth of penetration, but because of large wavelength, resolution is poorer. High-frequency transducers provide excellent resolution, but the beam is rapidly attenuated in tissue. They are therefore used to evaluate superficial tissues.
- Use as high a frequency transducer as possible to maximize resolution but still allow penetration to the depth needed.
- For transducer uses, see Table 4-9.

Ancillary Equipment

This may include a guided biopsy attachment for the transducer, calipers, a screen-labeling device, and an M-mode/B-mode split screen. Portability of the machine must also be considered.

Ultrasonographic Accessories

- Positioners
  - V-trough is easily constructed from wood or Plexiglas.
  - Surgical table can be formed into a V-trough.
  - Cardiac table (wood or Plexiglas) with holes so that the transducers may be brought up under the recumbent patient. Lateral recumbency causes the heart to lie against the chest wall, providing an ultrasonographic window to the heart.
- Standoff pad to place between the transducer and the skin for imaging superficial tissues.
- Coupling gel is necessary to transmit sound from the transducer through the skin.
- Numerous brands are commercially available.
- Water-soluble, hypoallergenic gel is available.

Table 4-9. TRANSDUCER SELECTION

Transducer Type	Use
7.5 MHz	Eye, feline heart and abdomen, small canine abdomen (<25 lb), testicles
5.0 MHz	Medium-size canine (<55 lb) heart and abdomen
3.5 MHz	Very large-breed canine heart and abdomen

Image Storing

There are various methods of preserving the image for inclusion in the animal's medical record:

- Polaroid camera—Heat-sensitive, thermal-paper recorder
- Multiformat camera—Can record multiple images on x-ray film
- Videotape—Images are recorded, allowing evaluation by others at a later time
- Digital images or digital video

Ultrasound Technique

- Patient preparation
  - Tranquilization is usually not required, but the patient must always be adequately restrained.
  - The most common problem in obtaining good-quality images is poor transducer skin contact. Clip the hair over the area to be imaged with a #40 blade. Hair tends to trap air, acting as a barrier to the ultrasound. Clean the exposed skin to remove dirt, oil, and debris before applying the coupling gel to help achieve the best image.
- Patient positioning
  - Most abdominal imaging is done from the ventral surface. Alternate scanning planes from lateral and lateral intercostal can be chosen to avoid gas. When gas is a problem, gentle abdominal pressure from the transducer usually displaces it.
  - The heart is imaged through the intercostal spaces, usually while the animal is in lateral recumbency.
- Ultrasound image
  - It is a two-dimensional representation of a three-dimensional object.
  - Ultrasound reflects the anatomy tomographically (cross-sectionally).
  - Ultrasound permits identification of internal organ architecture.
- Image viewing
  - Abdomen (Figs. 4-24 and 4-25)
  - Cardiac
  - Longitudinal scan: Cardiac base to the right
  - Transverse scan: Pulmonary valve (outflow tract) on the right of the screen

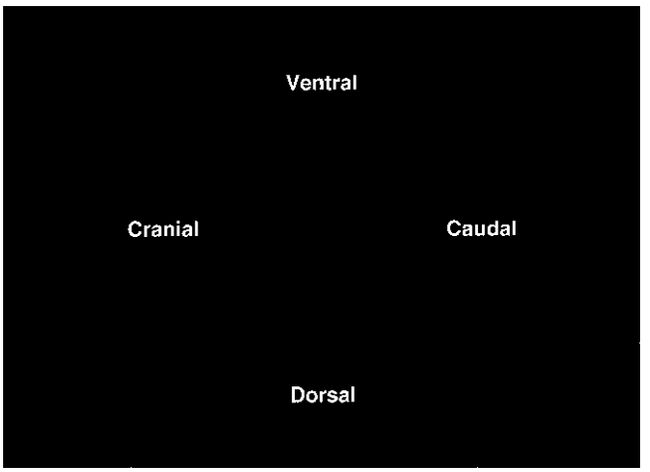

Figure 4-24. Viewing a longitudinal (sagittal) ultrasound image.

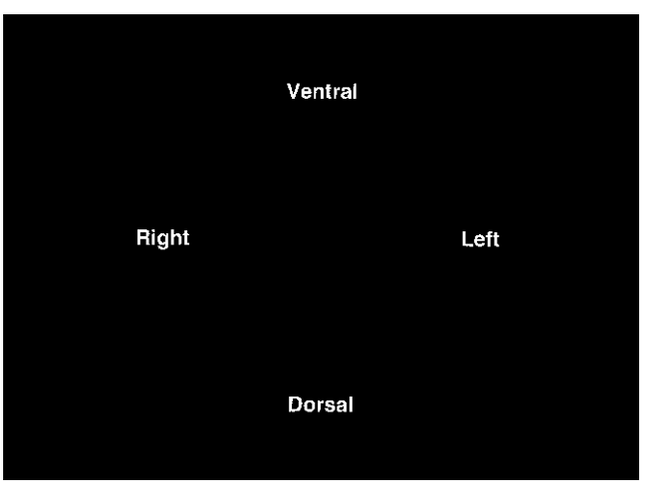

Figure 4-25. Viewing a transverse (axial) ultrasound image.

Principles of Interpretation

Ultrasound Terminology

- *Anechoic:* Area void of echoes (seen as black).
- *Hypoechoic:* Lower level of echogenicity (darker) than adjacent structures.
- *Hyperechoic:* Higher level of echogenicity (brighter) than adjacent structures.
- *Isoechoic:* Level of echogenicity similar to adjacent structures.
- *Complexly echogenic:* Area of multiple echogenicities.
- *Ultrasonographic barriers:* Highly reflective or absorptive interfaces within the body that cause an almost complete attenuation of the sound beam. Examples include bone, mineral, and air. This barrier results in an absence of echoes deep to the interface (acoustic shadow).
- *Ultrasonographic windows:* Soft-tissue organs adjacent to the body wall used to help avoid gas or bone and to facilitate deeper imaging. Examples include imaging through the spleen on the left lateral abdominal wall to identify the left kidney and imaging through the urinary bladder to identify the area where sublumbar lymph nodes are found.
- *Acoustic enhancement (through transmission):* Sound passes through an anechoic structure with little attenuation and emerges with more intensity than expected in surrounding echogenic areas. This occurrence is expected deep to fluid-filled structures (e.g., gallbladder and hepatic cyst).

Organ Echogenicity

- Rank of abdominal parenchymal organs from least to most echogenic:
  - Renal medulla
  - Renal cortex
  - Liver
  - Spleen
  - Prostate
  - Renal sinus

Ultrasound Use

See respective chapters for ultrasound use in specific diseases. See Table 4-10 for an overview of ultrasound in various organs.

Interventional Ultrasound

- Uses
  - Ultrasound-guided needle biopsy for histopathology and culture
  - Ultrasound-guided fine needle aspiration (FNA) for cytology and culture
  - Cystocentesis to obtain urine (small bladder, difficult animals)
  - Gallbladder aspiration for culture and cholangiography
  - Abscess diagnosis and drainage
  - Cyst diagnosis and drainage
  - Renal pyelocentesis
- Equipment
  - Real-time B-mode scanner
  - Transducer biopsy guide (or can be done freehand)
  - Needles, syringe, slides, culture medium, formalin containers
  - Sterile glove or transducer cover
  - Sterile ultrasound gel or alcohol
  - Sedatives, lidocaine
- Patient preparation
  - Complete an abdominal ultrasound examination.
  - Choose the site for FNA biopsy.
  - FNA: Rarely need sedation; sterile preparation of skin and transducer sterile glove cover.

†Lipidosis, steroid hepatopathy, suppurative hepatitis (dependent on severity of disease).
‡Glomerulonephritis, amyloidosis, ethylene glycol toxicity, renal dysplasia (dependent on severity of disease).
+++, good; ++, fair; +, poor.

- Tissue biopsy: Sedation and/or local anesthesia; general anesthesia is sometimes necessary. Surgical preparation of skin and transducer.
  - Sterile glove cover.
  - Determine packed cell volume (PCV); total plasma protein, activated clotting time, and platelet count.
  - Check prothrombin time and partial thromboplastin time.
  - Monitor patient closely for signs of internal hemorrhage for 3 to 4 hours following biopsy.
- Methods
  - Guided: Transducer has an attachable biopsy guide. Ultrasound machine has biopsy capabilities (software). Biopsy guide maintains needle in the scanning plane so that the entire procedure can be seen.
  - Directed: Image the organ or lesion of interest. Determine the location, entrance angle, and depth. Obtain biopsy or aspirate blindly without ultrasound observation. More dependent on sonographer's experience. Biopsy guide and biopsy-capable machine are not necessary.
  - Freehand: Localize biopsy site with transducer perpendicular to the skin. Place the needle with the other hand into the scanning plane to the desired depth. Biopsy procedure can be observed in real time and depends more on sonographer's experience. Biopsy guide and biopsy-capable machine are not necessary.
- Complications: Very low incidence with all procedures
  - Peritonitis
  - Hemorrhage
  - Tumor spread to local tissues

Chapter 5

Fluid Therapy for Dogs and Cats

Shane W. Bateman / Dennis J. Chew

Fluid therapy can be the single most important therapeutic measure used in seriously ill animals. Effective administration of fluids requires an understanding of fluid and electrolyte dynamics in both healthy and sick animals. An overview of a general approach to fluid therapy decision making can be found in Figure 5-1.

DECISION-MAKING CHECKLIST

Answer these questions to decide when fluid therapy is needed:

- Does the patient have a form of shock that requires fluid resuscitation?
- Does a serious deficit (or excess) of fluid or water exist?
- Is there an anticipated loss of substantial fluid volume?
- Are there serious electrolyte disturbances (excesses or deficits)?
- Is there a serious disturbance in the acid-base balance?
- Is there a serious disturbance in oncotic pressure or excessive protein loss?
- Is there an immediate need for full nutritional support with calories and protein?
- Does the patient have an anemia that may be affecting oxygen delivery?
- Does the patient have a coagulopathy?

Answer these questions in order to provide appropriate fluid therapy:

- What type(s) of fluids will be given?
- What volume of fluids will be given?
- How fast will fluids be given?
- Through what route will fluids be given?
- What, if any, supplements will be added to commercially available fluids?
- If more than one fluid type is being given, can they be administered together?
- If medications are to be administered with fluids, are they compatible?

▼ ***Key Point*** If no laboratory testing is immediately available, start correction of dehydration with isotonic-balanced electrolyte solutions.

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

Figure 5-1. General decision tree for fluid therapy. (From Finco DR: A scheme for fluid therapy in the dog and cat. J Am Anim Hosp Assoc 8:178–180, 1972.)

INDICATIONS FOR FLUID THERAPY

- Most commonly for resuscitation from shock syndromes and the correction of dehydration, hypokalemia, and metabolic acidosis
- Less commonly for specific correction of other electrolyte disturbances (sodium, potassium, chloride, calcium, or magnesium), acid-base disturbances (metabolic alkalosis or mixed acid-base disorders), and disorders of oncotic pressure

- For parenteral nutrition (see Chapter 3)
- For treatment of anemia and coagulopathies (see Chapters 22 and 23)

DISTRIBUTION OF BODY WATER AND ELECTROLYTES

Water

- Total body water (TBW) represents 50% to 70% of body weight in adults. Usually 60% is arbitrarily chosen as an average figure, although cats possess slightly less water. Young animals and especially neonates possess more water (70%).
- Two-thirds of TBW is within cells, so intracellular water (ICF) represents on average about 40% of body weight.
- One-third of TBW is outside of cells, so extracellular water (ECF) represents on average about 20% of body weight. The ECF comprises both the interstitial fluid and the fluid in the intravascular space.
- The distribution of ECF between the interstitial and the intravascular spaces is about 75% to 25%, respectively. Thus the interstitial fluid comprises about 12% to 14% of the body weight, and the intravascular fluid comprises about 6% to 8% of body weight.

Electrolytes

- Sodium and chloride exist in high concentration in ECF and low concentration in ICF.
- Potassium, magnesium, and phosphorus exist in high concentration in ICF and low concentration in ECF.

MAINTENANCE REQUIREMENTS

Maintenance is defined as the volume of fluid (ml) and the amount of electrolyte (mEq or mg) that must be taken in on a daily basis to keep the volume of TBW and the electrolyte content normal. Obligatory losses of water and electrolytes occur daily as a consequence of normal metabolism. Water taken into the body in all of its forms is equal to the loss of water in the normal animal. See Figure 5-2 for specific maintenance requirements of electrolytes and water in caged dogs and cats that have normal food intake.

- Water can be taken in by drinking, combined mechanically with food, or derived from metabolism of food or tissue breakdown.
- Water is lost from the body through evaporation during breathing, from feces, and from urine.
- Obligatory loss of electrolytes occurs in fecal water and in urine, but the overall loss of electrolytes is proportionally less than the loss of water.

Figure 5-2. Maintenance fluid and electrolyte requirements for caged normal dogs and cats. (Finco after Harrison JB: J Am Anim Hosp Assoc 8:179, 1972.)

Table 5-1. DAILY FLUID REQUIREMENTS FOR HOSPITALIZED NON-ANORECTIC DOGS*

Body Weight (kg)	Total Daily Fluids (ml/day)	Total Daily Fluid per Body Weight (ml/kg/day)	Hourly Rate of Total Daily Fluid (ml/hr)

8.0	380	48	16
8.5	398	47	17
9.0	416	46	17
9.5	433	46	18
10.0	450	45	19

*Based on 80 × BW $(kg)^{0.75}$.

- In most situations, the kidneys conserve sodium and excrete excess amounts of potassium, resulting in urine that typically has a much lower concentration of sodium and a higher concentration of potassium compared to plasma.
- The volume of fluid required daily varies with the size of the animal. Large patients (with low mass-to-body surface area ratios) require less fluid per kilogram on an individual basis than small animals (with high mass-to-body surface area ratios), as shown in Table 5-1 for dogs and Table 5-2 for cats.
- Maintenance volume is comprised of two subcomponents:
  - *Insensible losses* (not readily measured losses from respiratory evaporation and the passage of normal feces) are estimated at 20 ml/kg/day in normal animals but can increase during febrile states, panting, and high environmental temperatures.
  - *Sensible losses* (readily measured as urine production) are estimated to be 20 to 40 ml/kg/day in normal animals that are consuming food.
- Urine output can dramatically decrease during:
  - Acute intrinsic renal failure—Oliguria or anuria
  - Urinary obstruction—Anuria
  - Severe dehydration—Oliguria
- Urine output can dramatically increase during:
  - Polyuric renal failure
  - Post-obstructive diuresis
- Consider maintenance fluid therapy for hospitalized patients who are not eating and drinking on their own but are not dehydrated. Maintenance fluids should be low in sodium, chloride, and osmolality and high in potassium compared to normal plasma.

▼ ***Key Point*** Lactated Ringer's and 0.9% sodium chloride solutions are *not* ideal maintenance solutions because they contain too much sodium and chloride, are too high in osmolality, and do not contain enough potassium.

▼ ***Key Point*** A 0.45% sodium chloride solution (in water or in 2.5% dextrose) is more suitable as a maintenance solution due to its sodium and chloride content and its osmolality. It does not contain adequate potassium; therefore, potassium must be added.

DEHYDRATION (REPLACEMENT NEEDS)

Dehydration exists when TBW decreases to less than normal.

- Technically, dehydration refers to loss of pure water, but clinical fluid loss is usually accompanied by some loss of electrolytes.
- Acute fluid and electrolyte loss in any disease process is initially lost from intravascular fluid.
- Compensatory shifts of water and electrolytes from intracellular and interstitial compartments subsequently occur.
- The magnitude of these shifts depends on the tonicity and hydrostatic pressure of the remaining extracellular fluid. Consequently, dehydration can occur to different degrees in the various compartments.

Causes of Dehydration

Decreased Water Intake (Hypodipsia, Adipsia)

- Lack of food intake also decreases available water (water from oxidation and that physically present within the food).
- Appetite and thirst centers may be depressed in systemically ill animals.
- Accidental or deliberate deprivation of adequate water and food decrease available water.

Increased Water Loss

- Urinary (polyuria): Common
- Gastrointestinal (vomiting, diarrhea): Common
- Respiratory (fever, panting)
- Skin (burns, large wounds)
- Excessive salivation

▼ ***Key Point*** Fluid losses from the urinary and gastrointestinal tracts are the most frequent causes of dehydration.

Characterization of Dehydration (Type)

Disease processes can display a spectrum of fluid and electrolyte loss combinations, from mostly water loss (hypotonic loss) to water loss with significant quantities of accompanying electrolytes (isotonic or hypertonic). Evaluation of the tonicity and sodium concentration of the extracellular fluid in a dehydrated patient will give clues to the nature of the fluid that was lost and helps determine the type of fluid that will be given as replacement during treatment.

The type of dehydration is defined based on the serum sodium concentration at the time of dehydration.

- *Isotonic dehydration* is the type that occurs most commonly. It is defined by finding a normal serum sodium concentration (145–157 mEq/L) in the presence of dehydration. It occurs because of loss of water and electrolytes in proportion to that found in normal serum (isotonic loss).
- *Hypertonic dehydration* is the next most common type. It is defined by finding an elevated serum sodium concentration (158 mEq/L or greater) in the presence of dehydration. It occurs as a consequence of predominantly water loss or water lost in excess of solute found in normal serum (hypotonic loss).
- *Hypotonic dehydration* is the least common type. It is defined by finding a low serum sodium concentration (143 mEq/L or less) in the presence of dehydration. It theoretically occurs as solute is lost in excess of the concentration found in normal serum (hypertonic loss), but this is probably not the most significant mechanism. More likely, it is the loss of isotonic fluid and concurrent intake and absorption of hypotonic fluids (such as drinking of water) with the net dilutional effect on the remaining extracellular sodium concentration below normal.

Detection of Dehydration

Clinical tools to detect dehydration are limited in both sensitivity and specificity. There is no single test or procedure to accurately assess the magnitude of dehydration. Integration of historical findings, abnormalities on physical examination, and laboratory measurements will be necessary to quantify dehydration. Dehydration is not detectable by clinical means until approximately 5% of body weight in water has been lost. An acute loss of greater than 12% body weight in water is considered life threatening (Table 5-3).

History

History often leads the clinician to suspect dehydration and to assess its magnitude more accurately. Question

Table 5-3. PERCENTAGES OF DETECTABLE DEHYDRATION

Dehydration	Signs
<5%	Not detectable on physical exam; history is suggestive of losses; acute body weight changes
5%	Subtle loss of skin elasticity
6–8%	Mild delay of skin tent, slight prolongation of CRT, dry mucous membranes
8–10%	Obvious delay of skin tent, slight prolongation of CRT, dry mucous membranes, eyes slightly sunken in orbits
10–12%	Severe prolongation of skin tent, eyes sunken in orbits, dry mucous membranes, signs of shock likely present (prolonged CRT, tachycardia, weak pulses etc.)
>12%	Moribund

*CRT, capillary refill time.

the owner about volume of intake (adipsia, hypodipsia, polydipsia, or normal intake of water). Because volume of water intake may, in part, be a function stimulated by food intake, note also the presence or absence of anorexia. Abnormal losses of body fluid may be determined from owner responses to questions about vomiting, diarrhea, polyuria, panting, excessive salivation, or other bodily discharge. The duration of these historical signs and the magnitude of losses affect the magnitude of clinically detectable dehydration.

Physical Examination

Physical examination provides general guidelines for detecting dehydration but is subjective (see Table 5-3). Signs of listlessness and depression may occur from dehydration but may be partially attributable to the underlying disease or to concomitant electrolyte and acid-base abnormalities. As dehydration becomes more severe, decreased skin turgor, sunken eyes, dryness of mucous membranes, tachycardia, diminished capillary refill, and signs of shock may occur. An accurate and recent body weight, when available, can be used for comparison to evaluate change in body weight as an indicator of body water change.

▼ ***Key Point*** An acute increase or decrease in an animal's body weight often reflects acute gain or loss of body water. This is the most sensitive clinical tool for assessment of dehydration and rehydration. An acute loss or gain of 1 kg is the equivalent of losing or gaining 1 L of fluid.

Skin Turgor

Skin turgor assessment during physical examination is important for estimating the percentage of body weight loss due to dehydration. Skin turgor is evaluated by determining the time required for skin gently lifted from the body to return to its original position (referred to as the skin pinch or skin tent). Normal skin pliability (skin turgor) depends on hydration of the tissues in the area tested. Skin turgor is largely determined by hydration status of the interstitial tissues, although both vascular and intracellular hydration also contribute. Elastin and adipose within skin and subcutaneous tissues will also influence the apparent skin turgor. Choose skin from the trunk as a test area. Avoid dependent areas and skin from the neck. Normal skin returns immediately to its initial position when lifted a short distance and released. Dehydrated skin shows varying degrees of slow return to the original position. As dehydration progresses, the time required for the return of the skin pinch to its initial position becomes greater. The clinician assigns increasing percentages of dehydration to abnormal skin turgor of increasing severity (see Table 5-3).

Skin Turgor Artifacts

Many artifacts confuse interpretation of skin turgor.

- Skin turgor of obese animals may appear normal despite dehydration, owing to the large amounts of subcutaneous fat.
- The skin of an emaciated animal with normal hydration may fail to return to its normal position owing to a lack of subcutaneous fat and elastic tissue. Consequently, underestimating dehydration in obese animals and overestimating dehydration in emaciated animals can occur.
- Avoid testing cervical skin because redundant skin in the neck area confuses the result.
- Skin turgor changes in longhaired animals are more difficult to detect than those in shorthaired animals.
- Differences in turgor assessment can occur in the same animal in the standing versus recumbent positions.

▼ ***Key Point*** Dehydration may be as much as 5% of body weight loss in lean dogs and 10% or more in obese dogs before loss of skin turgor is detected.

Other Physical Examination Artifacts

- Dry mucous membranes may occur in animals that pant continually and in those given anticholinergics.
- Sunken eyes may be seen with catabolic diseases that decrease the soft tissue behind the globe or with atrophy of the muscles of mastication.

▼ ***Key Point*** Assessment of fluid, electrolyte, and acid-base status will frequently be in error if only the history and physical examination are available for interpretation. The more seriously ill an animal is, the more important evaluation of laboratory data becomes.

Laboratory Assessment of Dehydration

Packed Cell Volume and Total Plasma Protein

Simple laboratory testing is helpful in evaluation of intravascular hydration. Packed cell volume (PCV) recorded in percentages (SI unit: L/L) and total plasma protein (TPP) recorded in gm/dl (SI unit: g/L) can be rapidly and inexpensively determined using microhematocrit tubes and a refractometer. These two tests require only a few drops of blood and can be taken by capillary action from a 25-gauge venipuncture. TPP concentration may be more helpful in the detection of dehydration than PCV. Increased TPP and PCV provide documentation for intravascular dehydration. Simultaneous evaluation of PCV and TPP is recommended in order to minimize interpretation errors due to preexisting anemia or hypoproteinemia. (Table 5-4) Additional value is obtained when PCV and TPP are followed

Table 5-4. INTERPRETATION OF CHANGES IN PACKED CELL VOLUME (PCV) AND TOTAL PLASMA PROTEIN (TP)

PCV	Total Protein	Possible Interpretation
↑	↑	Dehydration
↑	**N** or ↓	Splenic contraction
		Erythrocytosis
		Hypoproteinemia with dehydration
N	↑	Hyperproteinemia
		Anemia with dehydration
		Hypertonic dehydration (RBC shrinkage)
↓	↑	Anemia with dehydration
		Anemia with pre-existing hyperproteinemia
↓	**N**	Non-blood-loss anemia, normal hydration
N	**N**	Normal hydration
		Dehydration, after secondary compartment shift
		Dehydration with pre-existing anemia + hypoproteinemia
		Acute hemorrhage
↓	↓	Blood loss anemia
		Overhydration

serially as increasing values identify progressive dehydration.

Urinalysis

Urinalysis (UA) is important in all cases of suspected dehydration. An elevated specific gravity (SG) represents the healthy kidneys' response to decreased perfusion. The finding of dilute urine (<1.030 SG) from a dehydrated animal immediately incriminates the kidneys as a major cause of, or contributor to, the dehydration.

Serum Biochemistry

Evaluation of serum electrolytes may help characterize the nature of the fluid that was lost.

Blood Gases

Abnormalities in blood-gas values may appear in dehydrated animals owing to net loss or gain of acid or buffer. The most common acid-base disturbance in dehydrated patients is metabolic acidosis that typically develops because of a decrease in urine production and an impaired ability of the kidneys to excrete the daily acid burden. In addition, moderate to severe forms of dehydration are accompanied by decreased perfusion to major tissue beds, resulting in a switch to anaerobic metabolism and the production of lactic acid.

▼ ***Key Point*** Animals may be severely dehydrated yet exhibit little or no change in their serum biochemical test results. Likewise, their PCV or TPP can be normal in the face of dehydration.

Anticipation of Dehydration with Specific Diseases

Dehydration should be anticipated in sick animals with certain disease syndromes known to predispose a patient to dehydration regardless of physical exam or laboratory findings. For example, a collapsed diabetic is very likely to be dehydrated, as is an animal with advanced chronic renal failure or a patient with upper intestinal obstruction.

Correction (Replacement) of Dehydration

The *volume of fluid* to be replaced is calculated as follows based on the assessed percentage of dehydration and the patient's present body weight:

- % dehydration × weight (kg) = L of fluid to be replaced.
- % dehydration × weight (lbs) × 500 = ml of fluid to be replaced.
- Alternatively, if a known recent body weight is available for comparison, replace 1 L of fluid for every kilogram (500 ml/lb) of acute body weight loss.
- The *type of fluid* that is chosen to accomplish this rehydration is based primarily on the patient's ability to tolerate a sodium challenge, the serum electrolyte (sodium, chloride, and potassium) concentrations, and the presence of any acid-base disturbances.

▼ ***Key Point*** Initial replacement with adequate fluid volume is usually more important than correcting minor electrolyte or acid-base disorders.

- Administer to the patient both the volume and the type of fluid that has been lost or continues to be lost from the body. Base the volume calculation on volumetric measurement of the losses or, more practically, from estimates. Base the type of the fluid on actual measurements from the patient or, more commonly, on the predicted biologic composition of fluid losses associated with a specific disease.

▼ ***Key Point*** Choose a fluid type or add supplements to stock fluids so that electrolytes deficient in the plasma or body are administered and those that are excessive in the plasma are avoided.

Contemporary (Ongoing) Losses

Although initiation of fluid therapy is aimed at replacing fluid lost from the patient, persistence of uncontrolled signs or untreated diseases will permit the dehydrating process to continue. Consider replacement of contemporary or ongoing losses that begin after fluid therapy has begun. Estimate gastrointestinal fluid loss (e.g., from vomiting or diarrhea). When ongoing loss is from the urinary tract, temporary urethral catheter collection may increase the accuracy of estimating the magnitude of the loss. Less invasive but feasible methods of estimation include collecting urine in a container (free

catch from dogs or litter box from cats) and measuring the volume or weight change of the container.

Volume To Be Administered

The initial volume of fluids to be administered over the first 24 hours can be calculated (Figure 5-3). The multiples of maintenance volumes method is less accurate but is acceptable for routine use in uncomplicated cases of simple dehydration (Table 5-5).

FLUID THERAPY FOR SHOCK

See Chapter 156 for a discussion of shock treatment.

TYPES OF FLUIDS AND THEIR SELECTION

Crystalloid Solutions

Crystalloid fluids contain no large macromolecules, allowing them to redistribute quickly from the vascular space to the interstitial and intracellular fluid spaces. Thus they exert their greatest effect in rehydration or replacement of prior fluid loss. Expansion of the vascular fluid space initially occurs, but with time, redistribution minimizes this effect.

Table 5-5. ALTERNATIVE METHOD TO CALCULATE MAINTENANCE + DEHYDRATION NEEDS*†

Maintenance +% Dehydration	Multiplication Factor	ml/kg/day	ml/lb/day
M + 5%	1.80	110	55
M + 6%	2.00	120	60
M + 7%	2.17	130	65
M + 8%	2.33	140	70
M + 9%	2.50	150	75
M + 10%	2.70	160	80

*Maintenance (M) is defined in this table as 60 ml/kg/day or 30 ml/lb/day.
†Contemporary fluid losses are not considered in these calculations.

Method 1

_____ml = **Deficit** = estimated % dehydration × weight (kg), or
= estimated % dehydration × weight (lb) × 500

\+

_____ml = Maintenance = **use Table 5-1 (dogs), or Table 5-2 (cats)**
= 40–60 ml/kg/day depending on patient size

_____ml **Total 24-Hour Needs**

÷ **24**

_____ml/hr **Hourly Needs**

\+

_____ml/hr **Hourly Contemporary Losses**
= accrued volume of loss observed over time ÷ hours in observation interval

_____ml/hr **Hourly Fluid Rate** (administered for same number of hours as observation interval above and then recalculated)

Method 2

_____ml = **Deficit** = estimated % dehydration × weight (kg), or
= estimated % dehydration × weight (lb) × 500

\+

_____ml = **Insensible** = 20 ml/kg/day (10 ml/lb/day)

_____ml **Total 24-Hour Needs**

÷ **24**

_____ml/hr **Hourly Needs**

\+

_____ml/hr **Hourly Sensible Losses** (measured)

_____ml/hr **Hourly Fluid Rate** (administered until sensible losses are measured again)

Table 5-6. COMPOSITION OF COMMON COMMERCIAL FLUID TYPES

Fluid	Sodium (Na)	Potassium (K)	Chloride (Cl)	Calcium (Ca)	Magnesium (Mg)	Osmoles (OSM)	Bicarbonate Precursors
D5W (5% Dextrose in Water)	0	0	0	0	0	278	0
0.45% NaCl	77	0	77	0	0	154	0
0.45% NaCl + 2.5% Dextrose	77	0	77	0	0	290	0
0.9% NaCl	154	0	154	0	0	308	0
LRS	130	4	109	3	0	278	23 lactate
P-148, Norm-R	140	5	98	0	3	308	23 acetate/ 23 gluconate
3% NaCl	513	0	513	0	0	1026	0
5% NaCl	856	0	856	0	0	1712	0

Osmolality

Crystalloid fluids can be classified according to osmolality by comparison to the animal's normal serum osmolality of approximately 300 mOsm/kg. Table 5-6 lists the composition of a variety of commercially available crystalloid fluids. Osmolality of commercial fluids is largely determined by sodium and glucose concentrations. Fluids with osmolality of less than 300 mOsm/kg are hypotonic (e.g., 0.45% saline in water), those with osmolality of greater than 300 mOsm/kg are hypertonic (e.g., 5.0% dextrose added to 0.9% sodium chloride), while those with osmolality near 300 mOsm/kg are isotonic (e.g., lactated Ringer's solution, Plasma-Lyte 148, and Normosol-R). Physiologic saline (0.9% sodium chloride) at 308 mOsm/kg is also within the isotonic range. Lactated Ringer's solution is often referred to as an isotonic solution in some species, but at 272 mOsm/kg it is mildly hypotonic for small animals.

Replacement Fluids

Crystalloid fluids can also be classified by their intended function for maintenance or replacement. *Replacement fluids* must be formulated for specific electrolyte or alkali deficits. Additives such as potassium chloride, magnesium, calcium, or sodium bicarbonate will often be added to commercially available solutions, but this will vary greatly with the disease process and the patient's laboratory measurements. Replacement fluids are usually ideally suited to replenish fluid losses and resulting dehydration.

Maintenance Fluids

Maintenance fluids are polyelectrolyte solutions that differ greatly from serum as they are lower in sodium, contain additional potassium, and contain glucose. Although at administration they are isotonic, after the glucose is metabolized their effect is hypotonic. This class of fluids is intended for use in patients who have been rehydrated and are simply being maintained on IV fluids during hospitalization.

The amount of energy derived from dextrose in these fluids is insufficient to meet patient needs. Use parenteral nutrition solutions if nutritional support is necessary. The importance of introducing enteral nutrition in ill patients early in the course of hospitalization (when appropriate) also minimizes the need to switch to maintenance-type solutions after rehydration of the patient has been accomplished. Maintenance fluid and electrolyte needs can often be met with nutritional support rather than through maintenance crystalloid administration.

Patients with an intact renin-angiotensin-aldosterone axis should be able to excrete the higher sodium load present in replacement crystalloids if these fluids are utilized for a short-term basis after rehydration is accomplished. Maintenance crystalloid solutions with their lower sodium content are ideally suited for the treatment of patients with congestive heart failure or advanced liver or kidney disease, who cannot tolerate the sodium load present in replacement solutions, or of patients with true water losses and hypernatremia.

Colloid Solutions

Colloid solutions differ from crystalloids because they contain large macromolecules (natural or synthetic). These molecules, because of their size, do not readily pass through the normal endothelium, thus giving them oncotic pressure effects. This allows them to affect water movement from the interstitial fluid space. In addition, the large net negative charge carried by these molecules attracts sodium and thus water from the interstitial spaces, which contributes to their volume expanding effect. Depending on the clinical situation, colloid molecules exert most of their effect in the intravascular space, making them ideal for volume expansion of the intravascular space but less suitable for replacement of extravascular fluid losses.

Natural Colloids

Natural colloids are produced by the body, harvested from volunteer donors, and stored for later use. In small

Table 5-7. CHARACTERISTICS OF COLLOID SOLUTIONS

Fluid	Molecular Weight (MW) (KDa)	Range (KDa)	Solvent	Colloid Osmotic Pressure (COP)	Molar Subst'n
5% Albumin	69	—	—	20	—
25% Albumin	69	—	—	100	—
6% Dextran-70	70	10–80	0.9% NaCl or D5W	40	0.5
6% Hetastarch	480	10–3400	0.9% NaCl	30	0.7
10% Pentastarch	260–280	10–1000	0.9% NaCl	40	0.4–0.5
Oxypolygelatin	30–35	5.6–100	Electrolyte Solution	45–47	
Oxyglobin	200	65–500	Modified LRS	42	—

animal medicine, this group of fluids includes the blood transfusion components that possess albumin and other plasma proteins (whole blood and plasma). Indications for use of blood component therapy are covered elsewhere (see Chapter 22).

Concentrated Human Albumin

In human medicine, 5% and 25% concentrated albumin products are also manufactured. Unconcentrated natural colloids do not expand the vascular space except by the volume administered. Concentrated natural colloids will expand the vascular space by up to 5 times (25% albumin) their volume owing to their impressive oncotic pressure. Concentrated human albumin products have been used with success in small animals, but their use carries risk of adverse reaction. Most commonly, concentrated human albumin solutions are used when severe decreases (<12 mmHg) in colloid osmotic pressure (COP) are measured or the patient's albumin concentration is severely decreased (<1.5 g/L or <15 g/dl).

Synthetic Colloids

The commercially available *synthetic colloids,* which are currently finding more frequent use in small animal medicine, are all complex polysaccharide molecules. The reported average molecular weight, COP, and molar substitution ratio of these molecules are listed in Table 5-7. The complex behavior and pharmacokinetics of these molecules do not allow accurate prediction of actual biological behavior. As a result, the dose and duration of administration of these solutions vary with individual preference and the patient characteristics and requirements. In addition, availability of these products in some countries depends on national health and safety licensing.

In general, the smaller the average molecular weight, the more potent the effect on intravascular expansion. This is due generally to the higher COP of these solutions. Breakdown of synthetic molecules depends on their size (molecular size range) and the complexity of branching (molar substitution ratio). Molecules with higher size ranges and molar substitution ratios are more difficult to metabolize; thus these solutions tend to have a longer biological effect.

- Synthetic colloids should rarely be utilized by themselves but are useful adjuncts to standard crystalloid fluid therapy in several well-defined situations. Patients with hypoproteinemia and lowered oncotic pressure are likely to benefit from continuous infusions of hydroxyethyl starch (hetastarch or pentastarch) at doses of 20 ml/kg every 24 hours (cats—10–15 ml/kg every 24 hours) or more if needed. The measurement of COP is a useful monitoring tool to determine infusion rate and end point. In addition, synthetic colloid solutions may play a valuable role in shock resuscitation (see the previous section).
- Patients with diffuse vascular injury to the pulmonary vasculature and who are at risk for non-cardiogenic pulmonary edema formation may be very sensitive to sudden elevations in intravascular volume. Thus if increased oncotic pressure is desirable, continuous infusion rather than bolus administration of colloids is recommended.

▼ ***Key Point*** Use synthetic colloids with caution, and at very reduced doses, in patients with congestive heart failure and those with renal origin oliguria or anuria as rapid volume expansion could be detrimental.

- Of the three synthetic colloids mentioned in Table 5-7, dextran 70 has the most potential to interfere with hemostasis. While clotting times become elevated with use of the hydroxyethyl starches, clinically apparent hemostatic abnormalities are typically not encountered if the recommended dosages are utilized.
- Dextran 70 also carries a small risk of anaphylactic reaction, whereas reactions to administration of hydroxyethyl starches have not been reported. Consequently, and also as a result of the decreasing cost differential between dextrans and hydroxyethyl starch, dextrans are being used infrequently.

Fluids To Be Kept on Hand

▼ ***Key Point*** Clinical correction of most fluid problems can be accomplished by maintaining only a few stock solutions, usually lactated Ringer's solution, Plasma-Lyte 148, or Normosol-R; 0.9% sodium chloride; and 5% dextrose in water.

- It is convenient, although not essential, to have 2.5% dextrose with or without 0.45% sodium chloride available for use in patients who cannot tolerate high sodium loads. Mixing equal portions of 0.9% sodium chloride with 5% dextrose in water provides the same solution.
- An alkalinizing basic electrolyte solution (lactated Ringer's solution, Plasma-Lyte 148, Normosol-R) is most often chosen as a "physiologic" solution that is similar in composition to normal animal plasma with the exception of protein. It is usually the fluid of choice in the absence of laboratory data until more information about electrolyte, osmolality, and acid-base status is available from the laboratory.
- A 0.9% sodium chloride solution is chosen when "extra" sodium or chloride is needed to maintain volume expansion or for the correction of metabolic alkalosis.
- Low-sodium fluids (0.45% saline in 2.5% dextrose, Plasma-Lyte 56, Normosol-M, or 5% dextrose in water) are chosen when treating sodium-intolerant patients or patients with a water deficit (hypernatremia).
- It is useful to have one synthetic colloid solution available. Synthetic colloids should be administered in conjunction with crystalloids when there is lowered oncotic pressure or when rapid (and low volume) intravascular expansion is desired.

SUPPLEMENTATION OF PARENTERAL FLUIDS

After sodium, potassium considerations are most important. Hypokalemia is commonly encountered in hospitalized animals, particularly with prolonged anorexia and while receiving potassium-deficient fluids. Other supplements can include alkali, magnesium, dextrose, phosphate, calcium, and vitamins.

Potassium Supplementation

Potassium supplementation is usually provided as potassium chloride, although potassium phosphate is used in special situations. It is most common to use commercially available sterile vials with 2 mEq/ml of potassium for addition to fluids. Potassium supplementation to fluids is indicated if the serum potassium concentration is less than 3.5 mEq/L.

- The modified Sliding Scale of Scott (Table 5-8) recommends adding potassium chloride to maintenance fluid volumes proportional to the degree of hypokalemia; the lower the potassium concentration, the greater the amount of potassium added to the fluids. An exact number of milliequivalents for supplementation is not calculated using this method. Potassium supplementation using this scale can be started during correction of dehydration if fluids will be distributed evenly throughout the day.
- Alternatively, a fixed concentration of potassium from 20 to 30 mEq/L can be given in maintenance fluids and is particularly helpful when frequent monitoring of serum potassium is not possible. This concentration corresponds to the lower end of the Scott scale. Potassium up to 35 mEq/L can be given in subcutaneous fluids without irritation to local tissues.
- Potassium supplementation may still be indicated when its concentration is from 3.5 to 4.5 mEq/L and especially if ventricular arrhythmias are present. This can prevent the development of hypokalemia during fluid treatment and also can help replenish total body potassium deficits that are not yet reflected by the serum potassium concentration. High normal levels of potassium (>4.5 mEq/L) are helpful when managing arrhythmias because they reduce membrane hyperpolarization caused by low serum potassium levels.
- Maintenance needs for potassium in healthy dogs and cats is shown in Table 5-8 in mEq/day, but enhanced losses through the urine during fluid administration can be expected.

Table 5-8. MODIFIED SLIDING SCALE OF SCOTT

Serum K^+ (mEq/L)	mEq KCl Added to 250 ml	mEq KCl Added to 1000 ml	Maximal Infusion Rate (0.5 mEq/kg/hr)
<2.0	20	80	6 ml/kg/hr
2.1–2.5	15	60	8 ml/kg/hr
2.6–3.0	10	40	12 ml/kg/hr
3.1–3.5	7	28	18 ml/kg/hr
>3.5 < 5.0	5	20	25 ml/kg/hr

K^+, potassium; KCl, potassium chloride; mEq/L, milliequivalents per liter.

▼ ***Key Point*** Add approximately 20 to 30 mEq/L of potassium for maintenance fluids when serum potassium concentration is from 3.5 to 4.5 mEq/L.

- Caution should be used whenever potassium-enriched fluids are infused. The rate of potassium infusion is usually more important than the total number of milliequivalents. Do not exceed a rate of 0.5 mEq/kg/hr to lessen the risk for development of hyperkalemia or cardiotoxicity. Infusion of greater than 0.5 mEq/kg/hr should only occur in crisis situ-

ations and continue for no longer than 3 to 4 hours before the serum potassium is rechecked.
- Animals with alkalosis and translocation of potassium may not require vigorous potassium supplementation if the alkalosis can be corrected rapidly. Potassium can rapidly return from the cells to the ECF.
- Animals with severe emaciation have reduced lean body mass available for potassium uptake and should be less vigorously supplemented with potassium in their fluids.
- Reduced renal function and azotemia can lead to potassium retention and hyperkalemia during infusion of potassium-supplemented fluids, particularly if oliguria is present. Less vigorous potassium supplementation and careful monitoring is indicated in this situation.
- Potassium chloride supplementation increases the osmolality of fluids, particularly when high concentrations are provided. For example, potassium supplementation at 40 mEq/L increases the osmolality of the fluid by 80 mOsm/kg, 40 Osm each from potassium and chloride. If the infused potassium enters cells or is excreted, this lessens the effects of the osmolality.

▼ ***Key Point*** Although potassium supplementation is often beneficial, excessive supplementation can result in death of the patient due to hyperkalemia. Do not use potassium supplementation at higher concentrations unless serum potassium concentration can be measured on an urgent basis. Electrocardiographic monitoring may be needed during supplementation of fluids with potassium in animals that are at risk for development of hyperkalemia.

Alkali Supplementation

Addition of alkali to fluids is sometimes needed for partial correction of metabolic acidosis. It is not usually necessary or desirable to entirely correct metabolic acidosis to normal by supplementation alone.

- Add sodium bicarbonate to fluids when alkali replacement is needed quickly.
- Do not rely on bicarbonate precursors (lactate, gluconate, or acetate) in commercially available solutions to correct severe metabolic acidosis.
- Bicarbonate precursors require metabolic conversion to bicarbonate before they can contribute to correction of acidosis.
- Supplementation of bicarbonate is most safely accomplished when blood gas analysis is present to determine the contribution of the respiratory system to the acid-base disturbance.
- Bicarbonate buffers acid by combining with a proton to form carbonic acid, which is subsequently broken down by carbonic anhydrase into water and carbon dioxide ($HCO_3^- + H^+ \rightarrow H_2CO_3 \rightleftharpoons H_2O + CO_2$).
- Patients that do not have adequate ability to exhale CO_2 formed in this reaction are at risk for worsened acidosis by administration of bicarbonate.

▼ ***Key Point*** Patients with inadequate respiratory compensation for a metabolic acidosis or a mixed acidosis are at risk for worsened acidosis by administration of bicarbonate. Focus on fluid resuscitation, if they are in shock, or investigate the cause of respiratory dysfunction. Re-evaluate acid-base status using blood gas analysis prior to administration of bicarbonate.

▼ ***Key Point*** Do not add sodium bicarbonate to fluids that contain calcium (lactated Ringer's solution), as calcium precipitates may occur.

- Calculate alkali replacement from either the bicarbonate value reported on a blood gas analysis or the total CO_2 value on a serum biochemical profile. Total CO_2 (mEq/L) can be substituted for bicarbonate in these calculations since the difference is usually only 1 to 2 mEq/L.

Methods for Calculating Bicarbonate Dose

- Assume that normal HCO_3 is 24 mEq/L.
- Subtract measured patient HCO_3 from 24, which is equal to the HCO_3 deficit in mEq/L.

Method A

- HCO_3 deficit × 0.6 × body weight (kg) = "missing" mEq bicarbonate from TBW at the time of sampling
- Administer total calculated replacement mEq over 8 to 12 hours or longer; it may take as long as 18 hours for administered bicarbonate to equilibrate inside cells.

Method B

- HCO_3 deficit × 0.3 × body weight (kg) = "missing" mEq bicarbonate from ECF at the time of sampling
- Use this formula when multiple injections of bicarbonate are anticipated, ongoing production of acid or loss of alkali is anticipated, and access to multiple HCO_3 measurements is possible. Without access to blood gas analysis or total CO_2, it is difficult to know with any certainty the magnitude of need.

Empirical Method

If the clinical diagnosis and suspicion for metabolic acidosis is high, bicarbonate may be administered empirically.

- Estimate of mild acidosis: Give 3 mEq/kg bicarbonate over 24 hours

- Estimate of moderate acidosis: Give 6 mEq/kg bicarbonate over 24 hours
- Estimate of severe acidosis: Give 9 mEq/kg bicarbonate over 24 hours
- In crisis situations requiring bicarbonate, administer 0.5 to 1.0 mEq/kg of sodium bicarbonate over 5 to 10 minutes and reevaluate. Electrocardiographic monitoring is recommended during the injection if it is available.

Precautions for Bicarbonate

- Remember that along with bicarbonate, sodium is administered, which can result in hypernatremia, hyperosmolality, hypertension, overhydration, and volume overload if the administered sodium is not excreted.
- Overtreatment with alkali can result in alkalosis, paradoxical cerebrospinal fluid acidosis, shifts of ionized calcium, a shift of the oxyhemoglobin dissociation curve (decreasing oxygen unloading), and seizures.

Magnesium Supplementation

Magnesium has recently emerged as an important but seldom considered ion. It is a metabolic cofactor in hundreds of metabolic functions, most importantly as a cofactor in the sodium-potassium pump (NaK-ATPase). Deficiencies in magnesium can thus lead to potassium loss from the body. Hypokalemia and hypomagnesemia are often found concurrently in many ill or dehydrated patients. Magnesium is lost alongside other cations when urinary and gastrointestinal losses result in dehydration. Inadequate intake in anorexic patients will exacerbate hypomagnesemia.

- As magnesium is primarily an intracellular ion, serum measurements are often not reflective of total body stores. It is generally thought that low total serum magnesium is reflective of low total body magnesium status, but this is often a late finding. Ion-specific electrodes are more sensitive for detecting hypomagnesemia but are not in common use.

▼ ***Key Point*** In patients with documented hypokalemia, and especially hypokalemia that seems to be resistant to supplementation efforts, magnesium supplementation is indicated. In addition, patients with diabetic ketoacidosis, congestive heart failure, and ventricular arrhythmias (and concurrent hypokalemia) are likely to benefit from magnesium supplementation.

- Magnesium sulfate and magnesium chloride are the commonly available sources of magnesium. Magnesium sulfate is preferred to prevent excessive chloride administration. The dosage of magnesium sulfate supplementation is 2.5 to 5 mg/kg/hour and can be added to most commercially available fluid types. A loading dose of 30 mg/kg of magnesium sulfate can also be administered over 20 minutes to 1 hour prior to beginning the lower rate of hourly supplementation.
- Magnesium supplementation can be extremely helpful in achieving and maintaining high normal levels of potassium when treating cardiac arrhythmias.
- Do not use magnesium supplementation in oliguric patients as this is the primary route of excretion of excessive amounts.

Dextrose Supplementation

If supplementation with dextrose is necessary, use varying amounts of 50% dextrose to achieve the desired concentration or the percentage of dextrose in the final solution.

- To increase the dextrose concentration by 2.5%, add 25 g of dextrose or 50 ml of 50% dextrose to 1000 ml of stock solution (e.g., lactated Ringers solution). Long-term supplementation of dextrose through a peripheral vein should not exceed concentrations over 5%, as the hypertonicity can induce significant phlebitis.
- Indications include hypoglycemia due to sepsis, insulin overdosing, insulinoma, and liver disease. Dextrose supplementation at greater than 10% to 15% is necessary to provide sufficient calories for anorectic animals.

Vitamin Supplementation

The benefits of supplemental vitamins during parenteral fluid therapy in cats or dogs are plausible but not proven. Water-soluble vitamins can be conservatively added to parenteral fluids without known harm and may replenish rapidly depleted stores.

- Dogs or cats in polyuric renal failure may benefit from additional water-soluble vitamins in parenteral fluids because of urinary losses of these vitamins.
- Thiamine deficiency can be of clinical concern in cats and can develop during anorexia while on fluids, as the storage period of thiamine is short.
  - Initial signs of thiamine deficiency include anorexia, vomiting, and ataxia that can progress to dilated pupils and tonic ventriflexion of the neck, which may be confused with seizures. True seizures can also occur. Death usually occurs within 24 hours of onset of convulsions if the deficiency is not treated.
  - It is common practice to add 0.5 to 1.0 ml of water-soluble multi-vitamins to each liter of fluids to provide needed vitamins and to prevent thiamin deficiency.
  - B-complex vitamins are light sensitive, so the IV fluid bag should be covered to prevent degeneration. Fluids with B-complex vitamins added should

also be replaced every 24 to 48 hours to maximize the potential benefits of vitamin supplementation.

Calcium Supplementation

- Calcium gluconate and calcium chloride can be supplemented in replacement and maintenance fluids for the correction of symptomatic hypocalcemia. Many small animals with low serum albumin will have low total serum calcium concentrations. Most of these will not require calcium supplementation as the ionized calcium is not usually as depressed as the total calcium. When ionized calcium is substantially decreased, supplementation with calcium salts may be required.
- The percentage of calcium contained varies widely by the specific calcium salt. There is no difference in effectiveness of IV calcium salts to correct hypocalcemia when the dose is based on elemental calcium content. Calcium gluconate is often chosen as the calcium salt of choice because it is non-irritating if the solution is injected outside of a vessel. In contrast, calcium chloride is extremely irritating to tissues but provides more elemental calcium in each milliliter of solution.

Acute Infusion for Hypocalcemic Tetany

- Tetany or seizures due to hypocalcemia require treatment with IV calcium salts. Calcium is administered to effect at 5 to 15 mg/kg of elemental calcium (0.5–1.5 ml/kg of 10% calcium gluconate) over a 10- to 20-minute period.
- Monitor heart rate and electrocardiogram during acute infusion of calcium salts. Bradycardia may signal the onset of cardiotoxicity from an excessively rapid infusion rate of calcium.

▼ ***Key Point*** Treat severe symptoms of ionized hypocalcemia (tetany and seizures) by administering 0.5 to 1.5 ml/kg of 10% calcium gluconate intravenously over 10 to 20 minutes while observing a continuous electrocardiogram.

Continuous Intravenous Infusion

- Continuous IV infusion of calcium is recommended from 60 to 90 mg/kg/day of elemental calcium (2.5–3.75 mg/kg/hour) until oral medications provide control of serum calcium. Give initial doses in the higher range to patients with more severe hypocalcemia and decrease the dose according to calcium level achieved. Reduce the dose of IV calcium as oral calcium salts and vitamin D metabolites become more effective.
- Ten milliliters of 10% calcium gluconate provides 93 mg of elemental calcium. A convenient method to infuse calcium is available when IV fluids are given at a maintenance volume of 60 ml/kg/day (2.5 ml/kg/hour). Approximately 1, 2, or 3 mg/kg/hour of elemental calcium are provided by adding 10, 20, or 30 ml of 10% calcium gluconate, respectively, to each 250-ml bag of fluids.
- Do not add calcium salts to fluid therapy preparations that contain lactate, acetate, bicarbonate, or phosphates, since calcium salt precipitates can occur.
- Alkalinizing fluid therapy containing sodium bicarbonate decreases ionized calcium and may expose clinical signs of hypocalcemia in patients with borderline hypocalcemia; consequently, it should not be used.

Subcutaneous Injection

Never give calcium salts subcutaneously as severe skin necrosis and calcification have been observed in some patients, even when the calcium salts have been diluted prior to subcutaneous administration.

Phosphorus Supplementation

Hypophosphatemia is present when the serum concentration is less than 0.8 mmol/L (2.5 mg/dl). Mild hypophosphatemia (0.65–0.80 mmol/L or 2.0–2.5 mg/dl) is common and often transient. Hypophosphatemia often resolves quickly during therapy directed at the underlying cause. Severe hypophosphatemia (<0.48 mmol/L or <1.5 mg/dl) is uncommon but can be life threatening, particularly when less than 0.32 mmol/L (1.0 mg/dl). Use supplementation with phosphate salts when the serum phosphorus concentration is very low (<0.48 mmol/L or <1.5 mg/dl).

▼ ***Key Point*** Clinically significant hypophosphatemia that requires phosphate replacement therapy is most likely to be encountered in patients with diabetic ketoacidosis 12 to 48 hours after initiation of insulin therapy or in patients in whom enteral nutrition is initiated after prolonged periods of anorexia.

When necessary, sodium phosphate or potassium phosphate can be supplemented to replacement and maintenance fluids for the correction of symptomatic or severe hypophosphatemia.

- Do not add phosphate salts to fluids that contain calcium.
- Treat only if hypophosphatemia is severe and a concurrent likely cause is present.
- The dosage for phosphate supplementation is 0.01 to 0.03 mmol/kg/hour, intravenously, for 3 to 6 hours.
- Severe cases may require prolonged supplementation or higher dosages of phosphate (0.06–0.12 mmol/kg/hour intravenously).
- Continue supplementation only until the serum phosphorus concentration is greater than 0.65 mmol/L (2.0 mg/dl).

- Avoid oversupplementation that can cause hyperphosphatemia, hypocalcemia, tetany or seizures, soft-tissue mineralization, hyperkalemia (if using potassium phosphate), and hypernatremia (if using sodium phosphate).

GENERAL GUIDELINES FOR FLUID SELECTION

Serum Sodium Level as a Guide

Normal Sodium

If the serum sodium concentration is normal, the animal has isotonic dehydration and needs replacement fluids that are nearly normal in serum sodium concentration and osmolality. Lactated Ringer's solution, Plasma-Lyte 148, Normosol-R, or 0.9% sodium chloride would be appropriate selections.

Hypernatremia

If the serum sodium concentration is elevated, the animal has hypertonic dehydration and needs more water than salt for replacement (hypotonic fluid). Choose fluids that are effectively hypotonic (5% dextrose in water, 0.45% NaCl in 2.5% dextrose). Dextrose solutions in 2.5% to 5% concentration are considered effectively hypotonic because of rapid dextrose metabolism removing its contribution to osmolality. The magnitude of the elevation in serum sodium and the patient's clinical status will determine whether dextrose in water or dextrose in some concentration of saline should be administered. Lowering of severe hyperosmolality and hypernatremia excessively rapidly can be detrimental, particularly to the brain. A general guideline is to allow sodium concentration to fall no faster than 0.5 mEq/L/hour or no more than 12 mEq/L in 24 hours. Pure water without some electrolyte or glucose to add osmolality is not given as this can cause severe problems with hemolysis and rapidly decreased serum osmolality.

Hyponatremia

If the serum sodium concentration is low, the animal has hypotonic dehydration and needs additional sodium relative to water. Hypertonic fluid infusion is theoretically indicated, but clinically is not chosen unless the hyponatremia and hyposmolality are very severe and the patient is symptomatic. Isotonic fluids are usually chosen for replacement since the kidneys should excrete unnecessary water and reclaim needed sodium.

Other Laboratory Abnormalities

Further selection of fluid type requires laboratory measurement of albumin, total protein, potassium, chloride, magnesium, calcium, phosphorus, and blood gases. When serum concentration of an electrolyte is elevated, choose a fluid for infusion that is devoid or low in that electrolyte concentration. When serum concentration of an electrolyte is low, choose a fluid for infusion that contains high concentration of that electrolyte or provide supplementation of that electrolyte to the fluid. In some instances, supplemental electrolyte can be given to prevent deficits (as previously mentioned for potassium). Evaluate final osmolality of fluids for infusion following supplementation of base solutions to ensure that they are appropriate, as supplementation of base solutions often results in unappreciated hyperosmolality.

Selection of fluid type can be confusing when clinical problems dictate that disparate fluid types should be chosen; for example, use an acidifying solution (0.9% sodium chloride) in a patient that is severely acidemic, because high sodium content of this fluid is desirable. Thus in these situations, identify the most severe problem and choose the initial fluid to address this issue. Subsequently, as resolution of the most urgent problem is accomplished, correct secondary abnormalities. Fluid therapy is often dynamic, and changes of fluid type and additives are frequently needed over the course of therapy.

Preservatives

▼ ***Key Point*** Never use fluids containing preservatives of any kind for administration to cats, puppies, or small dogs because of the likelihood of severe toxic reactions.

- Benzoic acid derivatives are commonly used in fluids for their antibacterial and antifungal effects. Cats are extremely susceptible to toxic effects from these compounds even at low doses. Benzyl alcohol at 0.9% is commonly added to multiple dose vials of sodium chloride for injection.
- Clinical signs of toxicity are mostly neurological, and early signs include changes in behavior, apprehension, aggression, hyperexcitability (light and sound), salivation, marked ataxia, fasciculations of the muscles of the head and ears, widely dilated nonresponsive pupils, convulsions, coma, and death.

ROUTES OF ADMINISTRATION FOR PARENTERAL FLUIDS

The route of fluid therapy depends on the nature of the clinical disorder, its severity, its onset (acute versus chronic), the nature and magnitude of ongoing losses, and the composition of fluids to be given. The availability of personnel and equipment required for monitoring during IV therapy also influences decisions about the appropriate route of administration.

Subcutaneous Route

- Subcutaneous administration of fluids is common in dogs and cats; choose isotonic or mildly hypotonic fluids to enhance absorption.
- Subcutaneous infusions may be given under gravitational forces through IV administration tubing or by direct injection from a large-volume hypodermic syringe.

▼ ***Key Point*** Do not give 5% dextrose in water as an isotonic solution subcutaneously in cases of severe dehydration. Delayed absorption, with consequent equilibration of ECF electrolytes into the pocket of pooled, unabsorbed subcutaneous fluid, may occur.

- Absorption of subcutaneous fluid is unreliable in conditions characterized by peripheral vasoconstriction (e.g., shock, severe dehydration, or hypothermia). Never rely on this route for the emergency replacement of fluid in critically ill or severely dehydrated patients. This route may correct minimal dehydration or prevent dehydration in the anorexic animal.
- The volume of fluid that can be administered subcutaneously is limited by the patient's skin elasticity. Animals differ in their abilities to tolerate the infused volume comfortably.
- Choose the site of the subcutaneous infusions somewhere on the trunk so that the fluid does not gravitate into the limbs. Avoid areas with surgical wounds because fluid may drain from the incision or dissect through the healing tissues.

Intravenous Route

Give hypotonic, isotonic, and hypertonic fluids by the IV route as the need arises. Large volumes of fluid are more readily administered to a patient using the IV route. Rapid administration of fluid should always be administered intravenously.

▼ ***Key Point*** Use IV fluid administration whenever accurate delivery of fluid volume and potent pharmacotherapeutic agents are required.

Vein Selection

- The jugular vein and cephalic vein are most commonly chosen for indwelling IV catheterization. The lateral saphenous and femoral veins also may be used.
- Use the jugular vein in cats and small dogs to prevent occlusion of fluid flow when the animal's limb is bent.
- Use the jugular vein in serious diseases regardless of patient size. It is also easier to maintain aseptically if the patient has diarrhea.
  - Advantages of using the jugular vein include the ability to measure central venous pressure (CVP), the ability to administer hypertonic solutions and other irritating drugs because of greater dilutional effects from greater blood flow, and the ease of obtaining serial blood samples from the IV line (use care to avoid clotting within the line).
  - The prime disadvantage of peripheral veins is that limb position often changes the rate of fluid infusion owing to partial or complete occlusion of the indwelling catheter when gravity flow is used. When fluid pumps are used, this effect is minimized.

Catheter Selection

- In cats and small dogs use 20- to 22-gauge catheters; in medium and large dogs use 14- to 20-gauge catheters. Use short, larger-bore catheters, or catheterize two veins in emergency situations requiring rapid fluid administration. Clinician preference determines the type of catheter used.

Intravenous Catheter Care

- Always perform aseptic catheter placement using wide clipping of hair over the vein and a standard surgical scrub. After securing the catheter in the vein, place a gauze sponge with an antimicrobial cream over the puncture site.
- Catheter complications include thrombophlebitis, thromboembolism, bacteremia, bacterial endocarditis, and catheter-fragment foreign body.
- To minimize problems:
  - Place the catheter aseptically and keep the catheter site clean.
  - Check the catheter site once to twice daily. If no redness, swelling, pain, or patient discomfort when injecting are present, the catheter may be left in place. Routine catheter changes at 72 hours are no longer recommended.
  - Monitor the patient for fever, leukocytosis, and heart murmurs.
  - Ensure that all injections made into the IV catheter or lines are done aseptically.
  - Ensure that the IV line remains a closed and aseptic system. Do not disconnect the IV line unless absolutely necessary, and ensure aseptic technique is followed when changing IV fluid bags.
  - When the catheter is not in use, flush regularly to prevent clotting.

Intraperitoneal Route

- Severely anemic puppies and kittens may be transfused by this route (see Chapter 22 for details of blood transfusion).
- This route may be considered for rewarming very hypothermic animals.
- Use isotonic to mildly hypotonic fluids for rehydration (an IV route is preferred when possible).

Intraosseous Route

- Provides rapid access to circulation when venous catheterization is not successful or possible.
- Consider using in puppies and kittens and in emergency situations where immediate IV access is difficult.
- Blood and crystalloid solutions can be infused safely.
- Catheterize the bone marrow of the femur, tibia, or humerus with a bone marrow or spinal needle and secure it in place (see Chapter 3 for technique).

RATE OF FLUID INFUSION

The rate of fluid administration depends on the extent and rapidity of the fluid loss, as well as on the composition of the fluid to be infused. Rapid or extensive fluid losses demand rapid replacement. In chronic disorders, it is not always necessary to replace the dehydration deficit rapidly. Patients displaying symptoms of shock require a fluid resuscitation phase prior to correction of any dehydration that is present. For simple dehydration with no signs of shock, there are many acceptable methods to rehydrate the patient. Some clinicians prefer to calculate the dehydration deficit, add it to the daily maintenance requirements, and distribute this fluid load over 24 hours. Others prefer to replace part of the dehydration deficit over the first few hours (referred to as "front-end loading"). Deficit replacement of 75% to 80% on the first day and the remaining 25% deficit on the second day is recommended by some clinicians.

- Measure urine output during rapid fluid infusion as a guide to organ perfusion. With persistent oliguria, be careful about maximal fluid infusion and monitor CVP response to fluid challenge to avoid overhydration.

24-Hour Infusion Rate

- In less critical conditions, distribute fluids evenly throughout the day. Physiologically, this may be advantageous because it allows more time for adequate equilibration of water and electrolytes between the body compartments. Ideally, a constant or continuous infusion of IV fluids over a 24-hour period would accomplish this. This ideal situation may not be possible if very small volumes of fluid are being infused or if 24-hour monitoring of the IV lines is unavailable.
- Front-end loading of fluids to correct dehydration can be given over a 4- to 8-hour period when an animal's clinical condition dictates more rapid correction of dehydration. Maintenance and contemporary losses can then be infused evenly over the remaining hours of the day. If the intrinsic ability of the patient's tissues to absorb fluid is less than the volume of the fluid being administered, the difference will most likely be lost in the urine. In this situation, increased urine production is a misleading indicator of hydration status of the patient, so other physical examination and laboratory parameters as well as serial monitoring of the patient's weight must be considered.
- If fluid infusion can be observed for only part of the day, give the 24-hour needs over the number of hours that personnel can watch the drip, then flush the catheter with heparinized saline to maintain patency until infusion resumes. If severe dehydration has been corrected, give additional fluids subcutaneously until the IV drip can be restarted the next day.

Drip Rate

- The rate of infusion for the total 24-hour volume of fluid should be specified as to the required number of milliliters per hour and the number of drops per minute to ensure accurate delivery of prescribed fluids.
- IV administration sets are available in standard "macrodrip" volumes of 10, 15, or 20 drops/ml. Pediatric administration sets also are available in the "microdrip" volume of 60 drops/ml. Patient size and volume of fluid to be infused determine the choice between the microdrip and the macrodrip systems.
- The microdrip administration set is most suitable for cats and small dogs because it allows easier quantitation of small volumes of fluid for infusion.
- For small dogs and cats, consider the use of a Buretrol (Baxter Healthcare) or a similar device to accurately premeasure the volume of fluid to be administered. Fluids from the reservoir bag are then periodically used to reload the Buretrol device. The use of such a device minimizes the chances of overhydration because it allows controlled and accurate delivery of small volumes.
- Commercially available devices (Control-A-Flow; Baxter Healthcare) can also be used to limit gravitational flow to relatively accurate flow rates.
- Once the drip set has been adjusted to the desired rate, mark the IV bottle or bag with adhesive tape to monitor the hourly volume of fluids received. Disruptions of flow can be detected in this way to ensure that the desired volume of fluid is being administered over the desired timeframe.
- The rate of IV fluid infusion is important when considering fluids that have been supplemented with any additive or medication. Accuracy is enhanced by using infusion pumps or syringe pumps (see below).

"Ins and Outs"

- In hydrated animals with either severe oliguria or polyuria, measurement of urine output may be helpful for accurately matching the needs of the animal to the fluid therapy ("ins and outs"). Without

this technique, there is a tendency to overestimate the actual fluid needs in an oliguric animal (resulting in overhydration) and to underestimate the fluid needs in an animal undergoing extensive diuresis (resulting in failure to correct dehydration).

- Choose an observation interval (every 1–8 hours) and begin quantifying urine production. At the end of the first interval, a new fluid rate is calculated that will include the insensible losses for the upcoming interval (22 ml/kg divided by the observation interval) and the measured sensible (urine) losses from the previous observation interval. For example, a 10-kg dog will be placed on ins and outs every 6 hours. In the previous 6-hour period, 120 ml of urine was produced. The fluid amount to be given over the next 6 hours will be 120 cc plus insensible loss ($\{10 \times 22 = 37/6\}$ ml) to equal 157 ml of fluid.
- This type of close attention to fluid volume administration is of benefit in the initial management of critically ill animals, particularly when CVP and renal status are uncertain.
- Remember that with this technique the volume of fluid administered (ins) will exceed the volume of fluid (urine) that is measured (outs) by the daily insensible needs. If the patient is rehydrated, your calculations are accurate, and no other source of fluid loss exists, then the patient's weight should remain static.

Infusion Pumps

Infusion pumps provide an extremely accurate means of administering IV fluids.

- Enter ml/hr or drops/min depending on the type of machine.
- Most are equipped with an alarm system that indicates if fluid flow is interrupted.
- New pumps are expensive (refurbished, used machines may be surprisingly affordable).
- These pumps are especially useful for small dogs, cats, and animals receiving fluids supplemented with potassium or other agents.

Syringe Pumps

Syringe pumps provide an extremely accurate method of administering small volumes of medication or fluid into a patient's IV drip or directly into the IV catheter.

- Sophisticated machines exist that allow complex dosages (such as µg/kg/min) to be easily programmed.
- Drug administration errors because of mathematical error can thus be eliminated, and rapid changes to new dosing rates are easily and accurately accomplished.
- Most machines allow extremely accurate dosing of very small volumes (0.1–0.01 ml).
- Refurbished machines are becoming more widely available, making them cost effective for many practices.

MONITORING EFFICACY OF FLUID THERAPY

Perform a physical examination several times daily during the initial fluid management to document rehydration, prevent overhydration, and detect contemporary fluid loss. The indicators of successful fluid therapy are normalization of skin turgor, moistening of mucous membranes, strengthening of pulses, increased perfusion (decreased refill time), and increased alertness. Table 5-9 provides guidelines to assess the success of fluid therapy, and Table 5-10 lists possible reasons dehydration has not been adequately corrected.

Body Weight

- Increased body weight should occur during successful rehydration. An acute gain or loss of 1 kg suggests an increase or decrease of 1000 ml of body water (1 lb = 500 ml).

Table 5-9. DATA BASES TO EVALUATE EFFICACY OF FLUID THERAPY

	Minimum (Mildly Ill/Dehydrated)	Extended (Severe Dehydration/Collapse)	Advanced (Shock/Oliguria/ Heart Failure)
Body Weight	✓	✓	✓
PCV/TPP	✓	✓	✓
Urine Specific Gravity	✓	✓	✓
Electrolytes (Na, K, Cl)		✓	✓
Bicarbonate (Total CO_2)		✓	✓
Electrocardiogram		✓	✓
Blood Gas (ven ± art)			✓
Lactate			✓
Central Venous Pressure (CVP)			✓
Ionized Calcium (Ca)/Magnesium (Mg)			✓

Na, Sodium; K, potassium; Cl, Chloride.

Table 5-10. REASONS FOR FAILURE TO CORRECT DEHYDRATION ADEQUATELY

1. Calculation and mathematical error
2. Error in assessment of initial degree of dehydration
3. Larger contemporary losses than expected
4. Too-rapid infusion resulting in diuresis and loss of fluid from body
5. Mechanical catheter problems, calculated volume not infused
6. Increased sensible loss not appreciated (fever, panting)
7. Increased sensible loss not appreciated (polyuria)

- An anorexic animal, however, loses 0.1 to 0.3 kg of its body weight per day per 1000 calories of daily caloric requirement owing to tissue catabolism. Measure and record body weight accurately at least once daily.

Packed Cell Volume and Plasma Protein

- Follow PCV and TPP serially during fluid therapy. Decreases in both PCV and TPP suggest successful intravascular rehydration (see Table 5-4).

Central Venous Pressure

- In difficult cases (particularly those with renal or heart failure), monitor CVP to minimize chances of overloading the heart and causing pulmonary edema when administering fluids rapidly.
- Monitor CVP with a jugular catheter, the tip of which is in the cranial vena cava or near the right atrium. Normal CVP is 0 to 5 cm H_2O.
- A sudden increase in CVP during fluid therapy indicates the inability of the cardiovascular system to accommodate the rate of fluid administration. Reduce the rate of administration accordingly.
- A persistent increase in CVP following administration of a fluid challenge indicates adequate volume expansion of the patient. Patients with mild or moderate degrees of hypovolemia will have a rapid return to baseline CVP following fluid challenge.
- Signs of overhydration, unfortunately, can still occur even without a change in CVP.

Electrolyte and Acid-Base Status

- Closely monitor all animals receiving fluid therapy. Determine serial serum electrolyte values and acid-base status in severely dehydrated animals receiving fluid therapy at least every 12 to 24 hours. Ideally, animals that had serum electrolyte deficiency or excess or severe acid-base disturbances will show improvement toward normal values after appropriate therapy.
- Follow electrolyte determinations and acid-base status in those cases that had initially normal values to detect the possible consequences of volume expansion and changes in the underlying disease process.

▼ ***Key Point*** Successful fluid therapy ultimately depends on the clinician's ability to detect and correct the underlying cause for the loss of fluid and loss or retention of electrolytes. Identifying and stopping ongoing fluid losses is particularly important.

OVERHYDRATION

Overhydration rarely occurs as a spontaneous disorder; it usually is iatrogenic following fluid therapy. Inability to excrete free water, which can occur in a variety of renal and liver diseases and in congestive heart failure, predisposes a patient to overhydration.

Clinical Signs

- Body weight increases above and beyond that expected to accomplish rehydration.
- CVP is persistently elevated or increases suddenly.
- Increased volume and/or frequency of urinations may be noticed as the patient attempts to rid the body of excess water, but the volume excreted may not be sufficient to prevent overhydration.
- A gelatinous feel to the subcutaneous tissues may precede the development of obvious peripheral edema.
- Pulmonary edema, manifested as lung crackles and tachypnea, may be detected.
- Vomiting, diarrhea, serous discharge from the nose and eyes, and chemosis can develop.
- Venous overdistension may also be noted.

Laboratory and Radiographic Findings

- Progressive decreases in PCV and total protein may be measured (see Table 5-4).
- Radiographs may reveal increased lung density compatible with pulmonary edema; cardiac enlargement or pulmonary venous distension may be noted if congestive heart failure is imminent.

Treatment

- Immediate correction may be difficult when renal or cardiac function is impaired.
- Discontinue all IV infusions, and give furosemide from 2 to 4 mg/kg IV. Give another dose of furosemide (4–8 mg/kg IV) if no diuresis is seen within 15 minutes.
- Morphine may be considered as a treatment to increase compliance of pulmonary vessels.

Chapter 6

Pain Management in the Surgical Patient

Richard M. Bednarski

Like anesthesia, the perioperative assessment of pain and the provision of analgesia have become an integral part of companion animal medicine. Regardless of the type of medical or surgical procedure performed, pain management must be considered a part of the perianesthetic drug plan.

▼ ***Key Point*** The keys to developing a successful perianesthetic analgesia plan include (1) understanding basic concepts of pain transmission and modulation; (2) recognizing and differentiating the signs of pain; (3) gaining a working knowledge of the pharmacology of analgesic drugs and techniques associated with their use; and (4) knowing how to integrate these drugs and techniques into a perianesthetic plan.

A multimodal approach to analgesia is generally more effective than reliance on a single drug or technique. One or multiple sites in the anatomic pain pathway are targeted. A multimodal approach involves choosing more than one drug or technique from the available categories of analgesic drugs. These are opioid analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), local anesthetics, alpha-2 agonists, and dissociative N-methyl-D-aspartate (NMDA) receptor antagonists. Several texts describe in detail the pharmacology and techniques associated with these drugs (see "Supplemental Reading"). This chapter suggests some perioperative analgesic protocols and techniques that can be used commonly in small animal practice.

DEFINITIONS

- *Pain:* Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. The inability to communicate in no way negates the possibility that an individual is experiencing pain and is in need of appropriate pain relieving treatment.
- *Nociceptor:* Specialized sensory nerve endings that respond to the mediators of tissue damage. These mediators are mechanical, thermal, and chemical.
- *Nociception:* The sensing and ascending neural transmission of a noxious stimulus. Nociception that is centrally processed can be interpreted as pain.
- *Somatic pain:* Pain caused by activation of nociceptors within the skin and musculoskeletal tissue. This is usually described in people as sharp and localized when associated with superficial tissue and dull or aching when associated with deeper tissues.
- *Visceral pain:* Pain that is poorly localized and described by people as a pressure-like or squeezing sensation. It is associated with activation of nociceptors within a body cavity.
- *Neuropathic pain:* Pain related to nervous system damage. This is usually described in people as a burning sensation.
- *Acute versus chronic pain:* Acute pain is the normal response to an inciting stimulus, such as the pain resulting from surgical stimulation, trauma, or thermal injury. Perioperative analgesic plans are formulated to minimize this type of pain. Chronic pain persists longer than that associated with healing of an acute condition or that associated with a malingering condition. Perianesthetic analgesia can temporarily alleviate this type of pain.
- *Preemptive analgesia:* The concept of administering analgesic drugs to prevent central sensitization of pain pathways (see below). Often erroneously referred to as simply administering analgesics preoperatively.

PAIN PATHWAYS

- *Transduction:* Tissue injury releases chemical mediators (prostaglandins, histamine, and cytokines) that can activate nociceptors. Continued nociceptive stimulation sensitizes the nociceptors (peripheral nociceptive sensitivity), resulting in hyperalgesia (increased response to a painful stimulus) and allodynia (pain from a normally non-painful stimulus) localized to the area of insult.

▼ ***Key Point*** NSAIDs and local anesthetics can block or modify transduction. Preventing or reducing

nociception prior to applying the inciting stimulus can reduce pain perception. This is the concept behind preemptive analgesia.

- *Transmission:* Nociceptive signals are transmitted to the spinal cord by primary afferent A-delta or C fibers. The thinly myelinated A-delta fibers conduct rapidly and are responsible for rapid reflex responses such as limb withdrawal from the inciting stimulus. The non-myelinated C fibers conduct more slowly. Cell bodies of these fibers are located in the spinal cord dorsal horn. Axons from these neurons synapse in the superficial layers of the spinal cord dorsal horn. Activated dorsal horn neurons send their impulses toward the brain via ascending spinal tracts. Interneurons located within the dorsal horn can modify the nociceptive signals via the release of endogenous opioids. Continued C-fiber dorsal horn stimulation increases sensitivity of these neurons to nociceptive stimulation (central sensitization), resulting in allodynia in anatomic areas adjoining the area of initial insult. This central sensitization is referred to as "wind-up."
- *Perception:* Ascending nociceptive transmission results in perception or awareness of pain in some part of the body. Cortical and limbic systems of the brain are involved. This evokes the autonomic and affective behavioral aspect of pain.
- *Modulation:* Descending inhibitory signals from the brain act in the dorsal horn to modify nociceptive signals via opioids, norepinephrine, serotonin, and γ-aminobutyric acid (GABA).

▼ ***Key Point*** Opioid analgesics, alpha-2 agonists, GABA-mimetic drugs, and NMDA-receptor antagonists can modify nociception within the spinal cord dorsal horn.

PAIN ASSESSMENT

- Pain is an individual experience and can be difficult to quantitate given the diversity of species, breeds, and individual temperament.
- Pain-related behaviors such as vocalizing, guarding, lameness, and trembling are easily recognized. However some animals, particularly cats, will not develop these "obvious" signs (Table 6-1). Furthermore, vocalization can be a manifestation of emergence from anesthesia, breed or individual temperament, or opioid induced dysphoria.
- As yet, no one blood chemical value specifically relates to pain. Plasma glucose, cortisol, catecholamine, and endorphin concentrations are not specific for pain.
- Changes in physiologic variables such as heart rate, blood pressure, and respiratory rate are nonspecific for pain and can change in response to anesthetic recovery.
- In addition to recognizing the commonly perceived signs of pain, anticipating pain related to a type of procedure facilitates preemptive treatment (Table 6-2). In general, the greater the degree of tissue trauma related to a surgical procedure, the greater the pain. The degree of tissue trauma also relates to the surgeon's experience and skill as well as the duration of the procedure.

Table 6-1. SIGNS OF PAIN

Behavioral Signs
Vocalization
Withdrawal, avoidance, fear, and fear biting
Unwillingness to move
Refusal to lie down, sleep, or groom
Refusal to bear weight
Guarding
Trembling
Licking or mutilation of site
Withdrawal to the back of the cage or enclosure
Refusal to eat
Physiologic Signs
Tachycardia
Tachypnea
Bradypnea
Mydriasis
Ptyalism

PAIN SCORING SYSTEM

- Use a pain scoring system when assessing pain. A standardized scoring system minimizes person-to-person inconsistency in evaluation. A pain scoring system minimizes observer bias based on breed characteristics.
- Scoring systems range from extensive to simple and take into account combinations of physiologic, behavioral, and neurochemical responses. A simplified scoring system that relies on observation of behavior can be performed quickly (Table 6-3).

Table 6-2. PROCEDURES ASSOCIATED WITH SIGNIFICANT PAIN

Amputation, particularly of proximal limb
Fracture repair, particularly of proximal limb
Extensive soft tissue resections*
Total ear canal ablation
Thoracotomy, particularly median sternotomy
Onychectomy
Sectioning and extraction of large teeth
Extensive open abdomen procedures

*Generally significant tissue mass resection and severing of major nerve trunks result in relatively greater pain response.

Table 6-3. SIMPLIFIED PAIN SCORING SYSTEM

Reaction to Gently Probing of Wound While Animal Is Awake	
No response	0
Looks at wounded area, may slightly withdraw affected area	1
Turns toward wounded area, withdrawal of affected area, some vocalization	2
Dramatic response such as violent withdrawal, loud vocalization	3
Comfort	
Asleep, calm and resting quietly	0
Refusal to lie down or assume normal posture but willing to approach when coaxed	1
Severe vocalizing, thrashing, extreme guarding of affected area, withdrawn and motionless, unresponsive to coaxing	2
Physiologic Responses	
Normally expected postoperative changes in heart rate and respiratory rate	0
Tachycardia, tachypnea not explainable by other physiologic causes (dehydration, stress, hypoxemia, etc.), dilated pupils	2
Respiratory Pattern	
Normal	0
Guarded, mild abdominal	1
Marked abdominal	2
Observation and scoring must be influenced by observation of behavior prior to induction of painful stimulus	
Minimum score (no pain)	= 0
Maximum score (maximum pain)	= 9
Any score other than zero warrants consideration of analgesic therapy, with higher scores suggesting more potent and multimodal therapy	

- Regardless of the pain score, use common sense. If a given procedure would cause you pain, then administer perioperative analgesic therapy. If you think the animal is experiencing pain, administer analgesia.

ANALGESIC DRUGS AND TECHNIQUES

(Tables 6-4 to 6-8)

General Principles

- Consider preemptive analgesia as a part of every anesthetic plan.
- Consider multimodal analgesic therapy with some combination of opioid, NSAID, local anesthetic, NMDA-receptor antagonist, and alpha-2 agonist for more painful procedures (see Table 6-2) or for animals with higher pain scores.
- Analgesic drugs and techniques are compatible with general anesthesia. As with anesthetic drugs, their selection should be influenced by preoperative patient status (see Chapter 2).
- Assess postoperative pain using a pain scoring system (see Table 6-3) and treat for pain whenever indicated.
- Do not rely on drugs used to induce and maintain anesthesia (propofol, thiopental, isoflurane, or sevoflurane) to provide preemptive analgesia or postoperative control of pain.

Opioid Agonists

Opioid agonists (e.g., morphine, hydromorphone, fentanyl, oxymorphone, and meperidine) are generally considered the most potent analgesics for treating acute pain. Opioids are controlled substances and are subject to state and federal regulations.

Duration of Action

- Morphine, hydromorphone, and oxymorphone provide 4 to 6 hours of analgesia.
- Meperidine is relatively short acting (less than 1 hour), so it must be re-dosed more frequently than the other opioid agonists.
- Fentanyl is very potent but short acting (15–20 minutes). It is most suitably administered by continuous intravenous (IV) administration or a transdermal patch.

Administration

- Opioids combine well with acepromazine, alpha-2 agonists, and benzodiazepines for preoperative sedation and preemptive analgesia.
- They are most often administered parenterally as discrete boluses or they can be administered by infusion. Preservative free morphine is useful for epidural analgesia.
- Cats are more sensitive to opioid-induced dysphoria; give relatively low doses.

Side Effects

- Bradycardia is the most common cardiovascular side effect. Respiratory depression can occur during general anesthesia but is not generally an issue in awake animals.
- Prolonged opioid administration (days) can result in urinary retention and the need to periodically express the bladder or insert a urinary catheter.
- Opioids can induce dysphoric behavior (vocalizing and pacing) that can be confused with pain behavior. Opioid-induced dysphoria can be treated using small incremental boluses of naloxone (1–2 μg/kg), an opioid antagonist.

Opioid Agonist-Antagonist (Butorphanol) and Partial Agonist (Buprenorphine)

These two drugs are generally considered less potent analgesics than the opioid agonists. They are controlled substances and are subject to state and federal regulations.

Duration of Action

- Butorphanol lasts up to 2 hours in a cat but less than 1 hour in a dog.
- Buprenorphine is effective up to 8 hours. Onset of action is relatively slow (30 minutes), so it is not useful for immediate pain relief.

Table 6-4. OPIOID DRUGS FOR TREATING PAIN IN DOGS AND CATS

Drug	Dog Dose (mg/kg) (IV, IM, SC)	Cat Dose (mg/kg) (IV IM, SC)	Duration of Action (hr)	Comments	DEA Schedule
Morphine	0.2–1.0	0.1–0.2	2–4 in dogs 4–5 in cats	Histamine release possible with large IV bolus dose; CRI*: 0.1–0.3 mg/kg/hr; Epidurally†: 0.1 mg/kg preservative free product	II
Hydromorphone	0.1–0.2	0.1–0.2	2–4 in dogs 4–5 in cats		II
Oxymorphone	0.05–0.1	0.05–0.1	2–4		II
Fentanyl	0.004–0.008	0.002–0.004	<20 min	CRI*: 2–6 µg/kg/hr	II
Fentanyl Transdermal patch	25 µg/kg/hr in small dogs; 50 µg/kg/hr in medium dogs; 75 µg/kg/hr in large dogs; 100 µg/kg/hr in giant breeds	25 µg/kg/hr size	3–4 days	At least 6–12 hr (cat) and 18 hr (dog) to reach therapeutic concentrations	
Meperidine	2–5	2–5	0.5–1.0	Do not administer IV due to histamine release	II
Butorphanol	0.1–0.4	0.1–0.4	<1 in dogs; ≤2 in cats		IV
Buprenorphine	0.005–0.02	0.005–0.02	6–8	Useful orally in cats bid–tid; Epidurally†: 5 µg/kg	V
Pentazocine	2–3	1–2	≤2	Higher doses provide ≤2 hr	IV

*CRI, constant rate infusion; usually preceded by a bolus dose to rapidly achieve therapeutic plasma concentration. Use lower end of infusion rate in cats.
†Duration of action after epidural use is up to 24 hours for morphine and buprenorphine.

Table 6-5. OTHER SEDATIVE AND ANESTHETIC DRUGS FOR TREATING PAIN IN DOGS AND CATS

Drug	Dog Dose	Cat Dose	Duration of Action	Comments	DEA Schedule
Ketamine	CRI*: 2–10 µg/kg/min	CRI*: 2–10 µg/kg/min	Duration of infusion	Subanesthetic dose, useful as analgesic adjunct when given with other analgesics Epidurally: 2 mg/kg diluted in sterile 0.9% NaCl; 1 ml/4.5 kg body weight	III
Xylazine	0.1–0.2 mg/kg IV, IM	0.1–0.2 mg/kg IV, IM	<1 hr	Sedation accompanies analgesia, not recommended if cardiovascular compromise present	—
Medetomidine	2–10 µg/kg IV, IM	10–20 µg/kg IV, IM	1–2 hr	Sedation accompanies analgesia, not recommended if cardiovascular compromise present	—
Morphine/lidocaine/ketamine†	CRI*: 0.2/3.0/0.6 mg/kg/hr	0.2/3.0/0.6 mg/kg/hr	Duration of infusion and several hours beyond	Useful as an adjunct to inhalation anesthesia in dogs, compatible with other perioperative analgesics and anesthetics	Morphine: II Ketamine: III

*CRI, constant rate infusion.
†To 500 ml of crystalloid, add 10 mg of morphine SO_4, 150 mg of 2% lidocaine HCl, and 30 mg of ketamine HCl. Administer at 10 ml/kg/hr intra-operatively. Concentration can be adjusted (increased) to be compatible with postoperative maintenance fluid rates.

Table 6-6. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS FOR TREATING PAIN IN DOGS AND CATS

Drug	Dog Dose (mg/kg)	Cat Dose (mg/kg)
Aspirin	10–22 PO bid	10 PO q 48 hr
Carprofen	2 PO, SC, bid or 4 PO, SC, sid	4 one time only
Deracoxib	3–4 PO sid for ≤7 days	Not recommended
Etodolac	10–15 mg PO sid	Not recommended
Ketoprofen	2 PO, SC, initially followed by 1 PO daily	2 PO, SC, initially followed by 0.5–1.0 PO, SC
Meloxicam	0.2 PO, SC, initially followed by 0.1 daily for 2–3 days	0.3 SC, one time only
Naproxen	1.2–2.2 PO q 1–2 days	Not recommended
Tepoxalin	10–20 PO first day followed by 10 PO sid subsequent days'	Not recommended
Firocoxib	5 PO, sid	Not recommended

Administration

- Buprenorphine is effective and well accepted orally in cats. It is useful for "at home" administration.
- Buprenorphine can be used epidurally (see Table 6-4).

Side Effects

- Side effects are similar to those listed for opioid agonists.

Alpha-2 Agonists (Xylazine, Medetomidine)

Medetomidine and xylazine produce dose related analgesia for mild to severe pain. Analgesia is accompanied by a dose dependent sedation; it can be difficult to separate analgesia from sedation.

Table 6-7. LOCAL ANESTHETIC DRUGS

Drug	Duration of Action (hr)	Constant Rate Infusion (µg/kg/min)*	Nerve Block or Local Infiltration (mg/kg)†	Epidural (mg/kg)
Lidocaine	1	20–60	1–2	4
Bupivacaine	2–6	—	1–2	1–2
Ropivacaine	2–6	—	1–2	1–2

*Not recommended for use in cats because of cardiovascular depression.
†Includes maxillary and mandibular nerve blocks; nerve blocks for onychectomy; splash blocks; intercostal nerve blocks; and incisional line blocks.

Table 6-8. SAMPLE PAIN TREATMENT PROTOCOLS*

Example	Drug(s)	Comments
Ovariohysterectomy, castration, cystotomy, exploratory laparotomy or any elective surgical procedure with minimum to moderate tissue trauma	Parenteral opioid and or alpha-2 agonist as part of preanesthetic regimen; NSAID immediately pre- or post-surgery. For cats, oral buprenorphine continued for 1–3 days post-surgery	Any opioid listed in Table 6-4 is acceptable as long as attention is given to dosing interval. For onychectomy, also perform local nerve block of feet. Continue analgesic support for at least 24 hours post-surgery.
Fractures and severe soft tissue trauma†	Parenteral opioid agonist as part of the premedication plus one or more of the following: epidural opioid for rear limb fractures, abdominal procedures, and perineal surgery; local anesthetic nerve blocks for maxillectomy, mandibulectomy, or thoracotomy; Fentanyl patch applied 12–18 hours preoperatively; CRI‡ of morphine, fentanyl, lidocaine, or ketamine; CRI of a morphine, lidocaine, and ketamine combination.	Maximum analgesia is needed. Combinations involving several categories (multimodal) are most useful. For example, preoperative opioid pre-med with an epidural opioid, CRI opioid, or opioid combination. Continue postoperative analgesia for at least 48–72 hours.
Arthritis	NSAID	Use only if normal liver and kidney function are present. Follow manufacturer's recommendations for pre- and post-administration patient evaluation.

*Refer to drug tables for choice of specific drugs and dosing regimens. For procedures requiring general anesthesia, these recommended drugs are given perioperatively as part of the anesthetic plan (see Chapter 2). Pain treatment protocols depend on drug availability and the availability of qualified personnel to administer controlled drugs. Depending on the pain score, additional analgesic drugs may need to be administered.
†Tissue trauma of increasing magnitude requires relatively high doses and multimodal therapy using more than one category of drug.
‡CRI, constant rate infusion.

Duration of Action

- Xylazine: Less than 1 hour
- Medetomidine: 1 to 2 hours

Administration

- IV or intramuscular (IM) (also see Chapter 2)

Side Effects

- Cardiovascular effects include hypertension, bradycardia, bradyarrhythmia, and reduced cardiac output.

Local Anesthesia

The local anesthetic techniques described below are intended to augment, not replace, general anesthesia for the surgical procedures.

Local Anesthetic Drugs

- Lidocaine, ropivacaine, bupivacaine

Duration of Action

- Bupivacaine and ropivacaine have a 4- to 8-hour duration and lidocaine has a less than 1-hour duration of action after local infiltration or regional nerve blockade.
- Onset of action is shorter with lidocaine (a few minutes) than with ropivacaine or bupivacaine (30 minutes).

Administration

- Local anesthetic drugs are used for local tissue infiltration, regional nerve blockade, epidural administration, or intravenous infusion.
- Local infiltration or regional nerve blockade results in sensory and motor blockage.
- Lidocaine can be administered by intravenous infusion in dogs to treat mild to moderate pain.

Local Anesthesia for Onychectomy

See Chapter 114.

Nerve Blocked

- Br. of median, ulnar, radial.

Area Blocked

- Digits

Technique

Use ropivacaine or bupivacaine; note that both of these drugs are commercially available in varying concentrations. It is important to use the least concentrated formulation (0.2% for bupivacaine or 0.25% for ropivacaine) to provide sufficient volume for the block.

- Dose = 1 to 2 mg/kg. Approximately 1.5 ml per leg per 3-kg cat. This volume would be further divided if the procedure is performed on four limbs.
- Infiltration using a 25-gauge needle is just proximal to carpus and deep to the flexor tendons (palmar) and extensor tendons (dorsal).

Anesthesia of Mandible

For mandibular biopsy, mandibulectomy, and dental procedures, see Chapters 99 and 64.

Nerve Blocked

- Inferior alveolar branch of the mandibular nerve

Technique

- Insert a needle approximately 1 cm rostral to the angular process (caudal edge) of mandible against the medial surface to mandibular foramen.
- Inject 1 to 2 ml of 0.2% ropivacaine or 0.25% bupivacaine (less in cats).

Anesthesia of Upper Jaw

For maxillary biopsy, maxillectomy, and dental procedures, see Chapters 99 and 64.

Nerve Blocked

- Maxillary nerve deep at vertical portion of palatine bone

Area Blocked

- Maxilla and associated teeth

Technique

- Insert a 1- or 1.5-inch needle ventral to the zygomatic process and anterior to the ramus of the mandible.
- The needle is advanced until it contacts the palatine bone.
- Inject 1 to 2 ml of 0.2 % ropivacaine or 0.25% bupivacaine.

Intercostal Nerve Block

For thoracotomy, see Chapter 167.

Nerves Blocked

- Intercostal nerves proximally and at the caudal edge of the ribs

Area Blocked

- Chest wall

Technique

- Two intercostal spaces cranial to and two caudal to and including the space receiving the surgical incision

- Ropivacaine (0.2%) or bupivacaine (0.25%); 1 to 2 mg/kg divided among the five intercostal spaces

Epidural Anesthesia or Analgesia

For surgery of the caudal abdomen, tail, perineum, or anus.

- Opioids, local anesthetics, alpha-2 agonists, and ketamine have all been injected into the epidural space for analgesia (see Tables 6-4, 6-5, and 6-7).
- Local anesthetics produce a dose related sensory and motor blockade (epidural anesthesia).
- Opioids, alpha-2 agonists, or ketamine induce dose-related analgesia with minimal motor blockade (epidural analgesia).

Area Blocked

- Caudal abdomen, tail, perineum, and anus

Anatomy and Landmarks

- The lumbo-sacral space is located on the midline on a line drawn between the left and the right cranial-dorsal iliac spines.
- Palpate the spinous process of vertebrae L7 and the median sacral crest. The space is located midway between these structures.
- The spinal cord ends at L7 in the dog and between L7 and S1 in the cat.

Technique

- Position the animal in lateral or sternal recumbency.
- Clip hair and do an aseptic preparation. Surgical gloves should be worn when performing the procedure.
- A 22-gauge, 1- to 3-inch spinal needle is inserted on the midline. Advance the needle through the yellow ligament until a sudden loss of resistance is felt as the needle enters the epidural space. Depth of insertion will vary from 0.5 cm in a cat to 7 cm in a large-breed or obese dog.
- Slowly inject and withdraw the needle.
- The appropriate dose (mg/kg) is delivered in a 1 ml/4.5 kg volume.

Lidocaine Constant Rate (IV) Infusion

- Can be used as an adjunct to other analgesic therapy.
- Better for soft tissue pain rather than orthopedic.
- Dosage = 20 to 60 µg/kg/min, IV
- Begin with mid-range dosage for dogs. Cats may develop cardiovascular depression from lidocaine infusion.

Nonsteroidal Anti-inflammatory Drugs

These drugs traditionally have been used to treat chronic pain and to reduce inflammation as a result of their inhibition of the cyclooxygenase (Cox) 1 and 2 enzymes. Cox 1 is the normally present constitutive enzyme, and Cox 2 is induced during inflammation. Both enzymes may be involved in normal renal function.

- They potentiate the action of opioid analgesics.
- Injectable NSAIDs can be administered immediately before or after surgery. Oral NSAIDs can be prescribed postoperatively. NSAIDs do not produce sedation.
- They can cause gastrointestinal ulceration, liver, and kidney damage, and they should be used cautiously if at all in animals with hypotension, gastrointestinal, or renal disease.
- Do not use NSAIDs with corticosteroids.

Vaccination Guidelines for the Dog and Cat

Richard B. Ford

Proposed changes in vaccination protocols for companion animals, the safety of licensed vaccines, and advances in vaccine technology are among the most important issues practicing veterinarians face as we enter the 21st Century. While many would argue that these are already issues, the future promises to be especially challenging as the vaccines we use and the protocols we recommend undergo unprecedented change.

HISTORICAL BACKGROUND

Prior to 1998, vaccination recommendations were limited to the Compendium of Animal Rabies Prevention and Control, published annually by the National Association of State Public Health Veterinarians (at www.nasphv.org). In 1998, the American Association of Feline Practitioners (AAFP) published the first report of an Advisory Panel on Feline Vaccines recommending that *adult* cats be vaccinated every 3 years, rather than annually, against *feline parvovirus* (panleukopenia). Reaction to this report was profound. Veterinarians throughout North America voiced concerns that anything other than annual vaccination of adult cats against panleukopenia was inappropriate, irrational, and quite possibly detrimental to the health of the cat population. In December of 2000, the same Advisory Panel published a second iteration of the Guidelines for Feline Vaccination. In that report, the Panel expanded the "every 3 year" booster recommendation to include feline herpesvirus-1, feline calicivirus, and panleukopenia.

Then, in March 2003, the American Animal Hospital Association (AAHA) Canine Vaccine Task Force released its Guidelines on canine vaccination. In that document, 3-year booster intervals in adult dogs are recommended for distemper, parvovirus, adenovirus-2, and parainfluenza virus.

In 2004, some vaccine manufacturers announced results of challenge studies verifying the ability of their canine distemper, parvovirus, and adenovirus-2 combination vaccines to protect dogs against virulent challenge, thereby validating the recommendations outlined in the canine vaccination guidelines.

FUTURE VACCINATION ISSUES

It is important to remember, however, that despite the controversy over 3-year booster intervals for some vaccines, there are several strategic issues justifying the need for veterinarians to reassess recommendations for the selection and use of vaccines. Included among these issues are vaccine safety profiles, profound variation in exposure risk of individual dogs and cats, and changes in vaccine technology (e.g., recombinant vaccines). These issues will take on even more importance in the future as new vaccines continue to be introduced and as more veterinarians question the need for and safety of these products.

The introduction of so many vaccines in the past 10 years, and the promise of more to come, justify the need for the veterinary profession to critically address which

vaccines are administered to which patients and at which stage of life.

▼ ***Key Point*** To merely accept any and all newly licensed vaccines as part of an annual protocol for all patients is, quite simply, *wrong*.

THE VACCINE GUIDELINES

First, and most importantly, the published Canine and Feline Vaccination Guidelines do *not* represent vaccination *standards*. The Guidelines were never intended to be used as a set of enforceable requirements against which all practices would be held accountable. They are merely *guidelines*. However, the published guidelines are becoming templates for the standard of care appropriate to vaccination practices in the United States. For that reason alone, they are worth reading.

▼ ***Key Point*** Current editions of both the Canine and Feline Vaccination Guidelines and updates on new vaccines can be reviewed at www.dvmvac.com.

Secondly, the Canine and Feline Vaccination Guidelines *do* ***not*** *represent a vaccination protocol*. Attempting to use the Guidelines as *a defined protocol* in practice would be frustrating. Instead, the Guidelines serve as a tool for clinicians to use in developing a rational vaccination protocol appropriate for the individual patient. Vaccine selection and use in veterinary medicine remain the responsibility of the individual practitioner.

CORE VERSUS NON-CORE VACCINES

Canine and Feline Vaccination Guidelines are developed around the concept of **Core** and **Non-Core** vaccines. It is important to understand that Vaccination Guidelines merely suggest, *they do not mandate,* which vaccines should be Core or Non-Core. However, it is in the interest of the individual practice to establish which vaccines meet the definition of Core, then ensure that information is communicated to *all* professional staff, technicians, and office staff, thereby assuring consistent, clear communication to clients.

Core Vaccines

Core vaccines are those vaccines recommended for administration to every dog or cat presented to the practice. Recommendations for designating a particular vaccine as **Core** are determined by: (1) severity of disease caused by the agent, (2) the risk of transmission of the agent to susceptible animals, and (3) the potential for a particular infection to be zoonotic.

Non-Core Vaccines

Non-Core vaccines, on the other hand, are those vaccines recommended for administration to a dog or cat that has a reasonable risk of exposure to a known infectious agent. Examples include the feline leukemia virus (FeLV) and canine Lyme borreliosis (*Borrelia burgdorferi*) vaccines.

DURATION OF IMMUNITY

Perhaps one of the greatest paradigms challenged by the publication of Canine and Feline Vaccination Guidelines is the time-honored "annual booster recommendation." Recommendations that some vaccines can be administered 3 years (or more) apart without reduction in protective immunity have not been universally accepted. However, the fact remains that over the last decade, the quality of companion animal vaccines has improved. Recent studies have clearly shown that the duration of immunity for many, although not all, canine and feline vaccines is well beyond 1 year. Clearly there is a growing body of data that validates triennial booster vaccination in adult dogs and cats for those vaccines listed in the guidelines as "Core." However, some vaccines (e.g., *Bordetella bronchiseptica,* leptospirosis*, and Chlamydophila felis* vaccines*)* may *not* consistently provide a 1-year duration of immunity, despite a product label (package insert) stipulating "annual booster recommended."

ANNUALIZED VACCINATION PROTOCOLS

The fact that the Canine and Feline Vaccination Guidelines recommend triennial vaccination for certain vaccines in no way stipulates that adult dogs and cats should *only* be vaccinated every 3 years. In fact, annual vaccination does represent a high standard of medical care *as long as the vaccination appointment incorporates a thorough health and wellness examination.*

Considering the large population of pet dogs and cats and the remarkable spectrum of risk factors for exposure to infectious pathogens, it is quite unreasonable to assume that a single vaccination protocol would be applicable in all patients seen in practice. Two of the most important variables to consider when assessing risk are: (1) the **age of the patient**, and (2) the patient's **"lifestyle."** In implementing a vaccination protocol in clinical practice, it is critical for the clinician to consider these factors for the individual patient when recommending for, or against, Non-Core vaccines.

Tables 7-1 through 7-12 show *annualized* vaccination protocols for dogs and cats at moderate risk (applies to most), high risk, and low risk of exposure to infectious agents, while also taking into consideration the recommendations set forth in the Canine and Feline Vaccination Guidelines.

Table 7-1. ANNUALIZED VACCINATION PROTOCOL FOR DOGS AT **MODERATE RISK** OF EXPOSURE

Age at Vaccination	Vaccine
6–8 weeks	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Optional + Parainfluenza virus
10–12 weeks	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Rabies (1 dose at 12, 14, or 16 weeks of age) Optional + Parainfluenza virus + *B. bronchiseptica* (killed-parenteral, 2 doses required, 3–4 wks apart) + Leptospirosis (serovars as indicated at 12 wks or older)
14–16 weeks	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Rabies (now or at 12 wks) Optional + Parainfluenza virus + *B. bronchiseptica* (live-intranasal, 1 dose or the 2nd killed-parenteral dose) + Leptospirosis (serovars as indicated)
+1 year	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Rabies (booster required) Optional + *B. bronchiseptica* (intranasal or parenteral) + Parainfluenza + Leptospirosis (serovars as indicated)
+2 years	Optional + *B. bronchiseptica* (intranasal or parenteral) + Leptospirosis (serovars as indicated)
+3 years	Optional + *B. bronchiseptica* (intranasal or parenteral) + Leptospirosis (serovars as indicated)
+4 years	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Rabies Optional + *B. bronchiseptica* (parenteral) + Parainfluenza + Leptospirosis (serovars as indicated)
+5 years	Optional + *B. bronchiseptica* (parenteral) + Leptospirosis (serovars as indicated)
+6 years	Optional + *B. bronchiseptica* (parenteral) + Leptospirosis (serovars as indicated)
+7 years	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Rabies Optional + *B. bronchiseptica* (parenteral) + Parainfluenza + Leptospirosis (serovars as indicated)
Beyond 7 years	Cycle repeats as indicated

For any vaccine preceded by "+," see defining criteria in Table 7-2.
NOTE: All intranasal *B. bronchiseptica* vaccines also contain parainfluenza virus; some also contain canine adenovirus-2.
NOTE: In some States or municipalities, annual **rabies** vaccination may be required.

Table 7-2. DEFINING CRITERIA FOR **MODERATE-RISK** CANINES (APPLIES TO MOST DOGS)

***B. Bronchiseptica* Vaccination Is Indicated If**
Dog is ever boarded in a commercial kennel
Dog requires occasional grooming
Dog regularly has supervised walks/runs outside with likelihood of contact with other dogs

Parainfluenza* Vaccination Is Indicated If
Dog is ever boarded in a commercial kennel
Dog requires occasional grooming
Dog regularly has supervised walks/runs outside with likelihood of contact with other dogs

***Leptospira* Vaccination Is Indicated If**
The dog is 12 wks of age or older
Dog has opportunities for unsupervised outdoor activities
Cases of leptospirosis are known to have been confirmed in the area†
Dog has access (supervised or otherwise) to areas inhabited by "reservoir" hosts (e.g., opossum, skunk, raccoon, vole) or other domestic animals such as cattle, pigs, or horses

Lyme Borreliosis Vaccination Is Not Indicated Unless
Dog will travel to known endemic areas (Northeast or upper Midwest) and will spend time outside
Lyme borreliosis cases have been diagnosed (via IDEXX Snap 3Dx or Western Blot analysis) in the community
Dog is not receiving any form of topical tick preventative (e.g., fipronil)

*Note: Parainfluenza vaccine is combined with all intranasal *B. bronchiseptica vaccines.*
†Note: Risk of exposure is *not* limited to rural areas.

Table 7-3. ANNUALIZED VACCINATION PROTOCOL FOR DOGS AT **LOW RISK** OF EXPOSURE

Age at Vaccination	Vaccine	Age at Vaccination	Vaccine
6–8 weeks	Distemper (MLV or Recombinant) Parvovirus Adenovirus-2 Optional + Parainfluenza virus	+3 years	Health Examination Non-Core vaccines considered if risk assessment changes
		+4 years	Distemper (MLV or Recombinant) Parvovirus Adenovirus-2 Rabies (required in most States) Optional + Parainfluenza
10–12 weeks	Distemper (MLV or Recombinant) Parvovirus Adenovirus-2 + Rabies (1 dose at 12, 14, or 16 wks of age) Optional + Parainfluenza virus	+5 years	Health Examination Non-Core vaccines considered if risk assessment changes
14–16 weeks	Distemper (MLV or Recombinant) Parvovirus Adenovirus-2 + Rabies (now or at 12 wks) Optional + Parainfluenza virus	+6 years	Health Examination Non-Core vaccines considered if risk assessment changes
		+7 years	Distemper Parvovirus Adenovirus-2 + Rabies (required in most states) Optional + Parainfluenza
+1 year	Distemper (MLV or Recombinant) Parvovirus Adenovirus-2 Rabies (required in most states) Optional + Parainfluenza	Beyond 7 years	Cycle repeats as indicated
+2 years	Health Examination Non-Core vaccines considered if risk assessment changes		

For any vaccine preceded by "+," see defining criteria in Table 7-4.
Note: All intranasal *B. bronchiseptica* vaccines also contain parainfluenza virus; some also contain canine adenovirus-2.
Note: In some states or municipalities, annual **rabies** vaccination may be required.

Table 7-4. DEFINING CRITERIA FOR **LOW-RISK** CANINES (ONLY CORE VACCINES NEED BE ADMINISTERED)

***B. Bronchiseptica* Is Not Indicated Because**
Dog is never boarded in a commercial kennel
Grooming is not an issue
Dog lives exclusively indoors
Dog has no exposure to other dogs (or it occurs rarely)

Parainfluenza* Vaccination Is Indicated If
Dog is ever boarded in a commercial kennel
Dog requires occasional grooming
Dog regularly has supervised walks/runs outside with likelihood of contact with other dogs

***Leptospira Canicola*, *L. Icterohemmorhagiae*, *L. Pomona*, and *L. Grippotyphosa* Vaccinations Are Not Indicated Because**
There is no exposure to other dogs
There is no opportunity for unsupervised outdoor activity
The dog lives exclusively indoors
Leptospirosis is not known to occur in the area

Lyme Borreliosis Vaccination Is Not Indicated Because
Dog does not reside in a known Lyme borreliosis endemic area
Dog does not travel to known endemic areas
Dog neither lives in or travels into a known tick-vector area
Dog is reliably treated with topical flea and tick preparation
Dog has never known a tick and never will

*Note: Parainfluenza vaccine is combined with all intranasal *B. bronchiseptica* vaccines.

Table 7-5. ANNUALIZED VACCINATION PROTOCOL FOR DOGS AT **HIGH RISK** OF EXPOSURE

Age at Vaccination	Vaccine
6–8 weeks	Recombinant Distemper Parvovirus Adenovirus-2 Parainfluenza *B. bronchiseptica* (*intranasal* recommended)
10–12 weeks	Recombinant Distemper Parvovirus Adenovirus-2 Parainfluenza Rabies (at 12, 14, or 16 weeks) *B. bronchiseptica* (*intranasal* recommended) Optional + Leptospirosis + Lyme borreliosis (recombinant)
14–16 weeks	Recombinant Distemper Parvovirus Adenovirus-2 Parainfluenza *B. bronchiseptica* (*intranasal* recommended) Rabies (now or at 12 wks) Optional + Leptospirosis + Lyme borreliosis (recombinant)
+1 year	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Parainfluenza *B. bronchiseptica* (intranasal or parenteral) Rabies (required) Optional + Leptospirosis + Lyme borreliosis (recombinant)
+2 years	*B. bronchiseptica* (intranasal or parenteral) Optional + Leptospirosis + Lyme borreliosis (recombinant)
+3 years	*B. bronchiseptica* (intranasal or parenteral) Optional + Leptospirosis + Lyme borreliosis (recombinant)
+4 years	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Parainfluenza *B. bronchiseptica* (intranasal or parenteral) Rabies (required) Optional + Leptospirosis + Lyme borreliosis (recombinant)
+5 years	*B. bronchiseptica* (intranasal or parenteral) Optional: + Leptospirosis + Lyme borreliosis (recombinant)
+6 years	*B. bronchiseptica* (intranasal or parenteral) Optional: + Leptospirosis + Lyme borreliosis (recombinant)
+7 years	Distemper (MLV or recombinant) Parvovirus Adenovirus-2 Parainfluenza *B. bronchiseptica* (intranasal or parenteral) Rabies (required) Optional + Leptospirosis + Lyme borreliosis (recombinant)
Beyond 7 years	Cycle repeats as indicated

For any vaccine preceded by "+," see defining criteria in Table 7-6.
Note: All intranasal *B. bronchiseptica* vaccines also contain parainfluenza virus; some also contain canine adenovirus-2.
Note: In some states or municipalities, annual **rabies** vaccination may be required.

Table 7-6. DEFINING CRITERIA FOR **HIGH-RISK** CANINES

***B. Bronchiseptica* Booster Is Indicated If**
Dog is regularly boarded in a commercial kennel
Dog is routinely groomed at a facility where other dogs are maintained
Dog is regularly allowed outdoors and is unsupervised
Dog has regular exposure to other, unknown dogs
Dog is on a first-name basis with animal control officers

Annual *Leptospira* spp Booster Is Indicated If
Dog lives outside and is not constrained to a gated kennel
Dog lives on a farm and has ample outdoor activity
Dog is regularly allowed to roam freely
Dog lives exclusively outdoors.
Dog is used for hunting or other extended outdoor activity
Cases of leptospirosis are known to have been confirmed in the area
Dog has access (supervised or otherwise) to areas inhabited by "reservoir" hosts (e.g., opossum, skunk, raccoon, vole) or other domestic animals such as cattle, pigs, or horses

Annual Lyme Borreliosis Booster Is Indicated If
Dog resides in a known Lyme borreliosis endemic area (e.g., Northeast or upper Midwest)
Dog lives outside most or all of the time and does have tick exposure
Dog regularly travels to known endemic areas
Cases of Lyme borreliosis have been identified by serologic testing (IDEXX Snap 3Dx or Western Blot analysis) among dogs in the patient population
Dog is inconsistently treated with topical flea and tick preparation
Dog is only treated with over-the-counter tick preparations
Ticks are known to be constant companions for this dog

Table 7-7. ANNUALIZED VACCINATION PROTOCOL FOR CATS AT **MODERATE RISK** OF EXPOSURE

Age at Vaccination	Vaccine	Age at Vaccination	Vaccine
9–10 weeks	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) Optional + FeLV (recombinant, transdermal)	+4 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)
		+5 years	+ Rabies (recombinant)
12–14 weeks	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant) Optional: + FeLV (recombinant, transdermal)	+6 years	+ Rabies (recombinant)
		+7 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)
+1 year	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant) Optional + FeLV (recombinant, transdermal)	+8 years	+ Rabies (recombinant)
		+9 years	+ Rabies (recombinant)
		+10 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)
+2 years	+ Rabies (recombinant, transdermal)	Beyond 10 years	Cycle repeats as indicated
+3 years	+ Rabies (recombinant)		

For any vaccine preceded by "+," see defining criteria in Table 7-8.

Table 7-8. DEFINING CRITERIA FOR **MODERATE-RISK** FELINES (APPLIES TO MOST CATS)

FeLV Vaccine Is Indicated If

Cat lives indoors predominately, but *not* exclusively, *and*
Cat is less than 6 months of age, *and*
Cat is known to occasionally have contact with other cats of unknown health status, *or*
Other cats in the household are known to be FeLV infected, *or*
Other cats live in the household but are of unknown FeLV status, *or*
Other cats in the household are known to roam at will, *or*
Owner may bring stray cats into the household

***Bordetella Bronchiseptica* and *Chlamydophila Felis* Vaccines Are Not Indicated If**

Cat is an adult (current literature suggests that clinical *B. bronchiseptica* infections are most likely to occur in kittens), *and*
Cat does not have exposure to other cats, *and*
Any other cats in the household are known to be strictly indoor cats, *and*
Owner is unlikely to bring stray cats into the household

Rabies Vaccination in Cats

Is *not* required by many states and municipalities; however, in accordance with the Feline Vaccination Guidelines, rabies is a Core vaccine and is highly recommended for all cats.

Table 7-9. ANNUALIZED VACCINATION PROTOCOL FOR CATS AT **LOW RISK** OF EXPOSURE

Age at Vaccination	Vaccine	Age at Vaccination	Vaccine
9–10 weeks	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV)	+5 years	+ Rabies (recombinant)
		+6 years	+ Rabies (recombinant)
12–14 weeks	Panleukopenia (MLV) Herpesvirus and Calicivirus (MLV) + Rabies (recombinant)	+7 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)
+1 year	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)	+8 years	+ Rabies (recombinant)
		+9 years	+ Rabies (recombinant)
		+10 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)
+2 years	+ Rabies (recombinant)		
+3 years	+ Rabies (recombinant)		
+4 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant)	Beyond 10 years	Cycle repeats as indicated

For any vaccine preceded by "+," see defining criteria in Table 7-10.
Note: Although administration of rabies vaccine to cats may not be required by state or local statutes, it is recommended for all cats, regardless of risk.

Table 7-10. DEFINING CRITERIA FOR **LOW-RISK** FELINES (PROTOCOL CENTERS AROUND CORE VACCINES)

FeLV and FIV Vaccines Are Not Indicated If

Cat is known to be a strictly indoor cat, *and*
Any other cats in the household are known to be both FeLV and FIV-free and were tested within the last 12 months, *and*
Other cats in the household are known to be strictly indoor cats
Owner does not bring stray cats into the household

***Bordetella Bronchiseptica* and *Chlamydophila* Vaccines Are Not Indicated If**

The cat is an adult (current literature suggests that clinical *B. bronchiseptica* infections are most likely to occur in kittens), *and*
The cat does not have exposure to other cats, *and*
Any other cats in the household are known to be strictly indoor cats
Owner does not bring stray cats into the household

Rabies Vaccination in Cats

Is *not* required by many states and municipalities; however, in accordance with the Feline Vaccination Guidelines, rabies is a Core vaccine and is highly recommended for all cats.

Table 7-11. ANNUALIZED VACCINATION PROTOCOL FOR CATS AT **HIGH RISK** OF EXPOSURE

Age at Vaccination	Vaccine
9–10 weeks	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
12–14 weeks	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant) Optional + FeLV (non-adjuvanted) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+1 year	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+2 years	+ Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+3 years	+ Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+4 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (Recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+5 years	+ Rabies (Recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+6 years	+ Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+7 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+8 years	+ Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+9 years	+ Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
+10 years	Panleukopenia (MLV) Herpesvirus-1 and Calicivirus (MLV) + Rabies (recombinant) Optional + FeLV (recombinant, transdermal) + *B. bronchiseptica* + *Chlamydophila* (non-adjuvanted) + FIV
Beyond 10 years	Cycle repeats as indicated

For any vaccine preceded by "+," see defining criteria in Table 7-12.
Note: *Chlamydia psittaci* has been renamed *Chlamydophila felis* (the name on vaccine label may not reflect the new classification).

Table 7-12. DEFINING CRITERIA FOR **HIGH-RISK** FELINES

Both FeLV and FIV Vaccines Are Indicated If

Cat is known to roam at will and engage in fighting (risk of FIV in male cats is 4 times greater than in female cats), *or*
There is likely exposure to other cats with unknown health status, *or*
There are other cats in the household that are known to roam at will and engage in fighting, *or*
Owner regularly adopts (or hoards) cats

***Bordetella Bronchiseptica* and *Chlamydophila Felis* Vaccines Are Indicated If**

Cat is a kitten and resides within a cluster household (current literature suggests that clinical *B. bronchiseptica* infections are most likely to occur in kittens), *or*
Cat has regular exposure to other cats of unknown health status, *or*
There are other cats in the household known to roam at will and have contact with other cats, *or*
Owner regularly adopts (or hoards) cats

Rabies Vaccination in Cats

Is *not* required by many states and municipalities; however, in accordance with the Feline Vaccination Guidelines, rabies is a Core vaccine and is highly recommended for all cats.

Chapter 8

Feline Leukemia Virus

Robert G. Sherding

ETIOLOGY

Feline leukemia virus (FeLV) is an RNA retrovirus that is a transmitted both vertically (mother to fetus) and horizontally (cat to cat). FeLV infects cats worldwide and causes lymphoma, leukemia, bone marrow suppression, immunodeficiency, and a variety of other clinical syndromes. Fortunately, widespread testing and vaccination since the mid-1980s have resulted in a substantial decrease in the prevalence of FeLV infection.

Structure of the Virus

Certain structural components of the FeLV virion have clinical implications.

- *Core* contains the viral RNA and reverse transcriptase enzyme that allows DNA copies of the virus to be transcribed and inserted into the genome of infected host cells.
- *Core protein* (p27) is the group-specific FeLV antigen detected by conventional FeLV diagnostic tests.
- *Envelope glycoprotein* (gp70) defines the FeLV antigenic subgroup as A, B, C, or combinations of these; determines infectivity, host range, and pathogenicity; and elicits the protective host neutralizing-antibody response that occurs with natural exposure or vaccination. Only subgroup A is infectious.
- *Envelope protein* (p15e) is a mediator of FeLV-related immunodeficiency.

Prevalence

The prevalence of FeLV varies with age, health, environment, and lifestyle. Kittens less than 4 months of age are much more susceptible to infection than adults. Resistance develops with age, but even healthy adults can become infected. The prevalence of FeLV infection and related diseases, such as lymphoma, has been steadily declining over the last 2 decades because of client education, FeLV testing, and vaccination. Recent epidemiological surveys are few, and most of the older published surveys overstate the prevalence of FeLV compared with what is seen today. In the prevalence statistics below, the dates for earlier surveys are shown:

- Purebred catteries—Less 0.1% (if testing and vaccination are used)
- Healthy pet cats—Less than 1%
- Free-roaming stray and feral cats—1% to 4%
- Cats seen at U.S. teaching hospitals—2% (of 409,417 cats; 1972–1998)
- Cats tested at Tufts Laboratory—Decreased from 8% to 4% from 1989 to 1995 (of 13,000 cats)
- High-risk and clinically sick cats—13% (of 27,976 cats; 1990–1991)
- In highly endemic households with many viremic cats—30% to 70% of unvaccinated kittens compared with only 10% to 20% of unvaccinated adult cats

▼ ***Key Point*** Most purebred catteries have completely eliminated FeLV, and infection is rare in household pet cats. FeLV is most frequently found in multi-cat households that take in untested strays, especially kittens.

Transmission

▼ ***Key Point*** FeLV is contagious through prolonged close contact with infected cats. Transmission is primarily through saliva.

- Persistently viremic cats continuously shed large amounts of virus in saliva and, to a lesser extent, in naso-ocular secretions. Infected queens shed large amounts of virus in milk. Feces, urine, and fleas are less likely sources of infection.
- Transmission most often occurs through direct oronasal contact with infectious saliva during mutual grooming and sharing of food and water bowls or through bite wound inoculation of saliva.
- Transplacental transmission can occur, but milk-borne infection in nursing kittens is more common.
- Iatrogenic transmission of FeLV can occur through contaminated blood transfusions, needles, surgical and dental instruments, and endotracheal tubes.
- FeLV usually does not survive more than a few hours outside of the cat, up to a maximum of 48 hours

under optimal temperature and moisture conditions. Heat, drying, detergents, and disinfectants readily destroy FeLV.

▼ ***Key Point*** The risk of FeLV transmission is minimal in shelters and veterinary hospitals that house cats in separate cages and routinely use hand washing and disinfection procedures for cages, food and water dishes, and litter pans.

PATHOGENESIS

Sequence of FeLV Infection

The sequence of FeLV infection includes inoculation followed by replication in local lymphoid, systemic lymphoid, bone marrow, and polyglandular tissues.

- After oronasal or percutaneous inoculation, FeLV replicates in local lymphoid tissues and then in systemic lymphoid tissues throughout the body, such as lymph nodes, spleen, and thymus. Viral antigen may first become detectable in the blood (antigenemia) at this stage with enzyme-linked immunosorbent assay (ELISA) tests (see "Diagnosis"). A successful immune response may terminate the infection at this stage or even before antigenemia is detectable.
- If infection progresses, FeLV infects the bone marrow, leading to circulation of virus-infected leukocytes and platelets (cell-associated viremia) that are detectable in the blood by the immunofluorescent antibody (IFA) test (see "Diagnosis"). This usually indicates that FeLV has overwhelmed the host immune response and that the infection is likely to persist indefinitely.
- Concurrent with the development of viremia, FeLV infects glandular cells throughout the body (e.g., salivary glands, lacrimal glands, mammary glands, and mucosal epithelial glands). This leads to shedding of virus in most body secretions, with especially high concentrations of virus in saliva and the milk of lactating queens. At this stage, FeLV-infected cats are contagious to other cats in close contact, and queens can infect their nursing kittens.

Host Immune Response

Immunity to FeLV is the collective result of humoral antibody, cytotoxic T lymphocytes and other cell-mediated immune mechanisms, complement, and interferon. Humoral antibody responses have been characterized as follows:

- *Antiviral response* is mediated by neutralizing antibody directed against FeLV envelope antigens. Transient infection and recovery occur if the immune response is successful, whereas bone marrow infection and persistent viremia occur if the virus overwhelms the host immune response.
- *Antitumor response* is mediated by antibody directed against FeLV-associated antigens on the surface of FeLV-induced neoplastic cells.

Categories of Infection

The outcome of FeLV exposure depends on many factors, including viral dose and route of exposure, environmental conditions, and host factors such as the cat's age, innate immunity, vaccination status, and health status. Cats exposed to FeLV can be categorized as noninfected, persistently infected, transiently infected, or latently infected.

Cats That Resist Infection

Many cats exposed to FeLV do not get infected, either because of an inherent resistance to infection or because of insufficient exposure. The most important factor is age-related resistance in cats over 4 months of age.

Transient Infection

The majority of cats exposed to FeLV develop a transient replicating ("regressive") infection that is subsequently rejected by a vigorous immune response, resulting in a full clinical recovery.

- Transiently infected cats usually eliminate the virus swiftly within 4 to 6 weeks after exposure, with either no detectable antigenemia or a transient antigenemia lasting 1 to 5 weeks. However, FeLV-infected cats can potentially eliminate the virus at any stage, rarely even after many months or years as a persistent carrier.
- Many cats are vaccinated against FeLV, and upon exposure, most will resist persistent infection and instead go through a brief transient infection (see "Vaccination").
- Transiently infected cats frequently develop latent infection as they recover (see the next section).

Latent Infection

Non-viremic cats that "recover" from transient infection often become latent carriers of non-replicating FeLV for a variable period of time.

- In latent FeLV infection, non-replicating FeLV provirus remains dormant within the DNA genome of bone marrow and lymphoid cells of the cat. This can only be detected by specialized virus culture techniques or polymerase chain reaction (PCR) assays (see "Diagnosis"); thus, it is difficult to distinguish cats that have truly cleared the virus from cats with latent infection.

▼ ***Key Point*** Latent FeLV infection cannot be detected by conventional immunochromatographic (IC), ELISA, and IFA diagnostic tests.

- In most transiently infected cats, the latent stage of infection eventually is eliminated uneventfully within 6 to 9 months as part of the normal recovery process, but it sometimes can take a year or more. Latent infection persists indefinitely in an estimated 10% of "recovered" cats.
- The clinical significance of FeLV latency is the rare possibility of reactivation to a replicating infection, either spontaneously or in response to immunosuppression (e.g., corticosteroid-induced). In addition, reactivation of infection in latent-infected queens may rarely transmit FeLV to kittens in utero or during nursing.
- Latent infected cats have minimal risk of developing FeLV-related disease. They also have minimal risk of being contagious to other cats, except for the rare occurrences of reactivation mentioned above.

Persistent Infection

Cats with persistent or "progressive" FeLV infection have generalized lymphoid, bone marrow, and polyglandular infection with persistent cell-associated viremia and continuous shedding of virus. This widespread replicating FeLV infection persists for the remainder of the cat's life with only rare exceptions.

- Persistent infection eventually leads to fatal FeLV-related disease in most cats after a variable disease-free interval. The mortality rate in persistent FeLV-positive cats is 30% at 6 months, 60% at 2 years, and 90% at 4 years.
- Persistent infection will develop in approximately 10% to 30% of unvaccinated cats that receive continuous heavy exposure, such as living in an endemically infected household. In this situation, kittens less than 4 months of age are most susceptible, and the persistent infection rate can reach 70% in this group.
- Vaccination prevents persistent infection in many cats. Reducing the risk of exposure combined with vaccination has greatly decreased the prevalence of persistent FeLV infection.

CLINICAL DISEASE SYNDROMES

The clinical manifestations of FeLV are attributable to the oncogenic, cytopathic, and immunosuppressive effects of the virus. FeLV-induced neoplasia can be lymphoid or myeloid. Degenerative and cytopathic effects on various cells include bone marrow cells (anemia, neutropenia, thrombocytopenia), lymphocytes (T lymphocyte depletion, lymphoid atrophy, lymphoid hyperplasia), intestinal cells (enteritis), and the fetus and placenta (abortion, stillbirth). The immunosuppressive effects of FeLV cause profound immunodeficiency, resulting in susceptibility to a wide variety of opportunistic infections. In addition, FeLV-related immune dysfunction has been associated with immune-mediated and autoimmune diseases.

Nonspecific Clinical Signs

Presenting clinical signs that are common in FeLV-infected cats include weight loss, fever, dehydration, oculonasal discharge, anemia, diarrhea, stomatitis, and lymphadenopathy.

▼ ***Key Point*** The majority of FeLV-infected cats are asymptomatic at the time they are identified on routine screening tests during wellness exams.

Lymphoma and Leukemia

FeLV can be a primary cause of lymphoma, leukemia, and myelodysplasia. For additional information regarding diagnosis and treatment of these neoplastic conditions, see Chapters 26 and 27. In the mid-1970s, 70% of cats with lymphoma and leukemia were FeLV positive. Virus-negative alimentary lymphoma was uncommon. However, with the decline in prevalence of FeLV infection, FeLV-negative lymphomas now comprise 85% to 90% of the lymphomas seen in cats, and alimentary lymphoma is the predominant form. Some of these FeLV-negative lymphomas have molecular evidence of FeLV provirus, but most feline lymphomas are now caused by factors other than FeLV.

Alimentary Lymphoma

- Mesenteric lymph nodes—Palpable enlargement
- Stomach—Vomiting, anorexia, and weight loss
- Intestine—Diffuse infiltrative thickening of the intestinal wall or palpable obstructing mass (weight loss, vomiting, diarrhea, and inappetence)
- Liver—Diffuse hepatomegaly or nodular tumor masses within the liver (icterus, weight loss, vomiting, and abnormal liver tests)
- Spleen—Diffuse splenomegaly

▼ ***Key Point*** FeLV-negative alimentary lymphoma affecting middle-aged and older cats (mean age of 8 years) is now the predominant form of lymphoma in cats.

Mediastinal Lymphoma

Characterized by a cranial mediastinal mass due to lymphoma of the mediastinal lymph nodes or thymus.

- Pleural effusion (dyspnea)
- Tracheal compression (dyspnea, cough)
- Esophageal compression (dysphagia, regurgitation)
- Sympathetic trunk impingement (Horner's syndrome)
- Decreased cranial thoracic compressibility
- Mass palpable at thoracic inlet

Multicentric Lymphoma

- Generalized involvement of external and internal lymph nodes.
- Bone marrow, liver, spleen, and other extranodal sites are often affected.

Extranodal Forms of Lymphoma

Renal Lymphoma

- Signs—Nonspecific signs (early); renal failure and uremia (late)
- Kidneys palpably enlarged and nodular ("lumpy")

Ocular Lymphoma

- Retrobulbar mass—Mimics retrobulbar abscess
- Third eyelid mass—Mimics "cherry eye"
- Corneal infiltration—Mimics eosinophilic keratitis
- Uveal infiltration and hemorrhage—Mimics anterior uveitis or chorioretinitis

Neural Lymphoma

- Brain—Seizures, ataxia, blindness, behavior aberrations, motor deficits, and cranial nerve signs
- Spinal (usually extradural)—Paresis or paralysis
- Peripheral nerve—Variable neuropathies

Cutaneous Lymphoma

- Multiple firm, non-painful cutaneous nodules

Other Extranodal Sites for Lymphoma

- Nasal cavity, lung, heart, and urinary bladder.

Leukemia and Myelodysplasia

FeLV infection of bone marrow hemopoietic cells can result in acute lymphoid leukemia, non-lymphoid leukemia, or myelodysplasia (preleukemia). Clinical signs include pallor (anemia), petechial and ecchymotic hemorrhages (thrombocytopenia), fever, lethargy, weight loss, hepatosplenomegaly, and mild lymphadenopathy. Abnormal blast cells are usually identified in the blood and bone marrow. For additional information, see Chapters 22 and 27.

Acute Lymphoid Leukemia

- Acute lymphoblastic leukemia is characterized by extensive infiltration of the bone marrow with neoplastic lymphoblasts, often accompanied by neoplastic infiltration of the liver, spleen, and lymph nodes.
- The complete blood count (CBC) shows nonregenerative anemia, other cytopenias, and circulating lymphoblasts. Bone marrow cytology is diagnostic.

Acute Myeloid (Non-lymphoid) Leukemia

- This group of neoplastic diseases is characterized by the proliferation of one or more cell lines in the bone marrow at the expense and to the eventual exclusion of normal hemopoietic cells. These disorders are classified on the basis of the cellular origin of the abnormal cells as acute myeloblastic leukemia, acute myelomonocytic leukemia, acute monocytic leukemia, and erythroleukemia.
- Diffuse hepatomegaly, splenomegaly, and lymphadenopathy occur from extramedullary hematopoiesis and/or neoplastic infiltration. Neoplastic infiltration of the liver may cause jaundice.
- Anemia and thrombocytopenia are common, and the diagnosis is based on identification of neoplastic blast cells in the blood and bone marrow.
- Non-lymphoid leukemias are poorly responsive to chemotherapy.

Myelodysplasia

- Myelodysplasia (preleukemia) is characterized by anemia and other cytopenias caused by abnormal hemopoietic cell maturation in the bone marrow. The bone marrow is hypercellular and dysplastic, and it may have myelofibrosis.
- Myelodysplasia may progress to overt acute myeloid leukemia after a few weeks to months.
- The prognosis is poor, but blood transfusion and supportive care may be palliative.

Anemia and Other Cytopenias

FeLV-Related Anemia

Anemia is a common primary presenting clinical sign in FeLV-infected cats (see Chapter 22). Nonregenerative anemia is most common and is indicated by an absent or minimal reticulocyte response. Regenerative anemia with reticulocytosis also can occur.

Pathogenesis

- Nonregenerative anemia is associated with primary FeLV infection of bone marrow hemopoietic stem cells and supporting stromal cells, resulting in destruction, suppression, and abnormal maturation of erythrocyte precursors.
- Nonregenerative anemia can also be caused by disruption of the bone marrow from leukemia or myelodysplasia (see the previous section).
- Regenerative anemia associated with FeLV infection can result from immune-mediated hemolysis; from opportunistic hemotropic infections, such as *Mycoplasma haemofelis, Mycoplasma haemominutum* (formerly hemobartonellosis), *Ehrlichia,* and *Babesia;* or from blood loss related to thrombocytopenia.

Diagnosis

- Clinical signs of severe anemia are lethargy, weakness, tachypnea, mucous membrane pallor, anemic murmur, splenomegaly, retinal hemorrhages, and pica.

- CBC usually shows normochromic-normocytic or macrocytic nonregenerative anemia (packed cell volume [PCV] <10%).
- Reticulocytosis indicates regenerative anemia. Consider hemolytic causes. Evaluate blood smears for hemotropic organisms, and consider *Mycoplasma* PCR, which is more sensitive, or a therapeutic trial of doxycycline (see Chapter 22).
- Leukopenia or thrombocytopenia may accompany nonregenerative anemia, especially in myelodysplasia and leukemia.
- Bone marrow cytology in FeLV-related nonregenerative anemia is usually hypoplastic or aplastic, but it can be hypercellular, dysplastic, or neoplastic.

Treatment

- For regenerative anemia, treat the associated underlying cause of hemolysis.
- For nonregenerative anemia, use blood transfusion and palliative supportive care (median survival with treatment in 49 cats was 4 months).
- Recombinant human erythropoietin (Epogen, Amgen; 35 to 100 IU/kg SC q48h until PCV rises, then weekly) has been beneficial in some cats with FeLV-related nonregenerative anemia, but most do not respond. Endogenous erythropoietin is already elevated in many cases.

FeLV-Related Neutropenia

Neutrophils and myeloid precursors are often infected in FeLV (see Chapter 22).

- FeLV-induced neutropenia can be transient (in the first 3 to 5 weeks of bone marrow infection), persistent, or cyclic (8- to 14-day intervals). Neutropenia also can be associated with FeLV-induced leukemia or myelodysplasia.
- Signs include chronic or recurrent fever, bacterial infections, or life-threatening sepsis.
- Myeloblastopenia (panleukopenia-like syndrome) is characterized by profound panleukopenia (white blood cell count is 300–3000/µl) and acute enterocolitis with fever, vomiting, and bloody diarrhea. Intestinal epithelial cells are infected heavily with FeLV. Coinfection with panleukopenia virus is likely.
- Treat complicating bacterial infections with antibiotics. Some cats with persistent or cyclic neutropenia respond to prednisolone (2–3 mg/kg PO q24h).
- Recombinant human granulocyte colony-stimulating factor (rhG-CSF) (Neupogen, Amgen; 5 µg/kg SC daily) has been beneficial for stimulating myelopoiesis in some cases of FeLV-associated neutropenia; however, cats form antibodies against this human protein after a few weeks that limit the effectiveness of this treatment.

FeLV-Related Thrombocytopenia

Platelets and megakaryocytes are often infected in FeLV.

- Thrombocytopenia can be associated with FeLV-induced leukemia, myelodysplasia, or immune-mediated disease. This may lead to petechial and ecchymotic hemorrhages and gastrointestinal (GI) blood loss.
- Macroplatelets with bizarre shapes are a common incidental finding in viremic cats, especially those with severe anemia. These may be miscounted as red blood cells by electronic counters.
- Platelet dysfunction occurs but is clinically insignificant.
- Treat life-threatening thrombocytopenia with transfusion of whole blood or platelet-rich plasma. Treat suspected immune-mediated thrombocytopenia with prednisolone (2–3 mg/kg PO q24h).

Secondary Infections from Immune Suppression

FeLV causes profound lymphoid depletion and immune suppression (especially T lymphocytes). In addition, neutrophil, complement, and cytokine responses may be impaired. Thus, FeLV-infected cats have increased susceptibility to a wide variety of opportunistic infections. Some examples follow:

- Viral—Feline infectious peritonitis, herpesvirus
- Fungal—*Cryptococcus, Aspergillus,* dermatophytosis
- Protozoal—*Toxoplasma, Cryptosporidium*
- *Mycoplasma—M. haemofelis, M. haemominutum*
- Bacterial
  - Oral—Gingivitis, periodontitis, stomatitis
  - Respiratory infections—Rhinitis, sinusitis, pneumonia, pyothorax
  - Enteritis—*Salmonella, Campylobacter,* diarrhea of undetermined cause
  - Cutaneous—Pyoderma, non-healing sores, abscesses, draining fistulas
  - Septicemia

Peripheral Lymph Node Hyperplasia

- FeLV occasionally causes severe, generalized, nonpainful enlargement of peripheral and visceral lymph nodes (especially mandibular nodes) up to 3 times normal size. This lymphadenopathy is not neoplastic.
- This has been seen mostly in young adult cats (6 months to 2 years of age); 50% are asymptomatic and 50% have fever, anorexia, and depression.
- Most cases resolve in 2 to 4 weeks either spontaneously or in response to corticosteroids, cyclophosphamide, and vincristine. In some cats the lymphadenopathy recurs or develops into lymphoma months to years later.

Immune-Mediated Disorders

Several immune-mediated disorders have been associated with FeLV infection. The exact role of FeLV in these disorders is not fully understood, but it presumably involves viral antigen-antibody complexes or FeLV-induced disruption of immune regulation.

- Immune-mediated hemolytic anemia
- Immune-mediated thrombocytopenia
- Immune-complex glomerulonephritis
- Chronic progressive polyarthritis
- Pemphigus-like mucocutaneous disorders
- Systemic lupus erythematosus-like syndrome

Reproductive Failure

FeLV-infected breeding queens frequently have reproductive failure associated with transplacental or milk-borne transmission of FeLV. Presenting clinical signs can include infertility, fetal resorption, abortion, stillbirth, "fading kitten syndrome" (viremic kittens), or milk-borne transmission to nursing kittens.

Miscellaneous

A role for FeLV in the following disorders has been suggested but unproved: multicentric osteochondromatosis (multiple skeletal tumors in young cats), olfactory neuroblastoma (a rare nasal tumor), chronic enteritis, seborrheic dermatitis, eosinophilic granuloma complex, cutaneous horns, idiopathic anisocoria, neurologic dysfunction, and degenerative myelopathy.

DIAGNOSIS

Diagnostic testing for FeLV infection is one of the most frequently performed procedures in clinical practice. FeLV tests are used to diagnose FeLV-related illnesses, to routinely screen healthy cats for subclinical infection, and to identify and eliminate FeLV infections in multicat households and catteries.

Diagnostic kits are widely available for rapid in-office screening for FeLV infection. These are based on ELISA or other IC technologies. Commercial diagnostic laboratories offer these as well as the IFA test. PCR assay and virus isolation are confirmatory tests that require a specialized laboratory.

▼ ***Key Point*** ELISA and other IC screening tests detect soluble FeLV antigen in serum or plasma (antigenemia). The IFA test detects intracellular virus in circulating leukocytes and platelets (cell-associated viremia), indicating bone marrow infection.

Indications for FeLV Testing

The American Association of Feline Practitioners recommends that the FeLV status of all cats should be known. Identification of FeLV-infected cats provides the opportunity to treat these cats and to prevent the spread of infection to other cats. FeLV status should be known before vaccination because it is useless to vaccinate a cat that is already infected. This also prevents preexisting infections being mistaken as vaccination failures. Indications for FeLV testing are listed in Table 8-1.

▼ ***Key Point*** To maintain a FeLV-negative household, test all new cats before entry.

ELISA and Immunochromatographic Tests

▼ ***Key Point*** ELISA and other IC tests are the preferred screening tests for FeLV, because they are rapid, widely available, slightly more sensitive, and detect infection earlier than the IFA test.

The membrane-based ELISA and other IC test kits detect soluble FeLV p27 antigen, a major viral core protein. These are sensitive screening tests that provide accurate results in less than 10 minutes. They are designed for rapid, point-of-care diagnosis of FeLV infection (Table 8-2).

Table 8-1. INDICATIONS FOR FELINE LEUKEMIA VIRUS TESTING

Test cats that have never been tested.
Test kittens at any age. Kittens can be born infected, or nursing kittens can be infected via milk.
Test cats prior to vaccination for FeLV.
Test cats that are newly adopted.
Test new cats before entering them into a household of healthy cats.
Test cats with potential recent exposure.
Test all cats in a cattery or household with FeLV, then separate infected and uninfected cats.
Test outdoor cats at least annually since they have ongoing risk of exposure.
Test cats with signs of illness consistent with FeLV.

Modified from the guidelines of the American Association of Feline Practitioners (www.aafponline.org).

Table 8-2. IC AND ELISA TEST KITS FOR FELINE LEUKEMIA VIRUS

Test Kit	Manufacturer	Format
Witness FeLV	Synbiotics	Membrane rapid immunomigration
ViraCHEK/FeLV	Synbiotics	Microwell ELISA
ASSURE/FeLV	Synbiotics	Saliva wand and tube ELISA
SNAP FeLV	IDEXX	Membrane ELISA
SNAP FIV/FeLV Combo	IDEXX	Membrane ELISA (also tests for FIV)

ELISA, enzyme-linked immunosorbent assay; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; IC, immunochromatographic.

▼ ***Key Point*** For the most accurate ELISA or IC results, use non-hemolyzed serum or plasma rather than whole blood. Tests that use saliva and tears are unreliable and not recommended.

- For testing clinically ill cats, consider using a combination test kit that simultaneously tests for FeLV and feline immunodeficiency virus (FIV), since the clinical manifestations of these two diseases are often indistinguishable.
- ELISA and other IC tests detect viral antigen, not antibodies; thus, these tests are not affected by vaccination or maternal antibodies.

ELISA Test Interpretation

- Positive ELISA or IC test results indicate FeLV antigenemia. Both transient and persistent FeLV infections can be ELISA positive.
- Confirm positive ELISA or IC results, especially in healthy cats where the prevalence of infection is low, by retesting in 4 to 6 weeks and again at 3 months to distinguish transient from persistent infection and to rule out the occasional false positive caused by laboratory error. For retesting, consider using the IFA test as the confirmatory test, because the IFA correlates better with persistent infection and is slightly less susceptible to false-positive results (the see next section).
- Interpret weakly positive ELISA or IC reactions as suspicious or inconclusive, and repeat the test, preferably using a different testing method such as the IFA test or an outside laboratory.
- False-negative ELISA or IC results are highly unlikely because of the inherently high sensitivity of these tests. However, cats tested in the early stages of infection may not yet be antigenemic at the time of the first test. Most cats become antigenemic within 4 weeks of exposure, but it can take up to 3 months and in rare cases longer. Thus, retest all ELISA-negative cats that have a possibility of recent exposure 4 weeks later and again at 3 months.

Immunofluorescent Antibody Test

▼ ***Key Point*** The IFA test is the preferred confirmatory test for FeLV, because it is slightly more specific than ELISA and other IC tests, and it correlates highly with persistent infection.

The IFA test is a confirmatory test performed by commercial labs to detect FeLV p27 antigen within the cytoplasm of circulating neutrophils and platelets on blood smears. A positive IFA indicates established FeLV infection involving the bone marrow.

- The IFA test is very specific for FeLV and is highly correlated with persistent infection and the results of virus isolation; thus, use the IFA test to confirm positive ELISA or IC results.
- Provide the lab with at least two high-quality, air-dried, unfixed blood or bone marrow smears.

Immunofluorescent Antibody Test Interpretation

- Positive IFA results indicate an advanced stage of FeLV infection. Up to 96% of IFA-positive cats remain persistently infected. However, in healthy IFA-positive cats, retest monthly for up to 3 months to be certain whether infection is persistent or transient.
- False-positive IFA results are very rare but can occur from poor-quality blood smears that are too thick and cause nonspecific binding of the conjugate. Platelet clumping and eosinophilia also can cause rare false-positive results.
- False-negative IFA results may occur in cats with low neutrophil and platelet counts. Perform the IFA test on bone marrow smears in this situation.
- The IFA may be negative in early and transient ELISA-positive infections, because the IFA does not become positive until the virus is established and replicating in the bone marrow.

Discordant Test Results

Discordance is when conflicting results occur with different tests, most often when a cat is ELISA positive and IFA negative. This can result from laboratory error (most often a false-positive ELISA result) or from biologic factors.

- Discordant results can indicate early or transient infection when ELISA-positive antigenemia can precede the bone marrow replication stage required for a positive IFA. Early infections may be only ELISA positive for a few weeks until bone marrow replication starts and the IFA becomes positive. Transient infections are usually eliminated by a successful immune response within 3 months or less; thus, retesting monthly for up to 3 months usually resolves whether the infection is transient or persistent.
- The rare phenomenon of persistently discordant test results, i.e., when a cat is repeatedly IFA negative but persistently antigenemic (ELISA positive), can be explained by sequestration of replicating FeLV infection in sites other than the bone marrow or by defective replication that produces FeLV antigens but not the whole virus. PCR testing (see below) is helpful in such cases.

Polymerase Chain Reaction Testing

PCR is a highly sensitive confirmatory test that detects FeLV nucleic acid sequences in blood, bone marrow, or biopsy specimens. PCR requires special laboratory expertise and a validated assay; thus, PCR is not yet widely available. Improper sample handling or technique can readily cause inaccurate results with PCR assays.

- For routine blood testing, PCR has no significant advantage over conventional FeLV tests; however, PCR may be helpful for determining the true status of cats with discordant results on conventional tests.
- PCR may be useful for detecting latent (non-replicating but reactivatable) FeLV infection.

Virus Isolation

Isolation of FeLV by culturing the virus from blood or bone marrow is a confirmatory test used primarily in research and is not readily available for clinical use. It is the preferred "gold standard" for validating the accuracy of other testing methods. Bone marrow culture can be used to detect latent, non-replicating, but reactivatable FeLV infection.

Neutralizing Antibody Tests

Serum neutralizing antibody titers are of limited usefulness in the diagnosis or clinical evaluation of FeLV infection. A positive titer merely indicates prior exposure to FeLV through infection or vaccination, but a titer does not confirm current active infection. Vaccine-induced antibody titers do not correlate well with the level of protective immunity.

TREATMENT

There is no proven effective treatment for FeLV, although various immune modulator and antiviral drugs have been used. The quality of life and possibly longevity of FeLV-infected cats are enhanced by general health care, palliative therapy, and treatment of secondary infections that arise.

General Recommendations

When a cat is found to be FeLV positive, optimize general wellness care for the cat and take measures to prevent the spread of infection to other cats. FeLV-infected cats can live for months to several years, especially healthy carriers identified on routine screening tests. The decision to treat or euthanize a cat with FeLV infection is an individual decision based on factors other than just the results of FeLV tests.

Preventing the Spread of Infection

- Confine FeLV-infected cats indoors to prevent the spread of infection to other cats and to reduce the cat's exposure to infectious agents carried by other animals.
- If the cat lives in a multi-cat household, test all other cats and separate infected and uninfected cats. It is especially important that FeLV-infected cats be isolated from kittens, because they are most susceptible. Prevent sharing of food and water dishes, litter pans, and any other item that could be a source of cross-contamination. Vaccinate all uninfected cats, but it is important to recognize that vaccination alone will not prevent infection in all cats.
- Spay or neuter FeLV-infected cats. This prevents mother-to-kitten transmission in utero or via infected milk. It also reduces roaming, aggression, and other stressful behaviors of sexually intact cats.

General Health Care

- Feed cats a nutritionally balanced and complete feline diet. Do not cats feed raw meat, uncooked eggs, or unpasteurized milk, because the risk of food-borne bacterial and parasitic infections is higher in immunocompromised cats.
- Provide optimal wellness care, including parasite control, core vaccinations, dental care, and a thorough semi-annual physical examination with a CBC, blood chemistry profile, urinalysis, and fecal examination. This facilitates early detection and treatment of FeLV-related conditions.
- Diagnose and treat secondary infections that arise because of immunosuppression promptly and aggressively.
- Avoid using corticosteroids and other immunosuppressive drugs except when clearly indicated.

Antiviral Therapy

Antiviral drugs are intended to directly inhibit virus infection and replication. Many anti-retroviral drugs developed for humans are not suitable for treatment of cats because of excessive toxicity, prohibitive cost, or lack of availability. Protease inhibitors developed for humans are species specific and not effective in cats. Two antiviral agents that may have a role in treating FeLV are interferons and zidovudine (AZT). Cats treated with antiviral drugs remain FeLV positive.

Interferons

Recombinant forms of interferon given parenterally in high doses can have both antiviral and immunomodulatory effects.

Feline Interferon-Omega

Recombinant feline interferon-omega (rFeIFN-ω) (Virbagen Omega, Virbac) has become available in Europe, and preliminary results look promising for treatment of FeLV. A placebo-controlled study in 81 FeLV-infected cats showed significant benefit in survival rate, clinical signs, and hematologic parameters with rFeIFN-ω given at 1,000,000 U/kg SC daily for 5 consecutive days in three cycles beginning on day 0, 14, and 60. No serious adverse effects were seen. Expense could be prohibitive for some owners.

Human Interferon-Alpha

A parenteral high dose (100,000–1,000,000 U/kg) of recombinant human interferon-alpha (rHuIFN-α) (Roferon, Hoffman-LaRoche; Intron-A, Schering-Plough) was shown to initially decrease virus load (i.e., FeLV p27 antigenemia) in FeLV-infected cats; however, this is unlikely to be effective as a long-term treatment because cats develop antibodies against the human protein within 6 to 7 weeks that inhibit the drug's activity.

Zidovudine

Zidovudine, a nucleoside reverse transcriptase inhibitor also known as AZT (Retrovir, GlaxoSmithKline; 5 mg/kg PO or SC q12h), has improved stomatitis associated with FeLV and FIV infections in a placebo-controlled study. Another study failed to show a beneficial response in chronically infected cats. Further evaluation is needed before AZT can be routinely recommended for treating FeLV. AZT causes dose-dependent myelosuppression in cats, so the CBC is monitored for nonregenerative anemia. Mild anemia in the first weeks of treatment is common and usually resolves. If the PCV drops below 20%, treatment is discontinued until the PCV recovers (usually 2–3 weeks), then AZT is restarted at half the original dose. Before administration, dilute injectable AZT in 5 ml isotonic sodium chloride to reduce local irritation.

Immune Modulator Therapy

Immune modulators are intended to stimulate the compromised immune function of FeLV-infected cats. Anecdotal reports of clinical improvement with these agents have not been substantiated by controlled studies; thus, conclusive evidence of a significant clinical benefit is lacking. Treated cats usually remain FeLV positive.

Human Interferon-Alpha

Interferons have antiviral effects at high doses (see the previous section) and immunomodulating activity at low doses. There are numerous anecdotal reports of clinical improvement in FeLV-infected cats treated with low-dose oral rHuIFN-α (Roferon, Hoffman-LaRoche; Intron-A, Schering-Plough), diluted to 30 U/ml and given at 30 units PO q24h for 7 days on alternate weeks. The mechanism of action is unknown but is presumed to involve a local immune-modulating effect on oropharyngeal lymphoid tissue. One placebo-controlled study in chronic FeLV-positive cats failed to show improvement in hematologic and clinical parameters.

Acemannan

Acemannan is a carbohydrate polymer derived from the aloe vera plant. For treatment of FeLV, acemannan (Carrisyn; Carrington Laboratories) has been given at 2 mg/kg intraperitoneally weekly for 6 weeks. In uncontrolled studies, no significant improvement was found in clinical and hematologic parameters, FeLV status, and clinical outcome.

Propionibacterium acnes

A commercial bacterial product of *Propionibacterium acnes* (ImmunoRegulin, ImmunoVet; 0.25–0.5 ml, IV, twice weekly then every other week for 16 weeks) has reportedly been beneficial for FeLV infection, but this has not been documented in placebo-controlled studies.

Staphylococcal Protein A

Staphylococcal protein A (SPA) (Sigma) is a purified bacterial cell wall polypeptide that has been given at 10 μg/kg intraperitoneally twice weekly for 10 weeks. Despite anecdotal reports of efficacy in FeLV, controlled studies have failed to show significant beneficial effects on survival, clinical findings, hematology, immune function, or viremia.

PIND-ORF

PIND-ORF (Baypamun, Bayer) is derived from inactivated parapox ovis virus and has been used in Europe as a nonspecific immune stimulant to treat FeLV. Despite anecdotal reports of improvement, a double-blind placebo-controlled study in 150 FeLV-infected cats failed to show significant benefit in survival rate, viremia levels, immune parameters, clinical scores, or hematology scores.

Palliative Therapy

Palliative care, such as antibiotics for secondary bacterial infections, fluid therapy, and nutritional support, may prolong survival in selected patients. Untreated lymphoma and leukemia are usually fatal within a few weeks to months, but anticancer chemotherapy can induce remission in many cats (see Chapters 26 and 27). The prognosis for cats with FeLV-related nonregenerative anemia or myelodysplasia is poor, although blood transfusions may prolong survival (see Chapter 22).

PREVENTION AND CONTROL

Because of the devastating consequences of FeLV infection and its prevalence in the cat population, prevention is of vital importance. Preventive measures include vaccination of individual cats to reduce susceptibility, restriction of free roaming outdoors to reduce exposure, and control measures to reduce the spread of FeLV in catteries.

▼ ***Key Point*** Vaccination reduces the risk of FeLV infection, but not all vaccinated cats are protected; therefore, effective prevention also requires measures that reduce the risk of exposure.

Kittens less than 4 months of age are most susceptible; thus, keep kittens isolated from other cats to minimize the risk of FeLV infection.

Vaccination

Adjuvanted and non-adjuvanted inactivated parenteral vaccines and a canary pox-vectored transdermal vaccine are currently available for prevention of FeLV. The pros and cons of FeLV vaccination are controversial, but overall, FeLV vaccine is considered a "non-core" vaccine that is used according to an individual benefit-risk assessment of each patient (see Chapter 7).

Indications

- Vaccination is recommended for cats with potential risk of exposure to FeLV, especially kittens. This should include cats allowed outdoors, cats living in multi-cat households with infected cats, or cats exposed to other cats of unknown status.
- Vaccination is not recommended for mature cats with minimal to no risk of exposure, such as cats restricted to closed, indoor, FeLV-negative environments.

▼ ***Key Point*** Vaccination is most indicated for cats living in multi-cat households (and shelters) with frequent exposure to new cats and for outdoor cats at risk of contact with other cats of unknown health status.

Administration

- If vaccination is deemed appropriate, administer two doses of vaccine 3 to 4 weeks apart, beginning as early as 8 weeks of age, followed by an annual booster (see Chapter 7). Give FeLV vaccines subcutaneously in the lateral aspect of the distal left rear limb.
- FeLV testing at or before the first vaccination is highly recommended. There is no proven beneficial or detrimental effect from vaccinating a cat for FeLV that already is infected.

Adverse Vaccine Effects

- Acute side effects are infrequent and include local swelling or pain, transient listlessness or fever, and injection site granuloma. Acute hypersensitivity signs (face and paw edema, vomiting, diarrhea, collapse) occur rarely. These effects are attributable mostly to adjuvants.
- Inflammatory nodules occasionally develop at the vaccination site. These can develop into vaccine-associated sarcomas in some cats weeks to years later (incidence is 1 per 10,000 vaccines). Excise or biopsy vaccination site lesions if they persist more than 3 months, are larger than 2 cm, or increase in size 1 month post-injection.
- For cats at risk of exposure, the benefits of FeLV vaccination far outweigh the risk of injection site sarcoma. However, the risk of vaccine-associated sarcoma may be greater than the risk of FeLV infection in well-controlled catteries and for indoor pet cats where the prevalence of infection is virtually nonexistent today.

Efficacy

- In general, many vaccinated cats that are exposed to FeLV develop transient viremia and sometimes latent infection despite vaccination; however, most vaccinated cats apparently are protected against persistent viremia and therefore against FeLV-related disease.
- As a general guideline for discussing vaccination expectations with animal owners, expect 70% to 90% of vaccinated cats older than 4 months of age to be protected against persistent FeLV infection.

Control in Multi-cat Households and Catteries

Control in FeLV-Positive Catteries

The following "test and removal program" is highly effective for eliminating FeLV from a household or cattery:

- Test all cats on the premises for FeLV (up to 30% may be persistently infected), and remove or strictly isolate all confirmed FeLV-positive cats.
- Quarantine the cattery so that there is no movement of new cats into the cattery.
- Vaccinate all FeLV-negative cats.
- Clean and disinfect the premises.
- Clean and disinfect or replace food and water dishes, litter pans, bedding, and toys.
- If infected and uninfected cats are separated but remain in the same household or facility, caretakers must take special precautions to prevent cross-contamination.
- Retest all cats every 1 to 3 months and continue to remove any confirmed FeLV-positive cats.
- Once all cats on the premises have had negative results on two successive tests 3 months apart, the cattery is considered "FeLV free."
- Then isolate all new incoming cats and test as described in the following section.

Control in FeLV-Negative Catteries

The following precautions should be taken for incoming cats:

- Obtain incoming cats from a source with a negative FeLV history.
- Screen incoming cats with ELISA; if test results are negative, vaccinate and then hold them in isolation for 3 months (in case they were recently exposed and are incubating FeLV).
- After a second ELISA-negative result at the end of the 3-month quarantine, new cats can join the cattery.

- ELISA-positive results should be confirmed by IFA or repeat ELISA; however, in cattery situations, the safest course is to consider any cat that has been ELISA positive at any time as too risky to allow into the cattery.

Chapter 9

Feline Immunodeficiency Virus

Robert G. Sherding

ETIOLOGY

- Feline immunodeficiency virus (FIV) is a member of the lentivirus subfamily of retroviruses. It is an RNA virus with outer envelope and nucleocapsid. FIV originally was isolated in 1986 from a cattery in northern California; however, retrospective assays of stored cat sera have shown that FIV has been widely distributed worldwide since at least the 1960s.
- FIV causes a lifelong infection and gradually progressive decline in immune function that leads to an acquired immunodeficiency syndrome. Manifestations include chronic weight loss, opportunistic infections, chronic inflammatory conditions, and increased risk for malignant neoplasia.
- At least 5 FIV subtypes (clades A through E) have been identified based on genetic differences. Subtypes vary in regional distribution and influence cell tropism and pathogenicity. Subtype A predominates in the Western United States, and subtype B is seen most often in the Eastern United States.
- Numerous wild feline species are susceptible to various subtypes of FIV, including lions, tigers, jaguars, snow leopards, panthers, and bobcats.

Epidemiology

Prevalence

The serologic prevalence of FIV infection has been surveyed in many countries, regions, and cat populations. FIV has been found worldwide.

- The prevalence in indoor pet cats in single-cat households is less than 1%.
- The prevalence in well-controlled purebred catteries is less than 2%.
- The prevalence in free-roaming stray and feral cats in the United States is 2% to 4%.
- The prevalence in a 1991 IDEXX survey of 27,976 sick and high-risk cats in the United States presenting to veterinarians was 7.4%. This included sick cats that had a prevalence of 11.6% and asymptomatic high-risk cats (defined as outdoor pet cats, cats exposed to outdoor cats, or cats in large multicat households) that had a prevalence of 4%.
- The prevalence in some countries in areas with a high density of free-roaming cats, such as Japan and Italy, may reach 25% to 30%.

Age and Gender Distribution

- FIV affects cats of all ages (reported range is 2 months to 18 years); however, the incidence increases with age, and FIV is most prevalent in cats 6 years of age and older.

▼ ***Key Point*** Because of a prolonged asymptomatic latent period, most FIV-infected cats with clinical signs are older than 6 years of age.

- Adult male cats outnumber females 3 or 4 to 1 (see "Transmission").

High-Risk Factors

- Adult, male cats living outdoors or exposed to free-roaming outdoor cats.
- Sexually intact males are at increased risk for fighting behavior that can lead to bite-wound transmission.
- Cats in high-density habitats are at increased risk for territorial fighting that can lead to bite-wound transmission.
- Cats living in large multicat households (>6 cats) that frequently introduce new cats.

Public Health Risks

- FIV is a feline host-specific virus, and there is no evidence that it causes human infection. People who have had intimate contact with infected cats or direct exposure to FIV through cat bites or lab accidents do not develop antibodies, illness, or any other evidence of infection.
- Because of their immunosuppressed state, FIV-infected cats may harbor a variety of other opportunistic pathogens that can infect humans who are immunocompromised.

Transmission

- FIV is shed in saliva and transmitted primarily through direct bite-wound inoculation during territorial fights (hence the higher prevalence in males). Experimentally, a single-tooth puncture wound from a FIV-infected cat is an efficient method of transmitting FIV.

▼ ***Key Point*** Direct inoculation of saliva through biting is the principal mode of FIV transmission. The highest risk for FIV is associated with territorial fighting and biting behavior in sexually intact, adult male cats living outdoors.

- Transmission through intimate contact during cohabitation is unlikely but not impossible. In a study that confined FIV-positive and FIV-negative cats together in the same cages for 2 years, only 1 of 20 negative sentinel cats became infected. Contact transmission has been suspected in rare cases in catteries, but the mode of transmission in most of these cases is undetermined. Fomite transmission is highly unlikely.
- Transmucosal transmission of FIV can occur experimentally through direct atraumatic contact of FIV with oral, vaginal, or rectal mucosa and through artificial insemination; however, these routes are unlikely to be important under natural conditions.
- Experimentally, acute and chronically infected queens may transmit FIV vertically to their kittens in utero or during passage through the birth canal (congenital infection) or postnatally through ingestion of infected milk (lactogenic infection). However, transmission from mother to offspring in these ways is infrequent under natural conditions. More commonly, infected queens pass colostral FIV antibodies to their nursing kittens, causing a false-positive FIV antibody test (e.g., ELISA or Western blot) for up to 6 months (see "Diagnosis").
- Transmission of FIV can readily occur through intravenous transfusion of contaminated blood.

Pathogenesis

- FIV has a primary tropism for lymphocytes but also infects macrophages, salivary glands, and the central nervous system.
- FIV primarily infects and gradually destroys subpopulations of T lymphocytes. This cytopathic effect causes a progressive loss of CD4+ lymphocytes, inversion of the CD4/CD8 ratio, and eventual loss of CD8+ lymphocytes in the late stages of infection. Cell-mediated immunity is impaired to a greater extent than antibody-mediated immunity.
- In addition, impaired production and dysregulation of various cytokines plays a role in the pathogenesis of disease.
- After a prolonged, clinically silent latent period that can extend for years, the progressive loss of T lymphocytes results in an immunodeficiency syndrome characterized by chronic and recurrent infections. FIV infection is lifelong and eventually fatal. The natural incubation period for FIV averages 5 years, corresponding to this lengthy latency.
- FIV has various mechanisms for evading the host immune response so that it can persist and replicate for life.

CLINICAL SIGNS

The clinical disease caused by FIV is influenced by the age and health of the cat, the strain of the virus, the dose and route of exposure, and the interaction with concurrent infectious agents.

▼ ***Key Point*** The most common clinical signs associated with FIV infection are stomatitis-gingivitis (50% of cases), recurrent rhinitis-conjunctivitis, progressive weight loss ("wasting"), diarrhea, and fever.

Acute Primary Infection

This initial phase begins within 4 to 6 weeks after exposure associated with initial viremia. The effects are mild and transient, and usually go unnoticed.

- Transient fever
- Neutropenia and lymphopenia
- Generalized lymphadenopathy characterized by follicular hyperplasia and plasmacytic infiltration
- Infrequent complications: sepsis, cellulitis, pustular facial dermatitis, anemia, diarrhea, and stomatitis

Asymptomatic Latent Infection

This is a prolonged latency period following seroconversion that usually persists several years before signs of immunodeficiency occur. Persistent lymphadenomegaly sometimes is seen during this stage.

▼ ***Key Point*** It is typical for FIV-infected cats to remain clinically healthy for several years before developing clinical signs of disease.

Chronic Disease Syndromes

Advanced FIV infection causes an acquired immunodeficiency syndrome and predisposes the cat to chronic or recurrent opportunistic infections and chronic inflammatory conditions that wax and wane and progressively worsen over months or years. This may involve any combination of the following manifestations.

General Manifestations

- Progressive weight loss and debilitation ("chronic wasting")
- Chronic recurrent bacterial infections that may resolve partially with antibiotics but recur
- Recurrent fevers of unknown origin
- Generalized lymphadenopathy
- Polyclonal hypergammaglobulinemia
- Persistent or recurrent anemia, leukopenia (neutropenia, lymphopenia), or thrombocytopenia

Chronic or Recurrent Bacterial Infections

- *Oral cavity* (most common)—Stomatitis, gingivitis, periodontitis (suppurative or plasmacytic)
- *Respiratory*—Purulent rhinitis and conjunctivitis; pneumonia; pyothorax
- *Intestinal*—Acute or chronic diarrhea due to enterocolitis that can be ulcerative, necrotizing, or pyogranulomatous
- *Cutaneous*—Pustular dermatitis, abscesses, purulent otitis
- *Urinary*—Recurrent urinary tract infections (cystitis, pyelonephritis)

Specific Opportunistic Infectious Diseases

- Viruses—Calicivirus, herpesvirus, poxvirus, papillomavirus
- *Chlamydophila felis*
- *Mycoplasma haemofelis*
- Bacteria—*Staphylococcus, Pseudomonas, Mycobacterium, Yersinia*
- Fungi—*Candida, Cryptococcus, Aspergillus,* dermatophytes
- Protozoa—*Toxoplasma, Giardia, Cryptosporidium*
- Parasites—*Demodex, Notoedres*

Stomatitis

- Chronic ulceroproliferative, lymphocytic-plasmacytic stomatitis is the most frequent clinical manifestation of FIV, affecting up to 50% of cats. Lesions often begin in the fauces (faucitis) and spread rostrally along the maxillary gingivae. Clinical signs include oral pain, inappetence, foul odor, and loss of teeth.
- Concurrent oral infection with calicivirus is found in most cases, suggesting it may be a cofactor.
- Teeth cleaning and medical treatments (e.g., antivirals, immunomodulators, antibiotics, or corticosteroids) usually provide only temporary improvement (see "Treatment" and Chapter 64). The most effective treatment for resolving this condition is full-mouth dental extractions with complete removal of all roots.

Neurologic Disease

- The likelihood of developing neurologic disease is age dependent (especially young kittens) and strain dependent.
- Pathogenesis—FIV is neurotropic, directly infecting microglia and astrocytes and leading to neuronal damage.
- Signs (variable)—Dementia, behavior abnormalities (agitation, rage, hiding, disrupted sleep pattern, loss of litter training), compulsive roaming, circling, facial twitching, licking motions, lip-sucking, gait abnormalities, and seizures.
- Neurologic exam (variable)—Abnormal mentation, anisocoria, delayed papillary reflexes, gait abnormalities, and abnormal postural reflexes.
- Electrodiagnostics (e.g., electroencephalogram, brain stem auditory evoked potential, visual evoked potential, and nerve conduction velocity; see Chapter 125) are often abnormal.
- Some cats improve neurologically with zidovudine (see "Treatment").

Neoplasia

- FIV-infected cats have increased risk of B cell lymphoma and myeloproliferative neoplasia.
- Various other neoplasms occur sporadically, for example, squamous cell carcinoma and adenocarcinoma.
- Tumors in FIV-infected cats are most likely secondary to impaired immune function rather than a direct oncogenic effect of FIV.

Other Feline Immunodeficiency Virus-Associated Diseases

- Ocular—Anterior uveitis, chorioretinitis, glaucoma, pars planitis, retinal hemorrhages, and retinal degeneration
- Lymphocytic polymyositis (immune mediated?)
- Nephropathy—Chronic renal failure, proteinuria, and renal lesions of glomerulosclerosis, microcystic tubular dilatation, and interstitial nephritis and fibrosis

DIAGNOSIS

- The routine diagnosis of FIV depends on the detection of anti-FIV serum antibodies using assays such as enzyme-linked immunosorbent assay (ELISA), immunofluorescent antibody (IFA), or Western blot. The American Association of Feline Practitioners recommends that the FIV antibody status for all cats over 6 months of age be known. Furthermore, periodic retesting is justifiable in cats with high risk of exposure, such as outdoor cats.
- Assays for virus are not routinely used because the concentration of FIV in the blood is low, making detection difficult. Virus isolation and polymerase chain reaction (PCR) are used in specialized research labs for detecting virus or viral antigen. Virus isolation is prohibitively expensive and time-consuming.

Assays using PCR are not yet sufficiently reliable or standardized to be recommended for routine clinical diagnosis.

Indications for Feline Immunodeficiency Virus Testing

- When cats are sick
- Healthy cats not previously tested
- Newly adopted cats
- Cats with potential exposure, such as bite wounds from any cat of unknown FIV status
- Before vaccinating cats with FIV vaccine
- Annual retesting of cats with high risk of exposure, such as cats living with an FIV-positive cat or going outdoors unsupervised

Assays for Antibody

▼ ***Key Point*** A confirmed positive FIV antibody test indicates persistent, lifelong FIV infection, except when interpretation is unclear because of antibodies induced by prior FIV vaccination or because of passively acquired maternal antibodies in young kittens (<6 months of age).

- Seroconversion usually occurs within 4 to 6 weeks after exposure; however, this is highly variable and it can take up to 6 months for FIV antibodies to appear in some cats.
- Maternal FIV antibodies acquired from colostrum in nursing kittens can cause positive test results in uninfected kittens up to 6 months of age; thus, reevaluate all positive kittens at 2-month intervals until 6 months of age to determine whether they are infected or not.

▼ ***Key Point*** Regardless of whether a positive or negative test result is obtained for FIV antibody, all kittens younger than 6 months of age must be retested after they reach 6 months of age to determine their actual status.

ELISA Antibody Test

- ELISAs are sensitive, accurate, and considered the preferred screening tests for FIV.
- ELISAs are simple and rapid enough for convenient in-office or point-of-care screening, such as SNAP FIV/FeLV Combo (IDEXX) that tests simultaneously for FIV antibodies and FeLV antigen.
- Occasional false positives occur; thus, confirm all positive ELISA results by Western blot or IFA at a commercial lab.
- False-negative results can occur in the early stages of acute infection before seroconversion has occurred or rarely in the terminal stages of immunodeficiency when antibody levels can fall below detectable levels.

Immunofluorescent Antibody Test

- Available in some commercial laboratories
- Accuracy comparable to ELISA tests but less convenient

Western Blot Test

- Detects antibodies against specific viral proteins, and is considered the "gold standard" for confirming ELISA-positive results
- Available in research and commercial laboratories

Assays to Detect Virus

- Virus isolation and PCR assays can be used to detect FIV in the blood, tissues, or body fluids of infected cats.

PCR Assay

- FIV is difficult to detect reliably by PCR because of wide genetic variability among field strains and because of low virus levels in blood during the prolonged asymptomatic latent phase of infection when most testing is performed.
- PCR assays would theoretically be useful in place of the antibody tests for early detection of infection prior to seroconversion and for diagnosis of terminal stages of infection when antigen levels may be high and antibody levels are depressed. Virus assays could also be used as an alternative to antibody testing in vaccinated cats.
- Based on the rate of false-positive and false-negative results, commercial PCR assays for FIV are generally too unreliable to be recommended. Although PCR assays are promising for the future, currently available commercial assays are not yet adequately standardized or validated. In addition, it is uncertain whether PCR assays detect all field strains of FIV found in cats.

Virus Isolation

- Virus isolation (culture) is a valuable research tool but is too impractical for use as a clinical diagnostic aid.

TREATMENT

▼ ***Key Point*** No currently available treatment is effective for eliminating FIV once infection is established; thus, assume that confirmed infections are lifelong and incurable.

- Even though FIV is incurable, healthy FIV-positive cats can live for years before developing clinical signs, and symptomatic cats often can be managed for months to years with supportive care, antiviral

therapy, immune modulators, and antibiotics as needed to control secondary infections.

- The goal of therapy in FIV is to decrease the virus load with antiviral therapy or to increase the host immune response through immune modulator drugs. Although some studies have shown clinical improvement in sick FIV-positive cats with these treatments, there is little or no evidence that immune modulation and antiviral therapy benefit health or increase longevity in otherwise healthy FIV-infected cats.

Specific Antiviral Therapy

- Current and future antiretroviral therapies developed for human immunodeficiency virus (HIV) may or may not be applicable to cats. Many of these drugs have not been suitable for treatment of FIV because of excessive toxicity, lack of efficacy, prohibitive cost, or lack of availability.

Zidovudine

- Zidovudine, a nucleoside reverse transcriptase inhibitor also known as AZT, is the most well-studied antiviral for treating FIV infection. In cats infected with FIV, zidovudine inhibits viral replication, decreases virus burden, improves immunologic parameters (such as the CD4/CD8 ratio), reduces clinical disease, and increases survival time. One placebo-controlled study showed regression of FIV stomatitis. Clinical improvement in various other FIV-related manifestations is reported.
- Give zidovudine (Retrovir, GlaxoSmithKline) at dosages of 5 mg/kg PO or SC q12h. Compound oral AZT in gelatin capsules or flavored syrup. Dilute injectable AZT in 5 ml of isotonic sodium chloride to reduce local irritation.
- Zidovudine has been well tolerated in cats treated for over 2 years. However, the drug is myelosuppressive, so monitor the complete blood count for nonregenerative anemia. Mild anemia in the first weeks of treatment is common and usually resolves. If the packed cell volume (PCV) drops below 20%, discontinue treatment until PCV recovers (usually 2–3 weeks), then restart at half the original dose.
- Unfortunately, mutation of the virus allows drug-resistant strains to emerge after several months of therapy.

Interferon

- Recombinant forms of interferon given parenterally in high doses can have both antiviral and immunomodulatory effects. Feline interferon-omega and human interferon-alpha have both been shown to significantly inhibit replication of FIV, but feline interferon-gamma has no antiviral effect and actually enhances FIV replication.
- Recombinant feline interferon-omega (rFeIFN-ω) has become available in Europe, and preliminary results look promising for treatment of feline leukemia virus and possibly FIV. Treatment with rFeIFN-ω (Virbagen Omega, Virbac) is given at 1,000,000 U/kg SC daily for 5 consecutive days in three cycles beginning on day 0, 14, and 60. Expense will be prohibitive for some owners.
- A parenteral high dose (100,000–1,000,000 U/kg) of recombinant human interferon-alpha (rHuIFN-α) (Roferon, Hoffman-LaRoche; Intron-A, Schering-Plough) may initially decrease virus load, but this is unlikely to be effective long term because cats develop antibodies against the human protein after 6 to 7 weeks that inhibit the drug's activity.

Other Antiviral Drugs

- Stampidine, an experimental nucleoside reverse transcriptase inhibitor, shows promise as a future treatment for FIV. In a preliminary study in chronically FIV-infected cats, stampidine given orally significantly decreased the virus load with minimal side effects.
- Protease inhibitors are a class of drugs that are frequently used to treat humans with HIV; however, protease inhibitors developed for HIV are species specific and not effective against FIV.

Immune Modulator Therapy

- Immune modulators are intended to stimulate the compromised immune function of FIV-infected cats. Anecdotal reports of clinical improvement with these agents have not been substantiated by controlled studies; thus, conclusive evidence of efficacy is lacking.
- Immune modulator agents that have been used to treat FIV include low-dose oral human interferon-alpha (Roferon, Hoffman-LaRoche; Intron-A, Schering-Plough; 30 units PO, daily on alternate weeks), bovine lactoferrin (40 mg/kg PO q24h), acemannan (Carrisyn, Carrington Labs), *Propionibacterium acnes* (ImmunoRegulin; ImmunoVet), and *Staphylococcus* protein A (SPA).

General Supportive Therapy

- Use antibiotics to treat cats with FIV-related bacterial infections, using culture and sensitivity guidance whenever possible. Response to antibiotics can be dramatic in some cases.
- For palliative treatment of stomatitis, use metronidazole (10 mg/kg PO q12h) and clindamycin (12.5 mg/kg PO q12h). Stomatitis may also improve with the immunotherapeutic agent, bovine lactoferrin (40 mg/kg PO or topically q24h), zidovudine (see "Specific Antiviral Therapy"), or anti-inflammatory doses of prednisolone (5 mg/cat PO q12h). Full-mouth dental extraction is required in refractory cases.
- Use fluid therapy and nutritional support as indicated by the patient's needs.

- Keep FIV-positive cats indoors to prevent exposure of the immunosuppressed cat to infectious diseases carried by other animals and to decrease the spread of FIV to other cats.
- Continue routine vaccinations in FIV-positive cats, although killed products are preferred. Studies have shown FIV does not interfere with the response to vaccination until the terminal stages.
- Avoid the use of griseofulvin to treat dermatophytes in FIV-positive cats because of an increased risk of griseofulvin-induced neutropenia.

PROGNOSIS

Healthy FIV-positive cats can live for several years before developing clinical signs. Even symptomatic cats can live for months to years with good quality of life. In one study of FIV-positive cats, 18% died in the first 2 years and another 18% had progression of clinical signs; however, more than 50% remained asymptomatic for the 2-year follow-up period.

PREVENTION

Prevent Exposure

▼ ***Key Point*** The best prevention for FIV is to prevent cats from roaming freely outdoors.

- Spay and neuter cats that go outdoors to reduce roaming and fighting behavior.
- Prevent exposure to high-risk cats, such as stray and feral cats or untested outdoor cats.
- Keep infected cats indoors and isolated from uninfected cats to reduce the risk to other cats. The risk of transmission among housemates that do not fight is considered low but possible.
- Spay and neuter FIV-positive cats. It is especially important to remove FIV-infected females from breeding programs.

Vaccination

- A killed, adjuvanted, dual-subtype, whole-virus FIV vaccine is currently available that contains FIV subtypes A and D (Fel-O-Vax FIV, Fort Dodge). The range of crossprotection against the other natural subtypes of FIV is uncertain. Until additional evidence of efficacy in the field becomes available, FIV vaccination is not recommended as a core vaccine for cats.
- Immediately prior to vaccinating any cat for FIV, first determine that the FIV antibody test is negative.

▼ ***Key Point*** FIV antibodies from vaccination and infection are indistinguishable; thus, cats vaccinated for FIV will be positive for FIV antibodies for at least 12 months, thereby eliminating the diagnostic usefulness of FIV antibody tests.

- Kittens born to vaccinated queens will be positive for passively acquired FIV antibodies for up to 12 weeks.
- An effective vaccine for HIV in humans has yet to be developed despite intensive efforts. New vaccine strategies are under development for both HIV and FIV. The natural host immune response to FIV infection is almost never effective, and what is needed to elicit protective immunity is not yet understood. This suggests that conventional approaches to vaccine development may not be successful for these lentiviruses.

Chapter 10

Feline Infectious Peritonitis (Feline Coronavirus)

Robert G. Sherding

Feline infectious peritonitis (FIP) is a progressive and highly fatal systemic disease of cats caused by feline coronavirus. Feline coronavirus most frequently causes inapparent enteric infection with fecal shedding of virus. Mild enteritis and diarrhea are seen rarely (see Chapter 14). A mutation of feline coronavirus during intestinal replication enables it to infect macrophages and cause FIP. Despite its name, the lesions of FIP are widespread and not restricted to the peritoneum. Effusive and non-effusive forms of FIP occur. Since its recognition in the 1950s, FIP has been one of the most studied diseases of cats, yet a definitive diagnostic test, an effective treatment, and a reliable vaccine are lacking. With the decline in prevalence of feline leukemia virus from vaccination, FIP has become the deadliest infectious disease of cats.

ETIOLOGY

Feline Coronavirus

- Feline coronavirus (FCoV) is a single-stranded enveloped RNA virus with distinctive petal-shaped peplomers projecting from the surface. There are two serotypes of FCoV that differ in cell culture characteristics. Serotype I predominates in North America and Europe, whereas Serotype II is more closely related to canine coronavirus (CCV) and predominates in Japan.
- Coronaviruses are found in many animals and are generally adapted for infecting epithelial cells of the respiratory or gastrointestinal tract. FCoV is closely related to CCV, swine transmissible gastroenteritis virus (TGEV), porcine respiratory virus, and some human coronaviruses. The CCV that causes enteritis and diarrhea in dogs (see Chapter 14) can infect cats and cause antibodies that crossreact with FCoV. Experimentally, CCV can cause enteritis, diarrhea, and even FIP in cats.

Pathogenesis of Feline Infectious Peritonitis

▼ ***Key Point*** FIP-causing coronaviruses are genetic mutants of harmless enteric FCoV.

- It was previously thought that cats were infected by two similar but distinct coronaviruses, the innocuous feline enteric coronavirus and the deadly FIP virus, but these are now considered phenotypic variants (biotypes) of the same virus. The non-mutated enterotropic FCoV typically causes a clinically inapparent infection of intestinal epithelial cells with fecal shedding of virus. During replication in the cat's intestinal tract, FCoV mutates frequently, especially in kittens, and this sporadically results in critical genetic mutations that enable FCoV to infect and replicate in macrophages.

▼ ***Key Point*** Any cat with inapparent FCoV infection has the potential to develop FIP if the virus mutates during replication to allow the mutated FCoV variant to infect macrophages. Viral replication in macrophages is the defining event in FIP.

- Macrophages then replicate the mutated coronavirus and carry it to target tissues such as the peritoneum, pleura, kidney, uvea, and nervous system, resulting in widespread immune-mediated vasculitis, disseminated perivascular pyogranulomatous inflammation, and exudative fibrinous polyserositis. These are the characteristic lesions of FIP.
- The pathogenesis involves circulating immune complexes, complement fixation, cytokine release, apoptosis of activated T lymphocytes, and vascular damage with necrosis and increased permeability.

▼ ***Key Point*** It is not the virus that causes widespread damage in FIP. The disease is a consequence of the cat's immune reaction to the virus.

- Natural immunity to FCoV is poorly understood but is presumed to be cell mediated rather than antibody mediated. Circulating FCoV antibodies can actually enhance progression of the disease.

EPIDEMIOLOGY

Prevalence

- FCoV is ubiquitous in cats worldwide. In many regions, 50% of cats are positive for coronaviral antibodies (i.e., seroprevalence). The majority of these seropositive cats represent current or past inapparent infection with non-mutated FCoV. Only some of these develop into mutated FIP-causing infections; thus, the prevalence of FIP is much lower.
- The prevalence of FCoV infection is highest in cats confined in crowded groups, such as catteries, shelters, and multiple cat households, where the seroprevalence ranges from 50% to 90%.
- In endemic catteries where the seroprevalence approaches 90%, most FCoV-infected cats remain healthy and only 5% develop FIP.
- The seroprevalence of FCoV in free-roaming feral and stray cats is 12% to 15%. The lower prevalence is presumed to relate to less social interaction and less exposure to fecally excreted virus than cattery cats.
- The seroprevalence in single-cat households is 15% or less.
- In a large survey of North American veterinary teaching hospitals, FIP was diagnosed in 1 of every 200 new feline accessions. This population mostly represents sick cats seen by veterinarians.
- FCoV can infect most wild felids, including the lion, cougar, cheetah, jaguar, leopard, bobcat, sand cat, caracal, serval, and lynx. Cheetahs are especially susceptible to developing FIP.

Risk Factors

▼ ***Key Point*** Whenever FCoV exists in a cat, so does the potential for developing FIP.

- FCoV infection occurs most often in young kittens after maternal antibodies dissipate, between 6 and 16 weeks of age; thus, the infection rate is highest in catteries where kittens are raised in association with virus-excreting adult cats.
- Young cats have increased risk for developing FIP. The peak incidence for FIP is between 6 months and 3 years of age, although cats of any age can be affected.
- Crowded group confinement (multicat households, purebred catteries, shelters) increases risk.
- Factors intrinsic to the shelter experience increase fecal shedding of FCoV up to 1 million-fold after 1 week.

▼ ***Key Point*** Most cats with FIP come from catteries and shelters.

- Any factor that increases FCoV replication in the intestines of an infected cat will increase the probability of the virus mutating to a form that can cause FIP. Thus, viral load, stress, immune impairment, corticosteroids, surgery, and concurrent disease (e.g., feline leukemia virus or feline immunodeficiency virus) can be risk factors for FIP.
- Inherited genetic susceptibility to FIP is a factor in some purebred cats and in cheetahs.

Transmission

- FCoV is primarily excreted in feces from cats with inapparent enteric infection. Healthy carriers often shed FCoV in their feces for at least 10 months, and some cats shed persistently for many years, possibly for life. One-third of healthy FCoV-seropositive cats are actively shedding virus. In high-density endemic catteries, up to 60% of healthy cats may be shedding virus at any given time.
- FCoV is usually inactivated in 24 to 48 hours at room temperature, but the virus can survive up to 7 weeks in dried fecal debris; thus, environmental contamination with small particles of used litter is an important source of infection. Contaminated surfaces, food and water dishes, and human clothing, shoes, and hands can act as fomites. Most disinfectants and detergents easily destroy FCoV.
- Transmission to uninfected cats most frequently occurs through oronasal contact with virus-containing feces or contaminated material from the environment. Contaminated litter and dust particles deposited on the fur are ingested during normal grooming activity.

▼ ***Key Point*** Indoor confinement in crowded groups increases exposure to large doses of infectious virus in feces in shared litter boxes.

- In catteries, kittens are most frequently infected as they lose maternal-derived immunity after 6 weeks of age through contact with feces from virus-shedding adult cats. Removing kittens from contact with adult cats at 5 to 6 weeks of age prevents infection (see "Prevention").
- FCoV can also be excreted in saliva, respiratory secretions, and urine, but these are unlikely to be important sources of infection.
- Transplacental transmission is possible but uncommon.
- Cats with FIP shed mostly the avirulent non-mutated FCoV, not the virulent mutated virus that causes FIP; thus, FIP itself is not directly contagious. Cats with FIP also excrete less FCoV than healthy carriers.

CLINICAL SIGNS

Cats with non-mutated FCoV infection of the intestinal tract infrequently develop clinical signs (see Chapter 14). This section describes the clinical manifestations of mutated, FIP-producing FCoV infection. Cats with FIP often present initially with nonspecific and non-localizing signs, such as fever, anorexia, inactivity, weight loss, vomiting, diarrhea, dehydration, and pallor (anemia). As the disease progresses, these signs worsen and additional clinical signs develop that indicate either body cavity effusions in the "wet" form of the disease or organ-specific abnormalities in the non-effusive or "dry" form (Table 10-1). Approximately 75% are effusive and 25% are non-effusive. Some cats manifest features of both effusive and non-effusive disease or change over time from one form to the other.

Incubation and Clinical Course

Incubation and Onset of Feline Infectious Peritonitis

- The natural incubation period is extremely variable, ranging from a few weeks to several years. Cats are at greatest risk for developing FIP within the first 6 to 18 months after initial infection with FCoV.
- This encompasses the unpredictable but often prolonged period of time it takes a carrier of the harmless, non-mutated FCoV to develop the critical viral mutation and then the time it takes the mutated virus to produce clinical disease.
- The onset of clinical signs is often insidious, but occasionally it is sudden, especially in young kittens.

Table 10-1. CLINICAL SIGNS AND LABORATORY ABNORMALITIES IN FELINE INFECTIOUS PERITONITIS

Nonspecific Signs
Chronic unresponsive fever of unknown origin
Unexplained anorexia, lethargy, and weight loss
Effusion Signs
Fluid distension of the abdomen
Dyspnea due to pleural effusion
Muffled heart sounds due to pericardial effusion
Scrotal swelling
Organ-Specific Signs
Abdominal disease
Enlarged, firm, irregular kidneys
Icterus and hepatomegaly
Intestinal pyogranulomatous mass
Splenomegaly
Pancreatitis
Mesenteric lymphadenopathy
Omental adhesions and mass
Neurologic signs (multifocal and progressive)
Uveitis (iridocyclitis; chorioretinitis)
Pyogranulomatous interstitial pneumonia
Testicular enlargement (orchitis)
Laboratory Abnormalities
Anemia (nonregenerative)
Neutrophilic leukocytosis or leukopenia; lymphopenia
Elevated serum protein (hyperglobulinemia)
Elevated serum liver enzymes and bilirubin (also bilirubinuria)
Azotemia of primary renal origin
Proteinuria of renal origin
Pyogranulomatous or fibrinous body cavity effusion
Elevated CSF protein and leukocytes (neutrophils)

CSF, cerebrospinal fluid; FIP, feline infectious peritonitis.

▼ ***Key Point*** Chronic fluctuating fever that is unresponsive to antibiotics is a frequent early sign of FIP.

Clinical Course

- Once viral dissemination occurs and clinical illness develops, FIP is virtually always progressive and fatal. However, there is considerable variation in the duration of clinical illness before death; 3 to 6 weeks is typical, but prolonged illness exceeding 6 months can occur, as can intermittent illness punctuated by periods of remission.
- For effusive FIP, the clinical course is usually acute (days to weeks).
- For non-effusive FIP, the course is often chronic and insidious (weeks to months).
- Cats with only ocular involvement sometimes survive for a year or more.

Effusive (Wet) Form of Feline Infectious Peritonitis

▼ ***Key Point*** In cats with the effusive (wet) form of FIP, the predominant location of the inflammatory fluid is the abdominal cavity in 62%, the thoracic cavity in 17%, or both cavities in 21%.

Abdominal Effusion (Peritonitis)

- Effusive FIP involving the peritoneal cavity causes progressive, non-painful, fluid distension of the abdomen.
- Effusion is detected by palpation and percussion of a fluid wave. In the early stages, a small amount of abdominal fluid may be detected by palpation of intestinal loops that feel excessively slippery, as though the serosal surfaces are highly lubricated. Pain on palpation is infrequent.
- Extension of the peritoneal inflammation may involve the gastrointestinal tract (vomiting, diarrhea), hepatobiliary system (jaundice), or pancreas (vomiting due to pancreatitis).
- Scrotal swelling may occur in intact males as a direct extension of the peritoneal inflammation and effusion into the testicular tunics.
- Adhesions may organize the mesentery, omentum, and viscera into an irregular, firm mass that is palpable in the cranioventral abdomen.

- Abdominal effusion is confirmed by radiography, ultrasonography, or abdominocentesis, and the results of fluid analysis are highly indicative of FIP (see "Diagnosis").

Thoracic Effusion (Pleuritis)

- Dyspnea, tachypnea, and exercise intolerance are the major presenting signs because lung expansion is restricted by compression from fluid in the pleural space.
- Cats with pleural effusion may prefer a sitting or sternal recumbent posture to facilitate breathing. Increased respiratory distress may occur with exercise, with physical restraint in the hospital, or with repositioning in lateral recumbency (i.e., orthopnea).
- Thoracic effusion may cause muffled heart and lung sounds on auscultation and hyporesonance and a horizontal fluid line on thoracic percussion.
- Thoracic effusion is confirmed by radiography or thoracocentesis (see Chapter 164). The results of fluid analysis are highly indicative of FIP (see "Diagnosis").

Pericardial Effusion

- Pericardial effusion due to fibrinous pericarditis may occur in FIP, with or without other effusions. In one survey, FIP was the second most frequent cause of feline pericardial effusion, accounting for 14% of cases.
- Pericardial effusion in FIP does not usually cause overt clinical signs. It may be suspected from auscultation (muffled heart sounds), thoracic radiography, or electrocardiography, and it is confirmed by echocardiography (see Chapter 151).

Non-effusive (Dry) Form of Feline Infectious Peritonitis

▼ ***Key Point*** The non-effusive (dry) form of FIP is characterized by multifocal pyogranulomatous inflammation and necrotizing vasculitis in various organs, such as the abdominal viscera (e.g., liver, spleen, kidneys, pancreas, and intestines), eyes, central nervous system (CNS), and lungs.

Pyogranulomas appear as multiple discreet or coalescing gray-white nodular masses of variable size on the surface and within the parenchyma of affected organs. These are often mistaken for tumors. Effusion is often minimal or absent. The specific organs affected and the degree of resulting organ failure determine the presenting clinical signs.

Kidney Disease

- Pyogranulomatous nephritis causes the kidneys to become palpably enlarged, firm, and irregular ("lumpy"), associated with pyogranulomas scattered over the surface and infiltrating throughout the renal cortex.
- Extensive renal involvement occasionally causes renal failure with polyuria-polydipsia and azotemia (increased blood urea nitrogen [BUN] and serum creatinine).
- Proteinuria is a frequent laboratory finding in renal FIP. In addition, large quantities of circulating immune complexes may lead to subclinical glomerulonephritis with any of the other forms of effusive and non-effusive FIP.

Liver Disease

- Pyogranulomatous hepatitis (hepatomegaly, jaundice, and signs of hepatic failure) may occur in FIP.
- The most consistent laboratory abnormalities are bilirubinuria and hyperbilirubinemia. Mild to moderate elevations of serum liver enzymes (alanine aminotransferase, alkaline phosphatase) and serum bile acids also may occur.

Disease in Other Abdominal Organs

- Pyogranulomatous lesions may cause palpable enlargement of the visceral lymph nodes, spleen, or omentum.
- Pyogranulomatous enterocolitis may cause diarrhea and diffuse or masslike intestinal thickening, especially in the ileocecocolonic region.
- Pancreatic involvement can occasionally cause pancreatitis and, rarely, diabetes mellitus.

Ocular Disease

- Ocular lesions of FIP are usually bilateral and affect the vascular tunic or uvea (uveitis). Lesions may sometimes cause blindness.
- Manifestations of exudative anterior uveitis (iridocyclitis) may include miosis, aqueous flare, keratic fibrinocellular precipitates, hypopyon ("mutton-fat" deposits of cells and fibrin), hyphema, anterior chamber adhesions (synechia), corneal edema, and deep neovascularization of the cornea (see Chapter 136).
- Chorioretinitis from posterior uveal involvement is detected by ophthalmoscopic examination and may include perivascular cuffing, exudative retinal detachment, and retinal hemorrhages (see Chapter 138).

Neurologic Disease

- Multifocal pyogranulomatous meningoencephalitis and myelitis are frequent in FIP. Inflammatory lesions are perivascular and often involve the meningeal and ependymal layers. In one report, 29% of cats with FIP developed neurologic signs. In a retrospective survey of 286 cats with neurologic disease, lesions indicating FIP of the CNS were found in 16%. In another large

survey, FIP was the most common spinal disease in cats.
- The neuroanatomic distribution of the lesions determines clinical signs; some of the most common are ataxia, tremors, vestibular dysfunction, seizures, posterior paresis, hyperesthesia, and behavioral changes. The relentless progression and multifocal nature of the signs are characteristic features of neural FIP.
- Neuropathies occasionally involve the cranial nerves (e.g., trigeminal or facial) or peripheral nerves (e.g., brachial or sciatic).
- Cats with neural FIP often develop secondary hydrocephalus when the inflammatory process obstructs the flow of cerebrospinal fluid (CSF). In one study of 24 cats with neural FIP, 75% had hydrocephalus. Dilatation of the ventricular and central canal system is identified on computed tomography (CT) and magnetic resonance imaging (MRI) scans. Meningeal enhancement also is seen on MRI.
- The diagnosis of neural FIP depends on CSF analysis (see the section on diagnosis).

Pulmonary Disease

- Pyogranulomatous pneumonia can be found in cats with FIP on thoracic radiographs or at necropsy, but in most cases this is clinically silent or only causes a mild cough.
- This appears radiographically as a diffuse, poorly defined, patchy or nodular interstitial pulmonary infiltrate.

Reproductive Disease

- Testicular enlargement caused by pyogranulomatous orchitis has been reported in FIP.
- Contrary to what has been speculated in the past, FCoV is not directly associated with cattery reproductive problems, neonatal deaths, or birth of weak or "fading" kittens.

DIAGNOSIS OF ENTERIC FELINE CORONAVIRUS

Fecal Virus Detection

- Non-mutated FCoV infection is characterized by persistent viral replication in enterocytes and fecal shedding of virus. Active fecal shedding of FCoV can be confirmed by reverse transcription polymerase chain reaction (RT-PCR) assay of feces (see the later section on RT-PCR assay) or by electron microscopy of feces. False negatives occur with both of these diagnostic techniques.
- The quantity of fecal virus can fluctuate, so ideally feces should be checked daily for 4 to 5 consecutive days before determining a cat is a non-shedder.

Intestinal Biopsy

- Intestinal biopsy shows nonspecific lesions of villous tip injury, with stunting and fusion of villi.
- Immunofluorescence or immunohistochemical staining for viral antigen in intestinal biopsies is confirmatory.

DIAGNOSIS OF FELINE INFECTIOUS PERITONITIS

The diagnosis of FIP is usually suspected from clinical signs and the results of routine laboratory evaluations (see Table 10-1). There is no single reliable confirmatory test for FIP; thus, base the clinical diagnosis of FIP on the combined results of well-chosen laboratory evaluations (e.g., hematology, serum chemistry, cytology, serology, and virology), diagnostic imaging, and histopathology (Table 10-2).

▼ ***Key Point*** Clinical signs and laboratory abnormalities in cats with FIP are not specific for the disease; however, collectively these may provide strong circumstantial evidence for a presumptive diagnosis of FIP.

Routine Laboratory Evaluations

- Hematology often reveals nonspecific abnormalities reflecting the chronic inflammatory response, such as nonregenerative anemia, neutrophilic leukocytosis or leukopenia, and stress lymphopenia.
- Total serum protein and serum globulins (especially gamma and alpha$_2$) are increased by the chronic immune stimulation in 70% of non-effusive cases and 50% of effusive cases, whereas serum albumin is often decreased. One study showed that a decreased serum albumin-to-globulin ratio (A/G < 0.8) indicates a high probability of FIP (92% positive predictive value); while an A/G > 0.8 suggests that FIP is unlikely (61% negative predictive value). Serum protein electrophoresis is usually not necessary.
- Serum chemistries may detect involvement of abdominal organs such as the liver (increased serum liver enzymes, bilirubin, and bile acids), kidneys (increased creatinine and BUN), or pancreas (increased pancreatic lipase immunoreactivity).
- Urinalysis findings may include proteinuria or bilirubinuria.
- Disseminated intravascular coagulation sometimes develops in FIP, resulting in prolonged coagulation times, decreased platelets, and increased fibrin degradation products (see Chapter 23).

Diagnostic Imaging

Diagnostic imaging is useful for identifying organ sites of involvement in FIP. Imaging also facilitates procurement of diagnostic fluid or biopsy specimens.

Table 10-2. DIAGNOSTIC FEATURES OF FELINE INFECTIOUS PERITONITIS

Parameter or Procedure	Findings Suggestive of FIP
Age	6 mo to 3 yr (but all ages affected)
Habitat	Cattery or multicat household
Signs (see Table 10-1)	Fever (unresponsive)
	Effusion (abdominal, thoracic)
	Liver disease (jaundice, etc.)
	Renal disease (renomegaly)
	Intestinal disease (GI signs)
	Ocular disease (uveitis)
	CNS disease (multifocal)
	Pulmonary disease (cough)
Clinical course	Progressive
Complete blood count	Anemia (nonregenerative)
	Neutrophilia or neutropenia; left shift
	Lymphopenia
	Neutrophil inclusions (immune complexes?)
Plasma proteins	Increased total serum protein
	Hyperglobulinemia (gamma, alpha$_2$)
	A/G ratio < 0.8
	Hyperfibrinogenemia (400–700 mg/dl)
Serum chemistries	Abnormal liver tests (increased ALT, ALP, bile acids, bilirubin)
	Azotemia (increased BUN, creatinine)
	Increased PLI assay (pancreatitis)
Urinalysis	Proteinuria, bilirubinuria
Radiography and ultrasonography	Effusions (abdominal, thoracic)
	Organomegaly (liver, kidney, intestine, etc.)
	Organ infiltration (lung)
CT and MRI brain imaging	Hydrocephalus, meningeal enhancement
Fluid analysis of effusion:	Yellow, clear, sticky, foamy, fibrinous
Protein	4–10 g/dl (A/G ratio < 0.8, globulin > 50%, gamma globulin > 32%)
Leukocytes	1,000–20,000 cells/µl
Cytology	Pyogranulomatous exudate
Cerebrospinal fluid analysis:	
Protein	50–350 mg/dl
Leukocytes	100–10,000 cells/µl
Cytology	Neutrophils > mononuclear
Serology	High FCoV antibody titer (see text)
RT-PCR assay	FCoV nucleic acid (in blood, fluid, or tissue)
Histopathology	Vasculitis and pyogranulomatous inflammation
	Positive immunofluorescence and immunohistochemistry

A/G, albumin-to-globulin ratio; ALP, alkaline phosphatase; ALT, alanine transaminase; BUN, blood urea nitrogen; CNS, central nervous system; CT, computed tomography; FCoV, feline coronavirus; FIP, feline infectious peritonitis; GI, gastrointestinal; MRI, magnetic resonance imaging; PLI, pancreatic lipase immunoreactivity; RT-PCR, reverse transcription polymerase chain reaction.

Radiography and Ultrasonography

Radiography is useful for confirming abdominal or thoracic effusion, abdominal organ enlargement (e.g., kidney and liver), or pulmonary infiltration. Affected abdominal organs (liver, kidney, spleen, pancreas, intestines, omentum, and lymph nodes) also can be imaged, aspirated, and biopsied using ultrasonography.

CT and MRI of the CNS

In cats with neurologic FIP, secondary obstructive hydrocephalus is a common finding on CT and MRI scans. Contrast enhancement of the meninges and ependyma also may be seen on MRI.

Fluid Analysis of Effusions

▼ ***Key Point*** Fluid analysis is usually sufficient for the clinical diagnosis of effusive FIP. The typical fluid in effusive FIP is a highly proteinaceous pyogranulomatous exudate.

- FIP fluid appears clear, viscous, and straw yellow or golden. It may be tenacious or sticky and contain

flecks or strands of fibrin. The fluid gets frothy when shaken because of its high protein concentration, and it may clot when refrigerated.

- FIP fluid has a high protein concentration, approaching that of plasma, ranging from 4 to 10 g/dl. Effusive FIP is highly likely if the total fluid protein is more than 3.5 g/dl and the globulin portion is greater than 50%. The A/G is usually less than 0.8. A gamma globulin percentage of greater than 32% by fluid protein electrophoresis is also highly indicative of FIP. An A/G ratio of greater than 0.8, or an albumin percentage greater than 50%, indicates that a disease other than FIP is highly likely.
- FIP fluid usually has a nucleated cell count ranging from 1,000 to 20,000 cells/µl, which is low compared with other exudates.
- The cytologic pattern of FIP fluid is pyogranulomatous exudate. The predominant cells are well-preserved (non-degenerate) neutrophils and macrophages with variable numbers of plasma cells and lymphocytes.
- Additional evaluations on effusions can include assay for anti-FCoV antibodies (see "Coronaviral Antibody Tests") and RT-PCR assay to detect coronaviral nucleic acid (see the later section on PCR assay). Antibody and RT-PCR assays on effusions may have higher diagnostic value than serum testing.
- Staining macrophages in effusions for intracellular FCoV antigen using either immunofluorescence or immunohistochemistry is the most definitive confirmatory test for effusive FIP, with 100% positive predictive value (see "Immunofluorescence and Immunohistochemistry").

Cerebrospinal Fluid and Aqueous of the Eye

- Analyses of CSF for neural FIP and aqueous fluid from the anterior chamber of the eye for ocular FIP have high diagnostic value. Both the protein concentration and the nucleated cell count (neutrophils, macrophages, lymphocytes) are increased in the CSF of most cats with neural FIP (see Table 10-2) and in the aqueous humor of cats with intraocular FIP.
- CSF and anterior chamber fluid can also be evaluated for the presence of anti-FCoV antibodies (see the following section). In FIP, the ratio of CSF or ocular antibodies to serum antibodies is generally much higher than the ratio of CSF or ocular total protein to serum total protein.
- A PCR assay of CSF and anterior chamber fluid for coronaviral nucleic acid is not as useful (see the section on PCR assay).

▼ ***Key Point*** Neurologic FIP is highly likely in cats that have the combination of progressive neurologic signs (especially if multifocal), increased CSF protein and leukocytes (especially neutrophils), and hydrocephalus on imaging.

Coronaviral Antibody Tests

Testing for coronaviral serum antibodies is informative as an epidemiological screening tool and as a diagnostic aid for FCoV and FIP if a reliable laboratory is used and the results are interpreted properly.

Principles of Feline Coronavirus-Antibody Testing

▼ ***Key Point*** A positive coronaviral antibody test means only that a cat has been exposed to some coronavirus at some time.

- Serology does not provide a definitive diagnosis of FIP because the antibodies in cats infected with harmless non-mutated FCoV are not distinguishable from the antibodies in cats with FIP. A large percentage of the healthy cat population is seropositive for FCoV antibodies, and most of these cats never develop FIP. In addition, seropositivity does not distinguish active from past infection.
- Antibodies to the related non-FCoVs (e.g., CCV and TGEV) crossreact with FCoV antibodies, lowering specificity further.
- Seroconversion after initial exposure to FCoV takes 1 to 3 weeks.

▼ ***Key Point*** A positive coronaviral antibody test does not confirm a diagnosis of FIP, and the absence of FCoV antibodies does not rule out a diagnosis of FIP.

- Many commercial diagnostic labs measure FCoV-antibody titers; however, methodologies are variable; thus, results cannot be compared between labs. For example, whether a feline or non-feline viral antigen is used in the test procedure will influence the titer values that indicate the lowest and highest titer levels.
- Use a reliable commercial diagnostic laboratory that measures quantitative FCoV-antibody titer levels. Avoid using rapid in-office enzyme-linked immunosorbent assay (ELISA) tests that merely report positive or negative results without titer quantification—this is less useful than titer information, and these tests give less consistent results than conventional serologic tests.
- Commercially available ELISA tests for detection of antibody to the 7b gene have been marketed as "FIP-specific tests." However, mutation of this gene is not specific for FIP, and this test has no advantage over conventional serologic assays.
- Serum or plasma samples for FCoV antibody testing can be refrigerated or stored at −20°C without affecting the test.
- FCoV antibodies also can be measured in effusions, CSF, or anterior chamber fluid (aqueous). Some studies suggest that these are more diagnostically

useful than serum testing but have similar interpretation pitfalls.

Indications

▼ ***Key Point*** Use the FCoV-antibody titer as a diagnostic aid for FIP rather than as a definitive diagnostic test. Interpret a positive titer to indicate that FIP is *possible* (low titer) or *probable* (high titer), when accompanied by supportive clinical findings. Interpret a negative titer to indicate that FIP is *unlikely.*

- Diagnostic aid in sick cats suspected of FIP
- Diagnostic aid in cats suspected of FCoV enteritis
- Healthy cats that have been exposed to cats with FIP or FCoV
- Screening catteries for the presence of FCoV
- Aid the process of creating an FCoV-free cattery
- Screening new cats before entering FCoV-free catteries

Positive Antibody Test Results

A positive FCoV-antibody titer in a cat can indicate any of the following:

- Clinical FIP caused by a mutant variant of FCoV
- Healthy carrier of non-mutant FCoV
- Recovered from previous FCoV infection
- Seroconversion to other non-FCoVs
- False-positive as a result of recent vaccination

Guidelines for Interpretation

▼ ***Key Point*** Coronaviral-antibody titers are not sufficiently specific to be used as a definitive diagnostic test. A positive titer, no matter how high, does not confirm a diagnosis of FIP.

- In healthy cats, the height of the antibody titer correlates with the virus replication rate in the intestine, the likelihood of fecal shedding, and the amount of virus shed in the feces.
- In general, low titers have the least diagnostic value.
- The highest measurable titer level for the assay used by the lab is highly suggestive of FIP but is still not confirmatory by itself. One study found 94% probability of FIP at the highest titer level.
- Rising antibody titers are not helpful because they are seen in healthy cats with non-mutated FCoV, and titers fluctuate unpredictably in both FIP and avirulent infections.
- Healthy carriers of non-mutated FCoV living in endemic cattery and multicat environments tend to have higher titers than individual pet cats; thus, high titers might be less meaningful in cattery cats. Less than 10% of cattery cats with titers ever develop FIP.

▼ ***Key Point*** A healthy cat that is negative for antibodies is likely to be free of FCoV and thus is not shedding virus, is not infectious to other cats, and is not at risk for FIP.

- False-negative test results are infrequent but occur in up to 10% of confirmed FIP cases; thus, a negative titer does not entirely rule out FIP. False-negative titers can result from low antibody levels seen with peracute infection (less than 10 days after exposure), the terminal stages of infection, or with consumption of antibody in immune complexes. A laboratory error or an insensitive assay system also explains some false negatives.
- The evaluation of FCoV antibodies in effusions was found to have good predictive value for FIP (90% positive, 79% negative), suggesting that fluid testing may be more diagnostically useful than serum testing.

Polymerase Chain Reaction

▼ ***Key Point*** Interpret the RT-PCR test with other clinical findings, and do not use this as the sole basis for diagnosis of FIP.

- The RT-PCR viral assay is used to detect coronaviral nucleic acid in blood, fluids, tissue, or feces.
- A positive result indicates the presence of FCoV, but it does not distinguish between the mutated, FIP-producing variants and non-mutated FCoV. Viremia occurs not only in FIP but also in healthy FCoV carriers. One study found that up to 80% of cats in endemic catteries can be viremic and RT-PCR–positive, and this was not predictive of FIP. Thus, RT-PCR by itself is not a reliable confirmatory diagnostic test.

▼ ***Key Point*** PCR assays do not distinguish between mutated and non-mutated FCoV.

- In general, effusions and tissue specimens are more likely than blood to be positive in cats with FIP. Plasma is more sensitive than serum. The lowest yield is in CSF and urine, so these are not recommended for routine PCR testing.
- Fecal RT-PCR can be used to document fecal shedding of FCoV, especially in healthy cats as a component of a cattery control program. Evaluate feces daily for 4 to 5 consecutive days. Retesting over several months is required to identify chronic persistent shedders.
- A false-negative RT-PCR results from degradation of sample RNA and poor laboratory technique. The primers used also may not detect all strains of FCoV.
- Samples for PCR require careful handling to avoid invalid results. Keep samples frozen and assay them as soon as possible for optimal results.

Histopathology

- Histopathology is considered the "gold standard" for confirming FIP. Thus, biopsy of affected tissues is a valuable diagnostic procedure for identifying the distinctive FIP lesions of vasculitis and pyogranulomatous inflammation.
- Coronavirus can be identified in tissue specimens by PCR, immunofluorescent antibody, and immunohistochemistry techniques (see the next section).

Immunofluorescence and Immunohistochemistry

- Staining of macrophages in tissue specimens and effusions for intracellular FCoV antigen using either immunofluorescence or immunohistochemistry is the most definitive confirmatory test for effusive FIP, with 100% positive predictive value (i.e., virtually no false positives).
- Do not rule FIP out when these tests are negative. False negatives occur frequently when there are insufficient infected macrophages in the specimen or when the viral antigen is masked by competitive binding with FCoV antibodies.

TREATMENT

▼ ***Key Point*** No treatment has been proved to reduce the risk of developing FIP in healthy antibody-positive FCoV carriers.

Treatment has not been proved to lower the high mortality rate of FIP (>95%) or to slow progression of the disease. Various antiviral, immunomodulating, and immunosuppressive drugs have been used to treat FIP, but efficacy is highly questionable. Some cats show temporary improvement of clinical signs with supportive care and anti-inflammatory therapy using corticosteroids. The best candidates for palliative medical therapy are cats that are eating, active, and in good body condition. Spontaneous remissions occur but are extremely rare. Euthanasia is appropriate in severely affected cats with poor quality of life.

▼ ***Key Point*** Nearly all cats with confirmed clinical FIP eventually die, regardless of treatment.

Antiviral Therapy

- Some antiviral drugs (e.g., acyclovir and zidovudine [AZT]) have no activity against FCoV. Other antiviral drugs (e.g., ribavirin) show in vitro activity against FCoV but are either too toxic for cats or ineffective when used clinically to treat FIP.
- Ribavirin-treated kittens, for example, had more severe clinical signs and a shortened survival time compared with untreated kittens. Ribavirin also causes serious side effects of hemolysis, bone marrow toxicity, and liver toxicity in cats.
- Interferons in high doses have both immunomodulating and antiviral activity (see below).
- New anticoronaviral drugs under development for treatment of human severe acute respiratory syndrome coronavirus might have future application in cats.

Immunomodulator Therapy

- Immunomodulators are intended to stimulate compromised immune function. Anecdotal reports of clinical improvement with these agents have not been substantiated by controlled studies; thus, conclusive evidence of efficacy in FIP is lacking.
- Nonspecific immune stimulation can theoretically potentiate the immune-mediated consequences of FIP.
- Immunomodulator agents that have been used unsuccessfully to treat FIP include *Propionibacterium acnes* (ImmunoRegulin), thioproline (Promodulin), acemannan (Carrisyn), levamisole, and cyclosporine.
- Human and feline interferons have been used to treat FIP (see below).

Interferon Therapy

Recombinant forms of interferon given parenterally in high doses can have both antiviral and immunomodulatory effects. Feline interferon-omega and human interferon-alpha have both been used to treat FIP.

Feline Interferon-Omega

- Recombinant feline interferon-omega (rFeIFN-ω) is available in Europe and Japan. To treat FIP, rFeIFN-ω (Virbagen Omega, Virbac) has been given at 1,000,000 U/kg SC every other day until clinical remission then once or twice weekly. Expense will be prohibitive for many owners.
- In a preliminary uncontrolled study of 12 FIP cats using rFeIFN-ω with prednisone (2 mg/kg PO q24h, tapered to 0.5 mg/kg q48h), 33.3% of the cats achieved complete remission for more than 2 years, 33.3% achieved partial remission but died after 2 to 5 months, and 33.3% failed to respond and died.

Human Interferon-Alpha

- Parenteral high-dose human interferon-alpha (rHuIFN-α) (100,000–1,000,000 U/kg IM) does not appear to be effective in FIP, and it is unsuitable for long-term treatment because cats develop antibodies against the human protein after 3 to 7 weeks that inhibit the drug's activity.
- Oral low-dose human interferon-alpha (Roferon, Hoffman-LaRoche; Intron-A, Schering-Plough) diluted to 30 U/ml and given at 30 units PO, daily for 7 days on alternate weeks, has reportedly improved appetite and well-being with minimal side effects. The rHuIFN-α given orally is destroyed by gastric acid

and does not achieve systemic levels, but it may exert immunomodulating activity on oropharyngeal lymphoid tissue leading to cytokine release.

Palliative Medical Therapy

Some cats transiently improve with supportive care combined with palliative medical therapy using a high dose of corticosteroid, with or without a cytotoxic alkylating agent such as chlorambucil or cyclophosphamide (Table 10-3).

- Corticosteroids and alkylating drugs have no effect on the virus, but by virtue of their anti-inflammatory and immunosuppressive effects, they are aimed at controlling the widespread immune-mediated inflammatory reaction that occurs in FIP.
- These drugs may adversely affect cellular immunity mediated by T lymphocytes and macrophages and thus have the potential to promote the viral infection.

▼ ***Key Point*** Only use immunosuppressive drugs to treat overt FIP. In healthy FCoV carriers and seropositive cats, these drugs could have the unwanted effect of promoting the onset of FIP.

- The principal side effects of alkylating drugs are anorexia and bone marrow suppression; thus, monitor a complete blood count periodically (see Chapter 26 for more details on the use of these drugs).
- Persistent drug-induced anorexia is a frequent problem when these drugs are given daily. An alternative is pulse administration, using a large dose of the drug once every 2 to 3 weeks. In this way, a few days after each dose the appetite usually rebounds and is maintained between treatment cycles.
- Regardless of the regimen chosen, if no response is noted within the first 2 to 4 weeks, consider the therapy ineffective and either modify or discontinue it. If a positive response occurs, continue the treatment indefinitely.

Supportive Treatment

These measures may improve quality of life and possibly survival time.

- Minimize stress as an exacerbating factor.
- Perform intermittent body cavity drainage of effusion as needed to relieve dyspnea.
- Give parenteral fluid therapy.
- Give nutritional support (via tube-feeding techniques; see Chapter 3).
- Give aspirin (10 mg/kg q72h) to inhibit platelet aggregation caused by vasculitis.
- Give antibiotics as needed to control complicating bacterial infections.
- Treat anterior uveitis with topical corticosteroids and atropine (see Chapter 136).
- Give blood transfusions (for severe nonregenerative anemia).

Table 10-3. TREATMENT FOR FELINE INFECTIOUS PERITONITIS

Mechanism of Action	Drug or Treatment*	Dosage
Immunomodulator and antiviral	Feline interferon-omega (Virbagen Omega)	1 million U/kg SC q48h until remission, then weekly
Immunomodulator	Human interferon-alpha (Roferon, Intron-A)	30 units PO q24h for 7 days on alternating weeks
Anti-inflammatory and immunosuppressive	Prednisone	2–4 mg/kg, q24h, PO
Immunosuppressive†	Chlorambucil (Leukeran) *or*‡	20 mg/m^2, every 2–3 wks, PO
	Cyclophosphamide (Cytoxan)	2–4 mg/kg, 4 days each week, PO, *or* 200–300 mg/m^2, every 2–3 wks, PO
Platelet aggregation inhibitor	Aspirin	10 mg/kg, q72h, PO
	Ozagrel HCl	5 mg/kg, q12h, SC
Topical ophthalmic for uveitis	Prednisone acetate (1%)	2–3 drops/eye q6h
	Atropine (1%)	1–3 drops/eye up to q6h for mydriasis
Supportive treatment	Minimize "stress"	—
	Parenteral fluid therapy	As needed to maintain hydration
	Nutritional therapy via tube feeding	See Chapter 3
	Body cavity drainage (thoracentesis)	As needed to relieve dyspnea
	Blood transfusion	As needed for severe anemia
	Antibiotics for complicating infections	Dosage based on the drug

*Cats most likely to respond are in good physical condition, are eating, and are free of neurologic signs, severe anemia, and feline leukemia virus or feline immunodeficiency virus infections.

†For conversion of body weight to body surface area (m^2), refer to conversion tables in Chapter 26.

‡Choose only *one* of these two alkylating agents, and combine with a corticosteroid.

PREVENTION

Vaccination

▼ ***Key Point*** The currently available FIP vaccine does not appear to be effective and is not recommended.

- A modified-live, temperature-sensitive strain of FIP coronavirus became available in 1991 as an intranasal vaccine for use in cats 16 weeks of age and older (Primucell FIP, Pfizer).
- The vaccine virus replicates locally in the nasopharynx and intestines but not systemically because of temperature sensitivity. It is supposed to stimulate local nasal and gut mucosal immunity, salivary immunoglobulin A antibody, and cell-mediated immunity. It does not protect against enteric FCoV infection.
- The lack of proven efficacy in kittens younger than 16 weeks of age is a fundamental pitfall, because under most circumstances kittens first become infected with FCoV between 6 and 16 weeks of age.
- The 2000 Report of the American Association of Feline Practioners Panel on Feline Vaccines states: "At this time there is no evidence that the vaccine induces clinically relevant protection and its use is not recommended."
- Various genetically engineered recombinant vaccines are under development and may become available in the future.

Control of Feline Infectious Peritonitis in Catteries

Control of FCoV infection in catteries, shelters, and multicat households is aimed at limiting virus spread, minimizing exposure, and reducing stress. Infection with FCoV is ubiquitous, so complete eradication is rarely feasible, and even if eradication is successful, reinfection frequently occurs. Test and removal based on FCoV antibody testing is not practical since it is typical for 80% to 90% of cats in endemic catteries to be seropositive. Depopulation and starting over would be required.

General Principles

▼ ***Key Point*** Do not consider healthy FCoV antibody-positive cats to be harmless. Seropositive cats frequently shed FCoV in their feces that contaminates the environment and infects other cats, and FCoV always has the potential to mutate and cause FIP.

- Be familiar with risk factors and transmission of FCoV (see "Epidemiology").
- Use good husbandry practices (e.g., good sanitation, ventilation, and feeding practices) and limit feco-oral contamination.
- Minimize overcrowding and stress. High-density housing allows a high level of fecal contamination of the environment, facilitating feco-oral spread of infection.
- Control feline leukemia virus in the cattery with vaccination, testing, and removal (see Chapter 8).
- Do not breed male and female cats that have a history of producing kittens that later developed FIP, because they potentially may pass on a genetic susceptibility to FIP.
- The risk of infection from cat shows and breeding exchanges is considered low; however, in these situations do not allow sharing of food, water, or litter.
- Only allow healthy seronegative cats to enter a coronavirus-free cattery. Ideally, before a cat can be safely mixed with other cats, confirm the absence of fecal shedding based on at least 4 consecutive negative fecal RT-PCR tests (although this may not be practical in many situations).

Control of Viral Exposure

The greatest source of viral contamination of the environment is from small particles of fecal debris and litter that are carried throughout the facility by movement of air, animals, and people. Any contaminated material can end up on the fur and thus be ingested by the cats. Consider the following control measures to reduce the environmental virus load and to minimize exposure:

- Use at least one litter box for every two cats. Locate litter boxes away from food and water bowls to avoid cross-contamination. Ensure that the area is easy to clean and disinfect.
- Scoop feces from litter boxes daily, and replace litter and disinfect litter boxes as often as possible (at least weekly).
- Dispose of used litter in sealed plastic bags.
- Use dedicated food and water bowls for each animal, and clean and disinfect bowls regularly.
- Brush the fur of cats regularly to remove contaminated fecal particles and litter that could be ingested during grooming.
- Reduce cross-contamination between cats by housing cats individually or in stable small groups of four or less.
- Avoid having too many kittens because they shed the greatest amount of virus.
- Ideally, identify and eliminate persistent carriers that continuously shed large amounts of virus by using fecal RT-PCR tests repeated over several months.

Control of Viral Spread in Kittens

Isolation and early weaning can be effective for controlling the spread of FCoV in kittens, as well as herpesvirus and calicivirus.

- Isolate queens 1 to 2 weeks pre-partum so that queens can give birth and nurse kittens in isolation from other cats in the cattery.
- Wean the kittens early and remove them from the mother at 5 to 6 weeks of age, coinciding with the time when maternal-derived immunity dissipates, then keep the litter of kittens isolated from all other cats until at least 16 weeks of age.
- Maintain strict quarantine procedures to prevent environmental or fomite transfer of FCoV.
- Confirm seronegativity at 12 to 16 weeks of age or prior to moving kittens to a new home to document effectiveness.
- The disadvantages of this approach are that it requires facilities for isolation and quarantine and that early weaning may adversely affect social development of the kittens.

Chapter

11 Feline Infectious Respiratory Disease

Robert G. Sherding

ETIOLOGY

Feline infectious respiratory disease is caused by a variety of viruses and bacteria, especially feline herpesvirus and calicivirus. The clinical signs that result from these infectious agents overlap and are often indistinguishable; thus, these infections are collectively referred to as feline infectious respiratory disease or upper respiratory infection (URI).

Viruses

Most infectious upper respiratory disease in cats is caused by these two highly contagious viruses:

- *Feline herpesvirus-1 (FHV-1):* Also known as feline viral rhinotracheitis (FVR)
- *Feline calicivirus (FCV):* A member of the vesivirus (vesicle-forming) genus

Bacteria

- *Chlamydophila felis* (formerly *Chlamydia psittaci*)
- *Bordetella bronchiseptica*
- *Mycoplasma felis*

TRANSMISSION

Routes of Infection

Transmission can occur by contact, fomites, and aerosol. Direct contact with infected cats and fomites are the most important sources of infection. The greatest risk of infection is in young kittens, unvaccinated cats, and cats confined in high-density groups (e.g., shelters, catteries, or multicat households).

▼ ***Key Point*** Overcrowded group confinement contributes to the spread of feline respiratory infections.

- *Direct contact:* Oral, nasal, and ocular discharges are infective.
- *Fomites:* These etiologic agents can survive and remain infectious on fomites such as contaminated cages, examination tables, food and water dishes, and human hands and clothing.
- *Aerosol:* Sneezing and coughing can propel aerosolized microdroplets with virus up to 4 feet.

Subclinical Carriers as Sources of Infection

Most cats that recover from FHV and FCV infection become subclinical carriers and shed the virus for prolonged periods. Subclinical carriers that are persistently infected (FCV) or latently infected (FHV) perpetuate these viruses within the cat population and serve as the principal source for outbreaks in catteries, multicat households, research colonies, veterinary hospitals, and shelters.

▼ ***Key Point*** Despite vaccination, subclinical viral carriers are common and account for the widespread prevalence of infections caused by FHV and FCV.

Feline Herpes Virus

- In recovered carriers, FHV persists lifelong in a latent form in the trigeminal ganglia and other tissues. Carriers may shed the virus intermittently coinciding with reactivation of latent virus infection. Recrudescence of shedding and clinical signs in latent FHV carriers can be triggered by stress, parturition, lactation, or glucocorticoids.
- Episodes of shedding generally persist for 2 weeks and can be accompanied by mild clinical signs.
- FHV survives up to 24 hours outside the host, causing a moderate risk of fomite transmission.
- FHV is susceptible to drying and most disinfectants.

▼ ***Key Point*** Shedding of FHV often is triggered by parturition and lactation in latent carrier queens at the time when their newborn kittens are most susceptible. This is an important source of URI in young kittens.

Feline Calicivirus

- Recovered FCV carriers shed the infectious virus from the oropharynx continuously for many months and sometimes years. Subclinical carriers are prevalent. Isolation rates of FCV from healthy cat

populations are 5% to 10% for pet cats, 20% for show cats, and 40% for colony cats.
- FCV is highly resistant with survival outside the host of 8 to 10 days, causing a high risk of fomite transmission.
- The preferred disinfectant is a 1:32 dilution of 5% sodium hypochlorite (bleach).

Chlamydophila felis

- Primarily shed from conjunctival secretions; prolonged shedding up to 18 months has been documented after experimental infections
- Survives for several days in conjunctival discharges
- Inactivated by lipid solvents, detergents, and 1:1000 quaternary ammonium

Bordetella bronchiseptica

- *B. bronchiseptica* can be isolated from many healthy cats, indicating a widespread subclinical carrier state. Prolonged oronasal shedding for at least 19 weeks after experimental infection has been documented.

CLINICAL SIGNS

Typical clinical signs of feline URI are sudden onset of anorexia, depression, fever, and naso-ocular discharge. Other signs specific to each etiologic agent are detailed in the following sections. Illness is more severe in young kittens and milder in previously vaccinated cats. Clinical disease caused by FHV and FCV is usually self-limiting within 5 to 10 days; however, some cats take 3 weeks to recover. See Table 11-1 for a comparison of the clinical manifestations of FHV and FCV.

Feline Herpesvirus

- FHV has an affinity for conjunctival, nasal, and upper airway (laryngotracheal) epithelium. Multifocal epithelial necrosis at these sites causes rhinitis, tracheitis, laryngitis, and conjunctivitis. FHV can also cause nasal turbinate necrosis and osteolysis.
- Signs include sneezing, lacrimation, serous to mucopurulent naso-ocular discharge, cough, hypersalivation, and loss of voice.
- Corneal involvement causes keratitis and herpetic ulcers. Ulcers can have a punctate, oval, or branching (dendritic) pattern (see Chapter 134).
- Infection during pregnancy may result in abortion or in a severe generalized form of infection in newborn kittens, characterized by fatal encephalitis or focal necrotizing hepatitis. Neonates also may develop panophthalmitis (ophthalmia neonatorum) that can permanently damage the eyes.
- Secondary bacterial complication of the lesions may worsen and prolong FHV disease. Bacterial pneumonia is a serious complication in young kittens.
- Extensive turbinate damage may lead to fibrosis and stenosis of the nasal passages and predispose the patient to chronic rhinitis.
- Ulcerative skin lesions are seen infrequently.

Table 11-1. CLINICAL MANIFESTATIONS OF FELINE VIRAL RESPIRATORY DISEASE

Manifestation	Feline Herpesvirus (FHV-1)	Feline Calicivirus (FCV)
Incubation	2–6 days	1–5 days
Duration	5–10 days (rarely to 3 weeks)	5–7 days (rarely to 2 weeks)
Anorexia, depression	Severe and frequent	Mild and inconsistent
Fever	Frequent	Inconsistent (diphasic)
Nasal signs	Sneezing—severe Discharge—marked Ulcerated nares Turbinate necrosis Sequelae—chronic rhinosinusitis, nasopharyngeal stenosis	Sneezing—mild Discharge—mild or absent Ulcerated tip of nose
Ocular signs	Conjunctivitis—severe (serous to mucopurulent discharge, chemosis, photophobia) Ulcerative keratitis Panophthalmitis (neonates) Sequelae—sicca, corneal sequestrum	Conjunctivitis—mild
Oral signs	Hypersalivation, rare ulcers	Frequent oral ulcers (tongue, palate) Sequelae—chronic stomatitis, gingivitis, faucitis
Pulmonary signs	Rare bacterial pneumonia	Occasional viral pneumonia
Other signs	Abortion Peracute neonatal death (hepatic necrosis) Ulcerative dermatitis	Limping syndrome (arthritis, arthralgia, myalgia) Interdigital paw ulcers Enteritis (diarrhea and vomiting) Acute hemorrhagic fever syndrome
Postrecovery carrier	Lifelong	Months to years
Shedding pattern	Intermittent (after stress; lasts 1–2 wks)	Persistent

Feline Calicivirus

▼ ***Key Point*** The pathogenicity of different FCV strains is highly variable, producing a diversity of clinical syndromes. The most consistent feature of FCV is oral ulceration.

FCV Respiratory Disease

- FCV has an affinity for oropharyngeal epithelium and alveolar pneumocytes of the lung.
- Infection is manifested most often as oral ulceration (tongue, palate, and fauces), mild rhinitis (sneezing), and conjunctivitis. Oral ulcers begin as vesicles that subsequently rupture and ulcerate. In some cats, the tip of the nose may be ulcerated and crusted.
- Viral interstitial pneumonitis may occur, but it is usually subclinical.

Other FCV Syndromes

- One FCV isolate reportedly causes consistent footpad and interdigital ulcers along with oral ulcers ("paw and mouth disease").
- FCV has been isolated from cats with chronic ulcerative or proliferative lymphocytic gingivitis, stomatitis, and faucitis. This may be a hypersensitivity response to persistent FCV infection, but the role of FCV in chronic oral disease is uncertain.
- Some FCV strains cause acute synovitis, fever, and joint pain (arthralgia and myalgia), with or without concurrent respiratory signs.
- FCV has been isolated from the intestines and feces of cats with acute and chronic enteritis.
- FCV has been isolated from the urine of cats with lower urinary tract disease, but a causative role has not been established.

Acute Hemorrhagic Fever Syndrome

- Highly virulent, variant strains of FCV have recently emerged in North America associated with several outbreaks of a systemic, acute febrile hemorrhagic syndrome. Most outbreaks have originated in hospitalized shelter cats.
- Clinical signs usually include high fever, upper respiratory signs, oral ulcers, and ulcerative dermatitis and subcutaneous edema of the face, pinnae, and distal limbs. Signs of systemic involvement are variable and include dyspnea, jaundice, vomiting, diarrhea, hematochezia, and epistaxis. Some cats develop pulmonary edema, pleural and abdominal effusion, hepatic necrosis, pancreatitis, disseminated intravascular coagulation (DIC), or gastrointestinal ulceration. The mortality rate is up to 50%.
- Widespread susceptibility is seen regardless of age, health, or vaccination status. Healthy, well-vaccinated adult cats can succumb rapidly to the disease. FCV vaccines do not appear to crossprotect against these variant strains of FCV.

Feline Chlamydophilosis

- *C. felis* is a primary conjunctival pathogen. Ocular signs predominate as acute or chronic follicular conjunctivitis with chemosis and mucopurulent discharge that can begin unilaterally and later become bilateral (see Chapter 133).
- Mild nasal discharge and sneezing are infrequent.
- Subclinical pneumonia (pneumonitis) is uncommon and only detectable histologically.

Feline Bordetellosis

- *B. bronchiseptica,* a cause of infectious tracheobronchitis (kennel cough) in dogs, may be a primary or secondary respiratory pathogen in cats, especially in kittens.
- Outbreaks of fatal bronchopneumonia have been attributed to *B. bronchiseptica;* however, infections are usually subclinical or characterized by mild self-limiting signs of fever, sneezing, and nasal discharge of less than 10 days in duration. Coughing is an inconsistent sign.

Complications and Chronic Sequelae

Subclinical Carrier States

- Cats recovered from FHV and FCV are subclinical carriers and infectious for other cats (see "Transmission").
- Recrudescence of latent FHV may be associated with recurrence of clinical signs as well as viral shedding.

Chronic Nasal Disease

Chronic rhinitis or sinusitis and nasal obstruction can occur after FHV infection. Potential causes are:

- Complicating bacterial sinusitis
- Permanent turbinate damage resulting from necrosis and osteolysis
- Obstructed nasal passages because of nasopharyngeal fibrosis and stenosis

Chronic Ocular Disease

FHV has been associated with the following chronic ocular conditions in cats. The role of FHV in the pathogenesis of some of these is unclear:

- Chronic bacterial or follicular conjunctivitis (see Chapter 133)
- Tear duct blockage or infection (dacryocystitis) (see Chapter 139)
- Keratoconjunctivitis sicca (see Chapter 139)
- Chronic ulcerative keratitis and stromal keratitis (see Chapter 134)
- Corneal sequestrum (see Chapter 134)
- Eosinophilic keratitis (see Chapter 134)
- Anterior uveitis (see Chapter 136)

Chronic Oral Disease

- Chronic lymphoplasmacytic stomatitis, gingivitis, and faucitis may be linked to chronic FCV infection (see Chapter 64).

DIAGNOSIS

For individual mildly infected cats, a diagnosis of "viral respiratory disease" or URI based on clinical signs and likelihood of exposure is adequate for patient management. Cultures, virus isolation, and polymerase chain reaction (PCR) assays allow definitive diagnosis and are indicated for evaluation of disease outbreaks in groups of cats.

▼ ***Key Point*** Severe naso-ocular signs are most consistent with FHV infection. Corneal ulceration is indicative of FHV, whereas oral ulceration is most suggestive of FCV. Persistent conjunctivitis is the predominant sign in chlamydophilosis.

Confirmatory Tests for Viruses

Direct Immunofluorescence

- Collect smears of nasal mucosa or conjunctiva.
- This is most useful for FHV. This also can be used for FCV, but it is less reliable than virus isolation.

Virus Isolation

- Submit cell culture swabs from the oropharynx, nasal cavity, or conjunctiva. Use viral transport media on ice.
- This is the gold standard for confirming FCV. It also is useful for FHV.

Polymerase Chain Reaction

- PCR assays can be used to identify FHV, FCV, *Chlamydophila,* and *Mycoplasma* in nasal, conjunctival, corneal, and oropharyngeal mucosal specimens. Submit mucosal swabs or scrapings in 1 ml of phosphate-buffered saline (PBS) and freeze at –20°C.
- *FHV:* PCR assay is the most sensitive diagnostic method for FHV.
- *FCV:* Reverse transcriptase-PCR assay is useful, but it is less sensitive than virus isolation.

Bacterial Culture

- *Bordetella:* Submit nasal, pharyngeal, or bronchial specimens for culture on selective media. For transport, use charcoal Amies transport medium (Beckton Dickenson).
- *Chlamydophila:* Submit conjunctival swabs in chlamydia transport media for cell culture.
- *Mycoplasma:* Submit conjunctival, nasal, or tracheobronchial specimens for specialized culture.

Detection of Inclusion Bodies

- *FHV:* Intranuclear inclusions can occasionally be identified in conjunctival biopsies (hematoxylin-eosin stain).
- *Chlamydophila:* Intracytoplasmic inclusions can be identified in some cases in scrapings of conjunctival epithelium (Diff-Quik stain), mostly during the first 2 weeks of infection.

Serology

- Serology is generally not very helpful because most cats have vaccine-induced antibody titers.
- A rising neutralizing antibody titer in serum from a convalescent animal indicates a presumptive diagnosis of FCV.

Ancillary Diagnostics

Complete Blood Count and Serum Chemistries

- Results of complete blood count (CBC) and other routine laboratory evaluations (e.g., serum chemistry profiles) are usually normal except in severe infections complicated by bacteria, in which a neutrophilic leukocytosis may be seen.
- Findings in caliciviral acute hemorrhagic fever can include hyperbilirubinemia, elevated serum liver enzymes, hypoalbuminemia, and coagulopathies (DIC).

Tests for Retroviruses

Persistent or recurrent signs of URI often develop in immunodeficient cats. Evaluate cats for underlying infections of feline immunodeficiency virus (FIV antibody test; see Chapter 9) and feline leukemia virus (FeLV antigen test; see Chapter 8) in the following situations:

- Cats with recurrent episodes of infectious respiratory disease
- Vaccinated adult cats with unusually severe signs
- Cats with signs that persist longer than 2 weeks

Diagnostic Imaging

- Consider thoracic radiography in severe cases suspected to have complicating bronchopneumonia.
- Use nasal radiography and computed tomography to evaluate cats suspected of having chronic nasal sequelae, such as frontal sinusitis, severe turbinate damage, or nasopharyngeal stenosis.

TREATMENT

▼ ***Key Point*** Treat infectious respiratory disease in cats on an outpatient basis whenever possible to prevent cross-infection of other hospitalized cats.

Feline infectious respiratory disease is self-limiting in most cats within 5 to 10 days. Treatment is mainly supportive in nature, often combined with antibiotics and antiviral therapy, depending on the severity. Rarely, severe or complicated infections may require parenteral fluid therapy, oxygen therapy, or intensive nutritional support therapy.

Supportive Treatment

- Provide rest and warm ambient temperature (inhibits FHV replication).
- Clean discharge from eyes and nares as needed.
- Provide fluid and nutritional support as needed. Advise owners to offer a variety of flavorful, aromatic foods and broths to encourage continued intake. Soft or liquefied foods are better tolerated in cats with inflammation of the oral cavity and pharynx. Cyproheptadine or oxazepam may stimulate eating in some inappetant cats. In cats with prolonged anorexia, parenteral fluid therapy and esophagostomy or gastrostomy tube feeding may be needed (see Chapter 3).
- To minimize inspissation of respiratory secretions, prevent dehydration (using parenteral fluid therapy if necessary) and promote airway humidification (humidifier or steamed room).
- Irrigate necrotic oral lesions with 0.2% chlorhexidine solution (Nolvadent).
- Oxygen therapy may be required in cats with bronchopneumonia and hypoxemia (see Chapter 3).

Antiviral Therapy

- The oral antiviral drugs used in human herpes (e.g., acyclovir and valacyclovir) are not active against FHV, are too toxic for cats, or both. Ribavirin is active against FCV in cell culture but is too toxic for cats.
- Topical antiviral drugs have a role in treating ophthalmic manifestations of FVR (see "Ophthalmic Therapy").
- Human interferon (human IFN-α_2; Roferon-A) and recombinant feline interferon have been empirically used orally and topically as nose drops or eye drops, but there is little or no evidence of efficacy.

L-Lysine Therapy

- Preliminary evidence suggests that daily supplementation of L-lysine may reduce replication and shedding of FHV in cats with acute and chronic latent infections. Arginine is an essential amino acid for FHV replication that acts as a growth promoter for FHV. Presumably through competitive inhibition, large doses of L-lysine antagonize the growth promoting effects of arginine and inhibit FHV replication.
- Administer L-lysine at 250 mg PO bid for kittens and 500 mg bid for adult cats. Give in an oral paste form (Enisyl-F; Vetoquinol/EVSCO) or as a powder added to the food. Vomiting occurs if not given with food.

Antibiotic Therapy

- In viral infections, consider broad-spectrum antibiotics to control secondary bacterial infection, such as oral amoxicillin/clavulanate, doxycycline, cephalosporin, or fluoroquinolone. Liquid forms are best for cats with painful swallowing.
- For *Bordetella, Chlamydophila,* and *Mycoplasma,* give doxycycline (5 mg/kg PO q12h; use liquid form, or give with food or water to prevent esophagitis). An alternative is a fluoroquinolone such as orbifloxacin (2.5–7.5 mg/kg, PO, q24h). Choose antibiotics for *Bordetella* based on a culture and sensitivity whenever possible.

Ophthalmic Therapy

- For herpetic corneal ulcer and other severe or refractory corneal manifestations of FHV, consider using a topical antiviral agent. These are expensive and often irritating. To be effective, apply every 4 to 6 hours for 2 to 3 weeks.
  - Idoxuridine (only available from compounding pharmacies)
  - Vidarabine (Vira-A; Parke Davis)
  - Trifluridine (Viroptic; Burroughs Wellcome): Most expensive and most irritating
- For *Chlamydophila* and *Mycoplasma,* use tetracycline ophthalmic ointment for 3 to 4 weeks.
- For complicating bacterial conjunctivitis, use triple-antibiotic ophthalmic ointment.
- Do not use topical corticosteroids in FHV. If an anti-inflammatory ophthalmic therapy is needed, use 0.2% cyclosporine (Optimmune) or another nonsteroidal agent.

PREVENTION

Incorporate FHV and FCV into all feline vaccination programs. Use good husbandry and other control measures to prevent the spread of disease in groups of cats confined together in catteries and shelters.

Vaccination

▼ ***Key Point*** Vaccination for FHV and FCV helps prevent clinical illness, but it does not prevent infection. It also does not prevent or eliminate the chronic carrier state or virus shedding.

- Modified live virus (MLV) injectable, inactivated virus (killed) injectable, and MLV intranasal vaccines are available. Intranasal vaccines induce faster and better protection while avoiding adjuvant-related side effects. However, injectable vaccines are also reasonably effective.
- Protection with FCV vaccination is variable because of the heterogeneity of FCV strains in cats. Vaccina-

tion probably does not induce crossprotection against all FCV strains.

- *FHV and FCV vaccines:* Initially give kittens at least two doses 3 weeks apart (usually 9 and 12 weeks of age or every 3–4 weeks until 12 weeks of age), then revaccinate 1 year later and revaccinate every 3 years thereafter (see Chapter 7). Do not use MLV vaccines in pregnant cats.
- *Chlamydophila and Bordetella vaccines:* These are not recommended for routine use but may be considered for cats in high-risk multicat environments (see Chapter 7). Vaccine efficacy and duration of immunity are not well established.

Vaccine Side Effects

- Local reactions and injection site sarcomas have been associated with adjuvanted killed vaccines.
- Transient fever, arthralgia, and myalgia can be seen after MLV vaccines.
- Mild postvaccinal sneezing and oculonasal discharge are common after intranasal vaccination. Oronasal exposure to the viral strains in injectable MLV vaccines by inadvertent aerosolization or licking from the haircoat also can cause clinical disease with sneezing, oculonasal discharge, and oral ulcers.
- MLV vaccines that are produced in feline kidney cell culture systems contain renal antigens that may stimulate anti-kidney antibodies in vaccinated cats; however, the significance of this is not yet known.

Control in Catteries and Shelters

- Vaccinate all cats against FHV and FCV. When faster immunity is needed (such as in outbreaks), use intranasal vaccine. In catteries apparently free of respiratory disease, consider using a killed injectable vaccine to avoid introducing an MLV strain into the group.
- Avoid incoming cats from infected sources. Isolate cats with signs of illness.
- FHV and FCV are perpetuated in catteries by virus shed from subclinical carriers and spread by contact, fomite, and aerosol transmission.

▼ ***Key Point*** Subclinical shedders of respiratory viruses are prevalent. Cats free of signs of disease are not necessarily free of infection, even if they have been well vaccinated.

- When introducing a new cat, there is always a risk that the incoming cat is a subclinical carrier that can be the source for an outbreak. Vaccinate and then isolate all incoming cats for 3 weeks. This protects the incoming cat from viruses in the cattery and protects the cattery from a new cat that might be incubating a viral infection or undergoing stress-induced shedding.
- In housing facilities for cats, avoid overcrowding, provide adequate ventilation (10 or more air changes per hour), maintain a warm nonfluctuating temperature, control humidity at approximately 50%, and provide separate cages or pens with solid partitions and separate food and water dishes.
- To prevent fomite transmission, clean and disinfect cages (1:32 sodium hypochlorite bleach solution) and minimize cross-contamination by personnel.
- Identify cats infected with *Bordetella* or *Chlamydophila,* and treat them with oral doxycycline and topical tetracycline ophthalmic ointment.

Control in Endemic Breeding Catteries

- In endemic catteries, kittens lose their maternal immunity at 5 to 7 weeks of age and often become infected by virus shed from carrier adults, especially their own lactating mother.
- To boost maternal antibody levels in kittens, vaccinate queens before breeding or during pregnancy. Only use inactivated vaccine in pregnant cats.
- Move queens into isolation 3 weeks before giving birth to prevent exposure of newborn kittens to carriers in the colony.
- Wean kittens early at 4 to 5 weeks of age and raise them in isolation to reduce risk of acquiring infection from a carrier mother.
- Use intranasal vaccine in kittens starting at 6 weeks of age, because it can induce local protection rapidly despite the presence of interfering maternal antibody. Maintain isolation until 1 week after the last dose of vaccine at 12 weeks.
- When possible, avoid using confirmed or suspected carriers in breeding programs, especially queens with a history of producing infected litters.

Chapter

12 Canine Infectious Tracheobronchitis (Kennel Cough)

Robert G. Sherding

Canine infectious tracheobronchitis (ITB), also known as kennel cough, is a collection of highly contagious infectious diseases of the canine respiratory tract that cause acute tracheobronchitis and sudden onset of a paroxysmal cough lasting several days.

ETIOLOGY

- The two most important causes of canine ITB are canine parainfluenza virus (CPIV) and *Bordetella bronchiseptica,* a gram-negative, aerobic coccobacillus.
- Other infectious agents occasionally isolated from coughing dogs include canine adenoviruses (especially CAV-2), canine herpesvirus, reoviruses (types 1, 2, and 3), and mycoplasmas; however, these are considered to be of minor importance.
- Clinical outbreaks of disease often involve concurrent infection with more than one of these agents. Clinical disease is more severe in animals co-infected with more than one agent.
- Cats can also occasionally develop clinical respiratory disease associated with *B. bronchiseptica* (see Chapter 11).

Transmission

▼ ***Key Point*** Canine ITB is highly contagious through direct contact with aerosolized respiratory secretions (via cough and sneezing) from infected dogs.

- These agents also can be transmitted by fomites (e.g., personnel, cages, and food and water bowls).
- Dogs infected with CPIV or CAV-2 shed the virus for only 1 week following recovery; however, dogs infected with *B. bronchiseptica* or mycoplasmas can become chronic carriers with persistent shedding.

▼ ***Key Point*** Canine ITB is commonly spread in dogs that are confined in high-density facilities with poor ventilation (e.g., boarding kennels, animal shelters, pet shops, veterinary hospitals, and lab animal facilities).

Pathogenesis

- Incubation period is usually 5 to 7 days (range of 3–10 days).
- Individually, these infectious agents cause mild self-limiting disease or are harbored in the airways of asymptomatic carriers. Mixed infections are common and have a synergistic effect in producing more severe clinical disease.
- The primary target of these agents is the upper airway epithelium. The result is epithelial injury, acute inflammation, and dysfunction of the airway cilia.

▼ ***Key Point*** In young puppies and immunocompromised animals, mixed infections or secondary bacterial invasion of the lower respiratory tract may cause life-threatening bronchopneumonia.

CLINICAL SIGNS

- Infection can occur at any time of year, but the highest incidence is in summer and fall.
- Acute onset of a loud, paroxysmal, hacking cough is due to tracheobronchitis. Even though the cough is sometimes described as dry-sounding, ITB is characterized by increased production of mucus.
- Cough may be high-pitched because of laryngitis and swollen vocal folds.
- Cough may be more frequent during exercise, excitement, or changes in temperature and humidity of inspired air.
- Cough may be elicited by tracheal palpation or pressure from the collar.

▼ ***Key Point*** Episodes of paroxysmal cough may be followed by gagging or retching that can be mistaken for vomiting or choking.

- Mild, serous, or mucopurulent naso-ocular discharge can be seen.
- Typically, affected dogs continue to eat, remain active and alert, and are nonfebrile. In severe cases, anorexia, depression, and fever may be present.

- Complicating bacterial pneumonia and even rare fatalities can occur with severe disease, especially in mixed infections in young or unvaccinated puppies from crowded environments such as pet shops and animal shelters.
- *Clinical course:* Clinical signs usually last 7 to 14 days in uncomplicated cases.

DIAGNOSIS

Consider ITB based on exposure history and clinical signs, especially the sudden onset of a severe cough in a previously healthy dog. A recent history of exposure to other dogs, especially under kennel conditions, is typical but not found in all cases. Hematology, radiography, airway cytology, and culture are not indicated unless ITB is severe with fever and bronchopneumonia. In typical uncomplicated ITB, these diagnostics are unremarkable or reveal nonspecific findings.

Hemogram

- *Mild ITB:* The complete blood count (CBC) is usually normal or shows a stress response (mature neutrophilia, lymphopenia).
- *Severe ITB:* Neutrophilic leukocytosis with a left shift is seen with complicating pneumonia.

Thoracic Radiography

- *Mild ITB:* Usually normal; a mild increase in interstitial lung density is seen occasionally.
- *Severe ITB:* Interstitial and alveolar pattern with lobar consolidation is seen with complicating bronchopneumonia.

Airway Cytology

- Evaluation of airway cytology is only indicated in severe, febrile, or complicated ITB. Obtain specimens by transtracheal aspiration, endotracheal tube lavage, or bronchoscopic lavage or swab (see Chapter 158).
- Findings include increased mucus, mucopurulent exudate, and sometimes bacteria.

Cultures

- Nasal swabs or tracheobronchial specimens can be cultured for *Bordetella* and mycoplasma.
- Isolation of *Bordetella* or mycoplasma allows only presumptive diagnosis, because these organisms can be harbored in the respiratory tract of subclinical carriers.

Virology and Serology

- Virus isolation can identify CPIV and CAV-2 from nasopharyngeal or tracheal swabs but is impractical for clinical use.
- Serology (paired acute and convalescent titers) can demonstrate viral exposure but has limited usefulness.

TREATMENT

Because many of the principles of treatment for bronchitis and bacterial pneumonia can be applied to dogs with ITB, refer also to Chapters 162 and 163.

General Guidelines

- Treat ITB on an outpatient basis whenever possible to prevent transmission to other hospitalized animals.
- For typical ITB, the disease is mild and self-limiting in 7 to 14 days; thus specific therapy may not be required. However, in most cases the empirical use of an antibiotic is justified along with an antitussive drug to control cough. If needed, an anti-inflammatory dose of a glucocorticoid can be used for the first few days in uncomplicated ITB.
- For severe, complicated ITB, treat aggressively for life-threatening bacterial bronchopneumonia (see Chapter 163). Avoid antitussives or glucocorticoids if bronchopneumonia is suspected.
- For cough that persists more than 14 days, consider causes other than ITB and evaluate further with thoracic radiographs, CBC, airway cytology and culture, and other diagnostics as appropriate.

Antibiotics

- For mild self-limiting ITB, antibiotics are optional, but most cases are treated empirically for possible *Bordetella* infection and to limit opportunistic secondary infections using one of the following:
  - Doxycycline (5–10 mg/kg PO q12h) for 2 to 4 weeks; effective for both *Bordetella* and mycoplasma
  - Amoxicillin/clavulanate (12.5–25 mg/kg POq12h) for 2 to 4 weeks
  - Azithromycin (5 mg/kg PO, once daily) for 5 to 7 days.
  - Others: enrofloxacin, trimethoprim/sulfa
- For severe ITB complicated by bronchopneumonia or for refractory *Bordetella* infection, choose antibiotics based on culture and susceptibility testing whenever possible.
- For refractory *Bordetella* infection, aerosolize gentamicin, 50 mg diluted in 2 to 3 ml saline, with a handheld nebulizer for 10 minutes every 12 hours for 3 to 5 days. Aerosolized antibiotic may be more effective against *Bordetella* because the bacteria attach to the cilia on the mucosal surface and are hard to reach with systemic antibiotics.

Antitussives

- In diseases with a productive cough, it usually is recommended to avoid antitussives, but in uncompli-

cated ITB (no fever or evidence of bronchopneumonia), the cough can be such a nuisance and source of discomfort for owner and patient that antitussives are often needed for relief.
- *Examples:* Hydrocodone (0.22 mg/kg PO q6–12h) and butorphanol (0.55–1.1 mg/kg PO q6–12h).
- Over-the-counter human cough medicines (dextromethorphan, guaifenesin) are not effective for treating ITB.

Corticosteroids

- Use anti-inflammatory dosages of corticosteroids (prednisolone 0.25–0.5 mg/kg PO q12h) as needed to control refractory cough in uncomplicated ITB. Limit use to 5 days or less, and do not use in dogs with bronchopneumonia.

Bronchodilators

- Efficacy of bronchodilators in ITB is not established, but these may reverse reflex bronchoconstriction triggered by airway irritation, thereby reducing discomfort and cough.
- *Examples:* Theophylline, aminophylline, albuterol, and terbutaline (see Chapter 162 for dosages).

Supportive Care

- Provide adequate fluid intake, airway humidification, nutritional support, and rest.

PREVENTION

Prevention strategies include vaccination and kennel management practices.

Vaccination

Guidelines for routine canine vaccination usually incorporate CAV-2 and CPIV. In dogs with high risk of exposure, *Bordetella* vaccination is an optional consideration, although it has only moderate efficacy. For specific vaccination recommendations, see Chapter 7.

- Both injectable and intranasal (IN) vaccines are available for CAV-2, CPV, and *Bordetella*. Vaccines for CAV-2 and CPIV contain modified live virus. *Bordetella* vaccines are derived from killed bacterins (injectable) or avirulent live culture (IN).
- The IN vaccines have advantages of stimulating local immunity, protection after one dose, more rapid onset of protection, and minimal interference from maternal antibody, allowing use in puppies as young as 2 to 4 weeks of age. Side effects of IN vaccines may include nasal discharge, sneezing, and cough beginning 2 to 5 days after vaccination.
- The maximum duration of immunity for these vaccines following initial puppy vaccination and a 1-year booster is not well established; however, immunity for CAV-2 and CPIV is expected to last for at least 3 years, whereas immunity for *Bordetella* may be only 6 months or less.
- For *Bordetella,* a booster is recommended 1 to 2 weeks prior to known exposure (e.g., boarding or showing) if the dog has not been vaccinated within the previous 6 months.

Kennel Prevention

- Avoid overcrowded, high-density confinement.
- Isolate infected (coughing) animals. In recovered animals, ITB viruses may be shed for 1 to 2 weeks, and *Bordetella* and mycoplasmas may be shed for 3 months or longer.
- Use caretaker hygiene to prevent fomite spread.
- Ensure proper kennel ventilation (at least 12 air changes per hour; 15–20 is optimal).
- Use disinfectants such as sodium hypochlorite (Clorox), chlorhexidine (Nolvasan), and benzalkonium Cl (Roccal-D).

PUBLIC HEALTH CONSIDERATIONS

Humans are potentially susceptible to *B. bronchiseptica,* especially if immunocompromised; however, the risk of acquiring infection from an infected pet is considered minimal.

Chapter

13 Canine Distemper

Robert G. Sherding

Canine distemper is a severe, highly contagious viral disease of dogs and other carnivores with profound effects on the respiratory tract, gastrointestinal tract, nervous system, and lymphoid tissue. It is seen worldwide.

ETIOLOGY AND EPIDEMIOLOGY

Canine distemper virus (CDV) is an RNA *Morbillivirus* in the *Paramyxoviridae* family. It is closely related to human measles virus.

Epidemiology

- *Distribution:* Enzootic worldwide.
- *Incidence:* All ages can be affected; however, the incidence is highest in young dogs (2–6 months of age), especially unvaccinated puppies that are exposed following the loss of passive immunity from maternal colostral antibodies.
- *Host susceptibility:* Domestic dogs and many wild carnivores, including the following:
  - *Canidae* family—Fox, dingo, coyote, wolf, jackal
  - *Mustelidae* family—Ferret, mink, weasel, marten, skunk, badger, otter
  - *Procyonidae* family—Raccoon, kinkajou, coati
  - Large *Felidae*—Cheetah, lion, jaguar, margay, ocelot
  - Others—Bear, panda, hyena, mongoose

Transmission

- Infected animals shed virus in all body secretions and excretions.
- The primary route of infection is by inhalation of the virus from aerosolized secretions or from fomites.
- The greatest opportunity for spread occurs where dogs are kept in groups (e.g., pet shops, kennels, animal shelters, and research colonies).
- Transplacental transmission is a rare source of distemper in neonates.
- Viral shedding usually ceases 1 to 2 weeks after recovery; therefore, "carrier state" transmission is not a big problem. Shedding for 60 to 90 days has been reported but is rare.
- The virus is labile in the environment, usually surviving only a few hours and no more than a few days outside of the host. It is readily destroyed by drying and by most disinfectants, such as phenols and quaternary ammonium.

PATHOGENESIS

The pathogenesis and severity of disease is affected by the viral strain and dose, the animal's age, and the effectiveness of the host's immune response.

Stages of Infection

- *Day 1:* Airborne exposure leads to infection of tissue macrophages of the upper respiratory tract.
- *Days 2 to 4:* Infection spreads to local lymphoid tissues of the tonsils, retropharyngeal lymph nodes, and bronchial lymph nodes.
- *Days 4 to 6:* Widespread infection of systemic lymphoid tissues involves the liver, spleen, abdominal lymph nodes, and lamina propria of the gastrointestinal tract. This corresponds to a transient fever spike and the onset of lymphopenia caused by viral damage to T and B lymphoid cells.
- *Days 6 to 8:* Viremia occurs.
- *Days 8 and 9:* The virus is disseminated to epithelial tissues (epitheliotropism) and the central nervous system (CNS) (neurotropism).
- *Days 9 to 14:* The subsequent outcome varies depending on the host's immune response and can include recovery, severe multisystemic clinical disease, or CNS localization.

Host Immune Response

- If the immune response fails to develop by days 9 to 14, the outcome is rapid, widespread dissemination of the virus to skin; glandular and epithelial organs, such as the respiratory and gastrointestinal tracts; and the CNS, causing acute encephalomyelitis. The results are multisystemic signs, a second fever spike, and a high mortality rate, especially in young puppies.
- If the immune response is sluggish or partial, multisystemic signs are mild or absent and recovery occurs; however, CNS localization can result in chronic

demyelinating encephalomyelitis with delayed onset of neurologic signs.
- If the immune response is rapid and effective, the infection is subclinical with complete recovery and elimination of the virus without clinical illness (by day 14 postinfection). It is estimated that more than 50% of CDV infections are subclinical. Delayed-onset CNS disease is occasionally seen in this group.

Role of Immunosuppression

- CDV causes severe immunosuppression associated with widespread lymphoid damage (apoptosis), impaired B and T cell–mediated immunity, circulating lymphopenia, thymic atrophy, and impaired cytokine responses.

CLINICAL SIGNS

The clinical signs of distemper are multisystemic and extremely variable. The mortality rate is variable depending on the virulence of the CDV strain and the age and immune status of the host.

General Systemic Signs

- Severe depression, anorexia, and dehydration
- Fever of 103°F to 105°F (39.5–41°C); diphasic (signs usually coincide with the second fever spike)

Respiratory System

- Rhinitis and conjunctivitis result in serous to mucopurulent naso-ocular discharge.
- Productive cough, tachypnea, dyspnea, and auscultation abnormalities are caused by pneumonia. This begins as an interstitial pneumonitis (primary viral effect) that rapidly develops into generalized bronchopneumonia complicated by secondary bacterial infection.

Gastrointestinal System

- Vomiting and diarrhea are the result of acute gastroenteritis.

Eyes

- Keratoconjunctivitis results in serous to mucopurulent ocular discharge.
- Chorioretinitis results in hyperreflective fundic lesions of retinal atrophy.
- Optic neuritis or serous retinal detachments results in blindness.

Nervous System

Acute encephalomyelitis predominantly destroys gray matter (neurons), whereas subacute or chronic nonsuppurative encephalomyelitis predominantly affects white matter (demyelination). CNS signs can occur simultaneously with other multisystemic signs or can be delayed in onset for 1 to 3 weeks or even months after apparent recovery from systemic illness. In some dogs, CNS involvement can occur as the only apparent clinical manifestation of infection. (For additional details concerning the neurologic manifestations of CDV, see Chapter 126.)

▼ ***Key Point*** Any region of the CNS can be affected by CDV. Diffuse or multifocal CNS involvement is typical. CNS signs tend to be progressive and can occur during, after, or in the absence of multisystemic illness.

- *Acute encephalitis:* Generalized seizures, so-called chewing-gum seizures, pacing, circling, and behavior changes
- *Midbrain, cerebellar, and vestibular:* Ataxia and other disturbances of gait
- *Spinal cord:* Disturbances of gait, abnormal spinal reflexes, paresis, and abnormal proprioception
- *Peripheral and cranial neuropathies:* Cranial nerve deficits including optic neuritis
- *Myoclonus:* Rhythmic, repetitive motor movements or muscle twitches

Other Clinical Manifestations

- Dental enamel hypoplasia (pitted teeth) can result from infection before eruption of the permanent teeth.
- Naso-digital hyperkeratosis of the foot pads and nasal planum ("hard pad disease"), which may be more frequent in dogs with CNS involvement.
- Abdominal pustular dermatitis.
- Viral cardiomyopathy has been observed in neonatal (<7 days old) infections.
- Young, growing large-breed dogs can develop metaphyseal osteosclerosis of the long bones.

DIAGNOSIS

▼ ***Key Point*** A presumptive diagnosis of canine distemper is based on typical clinical signs in a young dog (2–6 months of age) with a history of inadequate vaccinations and possibility of exposure to the virus.

In suspected cases of distemper, perform a complete blood count to assess leukocyte responses and thoracic radiographs to assess pneumonia. In dogs presenting with neurologic disease suspected to be due to CDV, use routine cerebrospinal fluid (CSF) analysis to distinguish CDV infection from other diseases. The presence of a CDV-specific antibody in CSF can confirm the diagno-

sis but requires a special laboratory. Special virology techniques can help substantiate a diagnosis of distemper; however, this is not practical or necessary in most clinical situations, and false-negative results are common.

Hematology

- Lymphopenia (beginning with the initial fever spike).
- Neutrophilic leukocytosis occurs later (associated with secondary bacterial complications such as pneumonia).
- Distemper inclusions are seen rarely in circulating lymphocytes, monocytes, neutrophils, and erythrocytes.

Thoracic Radiography

- Diffuse interstitial pneumonitis is seen early.
- A diffuse alveolar and bronchial pattern, air bronchograms, and lobar consolidation are seen later with secondary bacterial bronchopneumonia.

Cerebrospinal Fluid Analysis

- CSF may have increased cells (mostly lymphocytes) and/or protein, but normal findings do not rule out CDV (see Chapters 125 and 126).
- The presence of a CDV-specific antibody in CSF in greater concentration than serum is diagnostic of CDV, but not all cases have CSF antibodies.

Serology

- A single positive immunoglobulin G (IgG) titer is of no benefit, because it does not distinguish current infection from previous vaccination or exposure.
- The demonstration of a rising serum neutralizing an antibody titer or a CDV-specific IgM titer is suggestive but not diagnostic of recent CDV infection.

Virology

Various methods are available for demonstrating the virus or viral antigen in cells or tissues; however, with any of these procedures negative results do not rule out CDV.

- Intracytoplasmic viral inclusion bodies can sometimes be detected in peripheral blood cells, epithelial cells (cytology specimens), or biopsies, but inclusions are absent in many cases.
- Viral antigen can be identified by immunohistochemistry or fluorescent antibody techniques in cells from blood, CSF, cytology specimens (e.g., conjunctival scraping or tracheobronchial aspirate), or frozen tissue specimens.
- Virus isolation is difficult and expensive, and it mostly uses postmortem tissues.
- Polymerase chain reaction (PCR) assays have been used to test peripheral blood monocytes and tissues for CDV. These tests appear to be highly sensitive and specific under experimental conditions, but they are not yet readily available for clinical use.

TREATMENT

There is no effective antiviral treatment for CDV; therefore, treatment is supportive and symptomatic. Whenever possible, treat distemper in an isolation facility to prevent aerosol exposure of other hospitalized animals.

Symptomatic Treatment

- Give broad-spectrum antibiotics (extended-spectrum cephalosporin, fluoroquinolone, etc.) for secondary bacterial infection, especially pneumonia (see Chapter 163).
- For pneumonia, give antibiotics for secondary bacterial infection, maintain hydration with parenteral fluid therapy, and perform chest coupage (see Chapters 162 and 163).
- For vomiting and diarrhea, restrict food intake and administer antiemetics (see Chapter 67) and antidiarrheals (see Chapter 69) as necessary.
- For seizures, give a single dose of dexamethasone (1–2 mg/kg IV) for CNS edema, and consider anticonvulsant therapy using phenobarbital, diazepam, or potassium bromide (see Chapter 127).
- Provide general supportive care, such as eyes and nose kept clear of discharges; nutritional support; and adequate fluid intake or parenteral fluid therapy.

Prognosis

- Mortality rate varies but is highest in young puppies, especially those with high fever, severe multisystemic disease, severe pneumonia, or progressive neurologic disease.
- The neurologic deficits caused by CDV are often progressive and irreversible. It is justified to recommend euthanasia for patients with progressive neurologic signs that are severe and incapacitating.

▼ ***Key Point*** Do not be too optimistic with the owner, even with mild cases of distemper. The disease is often progressive despite therapy; and even animals that seem to be recovering can have a delayed onset of progressive, incapacitating neurologic disease.

Client Education

- Discuss the multiplicity of signs, likelihood of progression, and guarded to poor prognosis.
- Advise owners to isolate their animal from others to prevent spread of infection.

- Educate the client about proper immunization procedures for future reference.
- Recommend routine disinfection procedures and a 1-week waiting period before bringing another dog onto the premises.

PREVENTION

Passive Maternal Antibody

- The neonatal pup acquires passive immunity against CDV from its dam. Most of this maternal-derived antibody (Ab) comes from colostrum absorbed during nursing in the first few hours after birth.
- Maternal Ab protects most pups until after weaning and then gradually disappears between 8 and 14 weeks of age.
- When present, maternal Ab interferes with the response to vaccination; however, in most dogs it decreases to a level that allows successful immunization by 12 weeks of age.

Vaccination

▼ ***Key Point*** CDV vaccination is highly recommended for all dogs, and the efficacy of recombinant and modified live virus (MLV) vaccines is considered high. Vaccinate puppies at 6 to 8 weeks, 9 to 11 weeks, and 12 to 14 weeks of age. Give the first booster 1 year later and additional boosters every 3 years thereafter (see Chapter 7).

- Measles virus vaccine is not as protective as CDV vaccine, but a single IM dose can be used to provide temporary, partial protection in the presence of interfering maternal antibodies in young puppies 4 to 12 weeks of age who are in high-risk environments. This must be followed by CDV vaccine after 12 weeks of age.
- Rarely, postvaccinal encephalitis has occurred from 7 to 15 days after MLV distemper vaccination, primarily in neonatal puppies (<4 weeks of age); in severely ill, stressed, or immunocompromised dogs; or in very young puppies infected with parvovirus.

Chapter

14 Intestinal Viruses

Robert G. Sherding

Parvoviruses, coronaviruses, and rotaviruses are established causes of viral enteritis and diarrhea in dogs and cats and are discussed in this chapter. In addition, numerous other viruses of uncertain significance and enteropathogenicity have been found in the feces or intestines of dogs and cats.

- In dogs these include herpesvirus, enteroviruses, calicivirus, parainfluenza virus, adenovirus, and picornavirus.
- In cats these include astrovirus, calicivirus, reoviruses (types 1, 2, and 3), torovirus, and togavirus.
- In addition, the intestine may be involved as part of generalized viral infections in disorders such as canine distemper in dogs (see Chapter 13), and feline leukemia virus (see Chapter 8), feline immunodeficiency virus (see Chapter 9), and feline infectious peritonitis (see Chapter 10) in cats.

CANINE PARVOVIRUS

Etiology and Epidemiology

Canine parvovirus type 2 (CPV-2), a non-enveloped, single-stranded DNA virus, causes an acute, highly contagious enteritis of dogs that has been prevalent worldwide since the late 1970s. CPV is believed to have evolved from the feline panleukopenia virus or a closely related virus. Since 1980, variants designated CPV-2a and CPV-2b have evolved, the latter now being the predominant strain in North America. Both of these variants and a newer CPV-2c variant can also infect and replicate in cats.

Transmission

CPV infection occurs by the fecal-oral route. During acute illness, and for about 1 to 2 weeks after recovery, massive amounts of parvovirus (over 1 billion virions per gram of feces) are shed in the feces of infected dogs. Because the virus can survive and remain infectious for 5 to 7 months in the environment, fomites and environmental contamination play a major role in transmission. A peak seasonal incidence in the months of July, August, and September was found in a Canadian study, but this may vary by climatologic region.

Incubation

Signs of enteric disease usually begin 4 to 7 days after exposure, coincident with localization of virus in the mitotically active zones of intestinal crypt epithelia.

Age Incidence

Dogs of any age can be infected, but the incidence of clinical disease is highest in puppies between weaning and 6 months of age. Puppies younger than 6 weeks of age generally are protected by passive maternal antibody, whereas most mature animals have been immunized or have seroconverted from natural exposure.

Breed Incidence

All dogs are susceptible to infection; however, certain breeds have a higher risk for parvovirus infection and appear to be more susceptible to a severe form of the disease. These include rottweilers, Doberman pinschers, American pit bull terriers, German shepherds, and possibly Labrador retrievers. The biologic basis for these breed susceptibilities is unclear.

Pathogenesis

▼ ***Key Point*** CPV has an affinity for the rapidly dividing cells of the intestines, bone marrow, and lymphoid tissues and thus causes intestinal crypt necrosis, severe diarrhea, leukopenia, and lymphoid depletion.

- Intestinal epithelial damage from CPV causes breakdown of the intestinal mucosal barrier. This allows translocation of bacteria (especially *Escherichia coli*) and absorption of endotoxin, predisposing to bacteremia, endotoxemia, and the development of fatal systemic inflammatory response syndrome (SIRS).

Clinical Signs

- CPV causes sudden onset of anorexia, depression, fever, vomiting, diarrhea, and severe dehydration. The diarrhea can be profuse, foul smelling, and hemorrhagic. Abdominal palpation may reveal intestinal

loops that are painful and distended with fluid and gas.
- Hypothermia, hypovolemic shock, icterus, hemorrhagic diathesis (disseminated intravascular coagulation), and pulmonary edema because of acute respiratory distress syndrome may develop terminally in cases complicated by bacterial septicemia, endotoxemia, and SIRS.
- Death may occur in severe cases, particularly in very young puppies and in the highly susceptible breeds, and is usually attributable to dehydration, electrolyte depletion, endotoxic shock, or overwhelming bacterial sepsis associated with severe leukopenia. Septic puppies often develop hypoglycemia.
- The severity of clinical illness may be increased by factors such as stress, overcrowded or unsanitary kennel conditions, secondary bacterial infection, and concurrent diseases such as canine distemper, coronavirus, salmonellosis, campylobacteriosis, and intestinal parasitism (e.g., nematodes or giardia).
- In susceptible mature dogs, mild or inapparent infection that results in seroconversion without obvious clinical signs is common.
- In utero or postnatal infection can cause acute neonatal myocarditis in neonatal puppies that did not receive maternal antibodies. However, this form of perinatal parvoviral infection is rare because most nursing puppies receive abundant maternal antibodies from colostrum. Signs of parvoviral myocarditis include dyspnea caused by acute heart failure, sudden death caused by arrhythmias, and sometimes delayed-onset chronic congestive heart failure caused by chronic myocardial fibrosis.

Diagnosis

Suspect parvovirus infection in young dogs that have an abrupt onset of vomiting and foul-smelling bloody diarrhea, especially if associated with severe depression, fever, or leukopenia or if these signs follow potential exposure to infected dogs or fomites.

▼ ***Key Point*** Because of the difficulty in breaking through maternal antibody interference with vaccination in young puppies, prior vaccination does not necessarily exclude parvoviral infection, especially in puppies 6 to 20 weeks of age.

Hematology

- A complete blood count is particularly useful because approximately 50% of dogs with parvoviral enteritis develop severe leukopenia caused by lymphopenia and granulocytopenia, often with a total of only 500 to 2000 leukocytes/μl and sometimes less. Depletion of circulating mature neutrophils is caused by extensive loss of neutrophils through the damaged intestinal mucosa coupled with impaired myelopoiesis caused by bone marrow disruption from the virus. The severity of the leukopenia is generally proportional to the severity of the clinical illness. A rebound neutrophilia is a positive indicator of impending recovery.
- The hematocrit is variable. The PCV is often normal but can be moderately decreased (especially after rehydration with fluids) in some dogs because of intestinal hemorrhage. In some dogs, the PCV can be elevated initially because of hemoconcentration from dehydration.

Serum Chemistries

Serum chemistry abnormalities are variable and nonspecific. Findings may include electrolyte abnormalities (most frequently hypokalemia), prerenal azotemia, hypoglycemia, hypoalbuminemia, increased bilirubin, and increased liver enzymes (alanine transaminase and alkaline phosphatase).

Abdominal Radiography

Gas and fluid distention of the gastrointestinal (GI) tract due to generalized ileus is frequent in parvoviral enteritis and must be differentiated from small intestinal obstruction (e.g., foreign body or intussusception). Carefully palpate the abdomen to help rule out mechanical obstruction, including complicating intussusception. Barium contrast radiography often reveals mucosal irregularity (corrugation or scalloping) and prolonged transit time.

Serology

- Determination of an anti-CPV antibody titer in serum is not sufficient for diagnosis because up to 95% of dogs in the population have seroconverted from prior vaccination or natural exposure.
- Detection of early-appearing immunoglobulin (Ig) M antibodies by an indirect fluorescent antibody (IFA) test or 2-mercaptoethanol procedure provides presumptive evidence of recent infection because IgM antibodies are only found during or a few weeks after infection.

Virology

▼ ***Key Point*** Definitive diagnosis of parvoviral enteritis requires demonstration of active excretion of virus or viral antigen in the feces.

- Massive quantities of virus are shed in the feces during the acute illness, and shedding is over within 1 to 2 weeks after recovery. The most practical methods for detecting parvovirus in the feces are the commercially available, rapid in-office tests; including the enzyme-linked immunosorbent assays (ELISAs), such as the SNAP-Parvo Test (IDEXX Lab-

oratories) and ASSURE-Parvo Test (Synbiotics), or the rapid immunomigration assay, such as Witness CPV (Synbiotics). These tests are sensitive and accurate.
- Consider that false-positive results are occasionally seen on these CPV immunoassays 5 to 12 days following vaccination with modified live virus (MLV) vaccines. False-negative results occur rarely when fecal antigen is bound to neutralizing antibodies or viral shedding stops early.
- Other methods for detecting fecal excretion of parvovirus, such as hemagglutination, latex agglutination, electron microscopy (EM), virus isolation, and polymerase chain reaction (PCR) assay, are less convenient for routine clinical use because they require a commercial or research laboratory.

Necropsy

Necropsy diagnosis of parvovirus is based on identification of the characteristic intestinal lesions of necrosis of the intestinal crypt cells with secondary villous collapse and dilatation of the crypts with necrotic debris. Myeloid degeneration and widespread lymphoid depletion also are seen. Parvovirus can be demonstrated in frozen tissue samples by immunofluorescence and in fixed specimens by PCR.

Treatment

The treatment of parvovirus is mainly supportive and similar in most ways to the treatments used for other types of severe gastroenteritis. The intensity of the treatment depends on the severity of the signs. In dogs with fully developed clinical signs, withhold food and water for 12 to 24 hours to rest the GI tract, administer IV crystalloids to replace fluid and electrolytes, and give parenteral antibiotics to control bacterial complications. Initiate therapy whether or not definitive tests are done or while awaiting the return of results.

Fluid Therapy

▼ ***Key Point*** The cornerstone of treatment for CPV infection is IV fluid and electrolyte therapy.

See Chapter 5 for specific guidelines and procedures for fluid and electrolyte therapy.

- Use the intravenous route for fluid and electrolyte replacement using a balanced crystalloid solution (e.g., lactated Ringer's solution, Plasma-Lyte 148, or Normosol-R). For animals presented in hypovolemic shock, administer up to 90 ml/kg IV in the first 1 to 2 hours to restore hemodynamic stability (see Chapter 156), then switch to a maintenance rate. For most other animals, correct dehydration over the first 24 hours, then use a maintenance rate for fluids plus replacement of ongoing losses. Two to three times normal maintenance levels are often required. Continue fluid therapy until vomiting ceases and oral intake resumes.
- Add potassium (20–30 mEq/L) to IV fluids to control hypokalemia.
- Add dextrose to IV fluids at a 2.5% solution to control complicating hypoglycemia of sepsis. Monitor serum glucose and increase to 5% if needed to maintain serum glucose from 120 to 160 mg/dl.
- Consider supplementing magnesium according to guidelines in Chapter 5, as magnesium is often deficient in severe cases of parvoviral enteritis.
- Infuse colloid solution (e.g., hetastarch) at 20 ml/kg, IV, if infusion of balanced crystalloid solution does not restore hemodynamic stability or if serum albumin drops below 2 g/dl.
- Avoid administration of fluids by the subcutaneous route, especially in dogs with severe leukopenia, because this has been associated with secondary infection, cellulitis, and skin necrosis at administration sites.
- Monitor fluid therapy by tracking body weight, physical parameters, urine output, estimates of ongoing fluid losses (vomitus, diarrhea), and hematocrit and total plasma protein. Also evaluate serum potassium concentration daily and adjust potassium level added to IV fluids accordingly.

Antibiotics

- Administer bactericidal, broad-spectrum antibiotics to control bacterial complications. Initially, administer antibiotics parenterally.
- Use cefazolin or ampicillin in mild cases.
- Use cefazolin, ampicillin, or penicillin combined with an aminoglycoside (e.g., gentamicin or amikacin) or a fluoroquinolone (e.g., enrofloxacin) in severe and leukopenic cases. Fluoroquinolones may damage joint cartilage in young, growing pups. If an aminoglycoside is used, maintain hydration to prevent nephrotoxicity and monitor the urine daily for casts and proteinuria as early indicators of nephrotoxicosis.
- Consider a third-generation cephalosporin (e.g., ceftiofur; Naxel) combined with clindamycin in dogs with severe life-threatening bacterial sepsis.

Dietary Restriction

- Give nothing per os (fluid needs are met by IV infusion) for the first 12 to 24 hours. Prolonged food restriction may be detrimental to intestinal recovery. One study showed improved outcome in dogs treated with early enteral nutrition (using a nasoesophageal tube feeding starting at 12 hours) compared with dogs treated by prolonged dietary restriction.
- Persistent vomiting can sometimes take 3 to 5 days to abate in severe cases, sometimes requiring partial parenteral nutrition.

- When feeding is resumed, give small, frequent feedings of a bland and digestible diet, such as a commercial GI diet or cooked skinless chicken and rice, until GI function appears to have recovered. The transition back to regular feeding should be gradual.

Antiemetics

- For frequent or persistent vomiting associated with delayed gastric emptying that sometimes occurs in parvoviral infection, administer metoclopramide, a dopaminergic antagonist, at 0.5 mg/kg every 8 hours SC or most effectively as a constant rate infusion of 1 to 2 mg/kg every 24 hours diluted in IV fluids.
- For gastritis, control gastric acid secretion with an H_2 receptor blocker, for example, ranitidine (Zantac; 2 mg/kg IV, q8–12h), or famotidine (Pepcid; 0.5 mg/kg IV, q12–24h).
- If these are unsuccessful for controlling vomiting, consider the broad-spectrum phenothiazine antiemetic, chlorpromazine (0.5 mg/kg SC or IM, q6–12h), but not until dehydration has been corrected because phenothiazines have a hypotensive effect. Avoid the use of metoclopramide and chlorpromazine together because they can produce central nervous system excitation and, rarely, seizures.
- For persistent vomiting that is refractory to other treatments, give ondansetron (Zofran; 0.1–0.2 mg/kg slow IV, q6–12h), a serotonin-antagonist antiemetic.
- Avoid the use of anticholinergics in parvoviral enteritis because they can worsen GI hypomotility.

Antidiarrheals

- Parvoviral diarrhea is usually self-limiting, and treatment to control diarrhea is rarely needed as long as fluid needs are met; however, when diarrhea is profuse and persistent, administer loperamide (Imodium; 0.2 mg/kg PO, q8h).

Infusion of Whole Blood or Plasma

- Consider whole blood transfusion (5–10 ml/kg IV) for treatment of severe blood loss anemia and hypoproteinemia.
- Consider plasma infusion (5–10 ml/kg IV) for cases that develop disseminated intravascular coagulopathy. Plasma may also help correct hypoproteinemia, but hetastarch is a preferred source of colloid for raising colloid osmotic pressure. Plasma may also provide anti-CPV antibodies, but the benefit of this is questionable.

Treatment for Septic Shock

- Use the recommendations in Chapter 156 for fluid therapy in shock.
- Dexamethasone (2–4 mg/kg IV) can be used as a single dose to treat septic shock.
- Flunixin meglumine (Banamine), a nonsteroidal anti-inflammatory drug, is an alternative to corticosteroids as a single injection to treat septic shock. Beware of gastric ulceration; do not give repeated doses or combine with corticosteroids.
- Equine-origin, antiendotoxin hyperimmune serum (Septi-Serum, Immvac) is intended to bind and neutralize endotoxin, but efficacy is uncertain.

Immunotherapy

The following experimental treatments have been used for CPV infection:

- Recombinant human granulocyte colony-stimulating factor (rhG-CSF) has been used to treat other causes of neutropenia, but studies have failed to show improved survival or any beneficial effects in parvoviral neutropenia.
- Recombinant human bactericidal/permeability-increasing protein is used to treat human SIRS, but in a preliminary study in dogs with CPV enteritis it did not decrease circulating endotoxin or improve survival.
- Recombinant feline interferon-omega (rFeIFN-ω) (Virbagen Omega, Virbac), 2.5 million U/kg IV, daily for 3 consecutive days, decreased the severity of enteritis and improved survival in dogs with CPV enteritis in preliminary studies. This product is currently available in France but needs further study as a treatment for CPV.

Prognosis and Complications

▼ ***Key Point*** Most dogs with CPV enteritis recover if treated appropriately to control dehydration and bacterial complications.

- Most animals that survive the first 3 to 4 days of illness recover uneventfully. The survival rate with intensive therapy is 80% to 95%.
- Some animals succumb to bacterial sepsis and endotoxemia resulting from leukopenia, immunosuppression, and breakdown of the intestinal mucosal barrier caused by CPV. In general, the mortality rate is highest in young puppies.
- Complications may include hypoproteinemia, anemia, hypoglycemia (secondary to sepsis), disseminated intravascular coagulation (sepsis), SIRS, intussusception, liver disease, central nervous system signs (likely due to concomitant canine distemper), and various secondary bacterial infections, such as endocarditis, thrombophlebitis, pneumonia (caused by aspiration in some dogs), urinary tract infection, injection site abscesses, and intestinal salmonellosis and campylobacteriosis.

Prevention by Minimizing Exposure

- Dogs with CPV infection shed massive amounts of virus in the feces during their illness. The excreted virus as well as the fomites and premises that become contaminated are highly infectious for other dogs. Thus, instruct the owner of a CPV-infected dog to keep the dog isolated from other dogs until at least 1 week after full recovery.
- CPV is ubiquitous, and because it is so stable outside of the animal and easily transmitted by fomites, prevention of exposure is almost impossible. Nevertheless, until vaccinations are complete, keep young puppies isolated as much as possible from other animals and from potentially infected premises.

▼ ***Key Point*** Elimination of CPV from infected premises is difficult because the virus is so resistant; however, cleanup followed by disinfection with a 1:32 dilution of sodium hypochlorite bleach is effective.

Prevention by Vaccination

Vaccination is highly effective for prevention and control of parvovirus infection.

Maternal Antibody Interference

Although widespread vaccination against parvovirus has markedly reduced the incidence of the disease in North America, parvoviral enteritis continues to be a problem in puppies as they are nearing the end of their maternal antibody protection between 6 and 18 weeks of age. This is because of a period of susceptibility when maternal antibodies are too low to protect but at the same time high enough to interfere with the response to vaccination, especially when killed or low-titer MLV vaccines are used.

▼ ***Key Point*** In puppies from dams with high CPV titers, maternally derived antibody can persist at interfering levels for 18 weeks or more; thus, killed and low-potency MLV vaccines may not be able to break through this maternal antibody interference until as late as 18 weeks of age.

- In the first weeks of life, maternal antibody protects the puppy from infection, but at the same time it also interferes with active immunization.
- As the level of this maternal antibody gradually declines, there is a period of 2 to 4 weeks when puppies may be refractory to vaccination but susceptible to infection if exposed.
- Most suspected "vaccination failures" in puppies probably result from exposure to infection during this critical period of susceptibility.
- Because the age at which pups can respond to vaccination for CPV is unpredictable, vaccination protocols for puppies use a series of vaccinations in 3- to 4-week intervals.
- Attenuated (MLV) CPV-2 vaccines that are high titer and low passage (i.e., contain a high titer of a highly immunogenic strain of virus) are most effective at breaking through maternal antibody interference at a young age.

Recommendations for Routine Vaccination

▼ ***Key Point*** Vaccination against CPV is highly recommended for all dogs, and the efficacy of MLV vaccines is considered high.

- Vaccinate puppies using high-titer MLV CPV-2 vaccines at 6 to 8 weeks, 9 to 11 weeks, and 12 to 14 weeks of age. Give the first booster 1 year later and additional MLV boosters every 3 years thereafter (see Chapter 7).
- Advantages of MLV CPV-2 vaccines over killed vaccines are as follows:
  - Better magnitude of protection
  - More rapid onset of protection (as early as 1–3 days)
  - Longer duration of protection (≥3 years)
  - Better able to break through maternal antibody interference
  - Prevention of shedding of virulent CPV if exposed (killed vaccines protect only against clinical disease but do not prevent subclinical infection or shedding)

▼ ***Key Point*** Commercially available CPV-2 vaccines effectively crossprotect against all known field strains and variants of CPV.

- In unvaccinated dogs 16 weeks of age or older, give two initial doses of vaccine 2 to 4 weeks apart, although when high-titer MLV vaccine is used, a single primary dose is probably adequate.
- Avoid vaccinating pregnant dogs, but if necessary, use killed CPV vaccine instead of MLV. Also use killed instead of MLV in puppies less than 5 weeks of age, such as when early vaccination is needed in colostrum-deprived pups.

CANINE CORONAVIRUS

Etiology

Canine coronaviral enteritis is an acute contagious disease of dogs caused by an epitheliotropic virus that preferentially invades the mature enterocytes of the villous tips. The resulting villous damage, atrophy, and fusion cause diarrhea of variable severity. Canine coronavirus (CCV) is an enveloped, single-stranded RNA virus.

- CCV is considered of minor importance as a cause of enteritis in dogs.
- CCV is shed subclinically for months postinfection in chronic carriers and spreads rapidly by fecal-oral transmission. The incubation period is 1 to 4 days.
- CCV is closely related to feline coronavirus (see Chapter 10). Cats experimentally infected with CCV develop enteritis and sometimes feline infectious peritonitis.

Clinical Signs

- CCV rarely causes clinical disease, and when signs do occur they are typically mild and self-limiting. Acute diarrhea is the most frequent clinical sign. This may be accompanied by mild anorexia, depression, and vomiting. The character of the diarrhea varies from soft to watery and sometimes contains mucus. Bloody diarrhea and fever are infrequent.
- The signs are mild and easily confused with various other nonspecific causes of mild diarrhea of brief duration.

▼ ***Key Point*** Most CCV infections are subclinical; however, occasional epizootics of severe enteritis have occurred, primarily in puppies associated with kennels and dog shows.

Diagnosis

Consider coronaviral enteritis in dogs with an acute onset of signs of gastroenteritis, especially if other dogs on the premises are affected. Because coronaviral enteritis is usually non-fatal and the only treatment is supportive, definitive laboratory confirmation is not needed for effective case management except to document an epizootic outbreak. Coronaviral enteritis should, however, be distinguished from parvoviral infection, a more serious systemic infection.

▼ ***Key Point*** In contrast to CPV infection, fever, leukopenia, hematochezia, and fatalities are not typical of coronaviral enteritis.

- Routine hematology, serum chemistries, and abdominal radiography are usually normal.
- Definitive diagnosis requires laboratory detection of CCV in feces by EM, virus isolation, or PCR during the acute illness. Fecal examination by EM requires fresh feces (specimens can be kept refrigerated but not frozen). Both false-positive and false-negative results are a problem with EM because of misidentification of fecal particles. Virus isolation and PCR are performed in research labs and are not readily available to the clinician.

▼ ***Key Point*** The mere identification of CCV in a dog's feces is not proof that it is the cause of diarrhea or illness because CCV is shed in the feces of many healthy dogs.

- Serology can provide only a retrospective diagnosis via demonstration of a fourfold or greater rise in serum antibody titer in paired sera (at the time of illness and 2–6 weeks later).

Treatment

Treat coronaviral enteritis with nonspecific supportive measures such as fluid therapy and dietary restriction for 12 to 24 hours. Antibiotics are not necessary. Most dogs recover rapidly, although occasionally diarrhea persists 3 to 4 weeks. Rare fatalities have been reported, especially in neonates and mixed infections involving CPV or enteropathogenic bacteria.

Prevention

- Killed (inactivated) and modified-live CCV vaccines are commercially available; however, the efficacy, duration of immunity, and benefit from these products is questionable. Thus, CCV vaccination is not routinely recommended for most dogs (see Chapter 7). The CCV vaccine may be considered in selected situations in which exposure risk is high, such as in show and field trial dogs and kenneled (boarded) dogs.
- In general, immunity to coronaviruses is brief and is mediated by local (immunoglobulin A) immunity rather than the serum antibodies that would result from a parenteral vaccine. Parenteral vaccination does not prevent CCV infection, but it may reduce intestinal replication of virus and minimize clinical signs.

CANINE ROTAVIRUS

Etiology

Rotaviruses are non-enveloped, double-stranded RNA viruses that frequently cause neonatal diarrhea in humans and many other species of mammals and birds; however, canine rotavirus rarely causes diarrhea or clinical illness in dogs.

▼ ***Key Point*** Canine rotavirus is not an enteropathogen of major clinical importance in the dog.

- Antirotavirus antibodies are prevalent in surveys of normal dogs, indicating widespread subclinical infection.
- Rotaviruses are highly infectious and can persist in the environment for prolonged periods. Transmission is by the fecal-oral route.
- Rotaviruses replicate exclusively in the mature enterocytes of the villus tip, causing damage and blunting of the tips of the small intestinal villi.

Clinical Signs

- In adult dogs, rotaviral infection is usually subclinical. In young puppies, clinical signs of acute enteritis occasionally are seen.
- The diarrhea, which may be watery to mucoid, is usually self-limiting and of brief duration (5–7 days), although rare fatalities attributable to dehydration have been reported.
- Experimental inoculation of newborn gnotobiotic puppies with canine rotavirus results in diarrhea and mild to moderate villous atrophy. Deprivation of colostrum predisposes the patient to much more severe diarrhea.
- It is not possible to produce clinical disease or signs from experimental rotavirus infection in dogs older than 6 months of age.

Diagnosis

Definitive diagnosis is based on detection of rotavirus in feces by EM, virus isolation, or PCR. ELISA-based kits marketed for humans may not be reliable for detecting canine rotavirus.

Treatment

Rotaviral enteritis is treated like other types of acute diarrhea, with emphasis on supportive measures such as fluid therapy and dietary restriction or modification. Antibiotics are not needed. Most animals recover uneventfully with minimal treatment.

Prevention

Vaccines are not available for canine rotavirus. In neonates, the only group significantly threatened by rotavirus infection, the best protection is to ensure nursing of colostral antibodies in the first hours after birth.

FELINE PANLEUKOPENIA VIRUS

Etiology

Feline panleukopenia virus (FPV) is a severe, highly contagious parvoviral infection of cats. Panleukopenia is now a relatively rare disease in pet cats because of highly effective vaccines. Occasional infections are seen in unvaccinated kittens, especially those from shelters, farms, and urban stray populations. Cats also are susceptible to the closely related CPV variants CPV-2a, CPV-2b, and CPV-2c, but these only seem to infect cats sporadically.

- FPV can infect all species of *Felidae* as well as raccoon, ferrets, and mink.
- FPV is shed in all body excretions for up to 6 weeks, especially feces.
- FPV is very resistant to inactivation but can be inactivated with a 1:32 dilution of sodium hypochlorite bleach.
- FPV is ubiquitous in the environment, where it can survive readily for more than 1 year and can be transmitted by oropharyngeal contact with contaminated fomites.
- FPV has a predilection for rapidly dividing cells, particularly the following:
  - Intestinal crypt epithelium, resulting in acute enteritis
  - Hemopoietic tissue, resulting in panleukopenia
  - Lymphoid tissues, resulting in lymphoid depletion
  - In utero fetus, resulting in fetal death or cerebellar hypoplasia

Clinical Signs

Subclinical Infection of Adult Cats

Infection in susceptible adult cats is often subclinical. Acute enteritis and panleukopenia occur rarely in healthy adults. One study has identified FPV in heart tissue from cats with myocarditis and idiopathic cardiomyopathy using a PCR assay. The clinical significance of this finding is uncertain.

Generalized Infection of Kittens

The incidence and mortality rate are highest in young kittens. Clinical features are similar to those of canine parvoviral enteritis, with acute onset of anorexia, depression, a high fever from 104°F to 106°F (40–41°C), persistent vomiting, diarrhea, and progressive dehydration. Vomitus is usually a bile-stained fluid, and feces may be watery, mucoid, or bloody. Intestinal loops may be palpably thickened and firm (rope-like), fluid filled, and painful. There is increased susceptibility to bacterial sepsis and endotoxemia.

Perinatal Infection of Neonates

In utero infection of the fetus at the end of gestation or of the neonate in the first 2 weeks after birth may permanently damage the central nervous system and cause cerebellar hypoplasia. Affected kittens show nonprogressive signs of ataxia, hypermetria, falling to the side, broad-based stance, and intention tremors.

FPV also may invade the thymus of neonates, causing thymic atrophy and early neonatal mortality (fading kitten syndrome), and it may invade the retina, causing retinal dysplasia.

In Utero Infection of the Fetus

The only manifestation of infection in the pregnant cat may be transplacental infection of the developing embryo or fetus, leading to early embryonic resorption

(infertility), fetal death, fetal mummification, abortion, or stillbirth.

Diagnosis

Feline panleukopenia usually is diagnosed presumptively on the basis of typical clinical signs and leukopenia in a susceptible (unvaccinated) kitten.

▼ ***Key Point*** Profound leukopenia (total leukocyte count often <500/µl) is frequent and usually lasts 2 to 4 days before rebounding during recovery. The degree of leukopenia is proportional to the severity of clinical illness.

- Serum chemistry abnormalities are nonspecific and occur inconsistently but can include electrolyte depletion (especially hypokalemia), prerenal azotemia, and increased bilirubin and liver enzymes.
- If leukopenia persists more than 5 days or is accompanied by severe nonregenerative anemia, consider the panleukopenia-like syndrome that is associated with feline leukemia virus infection (see Chapter 8). Other panleukopenia "look-alike" diseases include acute salmonellosis, acute bacterial sepsis with endotoxemia, and GI foreign body with perforation and peritonitis (e.g., linear foreign body).
- Presumptive serologic diagnosis is based on paired neutralizing antibody titers. Definitive diagnosis requires fecal PCR or virus isolation, but these are not routinely available in clinical practice.
- Necropsy diagnosis is based on lesions of severe necrosis of intestinal crypts.

Treatment

- The treatment for feline panleukopenia is similar to that for canine parvoviral enteritis, mainly nonspecific supportive treatment such as intensive fluid therapy, parenteral antibiotics, antiemetics, nursing care, and restriction of dietary intake followed by enteral or parenteral feeding.
- In young kittens with panleukopenia, the mortality rate is high (50–90%). A guarded prognosis is justified until impending recovery is indicated by cessation of vomiting and diarrhea, return of appetite to normal, return of body temperature to normal, and rebound leukocytosis. However, serious complications that frequently indicate an impending fatal outcome include hypothermia, septic shock, overwhelming bacterial infection, jaundice, and disseminated intravascular coagulation.

Prevention

▼ ***Key Point*** Vaccination is highly effective for prevention of feline panleukopenia.

- Both attenuated (MLV) and inactivated (killed) FPV vaccines are available, but MLV vaccines are more effective and produce a more rapid onset of immunity. This can be an important consideration in high-risk environments such as shelters, where cats are housed in groups. Side effects associated with adjuvants in killed vaccines are avoided when MLV vaccines are used. Parenteral and intranasal MLV vaccines are available.
- Vaccinate kittens for FPV at least twice 3 weeks apart (usually 9 and 12 weeks of age) or every 3 to 4 weeks until 12 weeks of age. Give the first booster 1 year later and additional boosters every 3 years thereafter (see Chapter 7). Annual revaccination as recommended by manufacturers is not needed because antibody titers and resistance to FPV challenge persist 3 years or more after vaccination.
- Give two doses of vaccine, 3 to 4 weeks apart, for primary vaccination of adult cats.

▼ ***Key Point*** Use only killed FPV vaccine in pregnant cats and in kittens younger than 4 weeks of age. MLV vaccine given perinatally can infect the unborn fetus or the neonatal cerebellum.

FELINE CORONAVIRUS

Etiology

Feline coronavirus is a ubiquitous enteric virus in the cat population that invades the epithelium of the villous tip, resulting in villous atrophy and mild enteritis. A mutant variant of feline coronavirus causes feline infectious peritonitis (see Chapter 10).

▼ ***Key Point*** Feline coronavirus is shed in the feces of many normal cats, and a high percentage of cats are seropositive, indicating that inapparent infection is extremely prevalent.

Clinical Signs

- In young kittens, especially those 4 to 12 weeks of age, feline coronavirus causes an acute onset of mild enteritis with diarrhea. Feces are soft to fluid and rarely contain mucus and blood.
- Diarrhea is infrequently accompanied by vomiting, low-grade fever, anorexia, and lethargy.
- Clinical signs are usually mild and self-limiting within 2 to 4 days. Rare fatalities have been seen in kittens.
- In a small percentage of infected carrier cats, mutation of this coronavirus enables the virus to infect macrophages, leading to systemic dissemination and fatal feline infectious peritonitis (see Chapter 10 for a detailed discussion of FIP).

Diagnosis

Serology can identify a convalescent rise in coronaviral antibody titer. Subclinical coronavirus infection is widespread in cats; thus, seropositivity does not distinguish active and past infection. EM and PCR can be used to identify active shedding of coronavirus in fresh feces, but sensitivity is low with both of these diagnostic techniques.

Treatment

Uncomplicated coronaviral enteritis is usually self-limiting. Routine supportive measures such as fluid therapy and dietary restriction may be beneficial.

Prevention

This virus appears to be practically ubiquitous and spreads very efficiently through catteries; thus, prevention may not be practical. An intranasal feline coronavirus vaccine is available, but it does not appear to be effective and is not recommended.

FELINE ROTAVIRUS

Etiology

As in the canine, rotavirus has been isolated from the feces of both normal and diarrheic cats, especially kittens, but its enteropathogenic significance is unclear. Infection is restricted to the GI mucosa. Subclinical infection in mature animals is probably frequent, as indicated by surveys that found antibodies to rotavirus in 26 of 94 clinically healthy British cats and 23 of 50 cats in Louisiana.

Clinical Signs

Subclinical infection is typical, except in neonatal kittens that may develop mild diarrhea of 1 to 2 days duration.

Diagnosis

As in dogs, feline rotavirus can be detected in feces by EM, PCR, or ELISA.

Treatment

Rotaviral enteritis is self-limiting but, as for other types of acute diarrhea, supportive measures such as fluid therapy and dietary restriction may be beneficial. Most cats recover uneventfully with minimal or no treatment.

Prevention

Vaccines are unavailable for rotavirus. Because natural immunity is short lived, vaccination is unlikely to be warranted.

FELINE ASTROVIRUS

Etiology

Very little is known concerning this viral agent, but a few reports have identified astroviruses in the feces of cats with diarrhea, and mild diarrhea was reproduced experimentally in kittens. A survey of British cats determined a seroprevalence of less than 10%. Astrovirus infections in other species are limited to infection of the mature villous epithelial cells of the intestinal mucosa. Transmission is by the fecal-oral route.

Clinical Signs

Feline astrovirus appears to cause mild, nonspecific diarrhea 4 to 14 days in duration. Transient low-grade fever, depression, and inappetance also may occur, but affected cats otherwise remain well. Rarely, astrovirus has been implicated in diarrhea outbreaks in catteries. As with other enteropathogenic viruses, kittens are most likely to be affected.

Diagnosis

Feline astrovirus is detected in feces by EM or PCR. Some cats shed the virus subclinically. Serum antibody to astrovirus has been identified in cats, but its significance is uncertain.

Treatment

Diarrhea caused by astrovirus is treated like any other acute diarrhea with supportive measures such as fluid therapy and dietary restriction. Most animals recover uneventfully with minimal or no treatment.

Prevention

No preventive measures are available.

TOROVIRUS AND REOVIRUS TYPE 2

A syndrome of mild diarrhea in conjunction with idiopathic protrusion of the nictitating membrane (third eyelid) has been observed in cats, in some cases affecting clusters of cats in the same household. In a small number of these cats, type 2 reoviruses and a novel torovirus have been identified in the feces. Each of these viruses produced mild diarrhea in experimentally inoculated kittens, but protrusion of the nictitating membrane did not occur. The clinical significance of these viral agents is uncertain.

Chapter 15

Rabies and Pseudorabies

Robert G. Sherding

RABIES

Etiology

- Rabies virus is a rhabdovirus (genus *Lyssavirus*) that can cause fatal infection in all warm-blooded mammals. The virus primarily attacks the nervous system and salivary glands, and it is shed in saliva.
- Rabies has public health importance as a zoonotic infection that causes highly fatal encephalitis in humans. The incidence of human rabies in the United States is very low. Several countries are considered rabies free, including Great Britain, Australia (except for a bat variant), New Zealand, and the Scandinavian countries. Hawaii is also free of rabies.
- Rabies is transmitted in saliva from the bite of an infected animal. For both humans and domestic animals, the usual source is the bite of a rabid domestic animal or wild animal, especially reservoir species such as skunks, raccoons, bats, foxes, or coyotes. Some of these wild animals can shed rabies virus for prolonged periods in their saliva without evidence of clinical signs.
- Rabies virus is very labile outside the host, and it is readily inactivated by many disinfectants.

▼ ***Key Point*** Rabies is rare in dogs and cats in the United States; however, cats are more susceptible, and the incidence in cats is higher than in dogs. Wild animals are the principal reservoirs of infection.

Pathogenesis

Rabies virus is transmitted in saliva into a deep bite wound, where it enters the peripheral nervous tissue and spreads retrograde (centripetally) along peripheral nerves to the spinal cord and brain. Centrifugal spread then occurs along peripheral nerves from the central nervous system (CNS) to other tissues, such as the salivary glands. The incubation period before CNS signs occur is extremely variable, but it is usually 2 to 8 weeks. Incubation periods of up to 24 weeks have been reported in dogs and cats. Virus shedding in saliva begins a short time (less than 10 days) before neurologic signs appear and continues until the animal dies. The clinical course is 3 to 10 days.

Clinical Signs

The clinical progression of rabies, although variable, is divided classically into three phases: prodromal, furious, and paralytic. Death usually occurs within 3 to 10 days from the onset of signs; however, some animals develop atypical rabies and do not progress through these stages.

Prodromal Phase (2–3 Days)

This phase often passes unnoticed, but there may be subtle signs of erratic behavior, fever, slow corneal and palpebral reflexes, and chewing at the bite site due to pruritus.

Furious Phase (2–4 Days)

Initially, the forebrain region of the CNS is invaded, resulting in signs of erratic and unusual behavior (i.e., "mad dog syndrome") such as irritability, restlessness, barking, episodic aggression, vicious attacks on inanimate objects, pica, unexplained roaming, and abnormal sexual behavior. Ataxia, disorientation, seizures, and paralysis may develop.

Paralytic Phase (2–4 Days)

This form is most common. Progressive lower motor neuron paralysis develops, causing signs of ascending paresis or paralysis of the limbs (often affecting a bitten extremity first) or signs of cranial nerve paralysis, such as laryngeal paralysis (change in bark, dyspnea), pharyngeal paralysis (drooling, dysphagia), and masticatory paralysis (dropped jaw). These are followed by generalized paralysis, depression, coma, and death from respiratory paralysis.

Atypical Rabies

Some animals develop subclinical, chronic, or recovered infections rather than the typical furious and paralytic forms. This has been observed in dogs, cats, bats,

and skunks. These animals may survive and shed virus for extended periods.

Diagnosis

▼ ***Key Point*** Rapid laboratory confirmation of animal rabies is essential so that exposed humans can receive proper prophylaxis as early as possible. Definitive diagnosis requires laboratory testing of postmortem tissues.

Antemortem tests for rabies are too unreliable to be recommended; thus, always evaluate postmortem tissue specimens for diagnosis, especially the brain. For laboratory analysis of brain and salivary tissue for the presence of rabies virus or antigen, submit the animal's head chilled on wet ice in a leak-proof container, along with appropriate information and biohazard labeling. Specimens can be stored by refrigeration but not freezing, because thawing will ruin the specimen for subsequent virus detection.

Direct Fluorescent Antibody Test

This is the test of choice used by most laboratories for rapid, reliable confirmation of rabies antigen in tissues. Brain tissue is most often used for routine testing, but salivary glands can also be evaluated. The direct fluorescent antibody (DFA) procedure has also been used for antemortem detection of rabies antigen in skin biopsies; however, a high percentage of false-negative results limits the usefulness of the skin test.

Histopathology

This older, less sensitive test identifies intracytoplasmic neuronal inclusions called Negri bodies, which are found in 75% of rabid dogs but rarely in cats.

Mouse Inoculation Test

This is a backup confirmatory test in which DFA-positive brain suspensions are inoculated intracerebrally into mice; the mice then are sacrificed and their brains are examined by DFA testing 5 to 6 days postinoculation. The correlation between DFA and mouse inoculation tests is reportedly 99.9%.

Tissue Culture Inoculation Test

This test is similar to the mouse inoculation test except that cell cultures are inoculated and then examined by DFA testing 24 to 72 hours later.

Monoclonal Antibody Techniques

These techniques are used to identify specific antigenic variants of rabies virus and to differentiate vaccine virus strains from wild-type strains in DFA-positive brains.

Molecular Techniques

Rabies virus genomic RNA can be detected in brain tissue using molecular techniques such as polymerase chain reaction (PCR) and hybridization techniques. These are generally reserved for specimens with questionable DFA results.

Treatment

Rabies is almost always fatal in domestic animals. Because of the extreme public health danger, treatment is not warranted; therefore, quarantine or euthanize all animals suspected of rabies, and notify local health department authorities.

Prevention in Dogs and Cats

Rabies prevention requires vaccination and preventing pets from having contact with wild animals.

Vaccination

▼ ***Key Point*** Vaccinate all dogs, cats, and ferrets against rabies in accordance with local public health regulations and the Compendium of Animal Rabies Prevention and Control, published annually by the National Association of State Public Health Veterinarians (available at www.nasphv.org).

- Vaccinate as early as 3 months of age and 1 year later, then booster every 3 years in accordance with the product recommendations. Maternal antibodies from vaccinated females will protect neonates until 3 months of age. Immunity is not fully developed until 28 days after the initial rabies vaccination.
- *Side effects:* Adjuvants may cause local soreness, lameness, fever, lethargy, palpable inflammatory nodules, and rarely, injection-site sarcomas in cats. The rare neurologic complications of earlier attenuated (modified live virus [MLV]) vaccines are no longer a problem because only inactivated and recombinant rabies vaccines are currently available in the United States. In other countries where MLV vaccines are available, only use MLV vaccines that are derived from high egg passage or cell culture.
- Rabies serum titers may not correlate with protection and should not be used to determine the need for booster vaccination.
- Do not vaccinate wild animals or hybrids against rabies, even if they are kept as pets. The safety and efficacy of parenteral rabies vaccination in wildlife and hybrids (wild animal–domestic animal crossbreds) have not been established, and no vaccines are licensed for these animals.

Postexposure Management

Report all human and animal exposures to the local public health authorities. Recommendations for dogs

and cats exposed to rabies (bitten by a known rabid animal or a wild animal that is unavailable for testing) are as follows:

- In a previously vaccinated dog or cat that has been exposed, revaccinate immediately and keep under the owner's control for 45 days to observe for illness suggestive of rabies.
- In an unvaccinated dog or cat that has been exposed, recommend immediate euthanasia for examination of tissues. If euthanasia is not allowed by the owner, strict isolation is required for 6 months with vaccination either at entry or 1 month before release. If illness suggestive of rabies develops during isolation, immediate euthanasia and testing for rabies is required.

Prevention in Humans

Approximately 15% of humans untreated after a bite from a known rabid animal become infected. Once signs develop in a human, rabies is almost always fatal; thus, prevention is essential.

Pre-Exposure Prevention

- For pre-exposure prevention in humans in high-risk situations (e.g., veterinarians and their employees), immunization with human diploid cell vaccine (HDCV) or another vaccine approved by the Food and Drug Administration is recommended. Contact your state health department for specific recommendations.

Animal Bites to Humans:

For management of animals that bite humans, follow the Compendium of Animal Rabies Prevention and Control, published annually by the National Association of State Public Health Veterinarians (available at www.nasphv.org).

▼ ***Key Point*** Immediately notify local public health authorities when an animal bite to a human has occurred or whenever there is the possibility of contact with a rabid animal.

- When a healthy pet dog or cat has bitten a human, the owners must confine and observe the animal for 10 days. During confinement, the animal must be isolated from contact with other animals and confined in an escape-proof enclosure or building except for leash walking under owner control. Any signs of illness in the confined animal must be reported to local public health authorities.
- When a wild animal or a feral or stray dog or cat with unknown vaccination status has bitten a human, regard the animal as potentially rabid and sacrifice it immediately for laboratory examination of tissues under the guidance of local public health officials.
- Vigorously cleanse the wounds of an exposed human with copious amounts of soap and water to reduce virus in the wound. Ethanol (70%) and benzalkonium chloride (1–4%) are acceptable rabicidal disinfectants. Depending on the circumstances, public health authorities will decide immediately whether postexposure prophylaxis is indicated. Previously immunized humans generally receive two doses of vaccine (on days 0 and 3), whereas non-immunized humans are given five doses of vaccine (on days 0, 3, 7, 14, and 28) and rabies immunoglobulin.

PSEUDORABIES

Etiology

- Pseudorabies is a herpesvirus that predominantly infects pigs (also called Aujeszky's disease and mad itch). Most mammals are susceptible (but not humans), and infections are seen sporadically in dogs and cats in areas where the disease is enzootic in pigs.
- Pseudorabies in dogs and cats is almost always a direct result of ingestion of contaminated raw pork. Direct contact with pigs shedding virus in nasal secretions and saliva is rarely a source of infection.
- The virus invades nerve endings in the pharynx and travels by way of nerve fibers to the brain, where it causes acute fatal panencephalitis.

Clinical Signs

Pseudorabies in dogs and cats causes an acute disease that is almost always fatal within 3 to 5 days of exposure. Initial signs may include depression and inactivity or anxiety and restlessness. The most characteristic sign (but not seen in every case) is intense pruritus, especially involving the head and neck regions, that leads to excoriation and self-mutilation. Other signs may include fever, diarrhea, vomiting, copious hypersalivation, various cranial neuropathies, ataxia, and seizures. Progressive depression, dyspnea, coma, and death follow shortly thereafter. Death occurs within 48 hours from the onset of clinical signs.

▼ ***Key Point*** Suspect pseudorabies in a dog or cat with acute onset of violent, frantic scratching and self-mutilation around the face, head, neck, and ears, especially if there is a history of exposure to pigs or of ingestion of raw pork in an endemic area.

Diagnosis

- The clinical presentation of pseudorabies is indistinguishable from rabies and is similar to other forms of encephalitis.
- It is virtually impossible to make a definitive antemortem diagnosis of pseudorabies in dogs and cats. Routine hematologic and serum chemistry evalua-

tions are normal. Cerebrospinal fluid may show nonspecific increases in protein and mononuclear cells suggestive of viral encephalitis. The serologic tests used in pigs are not diagnostically useful in dogs and cats.

- Postmortem diagnosis is based on specialized testing of unfixed brain tissue for virus using immunofluorescent, virus isolation, animal inoculation, or molecular techniques. Routine histopathology may show characteristic viral inclusion bodies.

Treatment

No effective treatment is known.

Prevention

To prevent pseudorabies in dogs and cats in endemic areas, prevent direct contact with pigs and never feed raw pork. An effective vaccine is not available.

Chapter

16 Miscellaneous Viral Diseases

Robert G. Sherding

INFECTIOUS CANINE HEPATITIS

Etiology

Infectious canine hepatitis (ICH) is caused by canine adenovirus type 1 (CAV-1), a virus related to but distinct from CAV-2 that causes canine infectious tracheobronchitis (kennel cough; see Chapter 12).

Incidence

Dogs, foxes, coyotes, wolves, other wild canids, and bears are susceptible to CAV-1. Because of widespread use of highly effective CAV vaccines, ICH is rare and is seen almost exclusively in unvaccinated dogs. Wild canids are a reservoir for the virus.

Transmission

CAV-1 is acquired through oronasal exposure. The virus is found in all tissues and is shed in all secretions during acute infection. It also is shed for at least 6 to 9 months in the urine after recovery. CAV-1 is highly resistant to inactivation and disinfection, thus enabling spread by fomites and possibly ectoparasites.

Pathogenesis

- After oronasal exposure, CAV-1 causes viremia and disseminates to all tissues, especially targeting hepatocytes and endothelial cells. Hepatocyte injury results in acute hepatic necrosis or chronic hepatitis.
- Endothelial injury can affect any tissue, but CAV-1 is noted particularly for its effects on corneal endothelium (corneal edema, anterior uveitis), renal glomeruli (glomerulonephritis), and vascular endothelium (disseminated intravascular coagulation [DIC]).

Clinical Signs

Peracute Infection

Acutely ill dogs become suddenly moribund and die within hours.

Acute Systemic Infection

- A 5- to 7-day course is characterized by a fever of 103 to 106°F (39.5–41°C), vomiting, diarrhea, abdominal pain, tonsillitis-pharyngitis, cervical lymphadenopathy and edema, cough (pneumonitis), and hemorrhagic diathesis (petechiae, ecchymoses, epistaxis, and melena).
- Central nervous system (CNS) signs (disorientation, depression, stupor, coma, and seizures) may occur as a result of hepatic encephalopathy, hypoglycemia, or non-suppurative encephalitis.

Ocular Infection

Ocular disease can develop during acute infection, after recovery from inapparent infection, or after modified live virus (MLV) CAV-1 vaccines (no longer commercially available). Ocular findings include the following:

- Corneal edema (cloudy cornea; also called hepatitis blue eye)
- Anterior uveitis (blepharospasm, aqueous flare, miosis)
- Secondary glaucoma

Chronic Hepatitis

In infected dogs with partial immunity, a persistent hepatic infection that causes chronic hepatitis, and hepatic fibrosis has been reported.

Diagnosis

Suspect ICH based on clinical signs in unvaccinated dogs, especially young puppies.

Routine Laboratory Evaluations

ICH may cause neutropenia/lymphopenia (early), neutrophilic leukocytosis (later), increased alanine transaminase (ALT) and alkaline phosphatase (ALP) levels, thrombocytopenia and coagulation abnormalities typical of DIC (see Chapter 23), proteinuria, and occasionally hypoglycemia. The abdomen may contain a non-septic exudate.

Definitive Diagnosis

ICH can be confirmed by serologic testing, virus isolation, immunofluorescent studies, or histopathology (centrilobular hepatic necrosis with intranuclear viral inclusions); however, a definitive diagnosis is not needed for instituting supportive treatment measures.

Treatment

Treatment is supportive until recovery from the acute stage of infection and hepatocellular regeneration can occur. This usually requires parenteral fluid therapy using potassium and dextrose-supplemented solutions (see Chapter 5), treatment for DIC using fresh plasma or whole blood transfusion (see Chapter 23), treatment for hepatic encephalopathy (see Chapter 91), and antibiotics for secondary bacterial complications such as pneumonia or pyelonephritis.

Prevention

▼ ***Key Point*** Vaccination is highly effective for preventing CAV-1 infection.

- MLV canine adenovirus vaccines can induce effective immunity against ICH; however, only CAV-2 vaccines are recommended. This is because CAV-2 vaccines produce highly effective immunity against both adenoviruses with minimal side effects, whereas CAV-1 vaccine viruses can localize in the kidney and produce mild nephritis and urine shedding of virus or may localize in the eyes and produce anterior uveitis (in approximately 0.4% of vaccinates). The cloudy cornea is usually transient but sometimes irreversible.
- Vaccinate puppies using CAV-2 at 6 to 8 weeks, 9 to 11 weeks, and 12 to 14 weeks of age. Give the first booster 1 year later and additional boosters every 3 years thereafter (see Chapter 7 for comprehensive vaccination recommendations).

CANINE ACIDOPHIL CELL HEPATITIS

Etiology

A transmissible form of hepatitis has been described in dogs in Great Britain. Although the etiologic agent has not been identified, evidence strongly suggests that it is a virus and that it is distinct from CAV-1 and CAV-2.

Clinical Signs

Clinical forms of the disease, which may represent stages of progression, include acute hepatitis, chronic hepatitis, cirrhosis, and occasionally hepatocellular carcinoma. Early signs, such as anorexia, vomiting, and occasional fever, are nonspecific. Later signs reflect progressive hepatic failure (ascites, hepatic encephalopathy).

Diagnosis

Laboratory findings are nonspecific and typical of those found in other types of acute and chronic liver disease. Increased serum ALT and ALP activities are the most consistent abnormalities. Diagnosis depends on liver biopsy to identify hepatitis associated with characteristic acidophil cells.

Treatment and Prevention

Specific measures for treatment and prevention are unknown; however, supportive treatment for liver failure in general and specific treatment used in other forms of hepatitis and cirrhosis may be applicable (refer to Chapter 71).

CANINE HERPESVIRUS

Etiology

Canine herpesvirus (CHV) infects only canids. Its biologic behavior is similar to herpesviruses of other species. Infected dogs remain latent carriers for life. CHV is inactivated relatively easily outside the host.

Incidence

CHV is widespread in the canine population; however, it causes clinical disease almost exclusively in newborn puppies during the first 3 weeks of life.

Transmission

Perinatal infection is acquired before, during, or soon after birth. Transmission can occur in utero, during passage through the birth canal, or by direct oronasal contact with infectious secretions from the infected mother, littermates, or fomites. Respiratory and venereal transmission may occur in adults.

Clinical Signs

▼ ***Key Point*** Overt clinical signs of CHV occur almost exclusively in puppies from 3 weeks before birth until 3 weeks after birth. This is manifested as a reproductive failure in infected bitches or a highly fatal systemic disease in newborn puppies.

Fetal Infection

- Reproductive failure in infected bitches results from early fetal resorption, late-term abortion, or stillbirth associated with in utero CHV infection.

Neonatal Systemic Infection

- Infection at birth until 2 to 3 weeks of age leads to viremia and virus dissemination to all tissues, resulting in a fatal generalized form of disease. The incubation period is 3 to 6 days.

- The susceptibility to this form of CHV is related to the narrow temperature range of 35°C to 36°C needed for optimal growth of CHV, which coincides with the low body temperatures and lack of febrile responsiveness found in neonates in the first week of life.
- Neonatal infection causes multifocal lesions of necrosis and hemorrhage (DIC) in many organs, including the kidneys, adrenal glands, liver, spleen, gastrointestinal tract, lungs, and CNS.
- Signs include depression, refusal to nurse, incessant crying, subnormal body temperature, yellow-green diarrhea, abdominal pain, nasal discharge, petechial hemorrhages on mucosal surfaces, skin papules, and CNS signs (coma, opisthotonus, and seizures). Nursing ceases and death usually occurs within 24 to 72 hours.
- This form is seen mostly in neonates born to an infected but seronegative mother. Subsequent litters produced by the dam rarely are infected because of protective maternal antibodies transferred in colostrum.

Adult and Older Puppy Infections

- Marked resistance to CHV develops abruptly in animals after 1 to 2 weeks of age because of higher body temperature and better immune function; thus, infection beyond 2 weeks of age results only in mild or inapparent infection confined to the respiratory and genital tracts.
- Transient, mild respiratory signs and conjunctivitis with episodic shedding can occur.
- The primary manifestation in adults is lymphofollicular lesions on the vaginal or preputial mucosa, with or without mild hyperemia and discharge. Local genital infection may be a source of venereal transmission between adult animals and of vaginal transmission to neonates during birth.

Diagnosis

- *For infected neonates:* The age of onset and clinical signs are characteristic. Necropsy lesions are usually diagnostic. Virus isolation, immunohistochemistry, and polymerase chain reaction (PCR) on tissues are confirmatory. Positive serologic titers (virus neutralizing antibody) in the dam and surviving pups provide additional presumptive evidence.
- *For adult carriers:* Virus isolation from the oropharynx or genital lesions confirms the diagnosis.

Treatment

There is no effective treatment for CHV. Treatment of the neonatal form probably is not warranted because it is almost always fatal, and the few puppies that do recover often have irreversible neurologic sequelae (e.g., cerebellar dysfunction).

Prevention

- In breeding kennels, promote proper husbandry practices and maintain warm ambient temperatures for neonates.
- In kennels with CHV problems, consider isolating infected bitches and their litters; disinfect the premises (CHV is susceptible to most detergents and disinfectants); and administer hyperimmune antiserum (harvested from seropositive bitches that recently have produced CHV-infected litters), 1 to 2 ml, intraperitoneally, for prophylaxis in newborn puppies.
- An effective vaccine for CHV is unavailable.

CANINE VIRAL PAPILLOMATOSIS

Etiology

The canine papillomavirus causes mucocutaneous tumors that are benign and self-limiting. Virus-induced papillomas are multiple (often 50–100 separate tumor nodules) and occur in young dogs, in contrast to noninfectious papillomas, which are solitary and usually affect older dogs. Transmission appears to be by direct viral contact with oral mucosa. The incubation period is 1 to 2 months.

Clinical Signs

The three forms of infectious papillomatosis in dogs are oral, ocular, and cutaneous.

- *Oral papillomatosis* is by far the most common form and usually affects dogs younger than 2 years of age. Lesions begin as smooth, white mucosal elevations that develop into cauliflower-like warts on the lip margins, oral mucosa, tongue, palate, pharynx, and epiglottis. They usually increase in number and size for 4 to 6 weeks and then begin to regress. Common presenting signs are halitosis, ptyalism, reluctance to eat, and oral bleeding.
- *Ocular papillomatosis* is uncommon; it affects dogs 6 months to 4 years of age and is characterized by papillomas on the conjunctiva, cornea, and eyelid margins.
- *Cutaneous papillomatosis* is rare (see Chapter 30).

Diagnosis

The history and physical appearance of the lesions are adequate for diagnosis of oral and cutaneous papillomatosis. In the ocular form of the disease, confirmatory excisional biopsy is advisable to exclude other ocular tumors that may have a similar physical appearance. Immunohistochemical and PCR assays can be used to identify the presence of papillomavirus in tumor tissue.

Treatment

- For the oral form, treatment is not necessary because viral oral papillomas usually regress spontaneously within 3 months once immunity develops. There have been rare reports of failure to regress for more than 2 years. Ocular and cutaneous forms take longer to regress, often 6 to 12 months.
- Removal by surgical excision, cryosurgery, or electrosurgery is indicated for ocular papillomas and for oral lesions that interfere with eating or that bleed and discharge excessively. Submit tissues for biopsy to confirm the diagnosis. Removal of some of the tumors often triggers regression of the remaining ones.
- When regression fails to occur, remission can be induced in some dogs with weekly single-agent chemotherapy using vincristine or cyclophosphamide at the usual doses (see Chapter 26). Autogenous vaccines have also been used.
- Recovered animals and dogs older than 2 years of age usually are immune to papillomavirus.

FELINE VIRAL PAPILLOMATOSIS

An uncharacterized papillomavirus has been identified in a few cats with papillomas. Feline papillomas are located on the head, neck, dorsal thorax, and abdomen. They appear as slightly raised verrucous plaques rather than typical warts. Most affected cats have been on immunosuppressive drugs or infected with feline immunodeficiency virus. The diagnosis is based on tumor histopathology and immunohistochemistry or electron microscopy to document the presence of papillomavirus. Treatment has not been evaluated.

FELINE POXVIRUS

Etiology

Cowpox virus *(Orthopoxvirus)* causes disease in cats more often than in any other species, including cows, but has been recognized only in Europe and Asia. Poxvirus causes widespread skin lesions with occasional systemic involvement. The source of infection is contact with other infected cats (rare) or endemic rodent reservoirs, mainly through contaminated skin wounds. Cats have also been infected with *Parapoxvirus* and uncharacterized poxviruses.

Clinical Signs

- The initial inoculation site or skin wound (usually a bite wound on the head, neck, or forelimb) is called the primary lesion.
- Then, 1 to 3 weeks later, after a period of viremia and sometimes mild systemic signs (low fever, anorexia, depression, and mild upper respiratory signs), widespread secondary pox lesions develop. These lesions begin as multiple, small (1 mm) skin nodules that progress and increase in number over 2 to 4 days to become well-circumscribed ulcers covered with scabs. Most cats have more than 10 of these pox lesions. Buccal ulcers are seen occasionally.
- The scabs dry and fall off in 4 to 6 weeks, revealing underlying healing skin. Some lesions result in permanent bald patches.
- Susceptibility and severity of disease are increased by immunosuppressive conditions, such as feline leukemia virus or feline immunodeficiency virus infections or glucocorticoid therapy. Rarely, fatalities occur because of secondary bacterial infection.

Diagnosis

- Suspect feline cowpox virus in rural cats that hunt rodents in endemic areas, especially cats with typical secondary pox lesions after a recent history of a primary skin wound lesion.
- Confirmation is based on detection of virus in the scabs by fluorescent antibody staining (preferred method), PCR, electron microscopy, or virus isolation. Presumptive diagnosis is based on serologic assay for poxvirus-specific antibodies (indirect fluorescent antibody or enzyme-linked immunosorbent assay) or identification of the characteristic histopathologic abnormalities in skin biopsies.

Treatment

There is no specific treatment for poxvirus infections, but the disease is self-limiting and skin lesions regress in 4 to 6 weeks. Antibiotics and topical cleansing help control secondary bacterial infection of skin lesions, but take proper precautions (e.g., wear rubber gloves when handling cats) because cowpox virus is potentially transmissible to humans as a zoonotic disease. Corticosteroids are contraindicated.

RARE AND EMERGING VIRUSES

The following viral infections have been identified in dogs and cats, but the clinical significance is not yet established.

West Nile Virus

West Nile virus (WNV) is a flavivirus found worldwide in endemic bird populations and is transmitted by mosquitoes to birds, humans, horses, and occasionally other species such as dogs and cats. West Nile virus causes life-threatening meningoencephalitis in birds, humans, and horses. Experimental infection of dogs and cats produces viremia with little or no illness; however, sporadic naturally occurring cases of fatal acute encephalitis in dogs in the United States caused by WNV have been

confirmed by postmortem PCR assay of brain tissue. The seroprevalence in dogs and cats in endemic areas of North America appears to be low. Oral transmission of West Nile virus can occur in cats through ingestion of infected rodents.

Bornavirus

Bornavirus is a neurotropic virus that mostly infects horses and sheep, but it also causes a rare but fatal neurologic disease in cats and dogs, especially in central Europe and Japan. Non-suppurative meningoencephalomyelitis (especially gray matter) causes progressive neurologic signs of ataxia, circling (dogs), paresis, behavior changes, salivation, hyperesthesia (cats), loss of vision, and seizures. The diagnosis is based on postmortem demonstration of *Bornavirus* in brain tissue using PCR. The reservoir of infection is unknown, but transmission is presumed to be vector-borne. Human infections also occur.

Other Vector-Borne Viruses

Dogs and cats are susceptible to several viruses that are transmitted by arthropods, such as mosquitoes and ticks. In most cases these viruses target other host species; dogs and cats are merely incidental hosts that seroconvert after subclinical infection. Examples of vector-borne viruses that can infect dogs and/or cats include equine togaviruses (Eastern, Western and Venezuelan equine encephalitis), flaviviruses (St. Louis encephalitis, louping ill, yellow fever, and others), bunyaviruses (e.g., Rift Valley fever), and orbiviruses (African horse sickness and blue tongue).

Influenza Viruses

The avian influenza virus strain H5N1 that has caused fatal human infections in Asia also can infect cats and cause fatal pneumonia. Infection occurs through contact with or ingestion of infected poultry. Under experimental conditions, horizontal cat-to-cat transmission has been shown. Zoonotic cat-to-human transmission has not been ruled out.

Paramyxoviruses

Hendra virus in horses in Australia and Nipah virus in pigs in Malaysia are fatal zoonotic respiratory diseases that can be experimentally transmitted to cats. Fruit bats are the endemic reservoirs for these paramyxoviruses. Antibodies to human mumps paramyxovirus have been found in dogs, but experimental inoculation of dogs with mumps virus have been inconclusive.

Hantavirus in Cats

Hantavirus is endemic worldwide in rodent reservoirs. Serologic evidence of *Hantavirus* infection in cats has been found in North America, Europe, and Asia, and the virus has been demonstrated in lung and kidney tissue of cats. However, the clinical significance of this virus in cats is not yet known. Most if not all infections in cats appear to be subclinical. In humans, *Hantavirus* is a life-threatening zoonotic infection that causes hemorrhagic fever, renal syndrome, or pulmonary syndrome, depending on the strain of virus. The virus is transmitted in aerosolized rodent excrement and rarely by rodent bites.

Feline Foamy Virus

This feline *Spumavirus* is in the retrovirus family and was formerly known as feline syncytium-forming virus. Infection with this virus is very common in cats, with seroprevalence as high as 90% in some cat populations. This feline retrovirus is ubiquitous and has been studied for over 3 decades, but it has yet to be associated with clinical disease in cats except for early studies that found a statistical link to feline chronic progressive polyarthritis.

Feline Spongiform Encephalopathy

Feline spongiform encephalopathy (FSE) is a fatal neurologic disease that has primarily been seen in cats in Great Britain and a few other European countries since the 1990s concurrently with the European outbreak of bovine spongiform encephalopathy (BSE). The etiology of FSE is considered to be the same prion, or self-replicating protein, that causes BSE in cattle or scrapie in sheep. Cats are probably infected through ingestion of table scraps or prepared cat foods that contain prion-infected meat from cattle, sheep, or goats. After a prolonged incubation period, cats with FSE develop neurologic signs (e.g., behavior changes, ataxia, tremors, salivation, and hyperesthesia) that slowly progress to death. There is no effective treatment. The diagnosis is based on distinctive gray matter vacuolation and fibril deposits in the brain at necropsy. The occurrence of FSE is expected to decline now that strict regulations are in place for control of BSE and scrapie.

Chapter 17

Rickettsiosis, Ehrlichiosis, Anaplasmosis, and Neorickettsiosis

Robert G. Sherding

Microbial genetic analyses have recently led to the extensive taxonomic reclassification and renaming of several animal pathogens that are now found in the genera of *Rickettsia*, *Ehrlichia*, *Anaplasma*, and *Neorickettsia*. Pathogens in these four genera are obligate intracellular bacteria that are vector-transmitted by tick bites *(Rickettsia*, *Ehrlichia*, *Anaplasma)* or parasitized trematodes and aquatic insects that are ingested *(Neorickettsia)*. The geographic distribution of vectors determines regional prevalence of each infectious agent. In general, serologic cross reactivity is common among organisms within each genus, but minimal between genera.

The full scope of disease caused by many of these agents is still being defined. In high-prevalence areas with a heavy tick population, such as the southeastern United States, dogs are frequently infected with multiple tick-transmitted pathogens simultaneously; for example, dogs infected with *Ehrlichia* spp. and *Anaplasma* spp. may be co-infected with *Bartonella vinsonii (berkhoffii)*, *Borrelia burgdorferi*, or *Babesia* spp. Breitschwerdt has observed that the synergistic effects of these polymicrobial infections may lead to an unpredictable variety of chronic disease manifestations not seen with single-agent infections.

ROCKY MOUNTAIN SPOTTED FEVER

(Rickettsia rickettsiae)

Rocky Mountain spotted fever (RMSF) is a tickborne rickettsial disease of dogs and humans that is most prevalent in the Southeast, Midwest, and Great Plains regions of the United States. Because of its acute nature, most cases of canine RMSF occur during tick season, between April and October.

Etiology

Canine RMSF is a tick-transmitted infection caused by *R. rickettsii*, one of several rickettsial species included in the spotted fever group.

Transmission

- The main vectors for *R. rickettsii* are the American dog tick *(Dermacentor variabilis),* found primarily east of the Great Plains and in parts of the west coast, and the wood tick *(Dermacentor andersoni),* found in an area from the Rocky Mountains to the Cascades. These are three-host ticks; the permanent hosts are humans, dogs, and cats, and the reservoirs are rodents.
- Ticks usually acquire the organism through feeding on infected animals, although vertical transmission in tick populations also can occur.
- Ticks usually do not infect the hosts until they have been attached for a minimum of 5 to 20 hours. This infection also can be transmitted iatrogenically through blood transfusions.

Pathogenesis

- Once inoculated into the host via a tick bite, the organism quickly invades and replicates in vascular endothelial cells, resulting in widespread necrotizing vasculitis, altered vascular permeability, edema, platelet aggregation, and multi-organ damage (e.g., skin, brain, heart, lung, liver, and kidneys). The incubation period varies from 2 to 14 days.
- Only an acute form of clinical disease is recognized in dogs. The clinical illness lasts 7 to 14 days, with high mortality rate in untreated animals. In contrast to most other tickborne infections in dogs, *R. rickettsii* has not been associated with chronic or recurrent disease, and it does not persist in a chronic carrier form.

Clinical Signs

Exposure to *R. Rickettsii* can lead to either subclinical infection or an acute, rapidly progressive disease of short duration. Most dogs with acute RMSF present between April and October, coinciding with the tick season. The clinical signs and laboratory abnormalities are highly variable. Because of the acute course, ticks

may still be found on the dog (or may have been recently removed by the owner); however, a negative tick history by no means excludes RMSF.

Clinical findings in dogs with acute RMSF can include any of the following:

- **General signs:** Fever, anorexia, lethargy, vomiting/diarrhea, weight loss, and generalized lymphadenopathy.
- **Polyarthritis:** Poorly localized joint and muscle pain and lameness.
- **Ocular signs:** Schleral and conjunctival hyperemia and petechiae; retinal vasculitis and hemorrhages; and anterior uveitis and hyphema.
- **Neurologic signs:** Hyperaesthesia, tetraparesis, ataxia, vestibular signs, stupor, and seizures.
- **Cutaneous vasculitis:** Hyperemia, edema, and petechial-to-ecchymotic hemorrhages (face, distal extremities, scrotum, ventral abdomen); and skin necrosis and gangrene in severe cases.
- **Pneumonitis:** Cough, tachypnea, dyspnea, and exercise intolerance.
- **Myocarditis:** Cardiac arrhythmias or sudden death.
- **Other signs:** Icterus, orchitis, bleeding (epistaxis, melena, and hematuria), or oliguric renal failure.

Laboratory Findings

- Frequent hematologic findings include mild-to-moderate thrombocytopenia (>80% of cases), leukocytosis with a left shift, toxic granulation of neutrophils, monocytosis, and mild anemia. Rare findings are transient leukopenia (early) and overt disseminated intravascular coagulation (DIC) (late). Anti-platelet antibodies have been demonstrated in natural and experimental canine RMSF infections.
- Biochemical abnormalities, which reflect vascular injury and organ damage, can include hypoalbuminemia, increased serum liver enzymes, hyperbilirubinemia, azotemia, hyponatremia, hypochloremia, hypercholesterolemia, and metabolic acidosis.
- Synovial fluid is typical of neutrophilic polyarthritis, and cerebrospinal fluid has a mild increase in protein and cells (neutrophils).

Diagnosis

Suspect RMSF in dogs residing in endemic areas that present with an acute, rapidly progressive febrile illness and a recent history of tick infestation. The diagnosis of RMSF can be confirmed by serum antibody titers and polymerase chain reaction (PCR) assays that are readily available to practicing veterinarians through the Vector Borne Disease Diagnostic Lab at North Carolina State University. Submission requirements and forms are available at www.cvm.ncsu.edu/docs/tickbornediseaselab.html.

- Using the indirect fluorescent antibody (IFA) serologic test, a serum titer of >1:128 is presumptive evidence of RMSF; however, dogs often have a negative titer when tested early in the disease (first 5 days). A definitive diagnosis is established by a fourfold rise in paired titers (2–3 weeks apart); or based on a single titer of >1:1024 at 7 days or more after the onset of clinical signs.
- The prevalence of seropositivity is higher than the prevalence of the clinical disease and must be considered when interpreting titers. This is due in part to cross reactivity with nonpathogenic tickborne *Rickettsia* spp. High titers can persist for up to 1 year after successful treatment or recovery from the disease, which also must be considered.
- Rapid confirmation of the diagnosis can be established by PCR identification of rickettsial DNA in an EDTA blood sample or in tissues. Prior antibiotics can cause a false-negative PCR result.
- The direct immunofluorescence test can confirm the diagnosis by detecting rickettsial antigens in fresh or paraffin-embedded tissues, especially skin, as early as 3 to 4 days post-inoculation. Skin biopsies obtained with local anesthetic and a biopsy punch can be used. A positive result is highly specific for RMSF; however, false-negative results occur in up to 30% to 40% of cases (low sensitivity).

Treatment

- Doxycycline (5–10 mg/kg, PO or IV, q12h) for 14 days is the drug of choice for treating dogs with RMSF. Tetracycline (22 mg/kg PO q8h), enrofloxacin (3 mg/kg, SC or PO, q12h), or chloramphenicol (15–25 mg/kg, PO, IM, or IV, q8h) given for 14 days have also been effective for treating dogs with RMSF.
- Initiate supportive therapy as needed, but use extreme caution with fluid therapy because vascular damage predisposes the patient to severe edema.

▼ ***Key Point*** Do not delay treatment of dogs suspected of having RMSF. Initiate doxycycline while awaiting confirmatory diagnostic tests to prevent development of complications such as fatal central nervous system (CNS) disease, cardiovascular collapse, oliguric renal failure, or gangrene.

Prognosis

The prognosis is good when treatment is instituted promptly. Clinical response should occur within hours of initiating appropriate drug administration. The mortality rate is high if an ineffective antibiotic is used or treatment is delayed until the disease is advanced. Dogs with severe CNS signs may die within hours, before treatment takes effect.

Prevention

- Prevention of RMSF in dogs depends on minimizing tick exposure, using an effective tick preventative product on a regular basis, and routinely checking dogs for ticks and removing them promptly. Dogs that recover from RMSF are immune to re-infection.
- RMSF is one of the most important rickettsial diseases in humans. Dogs are not reservoirs or chronic carriers for *R. rickettsiae*, and thus dogs are considered minimal zoonotic risk. However, take precautions (i.e., wear gloves) when removing ticks or handling blood from a potentially infected dog.
- A confirmed diagnosis of RMSF in a dog is an indication that *R. rickettsiae* is endemic in the local tick population. Dogs can thus serve as sentinels for the potential risk of human exposure in a geographic area.

CANINE EHRLICHIOSIS

Canine ehrlichiosis is a tick-transmitted infectious disease of dogs caused by various species of *Ehrlichia*, a genus comprised of obligate intracellular gram-negative cocci that have a tropism for leukocytes. This intracellular location facilitates chronic persistence and resistance to antimicrobial therapy. Feline ehrlichiosis is discussed at the end of this chapter under Feline Ehrlichia-Like Diseases.

Etiology and Transmission

Ehrlichia organisms are transmitted to dogs through the saliva of an attached tick, and ticks become infected when they feed on the blood of an infected host. *Ehrlichia* species are distributed worldwide according to the geographic distribution of specific vector ticks. *Ehrlichia* organisms can also be transmitted iatrogenically through transfusion of contaminated blood.

- ***Ehrlichia canis*** is transmitted primarily by *Rhipicephalus sanguineous,* the common brown dog tick, and infection occurs worldwide in tropical and temperate climates. *E. canis* infections have been reported year-round throughout the United States, most frequently in the Southeast.
- ***Ehrlichia ewingii*** is transmitted by *Amblyomma americanum*, the lone-star tick, and probably other ticks (e.g., *Dermacentor variabilis*, *Rhipicephalus sanguineous*). Infection occurs predominantly in the Southern and Central United States, including Missouri, during tick season (spring and summer).
- ***Ehrlichia chaffeensis*** is transmitted by *Amblyomma americanum*, and infection occurs in the Southern United States.

Clinical Signs and Laboratory Findings

E. canis and *E. chaffeensis* most frequently infect circulating monocytes and mononuclear phagocytic cells in lymph nodes, spleen, liver, and bone marrow, resulting in widespread lymphoreticular hyperplasia, organomegaly (lymphadenomegaly, splenomegaly, and hepatomegaly), and hematologic abnormalities. *E. ewingii* infects granulocytes.

After a transient acute phase of infection, dogs either clear the infection, or in the case of *E. canis* infection, they enter a prolonged subclinical phase that can extend for months to years until they finally develop clinical signs of chronic-phase disease. Most dogs with *E. canis* infection are diagnosed in the chronic phase.

Acute Phase of Infection

The acute phase of canine ehrlichiosis begins 1 to 3 weeks after the bite of an infected tick. The clinical signs vary from mild to severe and last 2 to 4 weeks. The clinical presentation of acute ehrlichiosis can resemble RMSF (see previous section).

- Acute-phase infection causes transient fever, anorexia, lethargy, oculonasal discharge, generalized lymphadenopathy, splenomegaly, hepatomegaly, and moderate-to-severe thrombocytopenia.
- Less frequent manifestations that are seen in severe cases include neurologic signs due to meningoencephalitis (ataxia, paresis, hyperaesthesia, twitching, cranial nerve deficits); anterior uveitis and chorioretinitis; dyspnea or exercise intolerance due to pneumonitis; edema of the limbs and scrotum; and petechial and ecchymotic hemorrhages due to thrombocytopenia or platelet dysfunction.
- *E. ewingii* most frequently causes acute neutrophilic polyarthritis with lameness, stiffness, and joint pain and swelling. It also can cause acute meningoencephalitis and a variety of neurologic signs (ataxia, paresis, etc.).
- Laboratory findings during the acute-phase include thrombocytopenia (due to peripheral destruction of platelets), leukopenia, mild to severe anemia, hypercellular bone marrow cytology (especially megakaryocytic hyperplasia), mild hyperglobulinemia, and mild elevation of serum liver enzyme activities.

▼ ***Key Point*** Thrombocytopenia is the most consistent hematologic abnormality found in all stages of canine ehrlichiosis.

- Antibody titers may be negative during the acute phase because it takes 2 to 4 weeks to develop a significant titer.

Chronic Phase of Infection

After apparent recovery from the transient acute phase followed by a prolonged subclinical phase lasting

months to years, dogs with persistent *E. canis* infection develop a variety of chronic vague illnesses accompanied by lymphoreticular hyperplasia and bone marrow dysfunction.

- Clinical signs can be mild or severe, and may include weight loss, fever, spontaneous bleeding (petechiae and ecchymoses, epistaxis, melena, hematuria, hyphema), pallor due to anemia, generalized lymphadenopathy, splenomegaly, hepatomegaly, uveitis (anterior uveitis, chorioretinitis, retinal hemorrhages or detachments), meningoencephalomyelitis (ataxia, paresis, seizures, stupor, vestibular signs, etc.), polyarthritis, and intermittent limb edema.
- Chronic-phase ehrlichiosis may be more severe in German shepherds and Doberman pinschers.
- Hematologic findings can include nonregenerative anemia, thrombocytopenia, leukopenia, or all three (pancytopenia), due to bone marrow hypoplasia; lymphocytosis (occasionally composed of atypical or large granular lymphocytes); bone marrow and splenic plasmacytosis; and occasional Coombs'-positive hemolytic anemia.
- Other laboratory findings include hyperglobulinemia caused by polyclonal (or less often monoclonal) gammopathy; hypoalbuminemia; proteinuria; and a positive test for anti-nuclear antibodies (ANA). In some cases severe protein-losing nephropathy is associated with immune-complex glomerulonephritis.

▼ ***Key Point*** Clinical signs, physical findings, and laboratory abnormalities in dogs with chronic ehrlichiosis may resemble multiple myeloma or chronic lymphocytic leukemia.

Diagnosis

Canine ehrlichiosis must be differentiated from various other infectious and immune-mediated diseases that can present with similar clinical signs. The diagnosis of canine ehrlichiosis can be confirmed by cytologic visualization of organisms in blood or cytology specimens, and by serum antibody titers and PCR assays that are available to practicing veterinarians through the Vector Borne Disease Diagnostic Lab at North Carolina State University. Submission requirements and forms are available at www.cvm.ncsu.edu/docs/tickbornediseaselab.html. Blood culturing for *Ehrlichia* is not available except in research labs because it is difficult and expensive and growth takes up to 8 weeks.

▼ ***Key Point*** A confirmed diagnosis of *Ehrlichia* is a marker for exposure to ticks and the infectious agents they transmit. Consider using a serologic tick panel to test for other concurrent tick-transmitted infections, such as *Anaplasma*, *Rickettsia*, *Bartonella*, *Borrelia*, and *Babesia*.

Serology by Indirect Fluorescent Antibody

Serologic testing for *E. canis* antibodies using IFA is highly sensitive and reliable for presumptive diagnosis of canine ehrlichiosis.

- Antibody titers >1:64 are considered indicative of prior or active infection.
- Diagnostic titers may not be detected until 2 to 4 weeks after infection; thus, some dogs develop clinical signs before developing a positive titer. Most dogs with clinical signs are seropositive.
- Antibodies to one *Ehrlichia* species may or may not cross react with other species. *E. canis* titers are positive in most dogs with *E. chaffeensis* infection, but only half of dogs with *E. ewingii* infection.
- *Ehrlichia* antibody titers do not confer protection against reinfection. Titers persist for at least 9 to 12 months after treatment or recovery.

Serology by Enzyme-Linked Immunosorbent Assay

An ELISA-based test kit (SNAP 3Dx; IDEXX) for detecting *E. canis* antibodies is available as a rapid point-of-care screening test for canine ehrlichiosis. This tests simultaneously for heartworms and *Borrelia burgdorferi*, hence the name "3Dx".

- The SNAP 3Dx is calibrated to be positive at an IFA titer of >1:500. Limited studies have shown good correlation with IFA testing; the reported sensitivity is 71% to 95%, and the specificity is 99%.
- This assay is intended for *E. canis* and does not detect other *Ehrlichia* infections.

Polymerase Chain Reaction Testing

PCR for detection of *Ehrlichia* DNA in EDTA blood can be used to definitively diagnose canine ehrlichiosis and to identify the infecting *Ehrlichia* species. Always use PCR in conjunction with serologic testing, not in place of it.

- False-negative PCR blood tests can occur, especially in animals treated recently with antibiotics.
- In some dogs, splenic and bone marrow aspirates have been PCR positive when blood was PCR negative.

Cytology

Identification of intracellular *Ehrlichia* organisms (morulae) in peripheral blood leukocytes (buffy coat smears) is confirmatory; however, this is a time-consuming and highly insensitive means of diagnosis.

- Morulae can also be seen in bone marrow cells, cerebrospinal fluid leukocytes, joint fluid leukocytes, or fine-needle aspirates of the spleen or lymph nodes.
- Plasmacytosis also is frequently prominent in cytologic specimens from dogs with ehrlichiosis.

▼ ***Key Point*** Morulae within circulating monocytes are consistent with *E. canis* or *E. chaffeensis* infection, and morulae within circulating neutrophils are consistent with *E. ewingii* or *Anaplasma phagocytophilum* infection.

Treatment

- Doxycycline (5–10 mg/kg, PO, q12h for 28 days) is the drug of choice for treating canine ehrlichiosis. Tetracycline (22 mg/kg PO q8h for 21–28 days) is also effective. Alternatives include minocycline or chloramphenicol. Enrofloxacin does not effectively eliminate infection.
- Imidocarb dipropionate (2 doses of 5 mg/kg, IM, 2 weeks apart), a drug used to treat babesiosis, has been effective for resolving the clinical signs of ehrlichiosis; however, recent studies suggest that imidocarb is not efficacious for eliminating *E. canis* infection.
- Institute supportive therapy (e.g., blood or blood products, fluids) as needed.
- In selected cases, corticosteroids may be useful for immune-mediated complications, such as refractory thrombocytopenia, polyarthritis, vasculitis, or meningitis.

Monitoring of Treatment

- Clinical signs usually improve within 48 hours in acute-phase or mild chronic-phase cases.
- The platelet count should begin to increase within 2 to 7 days, and normalize by day 14. The platelet count should remain normal at 4 and 8 weeks after treatment if infection has been eliminated.
- Hyperglobulinemia should gradually resolve over 6 to 9 months.
- Most dogs become seronegative 6 to 9 months after elimination of *Ehrlichia* infection. Some clinically recovered dogs maintain high titers for years, suggesting either continued infection or persistence of antibodies. Reevaluate PCR in these cases.
- PCR should be negative at 2 weeks after successful treatment and remain negative at a 2-month recheck.

Prognosis

The prognosis for canine ehrlichiosis is good with appropriate treatment, unless the bone marrow is severely hypoplastic.

- Clinical response usually begins within 48 hours after initiation of doxycycline, but in the chronic form may take up to 3 to 4 weeks. Reevaluate the diagnosis in dogs that fail to improve within 1 to 2 weeks.
- Dogs with severe chronic disease with pancytopenia or aplastic anemia may take months to achieve full hematologic recovery. In some cases severe pancytopenia is fatal.

Prevention

Prevention of ehrlichiosis in dogs depends on minimizing tick exposure, using an effective tick preventative on dogs living in endemic areas (e.g., fipronil, imidacloprid/permethrin, or amitraz), and routinely checking dogs for ticks and removing them promptly.

- Dogs that recover from *Ehrlichia* infection are not immune against reinfection.
- Daily low doses of doxycycline (3 mg/kg PO q24h), tetracycline (6.6 mg/kg PO q24h), or repositol oxytetracycline (200 mg IM twice weekly) have been used successfully for prevention of ehrlichiosis in military dogs in highly endemic areas; however, this is not routinely advocated for pets because it might foster antimicrobial resistance.

Public Health

Infected ticks can transmit *Ehrlichia* spp. to humans on rare occasions. However, there is no evidence of direct zoonotic transmission from infected dogs or cats to people. Pets may carry infected tick vectors into an environment shared with people. The prolonged chronic carrier state of *Ehrlichia* spp. in dogs suggests that dogs have the potential to be reservoir hosts for infecting ticks that subsequently transmit infection to people. Pets also may serve as sentinels for the potential risk of human exposure in a geographic area.

ANAPLASMOSIS

(Anaplasma phagocytophilum)

Etiology

Anaplasmosis is caused by *A. phagocytophilum* (formerly, *E. equi*), an infectious agent that is transmitted by *Ixodes* ticks to dogs, cats, wildlife, horses, small ruminants, and humans. The white-footed mouse serves as the natural reservoir of infection. The highest prevalence of infection in the United States is in the Northeast, upper Midwest, and Pacific coast of California. Feline anaplasmosis is discussed under Feline Ehrlichia-Like Diseases.

Clinical Signs and Laboratory Findings

Most cases are identified in acutely infected animals; however, dogs can be chronically infected for at least 6 months.

- Clinical signs are nonspecific and often mild, such as fever, lethargy, and reluctance to move (arthralgia, myalgia, or polyarthritis).
- Lab findings are lymphopenia, thrombocytopenia, elevated alkaline phosphatase, and hypoalbuminemia.
- Intracellular organisms (morulae) may be visualized in neutrophils and appear identical to *E. ewingii*.

Diagnosis

Confirmation is based on finding granulocytic morulae, demonstrating a rising serum antibody titer in paired sera, or PCR detection of *A. phagocytophilum* DNA (available through the Vector Borne Disease Diagnostic Lab at North Carolina State University; www.cvm.ncsu.edu/docs/tickbornediseaselab.html).

Treatment

Dogs with anaplasmosis respond rapidly to doxycycline (5–10 mg/kg, PO, q12h for 14–21 days) or tetracycline (22 mg/kg PO q8h for 21 days).

Prevention and Public Health

Prevention of *A. phagocytophilum* depends on minimizing tick exposure, using an effective tick preventative product on a regular basis, and routinely checking dogs for ticks and removing them promptly. Infected ticks can transmit *A. phagocytophilum* to humans, but there is no evidence of direct transmission of *Anaplasma* infection from animals to people.

CANINE CYCLIC THROMBOCYTOPENIA

(Anaplasma platys)

Etiology

Canine cyclic thrombocytopenia is cause by *A. platys* (formerly *E. platys*), a bacterial organism that only replicates in platelets.

- It is presumed that *A. platys* is transmitted by ticks, but the specific tick species are not known. Experimentally the brown dog tick, *Rhipicephalus sanguineous*, did not transmit *A. platys*.
- In the United States, *A. platys* infection is reported most frequently in the Southeast and Gulf Coast states. One study of dogs in Louisiana found a seroprevalence of 40% in thrombocytopenic dogs and 50% in healthy kennel dogs.

Clinical Signs and Laboratory Findings

A. platys appears to be minimally pathogenic and is not associated with clinical signs in most dogs. Thrombocytopenia develops at 10 to 14 day intervals in association with cyclic *A. platys* bacteremia. Thrombocytopenic episodes are generally incidental findings in seemingly healthy dogs. Uveitis was reported in one infected dog.

- Thrombocytopenia is moderate to severe, with a nadir as low as 20,000 to 50,000 platelets/µl. Platelet aggregation is also impaired. However, signs of spontaneous bleeding are rare.
- Other laboratory findings can include mild normochromic-normocytic nonregenerative anemia, leukopenia, hypoalbuminemia, and hyperglobulinemia.

Diagnosis

The diagnosis is based on serology, PCR, or blood cytology. See Chapter 22 for a discussion of the differential diagnosis of thrombocytopenia. *A. platys* and *E. canis* often infect dogs concurrently; thus, consider evaluating dogs for both agents.

- Serologic testing by IFA detects antibodies against *A. platys* after 2 to 3 weeks. *A. platys* does not cross react serologically with *E. canis*, *A. phagocytophila*, or *N. risticii*.
- PCR detection of *A. platys* DNA is confirmatory. PCR is available through the Vector Borne Disease Diagnostic Lab at North Carolina State University; www.cvm.ncsu.edu/docs/tickbornediseaselab.html.
- *A. platys* organisms (morulae) are occasionally visualized within platelets as blue inclusions in Giemsa-stained blood smears; however, this is too insensitive to be used as the only diagnostic test.

Treatment

E. platys infection is effectively eliminated by doxycycline (5–10 mg/kg, PO, q12h for 14 days) or tetracycline (22 mg/kg PO q8h for 14 days).

Prevention

Prevention of *A. platys* infection depends on minimizing tick exposure, using an effective tick preventative product on a regular basis, and routinely checking dogs for ticks and removing them promptly.

NEORICKETTSIOSIS

(Neorickettsia risticii)

Etiology

Neorickettsia risticii, the agent that causes equine Potomac Horse Fever (formerly *E. risticii*), can also infect dogs and cats, but its clinical importance and the extent of its pathogenicity is not yet known. Feline neorickettsiosis is discussed under Feline Ehrlichia-Like Diseases.

- The vectors that transmit *N. risticii* infection are trematodes (flukes) that use snails and aquatic insects as intermediate hosts. Dogs and cats are presumably infected by ingesting free-living trematode stages in standing water, or by ingesting snails or aquatic insects that are parasitized by *N. risticii*-infected trematode metacercariae.
- *N. risticii* has a tropism for monocytes and enterocytes.
- Experimentally, inoculation of *N. risticii* induces subclinical infection or mild clinical illness in dogs and cats.

Clinical Signs and Laboratory Findings

- The clinical signs associated with *N. risticii* infection in dogs have included lethargy, intermittent vomiting, petechial hemorrhages and bleeding, arthralgia (polyarthritis), dependent edema, and posterior paralysis; however, a causative role for *N. risticii* is unproven.
- Laboratory findings have included anemia, thrombocytopenia, and coagulopathy.

Diagnosis

Infected dogs have positive antibody titers against *N. risticii*, and they do not cross react on serologic tests for *Ehrlichia* spp. Researchers have detected this neorickettsial infection in dogs by culture and PCR.

Treatment

The recommended treatment is doxycycline (5 mg/kg PO q12h) or tetracycline (22 mg/kg PO q8h) for 21 to 28 days, but efficacy may be variable.

Prevention

Prevention depends on minimizing exposure to the trematode vector by not allowing dogs to drink from standing bodies of water.

SALMON POISONING DISEASE

(Neorickettsia helminthoeca)

Salmon poisoning disease is a vector-borne neorickettsial infection that is only found in dogs in the Pacific Northwest. The vector that transmits this infection to dogs is a species of intestinal trematode (fluke) rather than ticks.

Etiology

Salmon poisoning disease is caused by *N. helminthoeca* and the Elokomin fluke fever agent (likely a variant strain of *N. helminthoeca*). These agents are closely related to *Ehrlichia* spp.

Transmission

Dogs acquire salmon poisoning disease after ingesting raw salmon (or other fish or salamanders) that contain the metacercariae of the fluke *Nanophyetus salmincola* infected with the causative *N. helminthoeca* organisms. These flukes require three hosts to complete their life cycle: a snail, a fish, and a fish-eating mammal or bird. The limited geographic distribution of the snail intermediate host explains why *N. helminthoeca* only occurs in dogs in the Pacific Northwest.

Pathogenesis

- Within 5 to 7 days after a dog ingests raw fish parasitized with infected fluke metacercariae, the flukes mature and attach to the dog's intestinal mucosa, thereby inoculating the *N. helminthoeca* organisms. The *Neorickettsia* infect the intestinal epithelium and mononuclear cells, and then disseminate to the mononuclear phagocyte system (MPS) organs (e.g., lymph nodes, spleen, liver), and to other areas such as the CNS and the lungs.
- The incubation period ranges from 5 to 21 days.
- Cats are not susceptible to salmon poisoning disease.

Clinical Signs and Laboratory Findings

- Clinical signs and physical examination findings in dogs with acute salmon poisoning include high fever (104–107.6°F) followed by hypothermia, anorexia, persistent diarrhea (usually hemorrhagic), vomiting, profound weight loss, mild serous naso-ocular discharge, and generalized lymphadenopathy, which can be marked.
- Because of the acute onset of fever and GI signs, salmon poisoning disease can resemble canine parvovirus infection.
- Laboratory abnormalities are nonspecific, but leukocytosis or leukopenia, thrombocytopenia, elevated serum alkaline phosphatase, and hypoalbuminemia are common findings.

Diagnosis

- Operculated trematode ova are usually found on direct fecal smears or by standard sugar flotation or fecal washing-sedimentation techniques; however, the presence of fluke infection does not necessarily confirm *N. helminthoeca* infection.
- Giemsa-stained fine-needle aspirates of enlarged lymph nodes usually reveal reactive lymph node hyperplasia with intracytoplasmic rickettsial bodies (pleomorphic, coccobacillary, purple staining) in macrophages.

Treatment

- Give doxycycline (5–10 mg/kg PO or IV, q12h) or tetracycline (22 mg/kg PO q8h) for 21 days. Because of the severe vomiting and diarrhea that occur in this disease, begin with parenteral doxycycline or oxytetracycline (7 mg/kg IV q8h) for the first 3 to 5 days. The response to tetracyclines is rapid, whereas untreated infections are often fatal.
- Give praziquantel (Droncit), at one dose of 10 to 30 mg/kg, PO or SC, to eliminate flukes.
- Use supportive treatment (e.g., fluid therapy, antiemetics, antidiarrheals, nutritional support) as needed.
- The prognosis is good with appropriate treatment.

Prevention

- To prevent the disease, keep dogs from feeding on raw infected fish. Keep dogs away from areas where fresh-caught salmon are being eviscerated and cleaned.
- Freezing (–20°C for 24 hours) or thoroughly cooking fish destroys the metacercariae and rickettsiae.

FELINE EHRLICHIA-LIKE DISEASES

Etiology and Transmission

Current evidence suggests that cats can be infected naturally with *E. canis*, *N. risticii*, and *A. phagocytophilum*. This is based on serology, PCR, and the visualization of *Ehrlichia*-like morulae within mononuclear cells and granulocytes of cats with doxycycline-responsive illness resembling the canine forms of these diseases.

The source of infection in cats is unknown, but transmission involving tick vectors is likely for *Ehrlichia* and *Anaplasma*. *Neorickettsia* is transmitted by ingestion of trematode vectors found in water, aquatic insects, snails, or possibly transport host prey (e.g., rodents).

Clinical Signs and Laboratory Findings

- The most frequent clinical signs are fever, lethargy, inappetance, gastrointestinal signs, weight loss, pallor, hyperaesthesia, and joint pain (neutrophilic polyarthritis). Splenomegaly, lymphadenopathy, and dyspnea due to interstitial pneumonitis have also been observed. Experimental infections in cats have generally been asymptomatic or resulted in mild illness.
- Laboratory abnormalities can include nonregenerative anemia, leukocytosis or leukopenia, thrombocytopenia, or pancytopenia. Hyperglobulinemia (polyclonal gammopathy) and the presence of anti-nuclear antibodies is reported.

Diagnosis

Feline *Ehrlichia*, *Anaplasma*, or *Neorickettsia* infections have been confirmed by visualization of organisms (morulae) in blood, serologic testing for the presence of antibodies, and PCR testing to detect organism DNA. Some cats have been serologically positive and PCR negative, while others have been PCR positive and serologically negative; thus, until these infectious agents are better understood in cats, both confirmatory testing methods should be used together.

Treatment

Cats suspected of *Ehrlichia*, *Anaplasma*, and *Neorickettsia* infection have responded to doxycycline (5–10 mg/kg PO q12h for 21 days), tetracycline (22 mg/kg PO q8h for 21 days), or imidocarb diproprionate (2 doses at 5 mg/kg IM, given 2 weeks apart).

Prevention and Public Health

Prevention of ehrlichiosis and related infections in cats depends on minimizing tick exposure, using an effective tick preventative product approved for use in cats, and routinely checking cats for ticks and removing them promptly.

Chapter 18

Borreliosis (Lyme Disease)

Robert G. Sherding

Lyme borreliosis is a polysystemic, tickborne disease caused by the spirochete *Borrelia burgdorferi*. The disease has been associated with polyarthritis in dogs, cattle, horses, and humans. Infection is widespread in the United States, and is endemic in the northeastern coastal states and the upper Midwest. Infection also occurs worldwide and is prevalent in areas of Europe. Borreliosis is transmitted to animals and people by deer ticks.

ETIOLOGY

Lyme borreliosis in dogs and humans is caused by at least 6 subspecies of the *Borrelia burgdorferi sensu lato* complex. The strain that primarily causes borreliosis in North America is *Borrelia burgdorferi senso stricto*. These eubacteria are spiral-shaped, flagellated, gram-negative spirochetes that are related to *Leptospira*, except they do not survive as free-living organisms outside of the host.

B. burgdorferi is easy to isolate from vector ticks but not from clinically affected patients. The organisms are microaerophilic and have special growth requirements. The outer membrane of the spirochete can undergo antigenic variation during the course of infection, which enables the organism to evade the host's immune response and cause persistent infection. Antigenic variation may limit the effectiveness of vaccines.

Dogs in endemic areas are commonly co-infected with other tickborne agents, especially *Anaplasma phagocytophila* (see Chapter 17), and mixed infections may contribute to the pathogenesis and severity of disease in some cases.

Prevalence

▼ ***Key Point*** The risk of *Borrelia burgdorferi* infection correlates with the prevalence of infected ticks in an area and the likelihood of being bitten by a vector tick.

- Borreliosis commonly affects dogs that have recreational exposure to tick-infested vegetation in endemic areas, especially outdoor sporting and hunting dogs.
- In the United States, over 90% of clinically affected dogs are found in the northeastern coastal states and Wisconsin and Minnesota. Within endemic regions, there are focal areas of high and low prevalence. The seroprevalence in dogs in highly endemic areas commonly reaches 50% to 90%, and 60% to 80% of the ticks in these areas may harbor *Borrelia* spirochetes. The seroprevalence in Southern and Western states is less than 4%.
- 95% of seropositive dogs are asymptomatic.

Transmission

Dogs are infected through the bite of an infected tick. The primary vectors of Lyme borreliosis are *Ixodes* spp. ticks, also called black-legged or deer ticks. These hard ticks are small (2–3 mm) 3-host ticks that have a 2-year life cycle with larval, nymph, and adult stages.

- In the Northeast, Southeast, and Midwest regions of the United States, *Borrelia burgdorferi* is carried by *Ixodes scapularis* (formerly designated *I. dammini*). In California and other western states, *I. pacificus* is the carrier. Various other *Ixodes* ticks are involved in Europe and Asia. Other species of ticks and biting insects such as flies and mosquitoes can carry *Borrelia* spirochetes, but these are not a significant source of transmission.
- Deer support the adult stage of *I. scapularis* but are not usually infected by the spirochete. Mice and other small rodents are the main reservoirs of borreliosis because they maintain the larval and nymphal stages of *I. scapularis* and can become infected with the spirochete. Migratory birds may be important reservoirs because they have the ability to transmit ticks and spirochetes over long distances. Dogs are incidental hosts.
- Western *I. pacificus* ticks are less efficient as vectors because they prefer to feed on lizards that contain borreliacidal factors.
- Direct transmission between dogs is unlikely. Uninfected dogs housed with infected carrier dogs for 1 year did not become infected. In utero transmission is not likely. Iatrogenic transmission by blood transfusion is a possibility.

▼ ***Key Point*** Transmission of *Borrelia* infection requires at least 48 hours of attachment and feeding by a vector tick.

- Once inside the animal host, *Borrelia* spirochetes live intercellularly in the skin and spread through connective tissue migration rather than hematogenously. A small area of erythematous skin around the tick bite may be seen in the first week.

CLINICAL SIGNS

▼ ***Key Point*** In endemic areas, most dogs in the population have serologic evidence of exposure to *Borrelia*, but never develop clinical signs, indicating that subclinical infection is common.

Most dogs develop persistent subclinical infection that may lifelong. Seroconversion occurs within 3 to 6 weeks after exposure. Clinical disease develops in only 5% of infected dogs, depending on age, immune status, strain of *Borrelia*, and dose of exposure (number of ticks). In experimental infections, clinical signs develop 2 to 5 months after tick exposure.

Polyarthropathy

Acute, chronic, or intermittent shifting-leg lameness due to polyarthritis is the most common clinical sign.

- Systemic signs can include fever, anorexia, lethargy, lymphadenopathy, and weight loss; however, many animals show no clinical signs other than lameness.
- Swelling and pain in one or more joints may be evident. Arthritis usually occurs first in the joint closest to the tick bite. The carpi are the most frequently affected joints.
- Chronic, progressive, non-erosive arthritis may develop in persistently infected dogs.
- Radiographically, affected joints may have joint effusion, but usually show little or no evidence of degenerative joint disease.
- Synovial fluid analysis reveals neutrophilic (suppurative) inflammation with leukocyte counts ranging from 2,000 to 100,000 nucleated cells per µl, similar to findings in idiopathic immune-mediated polyarthritis.

Renal Disease

A unique syndrome of protein-losing glomerulonephropathy and acute progressive renal failure ("Lyme nephropathy") has been associated with canine borreliosis, especially in Labrador retrievers and golden retrievers. *Borrelia* is not the proven cause, and mixed infections or an unrecognized co-infection by another tickborne agent could play a role.

- Renal lesions include immune-mediated glomerulonephritis, renal tubular necrosis, and lymphocytic-plasmacytic interstitial nephritis.
- Clinical findings can include acute vomiting, hypertension, edema, ascites, azotemia, hypoalbuminemia, hypercholesterolemia, proteinuria, and tubular casts in the urine. Most cases progress rapidly over 1 to 2 weeks and die despite therapy.

Other Manifestations

Meningitis, encephalitis, uveitis, and myocarditis with cardiac arrhythmias are seen rarely in association with canine borreliosis, but the relationship of these to *Borrelia* infection is uncertain.

Feline Borreliosis

Naturally-occurring clinical disease is not well documented in cats; however, many healthy cats are seropositive for *Borrelia* infection and experimentally infected cats develop polyarthritis, meningitis, pneumonitis, and lymphadenopathy.

DIAGNOSIS

Consider borreliosis in dogs from endemic areas with typical clinical signs, especially if there is a history of exposure to a wooded environment or tick-infested area. The diagnosis depends on finding the organism or antibodies directed against the organism. Serologic testing provides a presumptive diagnosis; however, in endemic areas many healthy dogs have been exposed and are seropositive, leading to a tendency to overdiagnose the disease. Definitive diagnosis requires identification of the *Borrelia* spirochetes by culture or polymerase chain reaction (PCR) assay, but these are not routinely available to the clinician.

In endemic areas, the differential diagnosis is challenging because other doxycycline-responsive tickborne infectious diseases are often prevalent as well, many of which cause clinical signs that overlap with borreliosis; such as infections caused by *Anaplasma*, *Ehrlichia*, *Rickettsia*, and *Bartonella* (see Chapters 17 and 19). Lyme borreliosis also is difficult to distinguish from immune-mediated polyarthritis (see Chapter 124).

▼ ***Key Point*** A positive *Borrelia* antibody titer is a marker for exposure to ticks and the infectious agents they transmit. Consider the potential for other tickborne diseases in any seropositive dog.

Serologic Tests for Borrelia Antibodies

Serologic tests for the presence of antibodies to *Borrelia* are widely available and used as indirect evidence of exposure. The traditional serologic tests are based on whole-cell enzyme-linked immunosorbent assay

(ELISA) or immunofluorescent antibody (IFA) techniques. These do not differentiate between antibodies from natural exposure and vaccination. The C6 antibody test and Western blot analysis are more specific for natural exposure.

ELISA and IFA Antibody Titers

The antibody titer detected by ELISA or IFA increases by 4 to 6 weeks after exposure, which is almost always before the onset of clinical signs; thus, ELISA or IFA titers are acceptable screening tests for Lyme borreliosis in unvaccinated dogs. Unfortunately, reliability and reproducibility of results vary between different commercial laboratories.

▼ ***Key Point*** Routine ELISA or IFA serologic testing does not differentiate between dogs with active Lyme disease and those with persistent antibodies from earlier exposure or vaccination.

Positive Titer

- In an endemic area, a positive titer can be an incidental finding resulting from prior infection. Antibody titers after natural exposure persist for years. Other causes of positive titers include prior vaccination, crossreactivity to other noncausative organisms (e.g., nonpathogenic *Borrelia* strains, *Leptospira* spp., oral spirochetes), and nonspecific reactions seen in other inflammatory conditions.
- Positive titers have a low predictive value for the development of clinical disease. In one study seropositive dogs were observed for 20 months, and less than 5% developed clinical joint disease.

▼ ***Key Point*** A positive *Borrelia* antibody test indicates exposure, but it does not prove that the clinical signs are caused by borreliosis.

- Paired titers (to identify a rising titer) are not helpful, and high titers can persist for years, even after treatment.
- Because dogs do not develop clinical disease before the rise in immunoglobin G (IgG) antibody, differentiation of immunoglobin M (IgM) and IgG is not useful. In addition, IgM titers persist for many months and do not indicate recent exposure.
- In cases suspected of neuroborreliosis, a high cerebrospinal fluid (CSF)-to-serum antibody titer ratio has been suggested as an indicator of central nervous system (CNS) antibody production and active neural infection.

Negative Titer

- False-negative antibody titer results are rare; thus, a negative titer in an animal with clinical signs rules out Lyme borreliosis with high probability.
- Evaluate animals with a negative titer and clinical signs suggesting borreliosis for immune-mediated causes of polyarthritis (see Chapter 124).

▼ ***Key Point*** Routine ELISA and IFA tests are highly sensitive screening tests, but they have poor specificity and thus are not suitable as confirmatory tests.

C6 Antibody Test

This test uses a synthetic C6 peptide as the antigen for detecting C6 antibodies against the highly conserved invariable region 6 (IR_6) of the outer surface protein (Osp) of *B. burgdorferi*. C6 antibodies are formed in response to natural exposure, but not in response to vaccination.

- The C6 antibody test is highly specific (99% specificity) for *B. burgdorferi*. The test does not crossreact with antibodies from prior Lyme vaccination or nonspecific antibodies against other spirochetes (e.g., *Leptospira*), thus eliminating the major causes of false-positives seen with traditional whole-cell ELISA and IFA tests.
- The C6 antibody test is more sensitive than traditional whole-cell ELISA for detecting early infections, detecting infections even as early as 3 weeks post-exposure, before clinical signs develop. This test may also be more sensitive for detection of certain strains of *Borrelia*, such as those found in Europe.

▼ ***Key Point*** The C6 antibody test (SNAP 3Dx) distinguishes between natural exposure and vaccine-induced antibodies.

- An ELISA-based test kit for C6 antibodies (SNAP 3Dx; IDEXX) is available as an in-office screening test for Lyme borreliosis. The kit simultaneously tests for heartworms and *Ehrlichia canis*, hence the name "3Dx". The manufacturer recommends a two-tiered testing approach, first using the in-office SNAP 3Dx test kit as the *qualitative* screening test for C6 antibodies. Positive results are then further characterized with a *quantitative* C6 antibody test on a serum sample sent to a reference laboratory.
- The quantitative C6 antibody test correlates with *Borrelia* load. In seropositive healthy dogs, a high level of C6 antibody may help to determine if treatment is warranted, although additional studies are needed to confirm this.
- In seropositive dogs with clinical borreliosis, the quantitative C6 antibody level can be measured prior to treatment and then used to monitor response to the therapy. The C6 antibody level usually declines by 3 months after successful antibiotic treatment. Current recommendations are to reevaluate the test at 3 and 6 months after treatment.

Western Blot Assay

The Western blot assay detects a pattern of antibodies against the Osp of the *Borrelia* spirochete that specifically indicates *B. burgdorferi* infection and excludes false positives caused by prior vaccination or nonspecific crossreactions to other organisms. In unfed infected ticks and during vaccine processing, OspA is prominently expressed by the spirochete, but in infected dogs OspC is most prominent. Western blot assay results that show a strong OspC response are specific for *B. burgdorferi* infection; whereas a strong OspA response indicates an antibody response to vaccination. The Western blot test provides similar diagnostic information as the C6 antibody test, but it is more cumbersome and expensive, and thus less useful for clinical situations.

Tests to Identify Borrelia Organisms

PCR and culture are specialized confirmatory tests used to identify *B. burgdorferi* organisms.

Polymerase Chain Reaction

PCR is highly specific but not yet routinely available. The fluid or tissue specimen chosen for PCR must contain *Borrelia* DNA for the result to be positive. False negatives are common because the location of the spirochetes in infected dogs is highly variable. *Borrelia* organisms do not usually spread hematogenously, so blood is not useful for PCR. The most reliable specimen is a skin biopsy near the tick bite site, or near the first joint affected. Joint fluid or synovium from affected joints may be used. Urine also can be tested. CSF testing is useful in cases with neurologic signs. PCR may not differentiate between viable spirochete organisms and nonviable remnants. It may take months following treatment or recovery for these non-infective remnants to clear and the PCR to become negative.

Culture

B. burgdorferi has fastidious growth requirements, and attempts to culture spirochetes from blood, joints, or tissues is often unrewarding. The highest isolation rate is from skin at the tick bite site. Synovium can also be cultured. *Borrelia* are rarely cultured from the blood. Although a positive culture is definitive confirmation of infection, culturing is difficult and not readily available for routine clinical diagnosis.

TREATMENT

Healthy Seropositive Dogs

Asymptomatic seropositive dogs do not need to be treated; however, they should be monitored for clinical signs of borreliosis, especially lameness, and given treatment if these occur. Monitoring for proteinuria and microalbuminuria as early indicators of Lyme nephritis has been suggested, but studies are needed to validate this approach.

▼ ***Key Point*** Treatment is rarely indicated for healthy seropositive dogs in the absence of clinical signs.

Dogs with Clinical Borreliosis

Treat dogs that have clinical signs compatible with Lyme borreliosis and a positive C6 antibody test. Use one of the following antibiotics.

- Doxycycline; 10 mg/kg q12h PO, for 4 weeks.
- Amoxicillin; 22 mg/kg q8h PO, for 4 weeks.
- Azithromycin; 5 mg/kg q12h PO, for 4 weeks, for refractory cases.
- Ceftriaxone; 25 mg/kg q24h, IV, for 4 weeks, for CNS involvement (rarely).

▼ ***Key Point*** Doxycycline is the treatment of choice for Lyme borreliosis.

- The response to antibiotic therapy is typically rapid (24 to 48 hours), especially in early infections.
- Some dogs remain persistently culture-positive and PCR-positive after antibiotics. Prolonged antibiotic therapy (weeks to months) may be required in these chronic, established infections.

▼ ***Key Point*** In longstanding infections the responsiveness to treatment may be inversely proportional to the duration of clinical signs.

- If the initial response to therapy is poor, reevaluate the diagnosis and look for concurrent diseases. Consider a diagnostic "tick panel" to exclude other concurrent tickborne infections, such as *Ehrlichia*, *Anaplasma phagocytophila*, *Rickettsia*, *Babesia*, and *Bartonella*.
- Use nonsteroidal anti-inflammatory drugs to control joint pain during episodes of recurrent arthritis.
- Avoid immunosuppressive doses of corticosteroids that can exacerbate *Borrelia* infection.
- Treat protein-losing glomerulopathy and acute renal failure with the measures described in Chapter 77.

PREVENTION

Vaccination

Killed whole-cell bacterins and recombinant OspA vaccine products are marketed for immunizing dogs against Lyme borreliosis using an initial series of 2 doses, 2 to 4 weeks apart, followed by annual revaccination. Recombinant vaccines may have less risk of adverse effects and are preferred by the author.

▼ ***Key Point*** Do not routinely vaccinate all dogs for Lyme borreliosis. Limit vaccination to high-risk dogs (e.g., outdoor, hunting, and field trial dogs) residing in tick-infested areas with a high prevalence of borreliosis.

- Crossprotectivity of vaccines against the multiplicity of *Borrelia* strains is uncertain.
- Vaccination of infected dogs has no known therapeutic benefit. The benefits as well as risks of vaccinating healthy seropositive dogs are unknown.
- A disadvantage of vaccination is that it causes false-positive results on routine serologic tests (see "Diagnosis").

Vector Control

▼ ***Key Point*** Tick bite avoidance is an important aspect of prevention.

Fipronil, permethrin, and amitraz are highly effective against ticks and for preventing *Borrelia*. Use one of these regularly for dogs residing in tick-infested areas. Always follow the label directions.

- Fipronil/methoprene monthly topical medication (Frontline Plus; Merial) is for both dogs and cats.
- Imidacloprid/permethrin monthly topical medication (Advantix; Bayer) is for dogs only, and is toxic in cats.
- Amitraz-impregnated collars (Preventic collar; Virbac) are effective for dogs, but lose activity when wet and can be toxic if ingested.
- Reduce the risk of exposure of animals by limiting their access to tick-infested areas.
- Periodically check animals for ticks and promptly remove them to decrease exposure to *B. burgdorferi*.

PUBLIC HEALTH

Human *B. burgdorferi* infections result from outdoor activities associated with exposure to tick vectors. In the United States, human Lyme borreliosis has been reported in nearly all states; however, 85% of cases occur in the Northeast and in Wisconsin, and Minnesota.

- Human Lyme disease begins several days after a tick bite as an expanding, annular, non-pruritic, erythematous rash (erythema chronicum migrans), and progresses to fever, flu-like symptoms, polyarthritis, meningitis, myocarditis, and uveitis.
- Infected dogs and cats do not directly transmit *Borrelia* to humans. Pets may occasionally transport infected ticks into the household on their haircoat, but this is a rare source of human infection.
- Transmission requires prolonged tick attachment (48 hours); therefore, measures that reduce tick exposure are the best means of preventing human infection. In tick-infested areas, the tick repellant N,N-diethyl-meta-toluamide (DEET) is recommended for exposed skin.

Chapter 19

Systemic Bacterial Infectious Diseases

Robert G. Sherding

A large number of bacteria can infect dogs and cats. This chapter focuses on leptospirosis, brucellosis, and bartonellosis. Chapter 18 is devoted to Lyme borreliosis. Other infectious diseases caused by bacteria are summarized in Table 19-1, and most are described in the respective organ-system chapters. *Bordetella bronchiseptica* is associated with the canine infectious tracheobronchitis (see Chapter 12). *Mycoplasma haemofelis* and *Mycoplasma haemominutum* are hemotropic infections (see Chapter 22). Mycobacterial infections are associated with chronic skin disease (see Chapter 39). Actinomycosis and nocardiosis are causes of pyothorax (see Chapter 164). Tetanus and botulism cause severe neuromuscular dysfunction (see Chapters 128 and 130, respectively). Salmonellosis, campylobacteriosis, yersiniosis, and *Clostridium perfringens* and *Cl. difficile* primarily involve the intestinal tract (see Chapter 69).

LEPTOSPIROSIS

Etiology

Leptospira are filamentous, motile, spirochete bacteria that infect many wild and domestic animals and humans. Over 200 leptospiral serovars have been described. A universal feature of pathogenic serovars is the ability to colonize the proximal renal tubules resulting in a prolonged renal carrier state and urine shedding.

In North America, canine leptospirosis is most frequently caused by serovars of *Leptospira interrogans* (serovars *L. icterohaemorrhagiae, L. canicola, L. pomona,* and *L. bratislava*) and *Leptospira kirschneri* (serovar *L. grippotyphosa*). Serovar *L. autumnalis* may also be emerging in some regions.

Transmission

▼ ***Key Point*** Infection is spread by recovered animals that shed *Leptospira* organisms in their urine for months to years after infection.

- Wild animal populations serve as reservoirs of infection that persistently shed *Leptospira* organisms and contaminate the environment. Suburban "backyard" wildlife such as raccoons, skunks, squirrels, voles, and other rodents may be especially important sources of infection.
- Exposure usually occurs by mucocutaneous contact with *Leptospira* organisms in the environment, most importantly contaminated surface water, but also food, bedding, soil, vegetation, or fomites. The organisms penetrate mucosa or abraded skin. In addition, transplacental, venereal, and bite-wound transmission can occur.

Prevalence

Canine leptospirosis appears to be a reemerging disease with increasing prevalence, especially involving serovars *L. grippotyphosa* and *L. pomona*. Middle-aged, male, large-breed outdoor dogs that live in peri-urban areas are most commonly affected; however, all dogs are at risk. The incidence is highest in late summer and early fall. Infection rates increase after wet periods of rainfall and flooding.

Pathogenesis

Leptospiremia occurs 4 to 12 days post-infection. The primary targets in leptospirosis are the kidneys and the liver. Vasculitis and disseminated intravascular coagulopathy (DIC) may result from widespread acute endothelial injury.

- *Leptospira* preferentially infect renal tubule epithelium, often causing acute tubular injury and renal failure. Renal colonization and urine shedding are prolonged, continuing for months to years after clinical recovery.
- *Leptospira* can injure hepatocytes, resulting in hepatocyte dysfunction, cholestasis, acute hepatic necrosis, jaundice, and occasionally chronic hepatitis and hepatic fibrosis (especially *L. grippotyphosa*).
- Infection typically is subclinical in vaccinated (immune) dogs and in nearly all cats.

Table 19-1. BACTERIAL DISEASES OF DOGS AND CATS

Disease	Etiology (Source)	Clinical Signs	Diagnosis	Treatment
Leptospirosis	*Leptospira interrogans* serovars: *canicola, icterohaemorrhagia, pamona, bratislava, grippotyphosa* (urine shedding)	Acute renal failure, acute hepatic failure, chronic hepatitis, vasculitis, DIC, anorexia, depression, fever, myalgia,	Serology (MA, ELISA); PCR	Penicillin, ampicillin, or amoxicillin, followed by doxycycline
Borreliosis (Lyme disease)	*Borrelia burgdorferi* (tickborne)	Fever, polyarthritis, acute renal disease	Serology (IFA, ELISA, C6 antibody); PCR	Doxycycline; tick control
Brucellosis	*Brucella canis* (aborted tissues, vaginal discharges, semen, urine)	*Male:* infertility, orchiepididymitis, scrotitis *Female:* abortion, infertility *Male and female:* lymphadenopathy	Serology (slide test, tube test, AGID), blood culture	Minocycline or doxycycline plus dihydrostreptomycin or gentamicin; spay or neuter
Bartonellosis	*Bartonella henselae* (in cats and dogs; flea vector); *B. vinsonii* (in dogs; tickborne)	*Cat:* subclinical, transient fever *Dog:* endocarditis, granulomatous and immune diseases, epistaxis *Human:* cat scratch disease, etc	Serology, blood culture, PCR	*Acute:* amikacin plus amoxicillin, *Chronic:* azithromycin, enrofloxacin, doxycycline *Prevention:* flea and tick control
Bordetellosis (kennel cough)	*Bordetella bronchiseptica* (respiratory secretions)	Acute tracheobronchitis (cough); rhinitis	Culture (airways)	Doxycycline, amoxicillin-clavulanate, or azithromycin
Botulism	*Clostridium botulinum* (neurotoxin in contaminated food)	Ascending neuromuscular paralysis	Clinical signs; toxin assay	Type C antitoxin; respiratory support
Tetanus	*Clostridium tetani* (neurotoxin in contaminated wounds)	Muscle rigidity, stiff gait, tetanic spasms, trismus, seizures	Clinical signs	Tetanus antitoxin; penicillin G or metronidazole; sedatives
Campylobacteriosis	*Campylobacter jejuni* (feces)	Watery mucoid diarrhea or subclinical carrier	Fecal culture, fecal microscopy	Erythromycin, neomycin, clindamycin, or fluoroquinolone
Salmonellosis	*Salmonella typhimurium, S. enteritidis* (feces)	Acute gastroenteritis: fever, vomiting, diarrhea, bacteremia; subclinical carrier	Fecal culture	Enrofloxacin, trimethoprim sulfa, or chloramphenicol
Yersiniosis	*Yersinia enterocolitica* (feces)	Diarrhea (rare) or subclinical carrier	Fecal culture	Cephalosporins, tetracyclines, etc.
Tyzzer disease	*Clostridium piliforme* (rodent feces)	Acute hepatic necrosis, necrotizing ileocolitis	Necropsy lesions, cell culture isolation	None (100% fatality)
Plague	*Yersinia pestis* (rodent fleas and rodent ingestion)	*Cat:* lymph node abscess, high fever, pneumonia, fatal septicemia *Dog:* mild fever or no signs	Lymph node cytology, culture, and IFA; serology; PCR	Gentamicin, doxycycline; flea control
Tularemia	*Francisella tularensis* (tickborne; ingestion of rabbits or rodents)	Fever, oral ulcers, lymphadenopathy, draining abscesses, fatal bacteremia	Serology (agglutinating antibody titer), culture	Gentamicin, doxycycline, or fluoroquinolones; tick control
Actinomycosis	*Actinomyces* spp. (oral flora migration, bitewounds)	Subcutaneous abscesses, draining fistulous tracts, pyothorax, osteomyelitis	Cytology (gram-positive filamentous rods), culture of exudate	Penicillin, clindamycin; debride wounds; drain and lavage pyothorax
Nocardiosis	*Nocardia* spp (soil via wounds, plant awns, inhalation)	Subcutaneous abscesses, draining fistulous tracts, pyothorax, pneumonia	Cytology (gram-positive filamentous rods); biopsy; culture of exudate	Trimethoprim-sulfa; debride wounds; drain and lavage pyothorax
Tuberculous mycobacteriosis	*Mycobacterium tuberculosis, M. bovis, M. avium* (*Dog:* inhalation) (*Cat:* ingestion of milk, meat, offal)	*Dog:* granulomatous pneumonia, hilar lymphadenopathy *Cat:* granulomatous enteritis, mesenteric lymphadenopathy	Cytology or biopsy (acid-fast bacteria); culture (slow-growing); PCR	For *M. tuberculosis* or *M. bovis*: euthanasia because of public health risks For *M. avium*: triple combination of rifampin, enrofloxacin, azithromycin
Feline leprosy	*M. lepraemurium* (contact with rats)	Ulcerating cutaneous nodules	Cytology or biopsy (acid-fast bacteria); PCR	Surgical excision; clofazimine alone, or with clarithromycin or rifampin (see Ch. 39)
Opportunistic (atypical) mycobacteriosis	*M. fortuitum, M. chelonei, M. smegmatis,* (skin contact with contaminated soil and water)	Ulcerating dermal nodules; nonhealing wounds; spreading subcutaneous fistulous tracts; panniculitis	Cytology or biopsy (acid-fast bacteria); culture	Enrofloxacin alone, or with azithromycin; for *M. cheloni* use clarithromycin (see Ch. 39)

AGID, agar-gel immunodiffusion; DIC, disseminated intravascular coagulation; ELISA, enzyme-linked immunosorbent assay; IFA, indirect fluorescent antibody; MA, microscopic agglutination; PCR, polymerase chain reaction.

Clinical Signs

- **Systemic signs**: This can include acute onset of anorexia, depression, fever, vomiting, dehydration, stiff gait and reluctance to move (generalized myalgia), and congested mucous membranes. Vascular collapse and peracute death are seen in some animals.
- **Acute renal failure**: Systemic signs combined with renal pain and polyuria-polydipsia (mild cases), oliguria, or anuria (severe cases).
- **Acute hepatic failure**: Systemic signs combined with jaundice and DIC.
- **Acute vasculitis and DIC**: Systemic signs combined with widespread tissue edema and petechial and ecchymotic hemorrhages, hematemesis, melena, hematochezia, and epistaxis.
- **Chronic hepatitis and hepatic fibrosis**: Signs of chronic liver failure develop; e.g., weight loss, ascites, jaundice, and hepatic encephalopathy.
- **Other findings**: Less frequent manifestations include uveitis, meningitis, myocarditis (arrhythmias), acute pulmonary hemorrhage and interstitial pneumonitis (cough, dyspnea), and abortion or stillbirths.

Diagnosis

Complete Blood Count (CBC)

- Leukopenia (early response to leptospiremia)
- Neutrophilic leukocytosis with left shift (at time of presentation)
- Thrombocytopenia; severe cases may have coagulation abnormalities of DIC (see Chapter 23)

Urinalysis

- Proteinuria, pyuria, cylindruria, bilirubinuria, glucosuria, and isosthenuria
- Darkfield microscopy of urine is unreliable and not recommended.

Serum Chemistries

- Azotemia—increased blood urea nitrogen (BUN), serum creatinine, and serum phosphorus
- Increased serum concentrations of liver enzymes (ALT, AST, ALP), bilirubin, and bile acids
- Increased serum creatine kinase (myopathy)
- Electrolyte imbalances reflecting renal and gastrointestinal effects

Diagnostic Imaging

- Kidney size can be normal or enlarged. Ultrasonographically, kidneys show increased cortical echogenicity in 75% of cases and pyelectasia in nearly 50% of cases. Some dogs have a distinctive echogenic demarcation of the corticomedullary border ("medullary rim sign"). Perinephric effusion may be seen.
- Liver ultrasonography is usually unremarkable. Nonspecific changes in echogenicity may be seen.
- Thoracic radiographs may show patchy alveolar, reticulonodular, or generalized pulmonary interstitial infiltrates with dorsocaudal distribution indicative of pneumonitis, vasculitis, or pulmonary hemorrhage.

Serology

▼ ***Key Point*** *Leptospira* organisms are fastidious, slow-growing, and difficult to culture, and they are difficult to identify in fluids or tissues; thus, the combination of serology and clinical signs is the most practical means of diagnosis.

Microscopic Agglutination Titer

▼ ***Key Point*** The presence of microscopic agglutination (MA) antibodies can indicate current infection, past infection, or prior leptospiral vaccination.

The MA test is the standard method for presumptive clinical diagnosis of leptospirosis. MA titers become positive after 1 week, peak at 3 to 4 weeks, and remain positive for several months after either natural infection or vaccination.

- Although single titers do not definitively diagnose current active infections, MA titers at 1:400 or greater are suggestive, and at 1:800 or greater they are highly indicative of leptospirosis. However, booster vaccines given in the preceding 2 to 3 months can produce titers that overlap with these values. Most post-vaccinal titers are 1:100 to 1:400, but rarely titers as high as 1:3,200 can occur within 3 months of vaccination. The magnitude of the MA titer can be blunted by early antibiotic therapy.

▼ ***Key Point*** The presumptive diagnosis of leptospirosis is based on a single high MA titer (≥1:800) with compatible clinical signs, or a 4-fold rise in MA titer in paired sera.

- MA titers can be negative in the first week of acute illness, requiring a second titer 2 to 4 weeks later for diagnosis. Use paired MA titers during acute illness and recovery (convalescence) to demonstrate a 4-fold rise in titer as a criterion to distinguish current infection from previous infection or vaccination. Because the timing of the titer peak varies, take a convalescent titer 2 to 3 weeks after acute illness, and possibly another 1 to 2 weeks later.
- Ideally, the lab will test for the various serovars listed in the Etiology section, and potentially others known to occur in the geographic region. The serovar with the highest titer is interpreted to be the infecting serovar and other serovars with lower titers are considered to represent nonspecific

crossreactivity and/or background titers from prior vaccination.

Combined Immunoglobulin Titers

Combined immunoglobulin M (IgM)-immunoglobulin G (IgG) enzyme-linked immunosorbent assay (ELISA) titers differentiate the early IgM antibody response of acute infection from the later IgG response that is seen with recovery, prior infection, or vaccination. Although the combined IgM-IgG ELISA helps to identify natural infection in vaccinated dogs, it does not distinguish between different serovars. The ELISA test is not as readily available as the MA test.

- The IgM titer becomes positive within the first week of infection (before the MA test) and peaks at 2 weeks.
- The IgG titer becomes positive 2 to 3 weeks after infection and persists for months.

Identification of Leptospiral Organisms

Leptospirosis can be confirmed by identification of *Leptospira* organisms by microscopy and culture. These tests are most useful for confirming positive serologic tests, and only positive results are meaningful. Because of low detection rates, negative results never exclude the possibility of leptospirosis. In addition, antibiotics rapidly eliminate the organisms from blood and urine so they will be undetectable by culture. Polymerase chain reaction (PCR) identification of leptospiral DNA may be a more reliable means of documenting infection.

Microscopic Identification

- Darkfield microscopy is used to detect leptospires on a wet mount of fresh urine. Accuracy is highly operator dependent, and the high rate of false positives and false negatives makes this an unreliable test.
- *Leptospira* organisms can sometimes be identified in urine or in tissues (e.g., by kidney and liver biopsy or cytology specimens) using Giemsa or silver stains, immunohistochemical staining, or fluorescent antibody techniques.

Culture

Culture for *Leptospira* is technically difficult and has a low detection rate; thus, it is rarely used for clinical diagnosis. The organisms are fastidious and may take several weeks to grow. The preferred specimen is fresh urine taken by cystocentesis prior to administration of antibiotics. In hydrated dogs, a low dose of furosemide (0.5 mg/kg, IV) prior to urine collection may optimize the recovery rate. Collected urine must be alkalinized to >pH 8 and transported in special media.

Polymerase Chain Reaction Test

PCR detection of leptospiral DNA in blood, urine, or tissues is highly sensitive and specific. It detects infection earlier than serology, and may be useful for identifying subclinical urine shedding. Unfortunately, validated PCR assays are not yet readily available to the clinician.

Treatment

Effective treatment requires general supportive therapy, treatment of the leptospiremic phase of infection, followed by treatment of the leptospiruric carrier phase of infection. With intensive management, survival rates of 75 to 90% can be expected. Most dogs recover completely, but residual chronic renal failure is a potential outcome.

- **For supportive care**: Administer intensive fluid and electrolyte therapy (see Chapter 5) and, depending on clinical findings, initiate appropriate treatment for acute renal failure (see Chapter 77), acute hepatic failure (see Chapter 71), and DIC (see Chapter 23), as recommended in other chapters in this book. Oliguric renal failure and fulminant DIC are life-threatening complications of leptospirosis that often need the most immediate attention and intensive care.

▼ ***Key Point*** The antibiotics of choice are penicillin derivatives for terminating leptospiremia, and doxycycline for eliminating leptospiruria.

- **For leptospiremia**: Initially give parenteral antibiotics, such as penicillin G (25,000–40,000 units/kg IV, q12h) or ampicillin (22 mg/kg IV, q6–8h). Once vomiting resolves, switch to oral amoxicillin (22 mg/kg PO, q8–12h) and continue treatment for 2 weeks.
- **For leptospiruria**: To eliminate the renal carrier state once amoxicillin treatment has been completed, give doxycycline (5 mg/kg PO q12h) for 2 weeks. Other alternatives for treating the carrier state include macrolides (erythromycin, azithromycin), fluoroquinolones, or aminoglycosides (avoid in dogs with renal impairment).
- For caretaker precautions, see the "Public Health" section.

Prevention

Because wild animal reservoirs harbor and shed leptospiral organisms that contaminate the environment, prevention of exposure is not a realistic expectation. Routine vaccination for leptospirosis helps to decrease the incidence and severity of canine leptospirosis and to reduce the zoonotic risks to pet owners.

- Bivalent *Leptospira* bacterins *(L. canicola* and *L. icterohaemorrhagiae)* have been widely used for routine

canine vaccination since the 1970s. Bivalent vaccines have reduced the incidence of infections caused by *L. canicola* and *L. icterohaemorrhagiae*, but they do not crossprotect against other serovars that now account for most leptospiral infections in dogs.
- Use multivalent vaccines that contain the serovars *L. pomona*, *L. grippotyphosa*, *L. canicola* and *L. icterohaemorrhagiae* to give a broader spectrum of protection.
- Vaccinate dogs over 12 weeks of age in high-prevalence areas or high-risk situations with at least 3 doses, 3 to 4 weeks apart, for primary immunization, followed by annual revaccination (see Chapter 7).
- Anaphylactic reactions (facial edema, pruritus, hypotension, or dyspnea) occur with leptospiral bacterins, and the incidence may be increased in small breeds and puppies less than 9 weeks of age. Newer improved vaccines derived from *Leptospira* antigenic subunits will likely cause fewer allergic reactions.

Public Health

Leptospirosis is a widespread and potentially fatal zoonotic infection. Most humans are infected through outdoor recreational activities in and around water, but animal caretakers and veterinarians are considered at risk because direct contact of mucous membranes or damaged skin with the urine of infected animals is a potential source of infection. Therefore, caretakers and pet owners must take proper precautions and maintain strict sanitation when treating dogs with leptospirosis. Consider the following preventive measures.

- Regard urine-contaminated objects as biological hazards.
- Require latex gloves for caretakers and handlers of dogs with leptospirosis.
- Avoid spray washing of contaminated cages or kennels, because it could aerosolize urine. Use protective goggles and face masks during cage cleaning.
- Use iodophor as a disinfectant for urine-contaminated areas.
- Treat all known and suspected shedders with doxycycline.
- Eliminate rodent infestations.

CANINE BRUCELLOSIS

Etiology

Canine brucellosis is caused by *Brucella canis,* a gram-negative aerobic coccobacillus. In addition, rare infections caused by *B. abortus*, *B. suis*, and *B. melitensis* have been reported in dogs in contact with livestock. Cats can be infected with *B. canis* experimentally, but are resistant and do not develop clinical signs. Rare zoonotic *B. canis* infections are seen in humans in contact with infected dogs.

Transmission

B. canis is transmitted by infected semen (venereal), vaginal discharges (at estrus, breeding, and post-abortion), aborted fetal tissues, and urine. Infection occurs by penetration of oronasal, conjunctival, and genital mucous membranes.

Pathogenesis

Brucella canis is an intracellular pathogen that can persist for years within the mononuclear phagocytes of the host. Brucellosis is characterized by a prolonged leukocyte-associated bacteremia that begins 1 to 4 weeks after infection, and can last from 6 months to over 5 years. Spontaneous recovery after 1 to 5 years depends on cell-mediated immunity. *Brucella* organisms most often localize in the following areas.

- Lymphoid and mononuclear phagocyte systems (resulting in lymphoreticular hyperplasia and occasional splenomegaly)
- Prostate and testes of male dogs (resulting in orchiepididymitis and infertility)
- Gravid uterus of female dogs (resulting in infertility, abortion, or stillbirth)
- Rarely, the eye (anterior uveitis), kidney (glomerulonephritis), or intervertebral discs (diskospondylitis).

Clinical Signs

Most infected animals have no overt clinical signs. Generalized lymphadenopathy, splenomegaly, and reproductive failure are the principal manifestations. Diskospondylitis and uveitis are less common. Fever and systemic illness are rare.

Male Reproductive Failure

Brucellosis causes infertility and physical findings of scrotal swelling, scrotal dermatitis, enlarged epididymides (epididymitis), and testicular atrophy. Various semen abnormalities result in sterility (see "Diagnosis" section).

Female Reproductive Failure

Brucellosis causes abortion of dead, partially autolyzed fetuses at 40 to 60 days of gestation without any other signs of illness; persistent discharge for 1 to 6 weeks after abortion; and failure to conceive (because of early fetal resorption).

Other Uncommon Forms of Brucellosis

- **Diskospondylitis**: This causes spinal pain progressing to paresis and ataxia with spinal cord compression. The radiographic appearance of diskospondylitis is distinctive, but other bacteria also can cause this.
- **Uveitis**: This manifests as anterior uveitis (aqueous flare, hyphema, secondary glaucoma, corneal edema)

or chorioretinitis (vitreal haze, retinal lesions or detachment).
- **Meningoencephalitis**: This is very rare and not well characterized.
- **Glomerulonephritis**: This is seen as subclinical proteinuria without azotemia.

Diagnosis

▼ ***Key Point*** Consider brucellosis in all canine infertility evaluations and bitches with late-term abortion.

- Routine CBC, urinalysis, and serum chemistries are normal except for occasional hyperglobulinemia.
- Lymph node cytology reveals nonspecific reactive hyperplasia.
- Semen abnormalities—more than 80% of sperm are morphologically abnormal (immature sperm, deformed acrosomes, swollen midpieces, detached tails, head-to-head agglutination); increased semen leukocytes; and aspermia in advanced cases.

Serology

▼ ***Key Point*** The diagnosis of brucellosis is a 2-step process. First, use a screening serologic test for presumptive diagnosis, then confirm positives with a high-specificity serologic test, a blood culture, or, ideally, both.

Because other bacteria elicit antibodies that crossreact with *B. canis*, false-positive results are common with agglutination tests. Hemolysis (hemoglobin) also causes false-positive results. False-negative titers are rare, but can result from sequestration of infection or recent antibiotics. In recent infections, it can take up to 4 weeks to seroconvert; thus, when screening dogs for entry into a breeding kennel, a negative test result on day 1 and again after 4 weeks is required.

Rapid Slide Agglutination Test

The rapid slide agglutination test (RSAT) (D-Tec CB; Synbiotics) is an inexpensive, in-office screening test that is used to identify suspects that need further testing. The RSAT detects antibodies to *B canis* cell-wall antigen. This highly sensitive screening test has an accurate negative predictive value, but false positives are common. Nearly 99% of negatives are true negatives. Only one half to two thirds of positives are confirmed to be truly infected; thus, all RSAT positives must be confirmed by a more specific serologic test, a blood culture, or, ideally, both.

Tube Agglutination Test

The tube agglutination test (TAT) is used to provide quantitative titer confirmation of positive RSAT results. The TAT titer is more specific than the RSAT, but because of false positives the TAT is not considered definitive (titers 1:50 to 1:100 are suspicious; titers ≥ 1:200 are highly suggestive).

Agar Gel Immunodiffusion

The agar gel immunodiffusion (AGID) is a sensitive and specific test for antibodies to either cell wall or cytoplasmic antigens of *B. canis*. The cytoplasmic-antigen AGID has the best specificity and is the preferred serologic confirmatory test for diagnosis of brucellosis. AGID is available at some commercial and state diagnostic laboratories.

Other Serologic Tests

Indirect fluorescent antibody (IFA) and ELISA titers for *B. canis* have high specificity and are used as confirmatory tests (titers of 1:50 to 1:100 are suspicious; titers ≥ 1:200 are diagnostic).

Bacterial Culture

- A positive *Brucella* culture is definitive evidence of infection. Whole blood is the preferred culture specimen because of the characteristically prolonged bacteremia of brucellosis. Urine, semen, vaginal discharges, and aborted fetal tissues also can be cultured.
- Negative cultures never rule out brucellosis because the bacteremia can be intermittent or transiently suppressed by antibiotics. Use a serologic test such as the RSAT to screen for infection, and then use blood cultures for confirmation.

▼ ***Key Point*** Although positive serologic tests are indicative of active brucellosis, a positive blood culture is the gold standard for definitive diagnosis and should be used whenever possible for confirmation.

Treatment

Brucella organisms are refractory to antibiotics because of their intracellular location. This is compounded by poor penetration of antibiotics into protected sites such as the testes, prostate, eyes, and the central nervous system (CNS). Always treat with at least two synergistic antibiotics. Single antibiotic therapy is not effective.

- The traditional antibiotic regimen is: minocycline (12.5 mg/kg, PO, q12h for 4 weeks) combined with dihydrostreptomycin (10 mg/kg, IM, q12h for 7 days, on weeks 1 and 4). Doxycycline (5–10 mg/kg, PO, q12h) is an alternative to minocycline, and gentamicin (5 mg/kg SC q24h for 7 days) is usually substituted for the dihydrostreptomycin, but is less effective. For refractory cases, a fluoroquinolone

or rifampin can be added as a triple antibiotic regimen.
- Bacteremia often recurs weeks to months after cessation of treatment; thus, three or more repeated courses of antibiotics guided by follow-up titers and blood cultures are often required.

▼ ***Key Point*** Eradication of *Brucella* with antibiotics is difficult and highly unpredictable. Cure may not be possible in some dogs.

- Recommend spay or neuter of infected dogs.
- Recommend caution for people in contact with *Brucella*-positive dogs because there have been rare cases of human infection with *B. canis*. Canine brucellosis is regarded as a low-level public health risk.

Prevention

▼ ***Key Point*** Eliminate all *Brucella*-positive dogs from breeding programs.

- Test all breeding stock for *Brucella* two times at a 4-week interval before entry into a breeding program and, ideally, test before each breeding in females and once or twice yearly in sexually active male dogs.

BARTONELLOSIS

Bartonella species are fastidious, aerobic, pleomorphic, gram-negative bacteria that infect dogs and cats through vectors such as fleas and ticks. *Bartonella* are considered to be hemotropic. They cause persistent bacteremia in mammalian reservoir hosts by localizing intracellularly in erythrocytes and vascular endothelium. This intracellular location of *Bartonella* organisms promotes (1) persistence in the blood, (2) efficient transmission by arthropod vectors, and (3) resistance to antibiotics and attack from the host immune system. Dogs and cats are infected by several species of *Bartonella*, and the list is growing. *Bartonella* bacteria have worldwide importance as causes of zoonotic infections in humans.

Feline Bartonellosis

Etiology

Cats are infected by at least 4 *Bartonella* species. Cats serve as the main reservoir host for *B. henselae*, a ubiquitous infection in cats that is transmitted by fleas and causes cat scratch disease and other conditions in humans (see "Public Health" section). Cats are also a reservoir for the less prevalent *B. clarridgeiae*, another cause of cat scratch disease. *B. koehlerae*, and *B. bovis* (formerly *B. weissii*) have been isolated sporadically from cats, but their clinical significance is unknown.

Transmission

▼ ***Key Point*** *Bartonella* infection is transmitted from cat to cat by fleas.

- *B. henselae* replicates in fleas and survives for days in flea feces. Feces from fleas feeding on bacteremic cats may be the main infective source of *B. henselae*.
- Direct horizontal transmission does not occur between infected and uninfected cats that co-habit in a flea-free environment.
- Vertical (in utero) and lactogenic transmission to kittens has not been shown.
- Transmission can occur through contaminated blood transfusions or injection needles.

Prevalence

- Cats are the main reservoir for *B. henselae*, and infection is common in cats worldwide. Seroprevalence indicating exposure varies by region, but ranges from 4% to 80% in the United States, and exceeds 50% of pet cats in warm, humid coastal and southern regions of the United States where fleas thrive. Up to 33% of pet cats are bacteremic (i.e., actively infected) in these high-prevalence areas.
- In a U.S. regional comparison in 271 young pet cats (age < 2 years), the prevalence of seroconversion/bacteremia varied from 67%/33% in Florida, to 62%/28% in Southern California, to 28%/12% in Washington, D.C. to only 12%/6% in Chicago.
- Factors associated with increase risk of infection include young age (<1 year), flea infestation, indoor-outdoor lifestyle, and origination from a shelter or stray situation.
- *B. clarridgeiae* accounts for 10% of *Bartonella*-infected cats in the United States, but over 30% in parts of Europe and Asia.

Pathogenesis

Most cats infected with *Bartonella* spp. are healthy carriers with chronic bacteremia. Experimental inoculation of cats with *B. henselae* results in bacteremia within 1 to 2 weeks coinciding with seroconversion, and transient signs of fever, lethargy, anorexia, regional lymphadenopathy, and occasional neurologic signs. Most infected cats maintain a persistent or episodic bacteremia for months to years.

Clinical Signs

Natural infections with *Bartonella henselae* are only rarely associated with recognizable clinical disease in cats. Most bacteremic cats are clinically healthy carriers. *Bartonella* infection has been associated with fever, lymphadenopathy, anterior uveitis, gingivitis/stomatitis, endocarditis, neurologic disease, and reproductive failure. Because so many healthy cats are carriers, it is

possible that the *Bartonella* isolated from cats with these conditions is coincidental rather than causative, or it may be a cofactor with other infections.

Diagnosis

Blood culture, blood PCR, and serologic testing can be used to evaluate the *Bartonella* infection status of cats, and these diagnostic procedures are readily available to practicing veterinarians through the Vector Borne Disease Diagnostic Lab at North Carolina State University. Submission requirements and forms are available at www.cvm.ncsu.edu/docs/tickbornediseaselab.html.

▼ ***Key Point*** Diagnostic testing is only indicated in cats suspected of clinical bartonellosis. Routine testing of healthy cats for *Bartonella* infection is not currently recommended.

Serology merely indicates exposure and the possibility of infection. Only culture and PCR can prove active infection. Most cats that have negative results on these tests are not actively infected. In some cats, however, bacteremia can be intermittent, resulting in occasional false negatives with culture and PCR.

Serology

Serologic testing is based on IFA or ELISA procedures for detection of antibodies against *B. henselae*. Serology has limited diagnostic value because a positive titer (>1:64) does not distinguish between prior exposure and active infection. In cats with acute illness (i.e., recent infection), paired titers over 2 to 3 weeks may be required to document seroconversion. Pre-adoption serologic testing of kittens and young cats may be useful, especially when the prospective owner is immunocompromised, because seronegative cats are unlikely to be infected. However, some false negatives occur with serology (up to 10% of seronegative cats may have bacteremia).

Blood Culture

Isolation of *Bartonella* spp. from bacteremic cats is much easier than in dogs or humans; thus, blood culture is a good confirmatory test for feline *Bartonella* infection. *Bartonella* cultures are slow growing, so results can take up to 8 weeks to obtain. False negatives occur when bacteremia is intermittent or suppressed by prior antibiotics, or with improper sample collection. Always obtain *Bartonella* cultures prior to administering antibiotics. Contact the laboratory for specific instructions on sample collection and submission.

PCR Assay

PCR detection of *Bartonella* DNA in blood is a confirmatory test that is comparable to culture in reliability, with the advantages of quicker results and speciation of the positives. False negatives are uncommon except when bacteremia is transiently suppressed by prior antibiotics. False positives are rare.

Treatment

The optimal treatment for eliminating *Bartonella* infection in cats has not been established. Infection is extremely refractory to antibiotics because of the intracellular location of the bacteria. In most cats, antibiotics transiently suppress the bacteremia without curing the infection. Relapse of bacteremia typically occurs several weeks after discontinuation of antibiotics. Thus, treatment is only indicated for cats with clinical disease attributable to bartonellosis.

▼ ***Key Point*** Treatment of healthy *Bartonella*-infected cats is not recommended and usually ineffective.

The following antibiotics have been suggested for clinical bartonellosis in cats. Use one or more antibiotics for a minimum of 6 weeks (after informing the owner of the uncertainty of antibiotic efficacy). Following treatment, evaluate blood cultures at 4- to 8-week intervals for at least 3 to 4 months to detect relapse.

- Macrolides (e.g., azithromycin, 7.5–10 mg/kg PO q12h)
- Fluoroquinolones (e.g., enrofloxacin, 2.5 mg/kg q12h PO; *caution*: higher doses can cause retinal degeneration and blindness in cats); can be used alone or in combination with amoxicillin
- Doxycycline (10 mg/kg PO q12h), or amoxicillin-clavulanate (15 mg/kg PO q12h), have also been used, but are considered less effective options.

Prevention

▼ ***Key Point*** Rigorous flea control is the most effective prevention against *Bartonella* infection in cats.

Use an integrated flea control program to reduce the risk of exposure to *Bartonella* (see Chapter 45 and Table 45-1 for a complete discussion of flea control options). For rapid killing of fleas on a cat that is already infested, use oral nitenpyram (Capstar, Novartis) or topical pyrethrin. Do not use permethrin; it is highly toxic in cats. For routine control of fleas, and thus prevention of *Bartonella* infection, use one of the following long-acting topical flea control products at least monthly.

- Fipronil/methoprene (Frontline Plus; Merial)
- Imidocloprid (Advantage; Bayer)
- Selamectin (Revolution; Pfizer)

▼ ***Key Point*** All cats used as blood donors should be seronegative and either culture-negative or PCR-negative for *Bartonella*.

Public Health

Domestic cats are the primary reservoirs for zoonotic human infections with *B. henselae* and *B. clarridgeiae*. Both agents cause cat scratch disease in healthy people, characterized by a small erythematous skin papule (inoculation granuloma) at the entry site after 7 to 12 days, followed in 1 to 2 weeks by variable malaise and benign regional lymphadenopathy that is usually self-limiting within 2 to 3 months.

Serious atypical manifestations of *B. henselae* develop most frequently in immunocompromised people, and can include bacillary angiomatosis, parenchymal bacillary peliosis, endocarditis, encephalopathy, neuroretinitis, arthritis, osteomyelitis, and relapsing fever with bacteremia. *Bartonella* is isolated from 3% of human endocarditis patients and 18% of febrile HIV-infected patients.

Transmission and Risk Factors in Humans

Most human infections occur through contamination of cat scratches and cat bites with flea excrement. Approximately 90% of the cats owned by people with cat scratch disease are bacteremic with *B. henselae*. Young, flea-infested cats are the greatest zoonotic risk.

- Cats under 1 year of age are most likely to infect people. Owners of kittens are 15 times more likely to develop cat scratch disease than owners of adult cats.
- The highest prevalence in people in the United States is in coastal and southern regions, especially in summer and fall, coinciding with the time of greatest flea activity.
- Seroprevalence is 3% to 6% in the general population, but 7% to 15% in veterinary health-care providers.

Prevention of Bartonellosis in Immunocompromised Pet Owners

Recommend that immunocompromised people avoid cats less than 1 year of age and cats with a history of flea infestation. Flea-free adult cats kept in a flea-controlled environment are least likely to infect people. Acquisition of a new cat from a private owner or breeder is preferable to adoption of a stray or shelter cat. In addition, seronegative cats are less likely to have bacteremia and thus are less of a potential risk, although not all seronegative cats are free of infection (see "Serology" section). Immunocompromised people should consider the following recommendations.

- House cats indoors to lessen the potential for flea exposure.
- Use flea control products regularly (see "Prevention" section).
- Wash hands after handling cats.
- Avoid rough play to reduce accidental cat scratches.
- Cleanse cat-inflicted skin wounds immediately, and seek medical advice.
- Do not restrain cats or pull cats from cat carriers.

Canine Bartonellosis

Etiology

Dogs can be infected by several *Bartonella* species, most commonly by *B. henselae* and *B. vinsonii* (ssp. *berkhoffii*), and sporadically by various others (e.g., *B. clarridgeiae, B. elizabethae, B. washoensis*). The most seroprevalent *Bartonella* species in dogs is *B. henselae*; however, *B. vinsonii* (*berkhoffii*) is the species most frequently associated with clinical disease.

Bartonella vinsonii (berkhoffii)

▼ ***Key Point*** Canine *B. vinsonii* (*berkhoffii*) infection is transmitted by ticks.

- *B. vinsonii* (*berkhoffii*) is transmitted by *Rhipicephalus sanguineous* ticks and possibly others (e.g., *Amblyomma americanum*, *Dermacentor* spp., and *Ixodes* spp). Coyotes serve as a major reservoir host of *B. vinsonii* (*berkhoffii*) infection in some areas (in California, 35% of coyotes are seropositive and 28% are bacteremic).
- Serosurveys have found *B. vinsonii* (*berkhoffii*) worldwide in dogs. The seroprevalence in the United States ranges from 1% to 3% of healthy pet dogs to 3% to 5% of sick dogs. The prevalence is much higher in dogs diagnosed with other tickborne infections.
- Risk factors include heavy tick exposure, living in a rural environment, and a free-roaming lifestyle.
- Coinfection with other tickborne infections is common, especially *Ehrlichia canis* (Chapter 17) and *Babesia canis* (Chapter 22).

Bartonella henselae and Other Species

- *B. henselae* and other *Bartonella* spp. in dogs are transmitted primarily by fleas. Cats are the primary reservoir host for *B. henselae* and *B. clarridgeiae*; rodents are the main reservoir for *B. elizabethae*, and squirrels for *B. washoensis*.
- The seroprevalence of *B. henselae* in dogs is highest in the flea-dense southeastern United States (10% of healthy pet dogs and 28% of sick dogs), but only 1% to 2% of dogs in many other areas.

Clinical Signs

Dogs experimentally infected with *B. vinsonii* (*berkhoffii*) develop persistent bacteremia and immunosuppression, but they have minimal clinical signs except for transient fever. Dogs with natural infection can be persistent subclinical carriers for months to over a year.

Various clinical conditions are emerging in association with canine bartonellosis, and this list is expanding. Most of these have been implicated by serologic and PCR evidence, but a definitive causative relationship is unproven. Some of these conditions may be the result of mixed infections with multiple tickborne pathogens.

- Valvular endocarditis (especially aortic valve) and myocarditis, mostly in large breed dogs, leads to arrhythmias, murmurs, syncope, sudden death, congestive heart failure, and systemic thromboembolism. The mortality rate is high.
- Prolonged or intermittent fever of unknown origin
- Granulomatous rhinitis; epistaxis; mucopurulent nasal discharge
- Granulomatous lymphadenitis
- Granulomatous hepatitis
- Granulomatous meningoencephalitis
- Anterior uveitis; chorioretinitis
- Peliosis hepatis is characterized by vascular proliferation and multifocal, blood-filled cystic spaces in the liver. This distinctive lesion has also been seen in immunocompromised humans with disseminated bartonellosis.
- Immune-mediated diseases
  - Immune-mediated hemolytic anemia
  - Immune-mediated thrombocytopenia
  - Polyarthritis
  - Protein-losing nephropathy
  - Cutaneous vasculitis
  - Positive anti-nuclear antibody (ANA) test

▼ ***Key Point*** Consider *Bartonella* infection in dogs with aortic valve endocarditis, unexplained granulomatous disease, unexplained epistaxis, or immune-mediated disease.

Diagnosis

The diagnosis of canine bartonellosis is based on serology and PCR assay in dogs with compatible clinical findings.

Nonspecific Clinical Findings

- **Hematologic findings** in dogs with clinical bartonellosis may include anemia, thrombocytopenia (in half of cases), eosinophilia (in one third of cases), monocytosis, and neutrophilic leukocytosis. Some dogs have proteinuria.
- **ANA tests** are positive in 10% of dogs infected with *B. vinsonii* (*berkhoffii*) alone, and in 45% of dogs with *B. vinsonii* (*berkhoffii*) combined with *Ehrlichia canis* or other tickborne pathogens.
- **Diagnostic imaging** can detect some of the lesions listed under "Clinical Signs." In particular, echocardiographic aortic valve lesions are found consistently in dogs with *Bartonella* endocarditis.
- **Aspiration cytologies and biopsies** may occasionally reveal intracellular bacteria that stain positive with silver stain within macrophages and lymph nodes.

Serology and PCR Assay

The diagnosis of canine bartonellosis is based on serum antibody titers and PCR assays that are readily available to practicing veterinarians through the Vector Borne Disease Diagnostic Lab at North Carolina State University. Submission requirements and forms are available at www.cvm.ncsu.edu/docs/tickbornediseaselab.html.

- *B. vinsonii* (*berkhoffii*) antibody titers of >1:64 indicate exposure and potentially active infection. Because the seroprevalence of *B. vinsonii* (*berkhoffii*) in the general dog population is low (<5% of dogs), clinically sick dogs with significant titers are presumed to be actively infected and are treated. Dogs with *Bartonella* endocarditis usually have very high titers (>1:512).
- Isolation of *Bartonella* spp. from blood cultures in dogs is rarely successful; thus, PCR detection of *Bartonella* DNA is the preferred confirmatory test for canine bartonellosis. PCR testing can be done on blood or fresh, frozen, or paraffin-embedded tissue specimens.

▼ ***Key Point*** Mixed tick-transmitted infections are common in dogs residing in high-prevalence areas. Consider testing all *Bartonella*-positive dogs for other tickborne infections, such as *Ehrlichia*, *Anaplasma*, *Rickettsia*, *Babesia*, and *Borrelia burgdorferii*.

Blood Culture

B. vinsonii (*berkhoffii*) is very difficult to culture from infected dogs compared with *B. henselae* in cats; thus, blood cultures are unreliable for diagnosing most dogs with clinical bartonellosis.

Treatment

Initiate antibiotic therapy in seropositive and/or PCR-positive dogs with clinical signs attributable to *Bartonella* infection. The optimal treatment for canine bartonellosis has not been established, but antibiotics that achieve high intracellular levels are recommended. In dogs, bacteremia is not as persistent or as likely to relapse as in cats. Effective treatment is indicated by a drop in the *Bartonella* titer after 3 to 6 months.

- **Treat severe or life-threatening clinical disease** (e.g., endocarditis or meningoencephalitis) with an initial combination of a parenteral aminoglycoside (e.g., amikacin) and a penicillin derivative (e.g., amoxicillin or ampicillin). After 1 to 2 weeks, continue for an additional 4 weeks with one of the antibiotics below.
- **Treat less severe or chronic disease** with a macrolide (e.g., azithromycin) or a combination of a fluoroquinone and amoxicillin. Doxycycline can also be used, but is not considered as effective. Continue antibiotics for at least 4 to 6 weeks.
  - Azithromycin (7.5–10 mg/kg PO q12h)
  - Enrofloxacin (5 mg/kg q12h PO) plus amoxicillin-clavulanate (15 mg/kg PO q12h)

- Doxycycline (10 mg/kg PO q12h)
- Rifampin can be added in refractory cases

Prevention

▼ ***Key Point*** Rigorous flea and tick control is the most effective prevention against *Bartonella* infection in dogs.

Reduce the risk of exposure to *Bartonella* spp. by limiting access to tick-infested areas. Use an effective long-acting topical flea and tick preventative at least monthly on dogs residing in flea and tick-infested areas, such as one of the following:

- Fipronil/methoprene (Frontline Plus; Merial)
- Imidacloprid/permethrin (Advantix; Bayer); for dogs only (permethrin is toxic in cats).
- Amitraz tick collar (Preventic; Virbac) plus topical permethrin for fleas

▼ ***Key Point*** Do not use dogs that are seropositive for *Bartonella* spp. as blood donors.

Public Health

Dogs have very rarely been implicated as the source of human *Bartonella* infections; however, dogs are capable of carrying ticks or fleas that could transmit *Bartonella* spp. to people.

MYCOBACTERIOSIS

The categories of mycobacterial infection in dogs and cats are (1) the systemic or tuberculous form, (2) the opportunistic form, and (3) the lepromatous form (feline leprosy). Each of these is caused by a different variety of mycobacterial species. This section describes systemic tuberculous mycobacteriosis. Chapter 39 is devoted to opportunistic mycobacterial infections and feline leprosy, which are primarily cutaneous infections characterized by ulcerating skin nodules and draining fistulous tracts.

Etiology

Mycobacteria are environmentally resistant, non-spore–forming, aerobic, acid-fast, gram-positive bacteria that infect a wide range of animals worldwide, including dogs, cats, and humans. Mycobacteria cause persistent intracellular infection leading to chronic granulomatous inflammation. Systemic tuberculous mycobacteriosis (i.e., classic tuberculosis) in dogs and cats is usually caused by infection with *M. tuberculosis*, *M. bovis*, or *M. avium*, with sporadic reports of *M. microti*, *M. microti*-like, and *M. simiae*.

- *M. tuberculosis* infection is an inverse zoonosis transmitted from infected humans to pets through inhalation of aerosolized sputum. Dogs are infected more than cats. Pulmonary infection is most common.
- *M. bovis* infection results from ingestion of unpasteurized milk, uncooked meat, or offal from infected cattle or wildlife such as deer. Cats are infected more commonly than dogs. The intestinal tract and abdominal viscera are usually involved.
- *M. avium* is ubiquitous in the environment, and infection results from contaminated water and soil, or infected poultry feces or carcasses. Siamese cats and basset hounds seem to have a genetic predisposition, and immunosuppression may play a role in some animals.
- *M. microti* and *M. microti*-like are rodent pathogens that occasionally infect cats that hunt prey.

Clinical Signs

Clinical signs are usually chronic and reflect the site of granulomatous lesions.

- **Cutaneous**: Dermal nodules and non-healing wounds with draining fistulous tracts, and regional lymphadenopathy.
- **Pulmonary**: Occurs mostly in dogs with *M. tuberculosis*. Granulomatous pneumonia and hilar lymphadenopathy cause signs of fever, weight loss, and chronic cough.
- **Intestinal**: Occurs mostly in cats with *M. bovis*. Granulomatous transmural enteritis and mesenteric lymphadenopathy cause anorexia, vomiting, diarrhea, weight loss, blood loss anemia, and peritoneal effusion.
- **Disseminated**: This is typical of *M. avium* infections that cause widespread granulomatous lesions in lymph nodes, liver, spleen, other abdominal viscera, thorax, CNS, eyes (uveitis), and bone.

Diagnosis

- Leukocytosis and hyperglobulinemia may be seen.
- Diagnostic imaging may identify granulomatous abdominal masses, pulmonary lesions, effusions, internal lymphadenopathy, or bone lesions.
- A presumptive diagnosis is established by finding acid-fast bacteria in cytologies or biopsies of lesions. Intracellular bacteria with clubbed shape and beaded appearance are typical and most abundant in *M. avium* infections.
- Definitive diagnosis and speciation require culture or PCR. Mycobacteria that cause systemic mycobacteriosis are slow-growing and culturing may take up to 6 weeks. The advantage of PCR is more rapid results.

▼ ***Key Point*** Intradermal tuberculin testing is inconsistent and unreliable in dogs and cats.

Treatment

Generalized systemic or tuberculous mycobacteriosis is resistant to treatment and has a poor prognosis.

Treatment requires a minimum of 6 months of multidrug therapy, and some cases require lifelong therapy. Drug toxicity and expense are often limiting factors.

▼ ***Key Point*** Euthanasia rather than treatment is generally recommended for dogs and cats infected with *M. tuberculosis* or *M. bovis* because of the poor prognosis and public health concerns.

- For *M. avium* infections, treat the animal for at least 2 months with triple therapy, using a combination of rifampin (10 mg/kg PO q12h), enrofloxacin (5 mg/kg PO q24h), and azithromycin (10 mg/kg PO q12h), followed by another 4 months of dual drug therapy using rifampin plus either azithromycin or enrofloxacin. Because of poor prognosis, euthanasia rather than treatment may be appropriate in many cases.
- Surgical excision and debulking of focal lesions or masses may increase the effectiveness of medical therapy.

Public Health

- *M. tuberculosis:* The potential risk of pet-to-human transmission is unlikely but possible, thus, euthanasia is recommended.
- *M. bovis:* Dogs and cats may transmit the infection to humans through their feces and can contribute to enzootic spread of infection on farms; thus, euthanasia is recommended.
- *M. avium:* Dogs and cats are unlikely to transmit infection to humans; thus, the zoonotic risk is considered minimal and treatment is an option, except in households with an immunocompromised person. The source of human infections with *M. avium* is contaminated soil and water rather than animals.

TULAREMIA

Tularemia is an arthropod-borne bacterial zoonosis caused by *Francisella tularensis*, a pleomorphic, gram-negative coccobacillus. Ticks, rodents, and rabbits are the primary reservoir hosts, but a wide variety of animal species are susceptible, including cats, dogs, livestock, and humans. Tularemia is seen throughout temperate regions of North America, Europe, and Asia. In the United States high-prevalence areas are Arkansas, Missouri, Oklahoma, and South Dakota.

Transmission

F. tularensis is considered highly infectious by several routes, including bites from tick and deerfly vectors, scratches and bites from infected animals (especially cats), inhalation of aerosolized organisms, and ingestion of contaminated food, carrion, or water. Infected animals develop intracellular infection of macrophages and hematogenous dissemination.

Clinical Findings

Cats are more susceptible to clinical disease than dogs, which can range from mild illness with transient fever to fatal overwhelming sepsis. Infected dogs develop mild self-limiting febrile illness or subclinical infection with seroconversion.

- Clinical signs in cats vary and can include anorexia, depression, fever, lymphadenopathy, draining abscesses, oral ulcers, pneumonia, hepatosplenomegaly, multifocal hepatic necrosis, and jaundice.
- Laboratory findings can include a high or low white blood cell (WBC) count with a left shift, thrombocytopenia, elevated serum liver enzymes, and hyperbilirubinemia.

Diagnosis

The diagnosis is based on serology and culture (consult state health department or Centers for Disease Control and Prevention, Atlanta, GA). PCR assay may also be useful when available.

- Serologic testing (by tube agglutination, microagglutination, or ELISA) is available through state diagnostic laboratories. Antibodies may not be detected until after 2 to 3 weeks; thus, the serologic diagnosis is based on a 4-fold increase in paired serum titers, 2 to 4 weeks apart.
- The preferred culture specimens are aspirates of bone marrow or lymph nodes, although *F. tularensis* can also be isolated from blood, exudates, and others tissues. Cultures are a human biohazard and must be done at a Biological Safety Level II or III (BSL-2 or 3) laboratory, such as certain state diagnostic labs.

Treatment and Prevention

Tularemia is a serious public health threat and infected pets can transmit infection to people; thus, notify local and state health authorities prior to treating an animal with this disease. Infected pets can be treated with gentamicin or enrofloxacin for a minimum of 10 days, or doxycycline for a minimum of 14 days. Use tick control on pets for prevention in high-prevalence areas.

FELINE PLAGUE

Plague is a flea-transmitted bacterial zoonosis caused by *Yersinia pestis*, a gram-negative, bipolar coccobacillus. Rodents are the primary reservoir hosts for *Y. pestis*, and rodent fleas transmit the infection to various other animal species including cats, dogs, and humans.

Plague is found worldwide except in Australia. In the United States, infections occur in the western states, especially New Mexico, Arizona, Colorado, and California, where the principal reservoirs are rabbits, prairie dogs, ground squirrels, woodrats, and mice.

Transmission

Cats are more susceptible to plague than dogs, and are mainly infected by bites from wildlife fleas, or from hunting and eating rodents and rabbits. Cats with the pneumonic form of infection can also directly transmit infection to people by aerosol droplets.

Clinical Findings

The incubation period is 1 to 4 days and the clinical course is rapidly progressive. Infected cats can develop the 3 classic clinical forms of plague: bubonic (lymph nodal), pneumonic, and septicemic. Clinical illness in infected dogs is rare; most dogs develop subclinical infection with seroconversion, or, rarely, transient fever with self-limiting submandibular lymphadenitis.

- **Bubonic plague**, the most common form in cats, is characterized by fever, malaise, and regional necrosuppurative lymphadenitis most often affecting submandibular lymph nodes. Affected lymph nodes become enlarged and painful, and may abscess and drain. Without adequate treatment, the bubonic form can rapidly progress to the septicemic form.
- **Pneumonic plague** can be from primary inhalation of infectious organisms from another animal with pneumonic infection, or it can be from secondary spread of bubonic or septicemic infection to the lungs. Pulmonary lesions include diffuse interstitial pneumonia with coalescing areas of necrosis and abscessation in the lung. Cats with pulmonary involvement pose a serious public health risk. Inadequately treated pneumonic infection can rapidly progress to septicemia.
- **Septicemic plague** is characterized by widespread hematogenous dissemination to many organs leading to systemic inflammatory response of sepsis, acute respiratory distress, septic shock, DIC, multiple organ failure, and death.

Diagnosis

Finding a homogeneous population of gram-negative coccobacilli in exudate from a lymph node abscess is presumptive evidence of feline plague in endemic areas. The diagnosis is confirmed by immunofluorescence detection of *Y. pestis* antigen, serology (single high titer or four-fold rise in paired titers), or culture. Confirmatory testing requires a state public health laboratory or the Centers for Disease Control and Prevention (Atlanta, GA). Consult the destination lab for specimen collection and submission requirements.

Treatment and Prevention

Feline plague is a serious public health threat and infected cats can directly transmit infection to people via oral secretions and aerolized respiratory secretions; thus, notify local and state health authorities when feline plague is suspected.

- To prevent risk to the owner, do not discharge infected cats to the care of the owner. Isolate the cat within a veterinary hospital. Veterinary personnel should use precautions when treating a cat with plague (gown, mask, eye protection, and gloves).
- Initiate antibiotic therapy immediately after diagnostic specimens have been collected; while awaiting for confirmation. Parenteral gentamicin (10 days) is the drug of choice for treating infected pets. Oral doxycycline (3 weeks minimum) can also be used as an alternative, or as a follow-up to gentamicin.
- For prevention in high-prevalence regions, use flea control on cats and restrict cats from roaming and hunting of prey.

Chapter 20

Systemic Mycoses

Robert G. Sherding

The four classical systemic mycoses of dogs and cats are histoplasmosis, blastomycosis, coccidioidomycosis, and cryptococcosis.

▼ ***Key Point*** Systemic mycoses are not contagious diseases. Infection results from contact with organisms in the environment, especially through inhalation.

Fungal infections with a predilection for individual organ systems are discussed elsewhere; thus, for deep cutaneous fungal infections see Chapter 40, for dermatophytosis see Chapter 42, for intestinal pythiosis see Chapter 69, and for nasal aspergillosis see Chapters 160 and 163.

▼ ***Key Point*** Histoplasmosis, blastomycosis, and coccidioidomycosis are endemic to defined regions of North America (Fig. 20-1).

HISTOPLASMOSIS

Etiology

- Histoplasmosis is caused by *Histoplasma capsulatum,* a dimorphic soil-dwelling fungus found in many temperate and subtropical regions of the world. In North America, the disease is most prevalent in the river valley regions of the central United States, especially in areas bordering the Mississippi, Ohio, and Missouri Rivers and their tributaries (see Fig. 20-1). Both dogs and cats are susceptible.
- At ambient temperatures, soil enriched by decomposing nitrogenous matter (e.g., bird feces or bat guano) provides an ideal growth medium for the mycelial phase of *Histoplasma.* The principal route of infection is by inhalation of airborne spores (conidia) and mycelial fragments in windblown soil; however, intestinal infection via ingestion also may occur. At body temperature (37°C), *Histoplasma* organisms transform into a yeast phase that causes a facultative intracellular infection of macrophages.

Pathogenesis

- Histoplasmosis primarily invades the lung and then spreads to the mononuclear phagocyte system (liver, spleen, etc.). The incubation period is 12 to 16 days. Widespread hemolymphatic dissemination can occur to virtually any tissue or organ system. Infection causes a granulomatous response.
- The outcome of infection is influenced by level of exposure; host cell-mediated immunity; age of the host (clinical disease is most common in young animals <4 years of age); breed (highest prevalence in sporting and hound breeds because of higher exposure risk); and immunosuppressive factors (corticosteroids may enhance dissemination).

Clinical Signs

Inapparent subclinical infections are common. The clinical forms of histoplasmosis are pulmonary, intestinal, and disseminated (multisystemic).

Subclinical Infection

An inapparent, self-limiting infection confined to the respiratory tract is the most common outcome of natural infection. The aftermath of this form is sometimes identified radiographically as multiple, discrete, calcified interstitial foci in the lungs (inactive encapsulated or healed lesions). Calcified tracheobronchial lymph nodes are seen less often.

Acute Pulmonary Infection

Acute pulmonary histoplasmosis is characterized by severe fulminant granulomatous pneumonia with signs of cough, tachypnea, dyspnea, abnormal lung sounds, fever, and severe malaise. Death from hypoxemia may occur despite treatment. The radiographic findings are diffuse or nodular interstitial pulmonary infiltrates, often with patchy coalescing alveolar densities and moderately enlarged tracheobronchial lymph nodes.

Chronic Pulmonary Infection

Chronic pulmonary histoplasmosis is more common than the acute form and is characterized by chronic

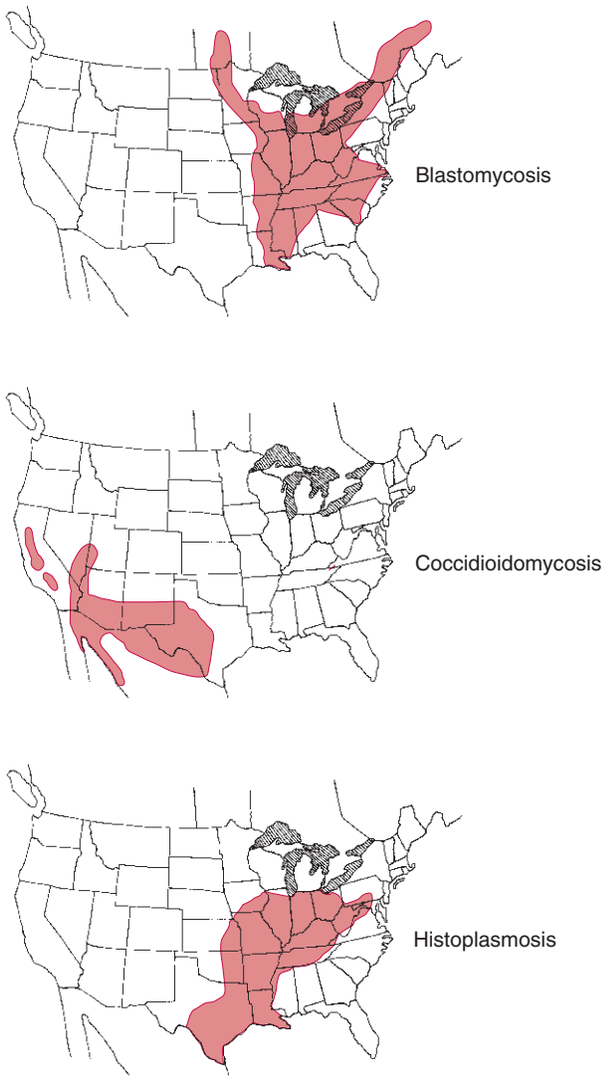

Figure 20-1. Geographic distribution of blastomycosis, coccidioidomycosis, and histoplasmosis in North America.

granulomatous pneumonia (diffuse or multifocal) with marked perihilar tracheobronchial lymphadenopathy that compresses the bifurcation of the trachea and mainstem bronchi. Clinical signs include chronic cough, exercise intolerance, and mild dyspnea with variable weight loss and fever. Radiographically, massive enlargement of the perihilar tracheobronchial lymph nodes and variable linear or nodular interstitial infiltrates are seen.

Intestinal Infection

Intestinal histoplasmosis is a common extrapulmonary form in dogs but not cats, and it may represent primary infection by ingestion. The colon, the small intestine, or a combination of both can be affected by extensive granulomatous thickening of the bowel wall and mucosal ulceration, often accompanied by mesenteric and visceral lymphadenopathy. Intractable diarrhea and progressive weight loss are the most consistent clinical signs. Other signs may include anorexia, lethargy, fever, anemia, vomiting, and abdominal effusion.

- ***Granulomatous colitis*** causes bloody-mucoid large bowel diarrhea with urgency and sometimes tenesmus. If the rectum is involved, mucosal proliferations may be detected by digital palpation of the rectum.
- ***Granulomatous enteritis*** causes intractable small bowel diarrhea, malabsorption, weight loss, palpably thickened intestines, and sometimes protein-losing enteropathy.

Disseminated Infection

Extrapulmonary dissemination causes a variety of clinical signs depending on the organs involved. Most cats develop this disseminated form of histoplasmosis. The mononuclear phagocyte system is a common site of dissemination. Manifestations can include anorexia, depression, fever, weight loss, and pulmonary involvement combined with any of the following:

- ***Bone marrow***—Nonregenerative anemia
- ***Lymph nodes***—Peripheral or abdominal lymphadenopathy
- ***Liver***—Hepatomegaly, icterus, ascites
- ***Spleen***—Splenomegaly
- ***Peritoneum***—Omental masses, mesenteric adhesions, nodular or granular serosal surfaces
- ***Eyes***—Exudative anterior uveitis, multifocal granulomatous chorioretinitis, optic neuritis
- ***Central nervous system (CNS)***—Ataxia, seizures
- ***Skin***—Cutaneous and subcutaneous nodules that ulcerate or fistulate, drain or crust over
- ***Bone***—Lameness and bone pain associated with proliferative or lytic bone lesions (osteomyelitis)
- ***Oral cavity***—Oral and lingual ulcers

Diagnosis

Consider histoplasmosis on the basis of clinical signs in animals from endemic areas. The results of routine laboratory evaluations are variable and nonspecific. Radiographic findings in the pulmonary form are often highly suggestive of a mycotic disease such as histoplasmosis. Identification of the *Histoplasma* organisms by cytology, biopsy, or culture is necessary for definitive diagnosis. Serology is unreliable.

Hematology

- Normocytic-normochromic nonregenerative anemia frequently results from chronic inflammation, dissemination of *Histoplasma* into the bone marrow, intestinal blood loss, or hemolysis.
- Neutrophilic leukocytosis or neutropenia with a left shift and monocytosis can be seen, and occasionally

pancytopenia in cats. *Histoplasma* organisms are occasionally seen within circulating monocytes or neutrophils on routine blood smears, especially if 1,000 cells are examined in differential cell counts or if buffy coat smears are examined.
- Mild to moderate, subclinical thrombocytopenia is common. Platelet counts of less than 50,000/µl are seen occasionally in association with macroplatelets in the circulation and increased megakaryocytes in the bone marrow, suggesting platelet consumption or destruction.

Serum Chemistry Evaluations

- Mild hypoalbuminemia, with or without concomitant hyperglobulinemia is common in intestinal and disseminated forms. Severe panhypoproteinemia occasionally occurs in dogs with protein-losing enteropathy.
- Hypercalcemia is reported in histoplasmosis.
- Elevated serum liver enzymes and bilirubin are seen with hepatic dissemination.
- Intestinal function tests may be abnormal in intestinal histoplasmosis (see Chapter 69).

Radiography and Ultrasonography

Thoracic Radiography

- Perihilar density around the tracheal bifurcation related to tracheobronchial lymphadenopathy (especially in dogs).
- Diffuse linear or nodular ("miliary") interstitial pulmonary infiltrates.
- Coalescing patchy alveolar infiltrates (especially in cats).
- Calcified pulmonary interstitial nodules (healed lesions), and calcified tracheobronchial lymph nodes indicate inactive lesions.

Other Diagnostic Imaging

- Hepatosplenomegaly; ultrasonography may show nodularity and abnormal echogenicity.
- Abdominal or thoracic effusions.
- Osteolytic and periosteal proliferative bone lesions.
- Barium contrast gastrointestinal (GI) radiography and GI ultrasonography may show diffuse irregularity and thickening of the intestinal wall, indicative of a diffuse infiltrative lesion.

Serology

- Serologic tests for histoplasmosis are unreliable; thus, every effort should be made to confirm infections through identification of the *Histoplasma* organisms.
- Complement fixation titers of 1:16 or greater or positive agar-gel immunodiffusion (AGID) (precipitin) tests are suggestive of histoplasmosis; however, false positives and false negatives are common.

Cytology

Exfoliative and fine-needle aspiration cytology generally are the most practical and high-yield methods for definitive diagnosis of histoplasmosis. Wright-Giemsa or Diff-Quik stains are ideal for identification of *Histoplasma* in cytology preparations. The organisms are found most often intracellularly within the cytoplasm of macrophages as round to oval yeast bodies, 2 to 4 µm in size, surrounded by a characteristic clear halo or "pseudocapsule" that results from shrinkage of the cytoplasm from the cell wall during fixation. The best source of cytologic specimens with potential diagnostic benefit depends on dissemination sites as indicated by clinical signs.

▼ ***Key Point*** Definitive diagnosis of histoplasmosis requires identification of *Histoplasma* organisms in cytology, biopsy, or culture specimens.

Respiratory Cytology

Use bronchoalveolar lavage, tracheobronchial washings, or fine-needle lung aspirates.

Intestinal Cytology

Use smears of rectal mucosal scrapings, impression smears of endoscopic biopsies, and ultrasound-guided fine-needle aspirates of abdominal lymph nodes or intestinal masses. Consider endoscopy of the colon and duodenum for the collection of diagnostic cytology or biopsy specimens. Histoplasmosis lesions appear endoscopically as areas of irregular mucosal thickening and proliferation that produce a corrugated or cobblestone appearance, with or without mucosal hemorrhage and ulceration.

Other Cytology Specimens

- Liver, spleen, or lymph node aspirates
- Bone marrow aspirates and buffy coat smears of blood
- Abdominal or thoracic effusions
- Skin lesion impression smears
- Oculocentesis cytology

Histopathology

Biopsies of affected tissues reveal granulomatous inflammation, but organisms are usually sparse and do not stain well with H&E stain. Detection of organisms in biopsies may be facilitated by the use of special fungal stains such as periodic acid-Schiff (PAS), Gomori methenamine silver (GMS), or Gridley stain.

Culture

Most specimens for cytologic or biopsy identification of *Histoplasma* are also suitable for culture. The *Histoplasma* mycelial phase grows on Sabouraud's dextrose at room temperature in 7 to 10 days, and the yeast phase

grows on blood agar from 30°C to 37°C. Use a diagnostic laboratory instead of in-clinic culturing, because fungal growth is potentially infectious for humans and poses a biohazardous risk to personnel.

Treatment

Refer to the "Antifungal Therapy" section at the end of this chapter for specific treatment regimens and drug dosages.

- ***Itraconazole*** is the treatment of choice for histoplasmosis that is not immediately life-threatening. Treat for a minimum of 4 to 6 months and at least 1 to 2 months beyond clinical resolution.
- ***Itraconazole plus amphotericin B*** is preferred for treating severe, rapidly progressive infections, preferably using lipid-complexed amphotericin to allow higher doses with less toxicity. Combined therapy is followed by azole therapy alone for 2 to 4 months and at least 1 to 2 months beyond clinical resolution.
- ***Fluconazole*** may not be as effective as itraconazole, but it can be used for refractory ocular and neurologic infections because of its better penetration of the eyes and CNS.
- ***Ketoconazole*** is less effective than itraconazole (especially in cats), and it has more side effects; however, it can be used if other antifungal drugs are cost prohibitive for the owner. It also can be combined with amphotericin B.
- ***Corticosteroids*** can be used with antifungal therapy to reduce perihilar lymphadenopathy when it is causing significant tracheobronchial obstruction. Only use if needed, and do not use for prolonged periods because corticosteroids can worsen fungal infections or facilitate dissemination.

BLASTOMYCOSIS

Etiology

- *Blastomyces dermatitidis* is a dimorphic soil-dwelling fungus with a geographic distribution in the central, mid-Atlantic, and southern Great Lakes regions of the United States, especially areas bordering the Mississippi River and its tributaries and along the St. Lawrence River region of the United States and Canada (see Fig. 20-1). The organisms reside in sandy, acidic soil near water. Most infected dogs live within ¼ mile of water.
- Inhalation of airborne spores (conidia) is the primary source of infection and leads to mycotic pneumonia. In addition, focal skin infection can occur from direct cutaneous inoculation through a wound. In tissues the fungi become budding yeast. Extrapulmonary dissemination is common in blastomycosis, especially involving lymph nodes, skin, eyes, bones, and CNS (cats). The incubation period is 1 to 3 months.
- Dogs are considered highly susceptible to blastomycosis, and the canine infection rate in endemic areas is 10 times the human infection rate. Young (<5 years) male, large-breed dogs are infected most frequently, especially pointers, hounds, and other sporting breeds, probably because of increased exposure through outdoor activities. Blastomycosis is rare in cats.

Clinical Signs

Pulmonary and disseminated forms of infection are seen. Nonspecific signs of fever, anorexia, weight loss, and depression are common. Signs may be acute (days) or chronic (weeks to months).

Pulmonary Infection

Lung lesions are present in 85% of cases. Cough, tachypnea, and dyspnea are typical presenting signs. Respiratory manifestations can include the following:

- Diffuse interstitial pyogranulomatous pneumonia
- Perihilar tracheobronchial lymphadenopathy
- Alveolar infiltration and consolidation
- Solitary mediastinal or lung masses
- Pleural effusion

Disseminated Infection

Extrapulmonary dissemination is common in blastomycosis, especially to the peripheral lymph nodes (50% to 60% of cases), skin (40%), eyes (40%), bone (20%), and to a lesser extent CNS, male genitalia, oral cavity, nasal cavity, and abdominal viscera.

- ***Cutaneous:*** Solitary or multiple circumscribed, raised ulcerating pyogranulomas; fistulas that drain pus or bloody fluid; deep abscesses (cats); paronychia; and regional lymphadenopathy
- ***Ocular:*** Anterior uveitis, chorioretinitis, retinal detachment, panophthalmitis, lens rupture, cataracts, secondary glaucoma, and blindness
- ***Bone:*** Osteomyelitis of distal limbs, with lameness and adjacent soft tissue swelling
- ***CNS:*** Most often in cats as seizures, dementia, blindness, or ataxia
- ***Genital:*** Pyogranulomatous orchitis and epididymitis in 16% of intact male dogs; also prostatitis

Diagnosis

Consider blastomycosis on the basis of clinical signs in animals from endemic areas. The results of routine laboratory evaluations are variable and nonspecific. Radiographic findings in the pulmonary form are often highly suggestive of mycotic infection. Serology provides a presumptive diagnosis, but identification of *Blastomyces* organisms is necessary for definitive diagnosis, usually by cytology.

Hematology and Serum Chemistries

- Typical findings are neutrophilic leukocytosis, monocytosis, lymphopenia, and mild nonregenerative anemia.
- Serum chemistries are usually unremarkable except for mild hypoalbuminemia, hyperglobulinemia, and occasional hypercalcemia (10% of cases).

Diagnostic Imaging

Radiography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are useful for evaluating the lungs and suspected dissemination sites and for guiding collection of cytology and biopsy specimens.

Thoracic Radiography

- Diffuse interstitial infiltrate or nodular pattern (often miliary) in 70% of canine cases.
- Perihilar tracheobronchial lymphadenopathy (30% of canine cases).
- Less frequent findings are alveolar infiltrates, lobar consolidation, solitary lung masses, mediastinal masses, pleural effusion, and cavitary lesions.

Other Diagnostic Imaging

- Radiography can identify lytic bone lesions with variable periosteal proliferation, most often in the distal limbs.
- Ultrasonography can identify involvement of abdominal viscera, testes, and prostate.
- CT and MRI can identify CNS lesions.

Serology

Serology can provide a presumptive diagnosis of blastomycosis when repeated attempts to identify organisms by cytology have failed. The highest titers are seen in dogs with disseminated disease. The AGID test is most reliable (90% sensitivity and specificity). Complement fixation is not as reliable as AGID, but a titer of 1:32 or greater is suggestive of blastomycosis.

Cytology and Biopsy

Identification of *Blastomyces* organisms by cytology, biopsy, or culture provides a definitive diagnosis. The best site and method for procuring specimens depends on the location of the lesions.

- Cytologies most often diagnostic for blastomycosis include skin impression smears, lymph node aspirates, pulmonary cytology (tracheobronchial washing, bronchoalveolar lavage, fine-needle lung aspirate), and vitreal aspirates; however, any affected tissue can be sampled. Organisms are also found in fluid specimens such as urine, prostatic washes, cerebrospinal fluid (CSF), or pleural effusion. Any routine cytology stain can be used.
- *Blastomyces* in tissues appear as thick-walled, extracellular yeast bodies (5–20 µm) with broad-based budding.

▼ ***Key Point*** *Blastomyces* organisms are usually plentiful and easily identified in lesions by cytology; thus, cytology is the initial confirmatory test of choice.

- The inflammatory pattern in blastomycosis is pyogranulomatous (macrophages and non-degenerate neutrophils). Special stains such as PAS, GMS, and Gridley may be used to identify fungal organisms.

Culture

Specimens for culture can be collected in a similar manner as for cytology. Mycelial growth occurs on Sabouraud's dextrose agar at 37°C after 1 to 4 weeks, and yeast will grow on blood or brain-heart infusion agar at 25°C in 1 to 2 weeks. Use a diagnostic laboratory instead of in-clinic culturing because fungal growth is potentially infectious for humans and poses a biohazardous risk to personnel.

▼ ***Key Point*** Human blastomycosis infection can result from accidental inoculation of infective material from animal patients (e.g., needle-stick injury and cuts from contaminated surgical or necropsy instruments).

Treatment

Refer to the "Antifungal Therapy" section at the end of this chapter for specific treatment regimens and drug dosages.

- ***Itraconazole*** is the treatment of choice for blastomycosis that is not immediately life threatening and does not involve the CNS. Treat for at least 2 to 3 months and until 1 month beyond clinical resolution. The cure rate with itraconazole is 75%.
- ***Itraconazole plus amphotericin B*** is the treatment of choice for life-threatening, rapidly progressive infections, preferably using lipid-complexed amphotericin B to allow higher doses with less toxicity. Combination therapy is followed by an additional 2 months of azole therapy.
- ***Amphotericin B*** is also effective by itself. It has a more rapid onset of action than azole drugs, but it has the disadvantages of parenteral administration and nephrotoxicity. Lipid-complexed forms are best but expensive.
- ***Fluconazole*** is generally less effective and more expensive than itraconazole for blastomycosis, but it is indicated for refractory ocular, neurologic, and prostatic

infections because of its better penetration of these sites.

- ***Ketoconazole*** is less effective than itraconazole for treating blastomycosis (the response rate is less than 50%, the relapse rate is higher, the duration of therapy is longer, and toxicity is more frequent); however, ketoconazole can be used if other antifungal drugs are cost prohibitive for the owner. It also can be combined with amphotericin B.
- ***Ancillary treatment:*** Use appropriate topical ophthalmic treatment in animals with uveitis and monitor for secondary glaucoma (see Chapters 136 and 137). Castration is indicated in intact males with testicular or prostatic infection.

Prognosis

Treatment is successful in 75% of cases. Dogs that live through the first 10 days usually do well.

- Treatment failures are most likely in dogs with severe hypoxemic pulmonary disease, CNS involvement, or widespread dissemination involving three or more organ systems.
- Irreversible blindness is a frequent complication of ocular blastomycosis.
- Relapses can occur in up to 20% of apparently recovered cases after several months and up to a year or more. Fortunately, most of these relapses can be successfully re-treated.

COCCIDIOIDOMYCOSIS

Etiology

- Coccidioidomycosis ("valley fever") is caused by *Coccidioides immitis,* a soil-dwelling dimorphic fungus found in the dry, desert-like, lower Sonoran regions of the southwestern United States, Mexico, and Central and South America (see Fig. 20-1). In the soil, *Coccidioides* fungi grow mycelia during periods of rainfall, and then arthrospores form when the soil dries. These fungal spores then become airborne in dry, windy conditions.
- Infection occurs by inhalation of windblown spores. An infectious dose in dogs may be as few as 10 spores. The incubation period is 1 to 3 weeks. Cutaneous inoculation may occur, but rarely. In body tissues, *Coccidioides* forms large spherules (20–100 µm) that release hundreds of endospores. Young, male, medium and large outdoor dogs are most often affected. *Coccidioides* is not contagious.

Clinical Signs

Coccidioides can cause subclinical, pulmonary, or disseminated infection.

Subclinical Infection

Self-limiting, subclinical pulmonary infection is the most common outcome of natural infection in healthy animals.

Pulmonary Infection

Clinically apparent pulmonary coccidioidomycosis is characterized by acute or chronic granulomatous pneumonia and perihilar tracheobronchial lymphadenopathy, associated with cough, fever, malaise, and occasionally dyspnea.

Disseminated Infection

Extrapulmonary dissemination is usually chronic (months to years) and insidious. Fever, anorexia, lethargy, and weight loss are common. Bone involvement is most common in dogs, whereas skin lesions are the predominant finding in cats.

- ***Bones and joints:*** Chronic lameness associated with painful bone swellings (osteoproliferative bone reaction), head and neck pain
- ***Skin:*** Ulcerated nodules and draining fistulas, frequently over bone lesions
- ***Regional lymphadenopathy:*** Associated with bone and skin lesions
- ***Abdomen:*** Granulomatous lesions of spleen, liver, lymph nodes, omentum, or kidneys
- ***Heart and pericardium:*** Myocarditis, pericarditis, congestive heart failure
- ***CNS:*** Behavior changes, hyperesthesia, seizures, etc.
- ***Eyes:*** Uveitis, retinal detachment, blindness

Diagnosis

Consider coccidioidomycosis on the basis of clinical signs in animals from endemic areas. The results of routine laboratory evaluations are variable and nonspecific. The radiographic lesions in the lungs and bones are often highly suggestive of the disease. The presumptive diagnosis is based on clinical findings combined with serology. Identification of *Coccidioides* organisms is necessary for definitive diagnosis; however, the organisms are generally sparse and difficult to find in cytology or biopsy specimens, so serology is more sensitive. Cultures are biohazardous for humans and not routinely used.

Hematology and Serum Chemistries

Findings may include a variable leukocytosis, monocytosis, and mild nonregenerative anemia. Hyperglobulinemia and hypoalbuminemia are common in chronic cases.

Radiography

- Thoracic radiographs often show a diffuse or nodular pulmonary interstitial pattern and perihilar lym-

phadenopathy. In cases with cardiac involvement, pericardial effusion or pulmonary edema may be seen.
- Dissemination to bone is common in dogs, especially to the distal aspects of long bones, resulting in multifocal osteoproliferative and, less often, lytic lesions. The spine can also be involved.

Serology

A reasonably reliable presumptive diagnosis can be based on the detection of antibodies against *Coccidioides*. The tube precipitin test, which detects the early immunoglobulin M (IgM) response, and the complement fixation test, which detects the later and sustained immunoglobulin G (IgG) response, are the traditional serologic tests. The newer immunodiffusion (AGID) and enzyme-linked immunosorbent assay tests for detecting *Coccidioides*-specific IgM and IgG are more reliable.

- The early IgM response becomes positive 2 weeks post-exposure and persists for 4 to 6 weeks. However, in some dogs, IgM titers may persist for months and can be detected simultaneously with high IgG titers, usually indicating dissemination or recrudescence.
- The later IgG response is detected after 8 to 12 weeks. High IgG titers (≥1:64) usually indicate severe pulmonary or disseminated disease.

Polymerase Chain Reaction

A sensitive and specific polymerase chain reaction (PCR) for detecting *Coccidioides* DNA is expected to facilitate the diagnosis of this disease once the test becomes available for clinical use.

Cytology and Biopsy

Definitive diagnosis depends on identifying the large *Coccidioides* spherules (20–200 µm) in affected tissues using cytology or biopsy; however, spherules are often sparse and difficult to find. Lesions show pyogranulomatous inflammation.

Culture

Coccidioides can be cultured on routine fungal media; however, special facilities are required because *Coccidioides* spores are a serious biohazard for humans and pose a substantial risk to laboratory personnel.

Treatment

Refer to the "Antifungal Therapy" section at the end of this chapter for specific treatment regimens and drug dosages.

▼ ***Key Point*** Disseminated coccidioidomycosis is difficult to cure, especially when bones are involved, and lifelong azole therapy may be required to prevent relapses.

- Treat with one of the oral azoles (ketoconazole, itraconazole, or fluconazole) for at least 8 months and a minimum of 4 months beyond clinical resolution. Use fluconazole to treat animals with CNS involvement.
- Amphotericin B lipid complex is indicated for fulminant infections and animals that do not tolerate azole drugs.
- Lufenuron, a chitin synthesis inhibitor licensed for control of fleas in dogs and cats, does not appear to be an effective antifungal agent despite initial anecdotal reports.

CRYPTOCOCCOSIS

Cryptococcosis is the most common systemic fungal disease of cats and is more prevalent in cats than in dogs.

Etiology

- Cryptococcosis is caused by *Cryptococcus neoformans*, a saprophytic yeast found in many regions of the world and throughout North America or by *C. gattii* in Australia and various subtropical regions. High concentrations of *Cryptococcus* can be found in pigeon droppings and in areas where pigeons and other birds roost. Infection is acquired by inhalation of the yeast organisms or basidiospores from the environment.
- The organisms are budding yeasts (4 to 7 µm) that possess a uniquely prominent polysaccharide capsule. This thick capsule is essential to the pathogenicity of *Cryptococcus* because it inhibits plasma cell function, phagocytosis, leukocyte migration, and complement. The capsule also allows the organisms to stand out in stained cytology preparations for easy identification and is the basis for the cryptococcal capsular antigen diagnostic test (see the related "Diagnosis" section).
- Dissemination from the nasal cavity can occur by hematogenous spread or by direct extension through the cribriform plate to the CNS or through the nasal bones to the paranasal soft tissues and skin.

Clinical Signs

Cryptococcosis can cause localized nasal infection or disseminated infection. Anorexia and depression are common, but fever occurs infrequently (<25% of the cases); in fact, temperatures exceeding 37°C inhibit *Cryptococcus*.

▼ ***Key Point*** In cats, *Cryptococcus* has a predilection for the nasal cavity, where the inhaled organisms initially deposit and cause granulomatous rhinitis and sinusitis.

Nasal Infection

Chronic upper respiratory signs are seen in up to 80% of cats with cryptococcosis and up to 50% of dogs.

- Common signs include sneezing, sniffling, and unilateral or bilateral mucopurulent nasal discharge, which may contain blood.
- Obstructing mucinous or granulomatous polyp-like masses often occur in the nostrils or nasal passages of cats and obstruct nasal airflow.
- Firm swellings over the bridge of the nose may cause nasal or facial deformity.
- Nasopharyngeal masses may cause stertorous breathing, inspiratory dyspnea, and voice change.

Disseminated Infection

▼ ***Key Point*** The preferred sites for cryptococcal dissemination are the skin, CNS, and eyes.

- ***Skin and subcutis***—(40% of cats; 20% of dogs) can have firm nodules that rapidly enlarge and then ulcerate and drain, mostly in the head and face area, often near the nostrils and planum nasale.
- ***CNS***—(25% of cats; 75% of dogs) hematogenous spread or local extension through the cribriform plate results in diffuse or mass-like granulomatous meningoencephalitis or myelitis. Signs may include behavior changes, seizures, circling, head-pressing, blindness, dementia, ataxia, paresis, head tilt, and cranial nerve (CN) deficits (CN II, VII, VIII).
- ***Eyes***—(25% of cats; 40% of dogs) often accompanies CNS dissemination; may include granulomatous chorioretinitis, exudative retinal detachment, optic neuritis, anterior uveitis, and blindness.
- ***Lungs***—Up to 50% of cats and dogs have subclinical cryptococcal lung infection at necropsy, but overt signs of lower respiratory tract disease are uncommon, especially in cats.
- ***Other dissemination sites***—May include peripheral lymph nodes (especially the submandibulars), pharynx and oral cavity, bone marrow, kidneys (30% of patients have renal granulomas at necropsy), liver, spleen, heart, and skeletal muscle.

Diagnosis

Consider cryptococcosis on the basis of clinical signs, especially in cats. The results of routine laboratory evaluations and radiography are variable and nonspecific. Serology provides a presumptive diagnosis, but identification of *Cryptococcus* organisms by cytology, biopsy, or culture is required for definitive diagnosis. In most cases cytology is a quick and easy way to confirm the diagnosis.

Hematology

The complete blood count is usually normal, except for occasional neutrophilia or eosinophilia.

Radiography

Nasal radiographs and nasal CT may show increased soft tissue density within the nasal cavity and frontal sinuses, turbinate destruction, and nasal bone destruction or expansion. Thoracic radiographs may show diffuse or nodular interstitial pulmonary infiltrates.

Serology

Serologic testing provides a presumptive diagnosis based on detection of cryptococcal capsular antigen in serum, CSF, or urine using latex agglutination. This is an antigen test that indicates the presence of cryptococcal organisms; it is not a test for an antibody response as with other fungal serologic tests.

- Positive titers in infected cats range from 1:10 to 1:100,000, with a median of 1:1,000.
- Commercial capsular antigen test kits have good sensitivity and specificity; however, false negatives occasionally occur in localized (non-disseminated) disease.
- False positives are rarely caused by interfering substances, such as in patients treated recently with hetastarch and in CSF contaminated with talc particles from latex gloves.
- The capsular antigen titer can also be used to monitor treatment response, a persistent titer indicating unresolved infection.

Cytology and Biopsy

Definitive diagnosis requires identification of the *Cryptococcus* organisms in cytologies (e.g., nasal exudate, CSF, skin exudate or impressions, lymph node aspirates, oculocentesis specimens, or urine sediment) using Gram's, PAS, new methylene blue, DiffQuik, or Wright-giemsa stains or in biopsies using mucicarmine, H&E, PAS, GMS, or Gridley stains. Cryptococcal yeast are usually numerous and easy to identify by their characteristic budding and prominent unstained capsule.

Culture

Cryptococcus can be cultured on Sabouraud's dextrose agar from the same specimen sources as cytology; however, growth can take from a few days up to 6 weeks, thus limiting the diagnostic usefulness of cultures.

Treatment

See the following section on "Antifungal Therapy" for dosages and additional details.

- ***Fluconazole*** is the treatment of choice for cryptococcosis. It is effective but costly. It has excellent penetration into the CNS and eyes, which are the preferred cryptococcal dissemination sites.
- ***Itraconazole*** is effective in most cases. It is slightly less effective, but more affordable than fluconazole.
- ***Ketoconazole*** is not as effective as either of the other azole drugs, and side effects are more frequent.
- ***Amphotericin B*** is highly effective for cryptococcosis, but it is inconvenient (parenteral route) and has more adverse effects (especially nephrotoxicity). Oral flucytosine can be given concurrently.

▼ ***Key Point*** Monitor treatment response with the cryptococcal capsular antigen test.

- Continue azole therapy for 6 to 12 months and at least 2 months beyond clinical resolution. The titer should become negative or drop to a low residual titer level in response to treatment. Reevaluate the capsular antigen test at 3 and 6 months after discontinuing treatment to assess for relapse.

Prognosis

- The prognosis is generally good for cats without CNS involvement. Cats with CNS involvement and dogs with any form of the disease have a guarded prognosis.
- Progressive decrease in the capsular antigen titer tenfold over 2 months is a good prognostic indicator.
- Cats with concurrent feline leukemia virus or feline immunodeficiency virus infection are less likely to respond to treatment.

UNCOMMON MYCOTIC INFECTIONS

A variety of opportunistic deep mycotic infections can occasionally lead to disseminated infection. These are summarized in Table 20-1. Many of these are described in greater detail in Chapter 40.

ANTIFUNGAL THERAPY

Most systemic mycotic infections in dogs and cats are successfully treated with an oral azole drug, parenteral amphotericin B, or a combination of both. Antifungal drugs are expensive, the treatment protocols are prolonged, and adverse side effects are considerable.

The duration of antifungal therapy is variable but should extend at least 1 to 2 months beyond clinical resolution. Relapses can occur 1 year or more after therapy is discontinued. If recrudescence occurs, reinstitute a full course of therapy or switch to another drug.

▼ ***Key Point*** The oral triazole, itraconazole, is the single-agent treatment of choice for most systemic fungal infections that are not immediately life threatening.

Fluconazole has the best penetration of the CNS, eyes, and prostate and thus may be the preferred treatment when these areas are involved, especially in cryptococcosis.

▼ ***Key Point*** Regardless of the treatment regimen, the unpredictable response in the disseminated forms of mycotic disease requires a guarded prognosis, especially if the CNS is involved.

Amphotericin B

Amphotericin B is a potent, broad-spectrum antifungal agent with rapid onset of action, but it must be given parenterally and is frequently nephrotoxic.

▼ ***Key Point*** The most effective treatment for severe fungal infections is lipid-complexed amphotericin B combined with an oral azole drug.

Indications

- As a single drug, amphotericin B is most effective for treatment of blastomycosis and histoplasmosis. It is moderately effective for coccidioidomycosis and cryptococcosis and occasionally effective for systemic candidiasis, zygomycosis, and pythiosis.
- In life-threatening, rapidly progressing cases of blastomycosis and histoplasmosis, combine amphotericin B for its rapid onset of action with an azole drug for an initial 2- to 4-week induction phase of therapy and then follow with long-term azole therapy.
- Amphotericin B is preferred over oral azoles if oral absorption might be impaired by vomiting or severe GI disease (e.g., intestinal histoplasmosis).

Pharmacology

Amphotericin B (AMB) is a polyene antibiotic for IV use that has both fungicidal and fungistatic actions. It binds to ergosterol in the fungal cell membrane, damaging the cell membrane and leading to fungal cell death. AMB also has beneficial stimulatory effects on host macrophages.

- AMB is not absorbed orally, so it must be given parenterally.
- AMB distributes well into most tissues, except for the CNS and eyes.
- AMB is cumulatively nephrotoxic, and azotemia during the course of therapy is common (see the "Adverse Effects" section).

Table 20-1. UNCOMMON DISSEMINATED MYCOTIC INFECTIONS

Disease	Etiology	Source	Location	Clinical Signs	Diagnosis	Treatment
Aspergillosis	*Aspergillus* spp.	Inhalation	Worldwide	Fever, draining tracts, lymphadenopathy, uveitis, chorioretinitis, dissemination to bone, kidney, liver, spleen, CNS, etc.	German shepherds; cytology (septate hyphae); culture	Itraconazole plus ABLC
Sporotrichosis	*Sporothrix schenckii*	Puncture wounds, bites, scratches	Worldwide	Draining skin/subcutis pyogranulomas; lymphadenopathy; dissemination to abdomen, lung, eyes, CNS, etc.	Cats > dogs; cytology (oval or cigar-shaped yeast); culture	Itraconazole (note: zoonotic considerations)
Pythiosis	*Pythium insidiosum*	Waterborne (warm); cutaneous or GI inoculation	Gulf Coast U.S., South America, Southeast Asia, Australia	*Cutaneous form:* Non-healing wounds, invasive ulcerated and draining skin/subcutis masses, nasopharyngeal lesions (cats) *GI form:* Chronic vomiting and diarrhea, GI bleeding, transmural granulomatous GI masses, GI obstruction, mesenteric lymphadenopathy	Dogs > cats; young, male large-breed working dogs; eosinophilia, anemia, hyperglobulinemia; abdominal imaging (masses); serum ELISA; biopsy (GMS+ stain, broad poorly septate hyphae) with culture, PCR, and immunohistochemistry	Aggressive surgical resection followed by itraconazole plus terbinafine
Lagenidiosis	*Lagenidium* spp.	Waterborne (warm); cutaneous inoculation (damaged skin sites)	Gulf Coast and southeast U.S.	Multifocal skin/subcutis nodular lesions with ulcers and draining tracts, lymphadenopathy, hind limb edema; lesions in aorta, vena cava, lung, mediastinum	Young large-breed dogs; biopsy (GMS+ stain, broad poorly septate hyphae) with culture, PCR, and immunohistochemistry	Aggressive surgical resection followed by itraconazole plus terbinafine
Zygomycosis	*Basidiobolus* spp.; *Conidiobolus* spp.	Cutaneous inoculation (damaged skin sites); inhalation	Ubiquitous saprophytes	*Conidiobolus:* Ulcerative nasal, nasopharynx, and palate lesions; multifocal skin and subcutis draining nodules *Basidiobolus:* ulcerative draining skin lesions with GI and lung lesions	Biopsy (GMS+ stain, broad poorly septate hyphae) with culture	Aggressive surgical resection followed by itraconazole
Phaeohyphomycosis	Numerous (see Chapter 40)	Traumatic implantation	Ubiquitous saprophytes	Granulomas of skin, subcutis, nasal, CNS, etc.	Biopsy (septate hyphae with melanin)	Surgical resection or itraconazole
Candidiasis	*Candida albicans*	Commensal mucosal yeasts; proliferate with immunosuppression, mucosal damage	Ubiquitous commensals	Fever, neutropenia, non-healing oral and GI mucosal ulcers, skin lesions, myositis, osteomyelitis, nephritis, microabscesses, signs referable to organs affected	Cytology (oval yeasts); culture; biopsy of tissue invasion	Itraconazole plus ABLC; correct underlying predisposing factors

ABLC, amphotericin B lipid complex; CNS, central nervous system; ELISA, enzyme-linked immunosorbent assay; GI, gastrointestinal; GMS, Gomori methenamine silver stain; PCR, polymerase chain reaction.

- Avoid concurrent use of other potentially nephrotoxic medications with AMB.
- Always follow the package insert instructions for reconstituting and handling AMB products.
- AMB is available in its original formulation as deoxycholate suspension and in three newer lipid-based and liposomal formulations.

▼ ***Key Point*** Lipid-based formulations of amphotericin B minimize the risk of nephrotoxicity, thus allowing higher doses and increased efficacy.

Dosage and Administration

Amphotericin B protocols are designed as a series of three infusions per week until a cumulative dose is achieved, with interruption of therapy if azotemia occurs. Amphotericin B therapy is combined and followed with long-term oral azole therapy in most cases.

Amphotericin B Deoxycholate

- ***IV in dogs:*** Give amphotericin B (Fungizone, ER Squibb) at dosages of 0.5 to 1.0 mg/kg, IV, q48h (3 times weekly), to a total cumulative dose of 6 to 10 mg/kg. Each dose can be given as a 10-minute bolus; however, infusion in 5% dextrose over 2 to 6 hours is preferred to reduce nephrotoxicity (see "Renoprotective Measures").
- ***IV in cats:*** Give amphotericin B at dosages of 0.25 to 0.50 mg/kg, IV, q48h (3 times weekly), to a total cumulative dose of 4 to 8 mg/kg. Infuse as for dogs.
- ***Subcutaneous protocol:*** A daily dose of 0.5 to 0.8 mg/kg is added to 0.45% saline with 2.5% dextrose solution (400 ml for cats, 500 ml for dogs <20 kg, and 1,000 ml for dogs >20 kg) then given SC q48h (3 times weekly) to a total cumulative dose of 10 to 20 mg/kg.
- ***Combination protocol:*** When amphotericin B is used with itraconazole or other azole, use the low end of the daily and cumulative dosage ranges for amphotericin B.

Lipid-Complexed Amphotericin B

- Lipid-complexed amphotericin B reduces the risk of nephrotoxicity up to 10-fold. Preferential uptake of lipid complexes by phagocytic cells delivers high concentrations of drug to target sites of inflammation and organs such as the liver, spleen, and lung, while renal uptake is decreased; thus, higher doses can be used with less risk of renal injury.
- Formulations include lipid complexed (Abelcet, Enzon), colloidal dispersion (Amphotec, Sequus), and liposome encapsulated (AmBisome, Fujisawa). Of these, amphotericin B lipid complex (ABLC) has been used most often in dogs and cats and is the least expensive.
- ***For dogs:*** Give ABLC at dosages of 2 to 3 mg/kg, IV, q48h (3 times weekly), for a total of 9 to 12 treatments to a total cumulative dose of 24 to 27 mg/kg. Dilute in 5% dextrose to a concentration of 1 mg/ml and infuse over 1 to 2 hours.
- ***For cats:*** Give ABLC at 1 mg/kg, IV, q48h (3 times weekly), for a total of 12 treatments to a total cumulative dose of 12 mg. Dilute and infuse as for dogs.

Renoprotective Measures

- Evaluate a urinalysis and renal function (serum creatinine, blood urea nitrogen [BUN]) before initiating AMB therapy, and monitor these frequently during treatment (once or twice weekly). In general, the earliest evidence of a renal effect is decreased urine-specific gravity. This is followed by abnormal numbers of renal cells and casts in fresh urine sediment, and eventually azotemia may develop.

▼ ***Key Point*** If BUN exceeds 50 mg/dl or serum creatinine exceeds 2.5 mg/dl during amphotericin therapy, suspend treatment until azotemia resolves. Azotemia is reversible in most cases.

- Always ensure that the patient is well hydrated prior to each dose of AMB.
- Consider the slow IV infusion method whenever possible. Give AMB diluted in 250 to 500 ml of 5% dextrose solution by slow IV infusion over a period of 2 to 6 hours.
- Other measures used less often to enhance renal blood flow and glomerular filtration rate include pretreatment sodium diuresis (0.9% sodium chloride, 10 to 20 ml/kg, IV, over 1 to 3 hours prior to AMB); concurrent administration of mannitol (0.5–1.0 g/kg, IV); furosemide (2 mg/kg, IV); or dopamine (3 to 10 µg/kg/min, by constant-rate IV infusion).

Adverse Effects

- The major adverse effect of AMB is dose-related nephrotoxicity caused by a combination of reduced renal blood flow (arteriolar vasoconstriction) and direct renal tubular injury. Although there is considerable individual variation in susceptibility to nephrotoxicity, most animals treated with AMB show some degree of renal dysfunction and azotemia. Nephrotoxicity is less of a risk with lipid-complexed AMB but still is a possibility.
- Other side effects of AMB include thrombophlebitis (local irritant effect), fever, anorexia, nausea or vomiting, hypokalemia, hypomagnesemia, distal renal tubular acidosis, cytopenias, cardiac arrhythmias, and perivascular irritation if extravasated. For infusion-associated nausea and fever, pretreat with an antihistamine such diphenhydramine.
- Local irritation and sterile abscesses occasionally occur with the subcutaneous protocol, especially if the AMB concentration is >20 mg/L.

Oral Azole Drugs

The azoles include the imidazole drug, ketoconazole, and the triazole drugs, itraconazole and fluconazole. These fungistatic drugs inhibit the biosynthesis of ergosterol in fungal cell membranes, thus inhibiting growth.

▼ ***Key Point*** The initial onset of clinical response to azole therapy has a lag time of up to 2 weeks.

Ketoconazole and itraconazole require an acidic environment for maximal absorption; the concurrent use of antacid drugs impairs absorption; and bioavailability is increased when taken with food. Fluconazole is not affected by gastric pH or by feeding. Fluconazole readily passes the blood-brain, blood-prostate, and blood-ocular barriers and thus achieves high concentrations in CSF, prostatic, and ocular fluids, as well as urine. Ketoconazole has the most dose-related side effects, and itraconazole has the least.

Itraconazole

Itraconazole is the initial treatment of choice for most dogs and cats with histoplasmosis, blastomycosis, cryptococcosis, and coccidioidomycosis if the infection is not immediately life threatening and the CNS is not involved. Itraconazole is more effective than ketoconazole with fewer side effects, but it is more costly.

Pharmacology

- Itraconazole requires an acidic pH for optimal absorption; thus, avoid concurrent use of antacids. Bioavailability is increased when given with food or cola beverages. Oral suspension is absorbed more consistently than capsules, especially in cats.
- Itraconazole does not penetrate the CNS, eyes, prostate, or urine as well as fluconazole does. Despite this, itraconazole is effective for treating most cases of fungal meningitis, uveitis, and prostatitis.

Dosage and Administration

The lag time between start of the drug and clinical response is 1 to 2 weeks. To shorten this, use a higher loading dose for the first 3 to 5 days. Sporanox oral suspension (10 mg/ml) is absorbed better than capsules, especially in cats. Treat for 1 to 2 months beyond clinical resolution.

- ***For dogs:*** Give itraconazole (Sporanox, Janssen), at dosages of 5 to 10 mg/kg, PO, q24h or divided bid, with food.
- ***For cats:*** Give itraconazole at dosages of 10 mg/kg, PO, q24h or divided BID, with food.
- ***Combination protocol:*** In animals with severe disease, combine amphotericin B with itraconazole as initial therapy for the first 2 to 4 weeks, then follow with long-term itraconazole therapy.

Adverse Effects

- Itraconazole causes less liver and GI side effects than ketoconazole, and it does not affect adrenal and testicular steroidogenesis. Anorexia occurs occasionally. Mild subclinical elevation of serum liver transaminases occurs in half the cases but does not usually require modifying treatment unless accompanied by anorexia, depression, and vomiting.
- Overt hepatotoxicity is rare, but if it occurs, stop treatment until appetite returns and liver enzymes return to normal (usually 2 weeks), then reinstitute treatment at one-half dose and monitor serum liver enzymes every 2 weeks.
- Cutaneous vasculitis with localized ulcerative dermatitis and limb edema is a rare side effect of itraconazole. This appears to be dose dependent and resolves when the drug is discontinued.

Fluconazole

The major advantage of fluconazole over other azoles is its excellent penetration of the CNS for treatment of fungal meningitis. It also is well absorbed on an empty stomach or in anorexic animals. The disadvantage of fluconazole is that it is expensive.

▼ ***Key Point*** Fluconazole is primarily indicated for mycotic infections of the CNS or eye that are refractory to itraconazole, and it is specifically indicated for cryptococcosis.

Dosage and Administration

Treat for 1 to 2 months beyond clinical resolution. Fluconazole is excreted by the kidney; thus, reduce the dose or use an alternative drug in animals with renal insufficiency.

- ***For dogs:*** Give fluconazole (Diflucan, Pfizer) at dosages of 2.5 to 5.0 mg/kg, q12–24h, PO or IV. Use twice the recommended daily dosage for the first day as a loading dose.
- ***For cats:*** For CNS involvement in cats, give fluconazole at dosages of 10 to 15 mg/kg, q12–24h, PO or IV, or 50 mg total dose, q12–24h.

Adverse Effects

Adverse effects are infrequent but can include GI intolerance, hepatotoxicity, and cutaneous eruption.

Ketoconazole

Ketoconazole has been used successfully to treat histoplasmosis, blastomycosis, and coccidioidomycosis when the more effective antifungal drugs are cost prohibitive for the owner. It is less effective against *Cryptococcus*. Ketoconazole is not usually effective against ocular and CNS mycoses.

Pharmacology

- Ketoconazole depends on hepatobiliary metabolism and excretion, and it is distributed widely except in the CNS, eye, prostate, and testes.
- Acidity is required for optimal absorption of ketoconazole; thus, avoid concurrent use of drugs such as H_2 blockers that inhibit gastric acid secretion.
- Bioavailability is increased and nausea and vomiting are minimized when ketoconazole is given with food.

Dosage and Administration

The oral dosage of ketoconazole (Nizoral, Janssen), ranges from 10 to 30 mg/kg/day. Divide this total daily dose into two or three doses for better GI tolerance. Give with food. Continue ketoconazole for at least 1 to 2 months beyond clinical resolution.

- ***For dogs:*** Give 10 to 15 mg/kg, q12h, PO with food.
- ***For cats:*** Give 5 to 10 mg/kg, q12h, PO with food, or a total dose of 50 mg, q24h. Cats generally are more susceptible to the side effects of ketoconazole. If tolerance is a problem in a cat, administer a dosage of 20 mg/kg on alternate days or switch to a different drug.
- ***Combination protocol:*** For severe infections, use amphotericin B in combination with ketoconazole for the first few weeks or use itraconazole.

Adverse Effects

- The most common immediate side effects of ketoconazole are anorexia, vomiting, and diarrhea. Minimize these GI side effects by dividing the daily dose and administering the drug with food.
- Longer-term side effects may include hepatotoxicity (hepatomegaly, elevated serum liver enzymes, icterus), weight loss, and haircoat changes (lightening of color, alopecia). Because of hepatic effects, it is advisable to monitor serum liver enzymes monthly during treatment. The liver, GI, and haircoat reactions are usually reversible with reduction in dose.
- Ketoconazole inhibits adrenal and testicular steroidogenesis. In dogs, but not cats, ketoconazole diminishes serum testosterone and cortisol while increasing serum progesterone. Ketoconazole is embryotoxic and teratogenic and thus should not be used in pregnant animals.

Newly Emerging Azole Drugs

A new generation of triazole antifungal drugs with greater potency and broader spectrum of activity is being developed for resistant fungal pathogens in humans. These drugs have not yet had clinical evaluation for treatment of mycotic infections in dogs and cats. New triazole drugs are costly, but they will likely have a future role for treatment of fungal infections in dogs and cats that are refractory to other available treatments.

Voriconazole

Voriconazole (Vfend, Pfizer) is a derivative of fluconazole with greater potency and broader spectrum of activity against many fungal pathogens, including invasive aspergillosis. It has excellent oral and IV bioavailability.

Posaconazole

Posaconazole (Noxafil, Schering-Plough) is a derivative of itraconazole with greater potency and broader spectrum of activity against aspergillosis and molds.

Ravuconazole

Ravuconazole (Bristol-Myers Squibb) is a fluconazole derivative with extended half-life.

Flucytosine

Flucytosine (Ancobon, Roche) is an antimitotic, antifungal drug used exclusively for its synergism with amphotericin B in the treatment of cryptococcosis. Flucytosine is most useful for CNS involvement, because it attains 60% to 80% of serum concentration in CSF. Use this drug only in combination with amphotericin B because fungal resistance develops rapidly if it is used alone.

- The dosage in dogs and cats is 25 to 50 mg/kg, PO, q6–8h.
- Side effects are common, including anorexia, vomiting, diarrhea, cytopenias caused by bone marrow suppression, and mucocutaneous drug eruptions (in dogs).

Terbinafine

Terbinafine (Lamisil, Sandoz) is an allylamine drug that blocks synthesis of ergosterol in the fungal cell membrane. The main indication is for treatment of dermatophytosis and cutaneous fungal infections. It has not been well evaluated in systemic mycoses of dog and cats. Terbinafine (5 to 10 mg/kg, PO, q24h) combined with itraconazole has reportedly been beneficial in some dogs and cats with pythiosis and lagenidiosis (see Chapter 40). Potential side effects include GI, hepatic, and cutaneous reactions.

Chitin and Glucan Inhibitors

These drugs inhibit the synthesis of either chitin or beta-glucan, two structural components of the cell walls of fungi that are not found in mammalian cells.

- ***Chitin inhibitors*** such as the nikkomycins and lufenuron have a limited spectrum, but they have been of interest for treatment of coccidioidomycosis. However, Lufenuron (Program, Novartis), a chitin synthesis inhibitor licensed for monthly flea control in dogs and cats, has not been an effective antifungal

agent for *Coccidioides* and other systemic mycoses despite initial anecdotal reports of its use in dogs.

- ***Beta-glucan inhibitors*** include echinocandins and pneumocandins, for example, caspofungin (Cancidas, Merck), micafungin, and anidulafungin. These are potent broad-spectrum antifungal drugs with activity against *Aspergillus, Candida,* and *Pneumocystis carinii.* These agents are very costly and considered investigational only at this time. Future indications for use of these drugs in dogs and cats will need to be determined.

PREVENTION

Because the principal source of systemic mycotic infection is airborne fungal elements from the soil, there is no practical means of prevention in endemic areas. High concentrations of *Histoplasma* can be found in chicken and bat excreta, and *Cryptococcus* is found in high concentrations in pigeon excreta; thus, exposure to these sources should be avoided. Systemic mycoses are not contagious diseases between animals.

Although humans can be infected from the same environmental point sources as animals, zoonotic transmission from animals to humans does not occur except very rarely by direct inoculation of an open wound with infected material from an animal. Vaccination for these mycoses is not available.

Chapter 21

Toxoplasmosis and Other Systemic Protozoal Infections

Robert G. Sherding

The protozoa that infect dogs and cats can be classified broadly into those that disseminate and cause systemic disease and those that primarily live in the intestinal tract. This chapter describes toxoplasmosis, the most important systemic protozoal infectious disease in North America, and other emerging systemic protozoal infections—neosporosis, hepatozoonosis, and leishmaniasis. These and other systemic protozoal infections are summarized in Table 21-1, including trypanosomiasis, babesiosis, cytauxzoonosis, encephalitozoonosis, acanthamebiasis, and pneumocystosis.

Protozoa that parasitize erythrocytes, such as *Babesia* spp. and *Cytauxzoon felis,* are discussed in Chapter 22. Enteric protozoal infections (coccidiosis, giardiasis, tritrichomoniasis, amebiasis, and balantidiasis) are discussed in Chapter 69.

TOXOPLASMOSIS

Etiology

Toxoplasma gondii is an obligate intracellular protozoan parasite with worldwide distribution. The feline species is the definitive host for this coccidium, but most warm-blooded animals can be infected as intermediate hosts, including dogs and humans. Only cats complete the coccidian life cycle with intestinal replication and passage of oocysts in the feces.

- Serologic surveys estimate that over 30% of cats and humans are seropositive and presumed infected.
- Seroprevalence in cats increases with age, and it is higher in male and domestic shorthaired cats.

Routes of Transmission

Warm-blooded vertebrates can be infected by ingestion of any of the three life stages of the parasite (see the next section) or transplacentally.

Ingestion of Tissue Cysts

Cats are mainly infected through the ingestion of meat and animal tissues (carnivorism) that contain dormant *Toxoplasma* cysts (bradyzoites). Sources include uncooked meat (or meat scraps scavenged from garbage) or hunted prey (mice, birds).

- Ingestion of raw or undercooked meat (especially pork) is an important source of toxoplasmosis in dogs and humans.
- Ingestion of tachyzoites passed in milk can cause lactogenic infection in nursing kittens. Ingestion of tachyzoites in raw (unpasteurized) milk, especially from goats, is a rare source of infection.

Ingestion of Fecal Oocysts

Food, water, and soil contaminated with cat feces containing sporulated *Toxoplasma* oocysts are potentially important sources of infection for intermediate hosts such as humans, dogs, livestock, and rodents.

- Compared with carnivorous feeding, this is a relatively minor source of infection in the primary host, the cat.
- Oocysts can be transported from defecation sites in soil by cockroaches, flies, and earthworms.

Transplacental Infection

When a pregnant animal or human becomes infected during gestation, *Toxoplasma* tachyzoites can cross the placenta and infect the unborn fetus, resulting in severe or fatal disease (see under "Public Health Considerations").

- For this reason, toxoplasmosis has major public health significance in humans.
- In dogs and cats, congenital toxoplasmosis is uncommon, but it is a potential cause of abortion, stillbirth, and neonatal mortality.

Stages of Infection

The three stages of *Toxoplasma* infection are (1) intestinal replication (cats only), (2) acute dissemination and intracellular replication, and (3) chronic tissue encystment.

Table 21-1. SYSTEMIC PROTOZOAN INFECTIONS OF THE DOG AND CAT

Diseases	Etiology (Source)	Endemic Locations	Clinical Signs	Diagnosis	Treatment
Leishmaniasis	*Leishmania infantum* (sand fly vector, bloodborne)	Endemic in North American foxhounds, Mediterranean region, Central and South America, Asia, Africa	*Disease primarily in dogs:* Chronic diffuse skin hyperkeratosis (dry scaling), dry brittle haircoat, skin nodules, mucocutaneous ulcers, fever, muscle atrophy, weakness, cachexia, anorexia, inactivity, vomiting, diarrhea, lymphadenopathy, splenomegaly, uveitis, conjunctivitis, bleeding (epistaxis, melena), glomerulonephritis, polyarthritis	*General:* Origin from endemic country or U.S. foxhound kennel; hyperglobulinemia, hypoalbuminemia, proteinuria, azotemia, elevated serum liver enzymes, anemia *Specific:* —Identify organisms by cytology (e.g., bone marrow) —PCR assay —*Serology:* Not as sensitive or specific	*Caution:* Zoonotic (indirectly) *See text for dosages* —Sodium stibogluconate (from CDC) —Meglumine antimonite —Allopurinol —Amphotericin B *Prognosis:* Fair to good for remission but poor for cure
American trypanosomiasis (Chagas disease)	*Trypanosoma cruzi* (reduviid "kissing" bug vector, bloodborne)	Southern U.S. (rarely), Central and South America	*Disease primarily in dogs:* Acute myocarditis (fever, weakness, sudden collapse, fatal tachyarrhythmias), chronic cardiomyopathy (after 1–3 years, heart failure, ascites, pleural effusion, edema), lymphadenopathy, splenomegaly, meningoencephalitis	*General:* Endemic region, abnormal cardiac evaluations (radiography, ECG, echocardiography) *Specific:* —Identify organisms in blood (direct or buffy coat smear) or lymph node aspirates —*Serology:* Exposure or active —PCR assay	*Caution:* Zoonotic (indirectly) *Investigational per CDC:* —Nifurtimox (Lampit, Bayer): 2–7 mg/kg POq6h for 3–5 mo —Benznidazole (Ragonil, Roche): 5 mg/kg PO q24h for >2 mo *Prognosis:* Good in acute cases; poor in chronic cases
Hepatozoonosis	*Hepatozoon americanum* (U.S only) (tickborne), *Hepatozoon canis* (worldwide) (tickborne)	U.S. (Gulf Coast states, Texas, Oklahoma), Brazil, Europe, Asia, Africa	*Disease primarily in dogs:* Episodic fever, cachexia, chronic myositis and periosteal bone proliferation (reluctance to move, general muscle pain, atrophy), bloody diarrhea, ocular discharge	*General:* Endemic region, mild anemia, severe neutrophilic leukocytosis, widespread periosteal bone proliferation *Specific:* Identify organisms in blood smear (in WBC) or in muscle biopsy (most reliable test)	*For H. americanum* (see text): —Clindamycin —Trimethoprim-sulfadiazine —Pyrimethamine —Decoquinate *For H. canis* (see text): —Imidocarb dipropionate *Prognosis:* Good for remission but poor for cure
Babesiosis	*Babesia canis, Babesia gibsoni,* etc. (tick vector, bloodborne)	*Dog: B. canis, B. gibsoni* (U.S. and worldwide) *Cat: B. felis,* etc. (Africa, Asia, South America)	Hemolytic anemia (pallor, depression, weakness, jaundice, hemoglobinuria, fever, splenomegaly), weight loss, subclinical carrier	*General:* Regenerative anemia (often Coombs' positive), thrombocytopenia *Specific:* —Identify organisms in Giemsa-stained smears of capillary blood (from ear or toenail) or splenic aspirate —*Serology:* IFA titer > 1:80 is positive —PCR assay	*Dogs:* —Imidocarb dipropionate (Imizol, Glaxo Wellcome): 5.0–6.6 mg/kg SC or IM, two doses 14 days apart —Phenamidine isethionate (Oxopirvedine, Merial): 15 mg/kg SC q24h × 2 days —Diminazene aceturate (Berenil 10%, Ganaseg): 3.5 mg/kg IM once, then repeat in 14 days

Table 21-1. SYSTEMIC PROTOZOAN INFECTIONS OF THE DOG AND CAT—cont'd

Diseases	Etiology (Source)	Endemic Locations	Clinical Signs	Diagnosis	Treatment
					Cats: —Primaquine phosphate: 0.5 mg/kg IM once *Prognosis:* Good but relapses are common
Cytauxzoonosis	*Cytauxzoon felis* (tick vector, blood-borne)	U.S. (south-central and southeastern states)	*Disease in cats only:* Anorexia, depression, high fever, anemia, jaundice, congestion and edema (of lungs, spleen, liver), shock, death in less than 1 week	*General:* Free-roaming in a wooded area *Specific:* —Identify organism in blood smear (ring-shaped RBC inclusions) or cytology of bone marrow, lymph node, or spleen —PCR assay	—Imidocarb dipropionate (Imizol): 5 mg/kg IM, two doses 14 days apart —Diminazene aceturate (Berenil): 2 mg/kg IM, two doses 7 days apart *Prognosis:* Poor No treatment known
Encephalitozoonosis	*Encephalitozoon cuniculi* (oronasal exposure to urine spores or ingestion of infected tissues)	U.S. (rarely), Europe, South Africa	*Neonatal disease in kennels:* Stunted growth, acute nephritis (renal failure) and encephalitis (depression, muscle spasms, ataxia, seizures, blindness, aggression, paralysis)	*General:* Nonregenerative anemia, azotemia, pyuria, hematuria, elevated CSF protein and mononuclear cells *Specific:* —Identify spores in gram-stained urine sediment —Serology and PCR	
Acanthamebiasis	*Acanthamoeba* species (water, sewage, soil)	U.S. (very rare; epizootics seen in greyhounds)	*Disease in dogs only:* Pneumonia (fever, cough, dyspnea, nasoocular discharge), encephalitis (ataxia, seizures), mimics canine distemper	Leukopenia; no diagnostic test available (identify organisms in lung biopsies)	—No established treatment protocol —Trimethoprim-sulfonamide: 30 mg/kg PO q12h
Pneumocystosis	*Pneumocystis carinii* (airborne)	—Worldwide (rare in dogs and cats) —Predisposition in miniature dachshunds with immunodeficiency syndrome	*Dogs (mostly miniature dachshunds):* Acute or chronic pneumonia in immunocompromised dogs (non-febrile, exercise intolerance, dyspnea, dry cough, weight loss)	*General:* Neutrophilic leukocytosis, diffuse radiographic alveolar and interstitial lung densities *Specific:* Identify organisms in lung cytology or biopsies (Giemsa and methenamine silver stains)	—Trimethoprim-sulfadiazine: 15–30 mg/kg PO q8–12h for 2–3 weeks —Pentamidine isethionate (Lomidine, Merial): 4 mg/kg IM q24h for 2–3 weeks *Prognosis:* Fair to guarded

CDC, Centers for Disease Control and Prevention; IFA, immunofluorescent antibody; PCR, polymerase chain reaction; RBC, red blood cell; WBC, white blood cell.

Intestinal Replication and Oocyst Shedding

This is also called the *sporozoite stage*. When cats ingest the meat of an infected intermediate host, the encysted *Toxoplasma* bradyzoites are liberated by the cat's digestive enzymes and invade the intestinal epithelial cells. Replication within the intestinal epithelium results in fecal excretion of millions of oocysts beginning 3 to 10 days after exposure and continuing for 1 to 3 weeks. Except for occasional transient diarrhea, clinical signs are usually absent until after oocyst shedding is over and the cat enters the next stage of infection.

- Infection by oocyst ingestion is a less important source in cats, but when it does occur, subsequent shedding of oocysts is delayed for 3 weeks or more and is much less pronounced.
- Excreted oocysts are oval-shaped, $10 \times 12\,\mu m$ in size, and unsporulated (uninfective). To become infec-

tious, oocysts first must sporulate, which takes 1 to 5 days in the environment.
- These sporulated oocysts are environmentally resistant and can remain infectious in the environment for months to years.

▼ ***Key Point*** Intestinal replication and fecal excretion of *Toxoplasma* oocysts, which can contaminate soil, water, and food and can infect other animals, only occurs in cats, the definitive host.

- Intestinal immunity lasting up to 6 years after the first exposure prevents significant oocyst production upon reinfection.

Dissemination and Intracellular Replication

This is also called the *tachyzoite stage*. Simultaneous with intestinal replication in cats, or after infection by ingestion or transplacental transfer in non-feline species, *Toxoplasma* disseminates to extraintestinal tissues via blood and lymph. These rapidly multiplying tachyzoite forms can parasitize almost any cell in any tissue. The tachyzoites eventually rupture and destroy infected cells, releasing organisms to infect new cells and thus producing foci of necrosis and inflammation.

- In a small percentage of animals, these lesions become extensive enough to cause overt clinical disease, with the signs dependent on which tissues are damaged most severely.
- In most animals, this rapid replication stage is brief, and, as immunity develops and before signs occur, aggregates of these organisms encyst and become dormant.

Chronic Tissue Encystment

This is also called the *bradyzoite stage*. Coincident with the onset of immunity, slowly multiplying bradyzoite forms develop and form large (10 to 50 µm) tissue cysts, especially in muscle, brain, and visceral organs.

- There is minimal host response to these cysts, and they can persist in this dormant form for the life of the chronic carrier animal.
- Encysted *Toxoplasma* usually do not cause any clinical signs except in rare instances when cysts rupture within the central nervous system (CNS) or eye or when the infection is reactivated to an acute stage because of loss of host immune competence.

▼ ***Key Point*** In carnivores such as the cat, the principal source of infection is ingestion of *Toxoplasma* organisms encysted in the meat of chronically infected food-producing animals, small mammals, and birds.

Clinical Signs

Clinical toxoplasmosis is recognized more frequently in cats than in dogs, but the spectrum of signs is similar for both species. Clinical signs depend on the location and extent of tissue damage that results from extraintestinal dissemination and rapid intracellular replication of tachyzoites. The most commonly affected organs are lung, eyes, liver, and pancreas, as well as CNS and skeletal muscle. Organ-specific clinical signs are usually accompanied by anorexia, depression, and fever (often >104°F and unresponsive to antibiotics).

- Clinical signs can occur at the time of initial infection (acute or primary toxoplasmosis) or from reactivation of encysted infection (chronic or secondary toxoplasmosis) caused by an underlying immunosuppressive condition.
- Clinical toxoplasmosis is most severe and often fatal in neonatal kittens infected transplacentally or through milk.

▼ ***Key Point*** Most animals with toxoplasmosis are asymptomatic and have only serologic evidence of infection. Up to 30% of cats in the United States have *Toxoplasma* antibody titers and are presumed infected, with the highest prevalence in free-roaming and feral cats that hunt for their food.

Ocular Signs

Ocular toxoplasmosis (uveitis) is one of the most common forms of the disease. Blindness may result.

- Anterior uveitis causes aqueous flare, keratic precipitates, hypopyon, glaucoma, and lens luxation (see Chapter 136).
- Chorioretinitis causes retinal detachment, hyporeflective lesions in the tapetal fundus, and white fluffy infiltrates in the non-tapetum (see Chapter 138).

Respiratory Signs

Acute necrotizing interstitial and alveolar pneumonia is common and can cause progressive dyspnea.

Neuromuscular Signs

- Encephalomyelitis can cause behavior changes, seizures, ataxia, circling, tremors, paresis or paralysis, and cranial nerve deficits, depending on location of the lesions within the CNS.
- Myositis can cause hyperesthesia, stiff gait, muscle atrophy, and weakness.

Hepatic and Digestive Tract Signs

- Diffuse necrotizing hepatitis and cholangiohepatitis can cause anorexia, vomiting, diarrhea, jaundice, and ascites.
- Pancreatitis can cause anorexia, vomiting, abdominal pain, and jaundice.

- Enterocolitis can cause vomiting and diarrhea.
- Mesenteric lymphadenitis can cause palpable abdominal lymph nodes.

Cardiac Signs

Myocarditis can cause cardiac arrhythmias, sudden death, or heart failure.

Reproductive Signs

Transplacental infection can cause birth of stillborn kittens or kittens that die of neonatal toxoplasmosis of the lung, liver, and CNS.

Laboratory and Radiographic Findings

Abnormalities found on routine diagnostics are varied and nonspecific.

Hematology and Serum Chemistries

- Hematologic findings are variable and may include leukopenia with degenerative left shift (in acute disease) or neutrophilic leukocytosis, mild nonregenerative anemia, lymphocytosis, or eosinophilia.
- Hepatitis can cause elevated serum bilirubin, liver enzymes, and bile acids.
- Pancreatitis can cause increased pancreatic lipase immunoreactivity in cats or serum amylase and lipase dogs.
- Myositis can cause elevated muscle enzymes (e.g., creatine kinase [CK] and aspartate aminotransferase [AST]).

Radiography

- Pulmonary toxoplasmosis can cause generalized coalescing, patchy alveolar and interstitial lung infiltrates, and mild pleural effusion.
- Involvement of abdominal viscera can cause peritoneal effusion and hepatomegaly.

Cerebrospinal Fluid Analysis

- Cerebrospinal fluid (CSF) protein may be normal or increased.
- CSF nucleated cell count is usually mildly increased with a predominance of small mononuclear cells.
- CSF can also be evaluated by serology and polymerase chain reaction (PCR) (see the next section).

▼ ***Key Point*** Clinical toxoplasmosis can be an opportunistic disease associated with immunosuppression; thus, consider underlying concurrent infections such as feline immunodeficiency virus, feline leukemia virus, and feline infectious peritonitis in cats and canine distemper in dogs. Immunosuppressive drugs (glucocorticoids, cyclosporine, or antitumor therapy) may also predispose to clinical toxoplasmosis.

Diagnosis

The diagnosis of clinical toxoplasmosis is usually based on the combination of clinical findings and serologic and PCR testing of blood, CSF, and aqueous humor. PCR assays and serologic tests for immunoglobulin M and G (IgM and IgG) are available to the practicing veterinarian through the Veterinary Diagnostic Laboratory (College of Veterinary Medicine, Colorado State University, Fort Collins, CO 80523) and other reference labs.

- Visual identification of tachyzoites in cytology or biopsy specimens is only possible in a small fraction of the animals with toxoplasmosis, but in those cases it establishes a definitive diagnosis.
- Visual identification of *T. gondii* oocysts in the feces of clinically healthy cats is possible during the brief intestinal replication stage, but this is not useful for diagnosis of clinical toxoplasmosis.

Serology

Enzyme-linked immunosorbent assay (ELISA) methods are generally most reliable for determining *Toxoplasma*-specific antibody titers. Positive IgG and IgM antibody titers document previous or current infection. The IgM titer reflects the early immune response and has the best correlation with clinically active toxoplasmosis.

▼ ***Key Point*** The presence of antibodies against *T. gondii* indicates previous or current infection but does not prove clinical disease as a result of infection; thus, only use serology in conjunction with other clinical information.

Immunoglobulin M Antibody Titer

The IgM titer rises initially 1 to 2 weeks after exposure, typically coinciding with the onset of signs; it peaks after 3 to 6 weeks and dissipates by 12 weeks in most cats, thus paralleling clinical disease activity.

- *Interpretation:* IgM titer ≥ 1:64 suggests active or recent infection.
- The IgM titer may persist up to 1 year in some cats when there is reactivation of chronic infection or delayed antibody class shift from IgM to IgG caused by concurrent feline immunodeficiency virus infection or glucocorticoid therapy.

▼ ***Key Point*** The serum IgM *Toxoplasma* antibody titer is the serologic test of choice for presumptive diagnosis of active or recent infection.

Immunoglobulin G Antibody Titer

The IgG titer rises initially 2 to 4 weeks after exposure and persists for years to life; thus, a single positive IgG titer does not distinguish previous infection from current active infection.

- *Interpretation:* A fourfold rise in the IgG titer in paired specimens over a 2- to 3-week period is indicative of active infection. Both specimens must be measured together in the same test run to avoid assay variation.

▼ ***Key Point*** A single, high serum IgG *Toxoplasma* antibody titer is *not* diagnostic of active infection, no matter how high the titer level.

Antibody Titers in Cerebrospinal Fluid and Aqueous Humor

The diagnosis of CNS and ocular toxoplasmosis is aided by evaluating the local production of *Toxoplasma*-specific IgG and IgM antibodies in CSF or aqueous humor using the calculated antibody coefficient (C-value), which distinguishes true local production of *Toxoplasma* antibodies from inflammatory leakage. This can be combined with PCR assay for *Toxoplasma* DNA in CSF or aqueous humor. Specimens must be collected prior to glucosteroid therapy. Aqueous humor and CSF assays are available at the Veterinary Diagnostic Laboratory (College of Veterinary Medicine, Colorado State University, Fort Collins, CO 80523).

$$\text{C-value} = \frac{\left[\begin{array}{c}T.\,gondii \text{ antibody (aqueous or CSF)} \\ \times \text{ Total antibody (serum)}\end{array}\right]}{\left[\begin{array}{c}T.\,gondii \text{ antibody (serum)} \\ \times \text{ Total antibody (aqueous or CSF)}\end{array}\right]}$$

- C-value of 1 to 8 is suggestive of ocular or CNS toxoplasmosis.
- C-value of >8 is conclusive evidence of local ocular or CNS antibody production.

▼ ***Key Point*** The combination of antibody titers (especially IgM) and PCR assay on aqueous humor or CSF is the most accurate way to diagnose ocular or CNS toxoplasmosis.

Polymerase Chain Reaction and Antigen Assays

- PCR assay can be used to detect *T. gondii* DNA in blood, CSF, or aqueous humor. The PCR assay in blood can be positive in cats with and without clinical disease; thus, a positive PCR by itself does not confirm clinical toxoplasmosis.
- Toxoplasma antigen can be detected in cats initially 1 to 4 weeks after exposure and then intermittently for up to 1 year. This does not distinguish active from past infection and thus has no advantage over antibody titers.

Identification of Toxoplasma Organisms

Detection of Tachyzoites

Characteristic intracellular inclusions are occasionally identified in aspirate and impression smear cytologies stained routinely or in biopsies.

- Specimens to consider (depending on sites of involvement) include lung bronchoalveolar lavage (BAL), liver aspirates, lymph node aspirates, body cavity fluids, CSF, and aqueous humor by oculocentesis.
- *Disadvantage:* Tachyzoites are often sparse and difficult to find; thus, sensitivity of detection is generally low. However, in experimentally infected cats, BAL was a reasonably effective method of diagnosis.

Detection of Oocysts in Feces

Fecal oocysts are rarely detected because most cats are past the transient stage of oocyst shedding by the time clinical signs occur (see under "Stages of Infection"); thus, this is not a suitable method for diagnosis of clinical toxoplasmosis.

- *Procedure:* Use Sheather's sugar centrifugation-flotation (Sheather's solution: 500 g of table sugar, 320 ml of distilled water, and 6.5 g of phenol crystals melted in a hot water bath). Make a fecal suspension with 5–10 g of feces and water, then centrifuge one part fecal suspension with two parts Sheather's solution for 10 minutes at 1000 g and examine one to two drops from the meniscus.
- *Disadvantages:* Oocysts are small, easily overlooked, and morphologically indistinguishable from certain other coccidia (*Hammondia* spp., *Besnoitia* spp.) without specialized animal inoculation studies. Nevertheless, assume coccidian oocysts 10 × 12 µm in size in feline feces to be *Toxoplasma* until proved otherwise.

▼ ***Key Point*** Detection of fecal oocysts is not a reliable diagnostic test for clinical toxoplasmosis because oocyst shedding occurs only briefly and usually ends before clinical signs begin.

Treatment

Toxoplasmosis can be treated with clindamycin, trimethoprim-sulfonamide, or azithromycin. Localized ocular infection is most responsive. Approximately 60% of animals with generalized toxoplasmosis recover with treatment; thus, the prognosis is guarded. Mortality rate is highest in neonates and in animals that are severely immunosuppressed.

▼ ***Key Point*** Clindamycin is the initial drug of choice for treating clinical toxoplasmosis, and it penetrates the blood-brain and blood-eye barriers. It also reduces oocyst shedding.

- Clindamycin (Antirobe, Upjohn): 12.5 mg/kg PO or IM q12h for 28 days.
- Trimethoprim-sulfadiazine: 15 mg/kg PO q12h for 28 days.
- Azithromycin (Zithromax): 10 mg/kg PO q12h for 7 days.

- For uveitis, use 1% prednisone drops topically every 6 to 8 hours for 2 weeks.

Prevention in Cats

Prevent cats from ingesting tissue cysts in meat and prey animals.

- Do not feed cats raw meat, viscera, or bones, and do not allow them to scavenge these from garbage.
- Do not allow cats to ingest raw (unpasteurized) milk, especially from goats.
- Do not allow cats to roam free where they can hunt prey (mice, birds) for food.
- Do not allow cats to eat transport vectors (cockroaches, flies, earthworms).

Public Health Considerations

Toxoplasmosis is an important zoonosis in humans. Infection in immunocompetent people is inapparent or causes a self-limiting, flu-like illness. Infection during pregnancy can cause fetal toxoplasmosis, leading to stillbirth or severe ocular or CNS disease. Approximately 10% of people with AIDS develop toxoplasma encephalitis from reactivation of encysted bradyzoites.

Preventive Measures in Humans

Prevention of human infection is based on avoiding ingestion of sporulated oocysts in the environment or tissue cysts in undercooked meat. Contaminated drinking water has caused some outbreaks.

▼ ***Key Point*** Pregnant women and severely immunocompromised people should avoid contact with soil, cat feces, litter boxes, and raw meat.

- Do not eat raw or undercooked meat. Cook meat to 160°F to kill tissue cysts.
- Use good kitchen hygiene. Wash hands, cutting boards, sink tops, and utensils that come in contact with raw meat.
- Change the litter box daily to remove oocysts before they have 24 hours to become infective. Disinfect with boiling or scalding water.
- Wear gloves while gardening, or wash hands after gardening to prevent exposure to oocysts in soil.
- Wash fruits and vegetables thoroughly before eating to remove soil particles with oocysts.
- Boil or filter surface water before drinking if contamination is possible.
- Keep sandboxes covered when not in use so that cats cannot defecate in them.

Risks of Owning an Infected Cat

Direct contact with cats is highly unlikely to pose a risk of human infection. Oocysts shed in cat feces are the only means of transmission from cat to human. Exposure to oocysts is very unlikely from petting cats or from cat licks, bites, and scratches.

▼ ***Key Point*** Because of the way cats defecate, bury their feces, and keep their haircoats clean, transmission of *Toxoplasma* oocysts to humans by touching and caring for a pet cat is very unlikely.

- The question often is raised, how dangerous is a healthy pet cat with a positive *Toxoplasma* antibody titer? Most seropositive cats and cats with clinical toxoplasmosis have completed oocyst shedding by the time they develop a positive titer. Repeat exposure of a seropositive cat results in little or no shedding.
- Most cats that are shedding infective oocysts are seronegative and preclinical. Seronegative cats are non-immune and would be more likely to shed oocysts if exposed, thus posing a greater risk to its owner than a seropositive cat.

▼ ***Key Point*** Serologic testing of healthy cats for *Toxoplasma* antibodies has little public health benefit and is not recommended.

Environmental Control Measures

- Control the stray cat population to reduce contamination of the environment, soil, and water with oocysts. Cats that defecate in the soil are likely to be the same cats that must hunt for their food and thereby have a high risk of infection.
- To reduce entry of *Toxoplasma* into the food chain, prevent cats from roaming where food-producing animals and livestock feed are kept. Pork is the most likely source of cyst ingestion in people in the United States.

NEOSPOROSIS

Etiology

Neosporosis is a protozoan disease of dogs caused by *Neospora caninum,* a coccidian parasite that resembles the appearance of *Toxoplasma* and has a similar life cycle. Dogs and wild canids are definitive hosts, and other animals (especially cattle) are intermediate hosts.

- Dogs are infected by ingesting meat infected with tissue cysts containing bradyzoites or by transplacental transmission.
- Rapidly replicating tachyzoites disseminate and produce necrotizing lesions in many tissues or cause transplacental infection of a developing fetus. Clinical disease in dogs primarily reflects neuromuscular infection.
- As the definitive host, the dog completes the life cycle in its intestines and sheds fecal oocysts that become infective in the environment within 24 hours of passage.

- Clinical disease has not been seen in cats, but experimentally infected kittens develop encephalomyelitis and polymyositis.
- *N. caninum* has worldwide economic importance as a major cause of abortion in dairy cattle.

Clinical Signs

Multifocal, progressive neuromuscular signs predominate as a result of non-suppurative encephalomyelitis, polyradiculoneuritis, and fibrosing polymyositis.

- Clinical signs can include hind-limb paresis and ataxia progressing to ascending paralysis, hind-limb extensor rigidity, and muscle atrophy and contracture. Dysphagia and masticatory muscle involvement can be seen.
- Less common manifestations include myocarditis (arrhythmias), pneumonia (fever, dyspnea, cough), ulcerative or pruritic dermatitis, chorioretinitis, and multifocal intra-abdominal dissemination (hepatitis, pancreatitis).

▼ ***Key Point*** Subclinically infected bitches can transmit *Neospora* in utero to successive litters of puppies. Congenital neosporosis is particularly severe and often leads to in utero or neonatal puppy mortality.

Laboratory and Radiographic Findings

- Muscle involvement may cause increased serum levels of muscle enzymes (CK, AST) and abnormal electromyographic findings.
- CSF shows a moderately increased protein (20 to 150 mg/dl) and increased leukocytes (10 to 100 cells/μl) composed of a mixture of small and large mononuclear cells and neutrophils.
- Thoracic radiographs may show interstitial and alveolar infiltrates.

Diagnosis

- Presumptive diagnosis is based on the combination of compatible clinical signs and a *Neospora* antibody titer of >1:200 using immunofluorescent antibody (IFA) or ELISA. Serologic crossreactivity with *Toxoplasma* is minimal.
- Rarely, the diagnosis can be confirmed by identification of *Neospora* tachyzoites in cytologies of CSF, skin lesions, or BAL or in biopsies of infected tissues (e.g., muscle). Oocysts can be detected by fecal flotation or PCR, but oocyst shedding is not found in dogs with overt clinical disease. *Neospora* organisms can be distinguished from *Toxoplasma* by PCR, immunohistochemistry, or electron microscopy.

Treatment

Neosporosis is treated similar to toxoplasmosis using one or a combination of both of the following regimens.

- Clindamycin (15 mg/kg PO q12h) for 28 days
- Trimethoprim-sulfadiazine (15–20 mg/kg PO q12h) combined with pyrimethamine (0.5 mg/kg PO q12h) for 28 days

Treat all littermates of infected puppies. The prognosis for dogs with severe neurologic involvement is grave, and animals that recover usually have residual neurologic deficits.

Prevention and Public Health

- Do not breed dogs with a history of whelping infected puppies.
- Avoid glucocorticoids in seropositive dogs because of the potential for activating encysted infection.
- *Neospora* is seroprevalent in white-tailed deer; thus, do not let dogs have access to deer carcasses.
- Do not allow dogs to have access to bovine placental tissues (afterbirth) or aborted fetuses.
- Because *Neospora* infection has a large economic impact as a cause of bovine abortion, prevent dog feces from contaminating livestock feed and water.
- *Neospora caninum* antibodies have been detected in people, but it is not yet clear whether *Neospora* is a cause of zoonotic disease.

HEPATOZOONOSIS

Etiology

Hepatozoonosis is a tick-transmitted protozoan disease of dogs caused by *Hepatozoon americanum* or *Hepatozoon canis*. Ticks become infected during feeding on an infected dog. The infection is then transmitted to a new canine host when the tick is ingested, not by the tick bite.

- *H. americanum* is most common in North America and is transmitted by the Gulf Coast tick, *Amblyomma maculatum*. Infection is endemic in southern states in the Gulf Coast region (Texas, Oklahoma, Louisiana, Mississippi, Alabama, Florida, and Georgia).
- *H. canis* is transmitted by the brown dog tick, *Rhipicephalus sanguineous*, and occurs in Southern Europe, the Middle East, Africa, and Asia.

▼ ***Key Point*** *H. americanum,* the etiology of American hepatozoonosis, causes a more severe form of clinical disease than *H. canis,* which usually causes subclinical or mild disease.

- Uncharacterized *Hepatozoon* spp. have been reported sporadically in cats.

Pathogenesis

After an infected tick is ingested, *H. americanum* organisms disseminate widely and form numerous distinctive tissue cysts, especially in the muscles. The organisms

replicate until cysts rupture, eliciting a severe pyogranulomatous inflammatory response and disseminating more organisms to form new cysts.

▼ ***Key Point*** American hepatozoonosis is a chronic debilitating illness characterized by waxing and waning fever, extreme leukocytosis, polymyositis, proliferative periosteal bone lesions, and severe cachexia.

In contrast, *H. canis* has relatively low pathogenicity; clinical signs are absent or mild in many infected dogs. Severe disease is mostly limited to dogs with concurrent disease or immunosuppression. Muscle and periosteal involvement do not occur with *H. canis,* but organisms are frequently seen in circulating leukocytes.

Clinical Signs

Clinical signs begin within 4 weeks of ingesting an infected tick and continue to wax and wane as more organisms are released into muscle tissue, exacerbating myositis, muscle pain, and fever.

- Fluctuating fever (>104°F) and lethargy
- Myalgia, stiffness, lameness, painful gait, reluctance to move
- Hyperesthesia over the paraspinal muscles
- Progressive weight loss, weakness, and muscle atrophy
- Mucopurulent ocular discharge with each flare-up
- Transient bloody diarrhea
- Possible protein-losing glomerulonephropathy (due to immune complex glomerulonephritis or amyloidosis) in advanced cases

Laboratory and Radiographic Findings

The presumptive diagnosis of hepatozoonosis in dogs from endemic areas is based on the combination of typical clinical signs (fever, pain, and muscle wasting), extreme leukocytosis, typical serum chemistry abnormalities, and characteristic periosteal bone lesions on radiographs.

- The most characteristic hematologic finding is extreme neutrophilic leukocytosis (mean 75,000 to 85,000/µl; range 20,000 to 200,000/µl), consisting of mostly mature neutrophils with a mild left shift. Mild normocytic-normochromic nonregenerative anemia is also common. The platelet count is usually normal to increased. Dogs with thrombocytopenia should be evaluated for other concurrent tick-borne infections (see Chapter 17).
- Common serum chemistry abnormalities are increased alkaline phosphatase, hypoglycemia (in vitro artifact of high white blood cell count), hypoalbuminemia, and hyperglobulinemia.
- Radiographically, most dogs infected with *H. americanum* develop diffuse periosteal bony proliferations, most pronounced on the pelvis, long bones of the limbs, and vertebrae. The periosteal lesions may appear as smooth, lamellar thickening of the bone or irregular proliferations.

Diagnosis

▼ ***Key Point*** Muscle biopsy is the most reliable means of confirming American hepatozoonosis.

- Definitive diagnosis is based on visual identification of tissue stages of *H. americanum* organisms, which are most reliably found in skeletal muscle biopsies and rarely in circulating leukocytes on Giemsa-stained blood smears. In contrast, blood smears are usually diagnostic for *H. canis* infection.
- An ELISA-based serologic test for *H. americanum* has a sensitivity of 93% and specificity of 96%.

Treatment

No treatment has been found to effectively eliminate *H. americanum* from infected tissues in dogs. However, the following treatment has been shown to prolong survival and control clinical signs for extended periods, even years. Pain and fever improve within 48 hours of initiating treatment.

- For *H. americanum,* use the combination of clindamycin (Antirobe) (10 mg/kg PO q8h), trimethoprim-sulfadiazine (Tribrissen or Ditrim) (15 mg/kg PO q12h), and pyrimethamine (Daraprim) (0.25 mg/kg PO q24h) for 2 weeks to establish remission; and follow this with decoquinate (Deccox, Alpharma) (10–20 mg/kg PO q12h, mixed with food) for 2 years and possibly lifelong to maintain remission and prevent relapses. Decoquinate, an anticoccidial livestock feed additive, decreases recurrences by inhibiting development of the organisms released from tissue cysts, thereby preventing repeated cycles of reinfection and illness.
- Use nonsteroidal anti-inflammatory drugs as needed for pain and fever.
- Avoid corticosteroids because they can worsen the disease.
- For *H canis,* imidocarb dipropionate (Imizol) (5–6 mg/kg IM or SC, two doses 2 weeks apart) is highly effective and considered the drug of choice. It may be effective for *H. americanum.* Pretreatment with atropine (0.04 mg/kg SC), 30 minutes prior to imidocarb injections, reduces the parasympathomimetic side effects of imidocarb.

Prevention and Public Health

- Prevention depends on minimizing tick exposure, using an effective tick preventative product on dogs in endemic areas, and routinely checking dogs for ticks and removing them promptly.

- Zoonotic transmission from dogs to people does not appear to occur.

LEISHMANIASIS

Etiology

Leishmania spp. are flagellated protozoan parasites that cause vector-transmitted cutaneous and visceral diseases in dogs, humans, and other mammals. In most areas of the world, rodents and dogs serve as reservoir hosts, and infection is transmitted by sand fly vectors. Leishmaniasis occurs worldwide and is endemic in the Mediterranean region of Europe and South America. *Leishmania infantum,* a member of the *Leishmania donovani* complex, is the most frequently reported cause of visceral leishmaniasis in dogs.

▼ ***Key Point*** Visceral leishmaniasis is endemic in North American foxhounds and foxhound kennels.

- Other dog breeds have also been infected sporadically in North America. The source of infection in most of these cases has been traveling or living in an endemic country or importation from an endemic country.
- Cats are usually subclinically infected or only develop cutaneous leishmaniasis.
- Infection can also be transmitted iatrogenically by transfusion of contaminated blood.

Clinical Signs

Sand flies transmit infection during feeding on the host. Intracellular organisms (amastigotes) are disseminated by macrophages and cause cutaneous lesions, polysystemic vasculitis, lymphoreticular hyperplasia, hyperglobulinemia, and immune complex disease of the kidneys and joints. Dogs have subclinical infection for months to several years before developing clinical signs. Visceral leishmaniasis with cutaneous involvement is the most common form of disease in dogs.

- Fever, chronic weight loss, muscle wasting (despite normal appetite)
- Vomiting, diarrhea, melena
- Hepatosplenomegaly, generalized lymphadenopathy
- Ulcerative or granulomatous dermatitis characterized by non-pruritic facial alopecia, hyperkeratosis, scaling, mucocutaneous ulcers, and intradermal nodules on the muzzle, pinnae, ears, and foot pads
- Elongated brittle toe nails
- Anterior uveitis, conjunctivitis, blepharitis
- Cough; sneezing (rhinitis), epistaxis
- Neutrophilic polyarthritis (lameness, swollen painful joints)
- Glomerulonephritis, polyuria-polydipsia, renal failure
- Icterus

Laboratory Findings

- Hematologic findings are thrombocytopenia, anemia, lymphopenia, leukocytosis with a left shift, and occasional positive Coombs test.
- Other lab findings are polyclonal hyperglobulinemia (sometimes monoclonal), hypoalbuminemia, proteinuria, azotemia, increased serum liver enzymes, and the presence of antinuclear antibodies (ANAs).

Diagnosis

Presumptive diagnosis of leishmaniasis is based on clinical signs, international travel history, breed (foxhound), and antibody titer. Confirmation is based on cytologic identification of organisms (especially bone in marrow), detection of *Leishmania* DNA by PCR assay, or protozoal culture.

- Antibody titers develop 2 to 4 weeks after infection and decline 1 to 3 months after treatment. Infections are considered persistent; thus, a positive IFA antibody titer (≥1:64) is indicative of current "active" infection. Dogs occasionally have false-negative titer results. Trypanosoma causes crossreacting antibodies.
- Definitive diagnosis can be established in some dogs by cytologic identification of organisms (amastigotes; 2.5 to 5 µm × 1.5 to 2 µm) in aspirates of bone marrow (60% of cases), lymph nodes (30% of cases), or spleen; in impressions of skin lesions; or by the presence of organisms in biopsies of skin or infected organs.
- Confirmation can also be based on PCR detection of *Leishmania* DNA in aspirates of bone marrow (the specimen of choice), lymph nodes, or spleen. Blood PCR is useful but less reliable than bone marrow. Both antibody titers and PCR assay are available to practicing veterinarians through the Vector Borne Disease Diagnostic Lab at North Carolina State University. Submission requirements and forms are available at *http://www.cvm.ncsu.edu/docs/tickbornediseaselab.html.*
- The U.S. Centers for Disease Control, Division of Parasitic Diseases (CDC, Atlanta, GA; telephone: 770-488-4475) also provides diagnostic confirmation, including protozoal culture using bone marrow or lymph node aspirates.

Treatment

▼ ***Key Point*** Treat leishmaniasis with an antimonial drug plus allopurinol for inducing remission, followed by long-term allopurinol to prevent relapse.

Leishmania infection can often be controlled with medical therapy, but it is usually not curable in dogs. Since the organisms are not eliminated by treatment, relapses are common a few months after treatment is stopped. The prognosis for remission is variable. Dogs

with renal disease have a poor prognosis. The following drug regimens are recommended:

- *Allopurinol* (Zyloric, Glaxo): 15 to 20 mg/kg PO q12–24h, initially combined with sodium stibogluconate or meglumine antimonite, then continued alone for several months to maintain remission.
- *Sodium stibogluconate* (Pentostam, Wellcome): 30 to 50 mg/kg IV or SC q24h, combined with allopurinol, for 3 to 4 weeks or until resolution of signs and lab abnormalities; available in the United States through the CDC at *http://www.cdc.gov/ncidod/srp/drugs/drugservice.html.*
- *Meglumine antimonite* (Glucantime, Merial; available in Europe): 100 mg/kg IV or SC q24h, combined with allopurinol, for 4 weeks or until resolution of signs and lab abnormalities.
- *Amphotericin B lipid complex* (ABLC) (Abelcet, Enzon) at 3 mg/kg IV q48h (3 times weekly) for a minimum of five treatments. ABLC can be used as an alternative to antimonials in animals with good renal function. Dilute in 5% dextrose to a concentration of 1 mg/ml and infuse over 1 to 2 hours (see Chapter 20). Liposome-encapsulated amphotericin (AmBisome, Gilead Sciences) is a more expensive alternative.

Prevention and Public Health

- In endemic regions, avoid sand flies, especially at night when they feed, and use insecticides as premise sprays and topical applications to dogs. Deltamethrin collars are highly effective. Permethrin spray is also effective.
- Screen potential blood donors to prevent iatrogenic transmission.
- Direct contact with infected dogs is unlikely to pose a risk of human infection; however, dogs serve as a reservoir for infection of sand flies that can transmit infection to people. In highly endemic countries, control of canine infections is key to reducing leishmaniasis in people.

OTHER PROTOZOAL INFECTIONS

Other systemic protozoal infections are summarized in Table 21-1.

22 Erythrocytes, Leukocytes, and Platelets

Rose E. Raskin

ERYTHROCYTE DISORDERS

Anemia: Overview

Anemia is characterized by a reduction in the overall erythrocyte content, number of erythrocytes, or hemoglobin concentration. It is one of the most frequent hematologic abnormalities encountered in practice. Anemia is not a disease but rather the reflection of a disease state. Causes of anemia may be divided into three general categories: blood loss, hemolysis, and decreased erythrocyte production.

▼ ***Key Point*** Determine the cause of the anemia before giving supportive treatment.

Clinical Signs

- Primary signs of anemia relate to the reduction in oxygen-carrying capacity of the blood. The patient may present with lethargy, weakness, anorexia, heart murmur, tachypnea, and pale mucous membranes.
- Occasionally, the animal may appear normal, but routine blood evaluation before an elective surgical procedure may uncover the abnormality. Sedentary animals, especially cats, often have moderate anemia that goes unnoticed for long periods.
- Secondary signs of anemia often relate to the effects of increased blood cell destruction, such as icterus, splenomegaly, and hepatomegaly from extravascular hemolysis or extramedullary hematopoiesis and discolored urine from the effects of hemoglobin or excess bilirubin excreted.

Principles of Diagnosis

Several tests can be used to document and characterize the anemia morphologically or etiologically.

History and Physical Examination

Use the history and physical examination to determine the following:

- Occurrence of trauma or surgery
- Drug, chemical, or toxin exposure
- Underlying infectious, parasitic, or neoplastic disease
- Duration of disease, sites of blood loss, and presence of organomegaly

Complete Blood Count (Table 22-1)

- Packed cell volume (PCV) is the most accepted and least expensive method of documenting anemia. Spin microhematocrit tubes 5 minutes at a rate of 12,000 to 15,000 $\times g$ and measure the proportion of the concentrated cell population of the total plasma volume. Evaluate the plasma color after centrifugation. Alternatively, the hematocrit (Hct) can be calculated by multiplying the number of the erythrocytes in mil-

Table 22-1. HEMATOLOGY REFERENCE RANGES FOR DOGS AND CATS*

Parameter	Canine	Feline
PCV or Hct (%)	37–55	30–45
Hemoglobin (g/dl)	12–18	8–15
RBCs ($\times 10^6$/µl)	5.5–8.5	5–10
MCV (fl)	60–75	40–55
MCHC (g/dl)	32–36	30–36
Reticulocytes ($\times 10^3$/µl)	<80	<60 aggregate
Platelets ($\times 10^3$/µl)	200–900	300–700
WBCs ($\times 10^3$/µl)	6–17	6–18
Segmented neutrophils ($\times 10^3$/µl)	3–12	3–12
Band neutrophils (/µl)	0–300	0–300
Lymphocytes (/µl)	1000–5000	1500–7000
Monocytes (/µl)	150–1350	50–850
Eosinophils (/µl)	100–1250	100–1500
Basophils (/µl)	<100	<100
Plasma protein (g/dl)	6.0–8.0	6.0–8.0
Fibrinogen (mg/dl)	200–400	150–300

*These values are only meant as a guide; individual laboratories may vary in their ranges, depending on instrumentation and regional differences in animal populations.
Hct, hematocrit; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume; RBCs, red blood cells; WBCs, white blood cells.
Source: Purdue University, Veterinary Clinical Pathology Laboratory.

lions by the mean cell volume divided by 10. There may be 1 to 3 percentage units increased in PCV over Hct related to trapped plasma.

- Determine plasma protein or total solids by refractometer.
- Erythrocyte, or red blood cell (RBC), count usually is performed by an automated cell counter. This value is necessary for calculation of the erythrocyte indices.
- Hemoglobin (Hgb) concentration in grams per deciliter is determined most accurately by the cyanmethemoglobin method, using a colorimeter or spectrophotometer. Artifactual increases may occur with gross lipemia or an excessive number of Heinz bodies, both of which produce light interference.
- Mean cell or corpuscular volume (MCV) may be determined directly by the automated cell counters, or it may be calculated as follows: MCV (femtoliters) = PCV × 10 divided by RBC (10^6/µl).
- MCV reflects erythrocyte size and may be categorized as *macrocytic,* suggesting increased red cell turnover; *microcytic,* suggesting defective cell growth; or *normocytic,* unchanging cell size. Note that Akita and Shiba dogs normally have microcytic erythrocytes, while some toy and miniature poodles, as well as greyhounds, may have macrocytic erythrocytes.
- Other erythrocyte indices such as mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) help classify the types of anemia into *normochromic* and *hypochromic.* Decreased levels reflect the presence of reticulocytes or abnormal hemoglobinization. Increased levels occur artifactually from hemolysis. MCH may be calculated by dividing Hgb by RBC (10^6/µl) and multiplying this by 10, but it provides no additional value than MCHC, which is calculated by dividing Hgb by PCV and multiplying by 100.
- Blood smear evaluation involves quantitation of changes in size *(anisocytosis),* shape *(poikilocytosis),* and color *(polychromasia).* The presence of immature nucleated forms and basophilic stippling often signals abnormal erythropoiesis or defective circulation of erythrocyte precursors. Infectious parasites and Heinz bodies often require careful examination of the smear.

▼ ***Key Point*** The most important part of the complete blood count (CBC) is an evaluation of the blood smear for morphologic abnormalities.

Reticulocyte Count

This is the most accurate method to evaluate regeneration. Perform reticulocyte counts when the PCV falls below 30% in dogs and 20% in cats.

- Incubate equal volumes of blood and 0.5% new methylene blue stain together for 15 to 20 minutes; then make a routine blood smear and count the number of aggregate and punctate forms per 1000 erythrocytes. Absolute numbers of reticulocytes per microliter are calculated by the following formula:

$$\text{Absolute reticulocyte count/µl} = \text{Reticulocyte percentage} \times \text{RBC/µl}$$

- Dogs normally have 0% to 1% reticulocytes (0–80,000/µl). In healthy cats, aggregated reticulocytes range from 0% to 0.4% (0–60,000/µl) and punctate reticulocytes are less than 5% (<500,000/µl). Aggregate reticulocytes represent the most active or recent form of regeneration in the dog and cat. Punctate reticulocytes in cats, which do not stain as polychromatophilic cells, represent regenerative attempts that occurred 2 to 4 weeks previously.
- By using the PCV instead of the erythrocyte count, a corrected reticulocyte percentage may be calculated as follows:

$$\text{Corrected \% reticulocytes} = \text{\% Reticulocytes} \times \{\text{Patient's PCV/Normal PCV}\}$$

- Normal PCV is considered 45% for dogs and 35% for cats. A corrected percentage for a reticulocyte value greater than 1% indicates increased RBC regeneration. Once initiated at the bone marrow level, regeneration may take at least 3 days before reticulocytes appear in the circulation.

Fecal Examination and Urinalysis

These tests are performed to determine sources of blood loss and function of the kidney.

Biochemical Profile

Biochemical profiles may reveal organic disease that can affect the ability to regenerate erythrocytes.

Bone Marrow Evaluation

Bone marrow evaluation is necessary whenever regenerative attempts appear diminished. Hemolytic conditions do not warrant marrow examination unless the response is less than normally expected. Results always must be compared with a concurrent CBC to determine the current status of regeneration.

▼ ***Key Point*** Perform bone marrow evaluation by obtaining both aspirate and core biopsies together because each provides different information.

- This is a sterile procedure that may be performed with only local anesthesia, sedation with reversible analgesia, or general anesthesia.
- Sites frequently used in dogs include the dorsal ilium, humerus (best for obese animals), and femur (small dogs or puppies). Sites frequently used in cats include the femur and dorsal ilium by a transilial or perpendicular approach.

Bone Marrow Aspiration Biopsy Technique

1. Use an Illinois sternal disposable needle, 15 to 18 gauge, 1 to 2 inches long (Cardinal Health, Dublin, OH).
2. Pass the needle with the stylet through the cut skin and subcutaneous tissues and into the bone a few millimeters until it is firmly embedded.
3. Place a 12-ml syringe containing 0.5 ml of 5% ethylenediaminetetraacetic acid (EDTA) solution onto the biopsy needle and collect 1 to 2 ml of bloody material.
4. Place the marrow material on a plastic Petri dish and pick up the glistening particles with a glass pipette.
5. Gently expel this material out of the pipette onto a glass slide. Make a squash preparation by laying a second slide on the first and sliding them horizontally apart.

Bone Marrow Core Biopsy Technique

1. Use a Jamshidi aspiration biopsy disposable needle, 11 to 13 gauge, 2 to 4 inches long (Cardinal Health, Dublin, OH).
2. Pass the needle with the stylet through the cut skin and subcutaneous tissues.
3. Remove the stylet while advancing the needle 0.5 to 1.5 cm into the bone, depending on the size of the animal.
4. Twist the instrument sharply to cut the sample, and withdraw the needle slowly.
5. Remove the core sample and roll it onto a glass slide for cytologic examination; then place the sample in 10% buffered formalin for histologic fixation.

Principles of Transfusion Therapy

Therapy depends on the etiology of the anemia. Rapid decreases in PCV warrant replacement of whole blood. However, slow daily decreases in PCV of 1% to 3% may not cause clinical signs of dyspnea or weakness. Whole blood transfusion is discussed here, and blood component therapy is discussed in Chapter 23.

Cross-matching

Perform cross-matching before transfusion. The procedure, which involves collection of erythrocytes and serum or plasma from the donor and the patient, is as follows:

- Wash erythrocytes and pellet 3 times in 0.9% saline.
- Make a 4% cell suspension by adding 4.8 ml of saline to 0.2 ml of cells.
- Measure compatibility between donor and patient optimally at three temperatures: 37°C, 20°C, and 4°C.

▼ ***Key Point*** Perform cross-matching prior to all blood transfusions to prevent incompatibility reactions.

- Donors are incompatible if any agglutination or hemolysis occurs in the major cross-match. The types of cross-match are defined as follows:
  - *Major:* 100 µl donor cells + 100 µl patient serum/plasma
  - *Minor:* 100 µl patient cells + 100 µl donor serum/plasma
  - *Donor or patient controls:* 100 µl of donor or patient cells to 100 µl of donor or patient serum/plasma, respectively
- Under emergency conditions, donors may be used if mild agglutination occurs in the minor cross-match.

Cross-matching Procedure:

- After 15 minutes of incubation, centrifuge tubes at 280 ×*g* for 1 minute.
- Note any hemolysis in supernatant and gross agglutination of resuspended cells.
- Place a small drop on glass slide and examine for microscopic agglutination.

Whole Blood Transfusion

- In dogs, this procedure is best performed using animals negative for the dog erythrocyte antigen DEA-1 and DEA-7 blood types.
- Although most cats have type A blood, it is best to cross-match blood, because as little as 1 ml of mismatched blood can cause a fatal transfusion reaction in cats.
- Estimated dosage is 10 to 20 ml/kg in dogs or cats, with a maximum of 40 ml in an adult cat. A more specific guideline for the amount of donor blood in anti-

coagulant (ml) is as follows: kg × 80 (dog) or 60 (cat) × (desired PCV – patient PCV) divided by donor PCV.
- When performing whole blood transfusion, use appropriate filters and administration sets to retain clotted blood or debris.
- Warm blood before administration.
- For the first 30 minutes, keep the initial rate of administration slow (0.25 ml/kg) to observe any incompatibility reactions (recommended rate of whole blood infusion in general is 10 ml/kg/hour). The rate of infusion depends on the hydration status of the patient.
- Evaluate the hematocrit before and after transfusion to document relative improvement and to screen for hemolysis as an indicator of incompatibility.

Blood Loss Anemia

Large volumes of blood must be lost before appreciable changes occur in the numbers of erythrocytes or PCV. The immediate loss of blood results in little or no change to the PCV owing to the concurrent loss of erythrocytes and plasma fluids. Over the course of several hours to days, redistribution of fluids occurs, resulting in a lowered PCV and plasma protein. Depending on the amount of blood lost and the time period over which it is lost, regenerative responses may range from moderate to extremely weak. Chronic blood loss causes decreased iron stores, resulting in decreased erythrocyte production.

Etiology

Causes of blood loss include the following:

- Trauma
- Surgery
- External and internal parasitism
- Gastric ulcers
- Tumors of the gastrointestinal (GI) and urinary systems
- Splenic rupture
- Coagulation abnormalities

Treatment

Administer cross-matched whole blood for *acute* hemorrhage when the PCV drops to 20% to 25% in the dog or cat. Also consider autotransfusion if hemorrhage has occurred recently in a body cavity and the blood is not contaminated with bacteria or neoplastic cells.

Hemolytic Anemia

Causes of hemolytic anemia include congenital abnormalities, immune-mediated destruction, infections, chemical or toxic agents, mechanical fragmentation, and hypophosphatemia. The net effect of hemolytic loss of erythrocytes is often a very strong to moderate regenerative response (Fig. 22-1). However, in some cases, the anemia may occur so rapidly that the animal may have too little time to mount a regenerative response by the time the condition is recognized.

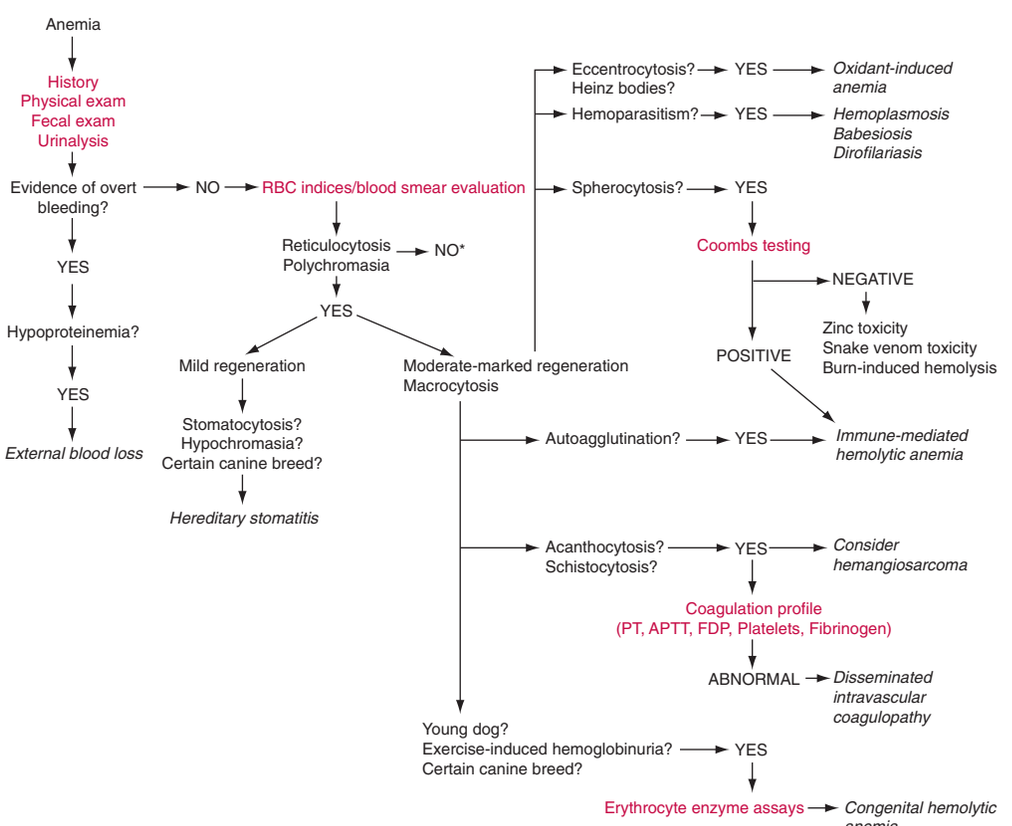

Figure 22-1. Diagnostic approach to common regenerative anemias in dogs and cats.* See Figures 22-2 and 22-3. (APTT, activated partial thromboplastin time; FDP, fibrin degradation product; PT, prothrombin time.)

▼ ***Key Point*** A period of 2 to 3 days is necessary for erythrocyte maturation and reticulocytosis once the stimulation from hypoxia or severe erythrocyte depletion has occurred.

- Depending on the severity or acuteness of the destruction and the conjugating ability of the liver, icterus may or may not be present.
- Plasma protein concentrations usually are normal.

Congenital Erythrocyte Abnormalities

Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is an erythrocyte enzyme deficiency associated with an autosomal recessive inheritance. During anaerobic glycolysis, pyruvate kinase is necessary for the production of adenosine triphosphate (ATP), which erythrocytes need to maintain their integrity and viability.

- The condition has been documented in several dog breeds, including the basenji, beagle, West Highland white terrier, Cairn terrier, American Eskimo dog, miniature poodle, Chihuahua, and pug.
- It has been reported in Abyssinian, Somali, and domestic shorthaired cats.

Clinical Signs

- Young animals usually present with anemia, exercise intolerance, tachycardia, and splenomegaly. The outcome of the disease is usually death by 4 years of age.
- Myelofibrosis and osteosclerosis may occur, resulting in reduced hematopoiesis.
- Frequent erythrocyte destruction may lead to hemosiderosis and failure of organs such as the liver.

Diagnosis

This disease is suggested clinically by the presence of an intense reticulocytosis (15–50%), along with frequent nucleated red cells in a young dog. Echinocytosis or erythrocytes with sharp projections unrelated to crenation may be seen in circulation.

- Polymerase chain reaction (PCR) based genetic tests are currently available for the basenji, West Highland white terrier, and Cairn terrier to detect affected and carrier animals.
- Definitive diagnosis for other breeds requires a special erythrocyte assay for the enzyme.

Phosphofructokinase Deficiency

Phosphofructokinase deficiency has been identified in English springer and American cocker spaniels as an autosomal recessive inheritance. This glycolytic enzyme deficiency causes a decrease in 2,3-diphosphoglycerate (2,3-DPG) concentration, resulting in an increase in intracellular pH. Erythrocytes from affected animals are especially fragile under alkaline conditions.

- Intravascular hemolysis may occur during hyperventilation-induced alkalemia, resulting in periodic bouts of hemoglobinuria and sometimes bilirubinuria.
- A constant state of hypoxia is produced by the low levels of 2,3-DPG, with subsequent increased oxygen binding to hemoglobin.
- The result is persistent reticulocytosis (10–30%) even though the PCV is normal or mildly decreased, except during hemolytic episodes.

Clinical Signs. The clinical signs may involve lethargy, pale or icteric mucous membranes, mild hepatosplenomegaly, myopathy, and fever. Dogs may have a normal life span if properly managed.

Diagnosis. The enzyme deficiency is diagnosed by specialized erythrocyte assays in homozygous and heterozygous animals. A PCR-based test is available to screen for affected and carrier animals of any age.

Hereditary Stomatocytosis

Hereditary stomatocytosis is an autosomal recessive trait in Alaskan malamutes associated with chondrodysplasia. The defect may involve abnormalities of the cell membrane or of ion transport, leading to increased water content and a larger cell size (96 fl). Morphologically, some erythrocytes appear to have a slit-like or mouth-like area of central pallor.

- Dwarfism is recognized clinically in affected Alaskan malamutes, and there is a mild hemolytic anemia and slight reticulocytosis (2%). Erythrocyte numbers are reduced, but the PCV remains normal because of enlarged erythrocytes.
- Other breeds associated with congenital stomatocytosis include Drentse Patrijshonds and miniature and giant schnauzers.

Feline Porphyria

Feline porphyria is an infrequent inheritable trait that results in an enzyme deficiency affecting heme synthesis.

- Clinical signs include pink urine, pinkish-brown teeth, and severe anemia resulting from the deposition of red non-heme pigments and the lysis of erythrocytes when exposed to sunlight. Skin photosensitization can occur; therefore, exposure to sunlight should be avoided.
- Discolored teeth often display red fluorescence under ultraviolet light.
- The disease can be prevented by not breeding carrier animals.

Hereditary Non-spherocytic Hemolytic Anemia

Hereditary non-spherocytic hemolytic anemia is recognized in two breeds: poodles and beagles. In both

breeds, erythrocytes are morphologically normal and enzyme activities are not affected.

Poodles. Poodles develop an autosomal dominant condition that resembles pyruvate kinase deficiency, but decreases in this enzyme are not demonstrable. Affected animals have a persistent macrocytic hypochromic anemia (PCV of 13–31%) with moderate reticulocytosis. It is clinically evident by 1 year of age and fatal by 3 years of age. Myelofibrosis, osteosclerosis, and hemosiderosis are present at death.

Beagles. In beagles, the condition presents with chronic anemia and moderate reticulocytosis. The mode of inheritance is likely autosomal recessive. The disease is less severe in beagles than in poodles, and the disorder can remain subclinical for up to 4 years in affected dogs. The short erythrocyte life span in beagles may be caused by an unidentified membrane abnormality.

Immune-Mediated Hemolytic Anemia

See the chapter on systemic immune-mediated diseases (Chapter 24).

Infectious Causes of Hemolysis

Hemoplasmosis

Hemoplasmosis or hemotrophic mycoplasmosis, previously known as hemobartonellosis, is caused by a mycoplasma organism that infects the erythrocytes of dogs *(Mycoplasma haemocanis)* and cats *(M. haemofelis* and *"Candidatus M. haemominutum").* It can be transmitted by ticks and fleas or by queens to their newborn kittens in the absence of blood-sucking arthropods. Splenectomy (especially in the dog), immunosuppression caused by glucocorticoid therapy, or stress in cats with latent *M. haemofelis* infection predispose to the development of clinical disease in the animal infected by the organism.

Clinical Signs. Clinical signs include those generally observed with anemia. Weight loss may occur if the anemia develops slowly, whereas acute, severe anemia produces sudden depression and icterus. Splenomegaly often is noted.

Diagnosis. Laboratory findings generally reflect a strong regenerative response in the CBC. The absence of marked anisocytosis or polychromasia in confirmed cases of feline hemoplasmosis may suggest peracute infections with too little time to respond or concurrent infection with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV).

- Thin smears, made directly without anticoagulant, assist in finding the epicellular organisms. Blood films should be well stained without precipitate to minimize any confusion in identifying the parasite.
- Cats often have coccoid or ring shapes, whereas dogs mostly have linear chain forms.
- A positive Coombs test result may be associated with feline hemoplasmosis, presumably because of erythrocyte membrane alteration.
- PCR-based assays are available for the diagnosis of hemoplasma infections in cats.

Treatment

- Consider whole blood transfusion if the anemia is severe.
- Prednisolone (2 mg/kg PO q12h) may be necessary initially to suppress the severe immune-mediated destruction of erythrocytes.
- Doxycycline (5 mg/kg PO q12h for 4 weeks) is preferred for dogs and cats.
- Enrofloxacin (5 mg/kg PO q24h for 14 days) can be used in cats intolerant of doxycycline.
- Cats who recover may become latent carriers.

Babesiosis

Babesiosis is a tick-borne protozoal disease affecting erythrocytes of dogs *(Babesia canis, B. gibsoni). B. canis* is common in kennel conditions and is associated especially with greyhounds. *B. gibsoni* has been associated with pit bull and American Staffordshire terriers. *Babesia felis* has not been reported in North American cats but is reported in Africa and southern Asia. Concurrent infections with other tick-borne agents such as *Ehrlichia canis* are common.

Clinical Signs. Clinical signs in babesiosis range from an acute hemolytic crisis to an unapparent subclinical form. Signs of the acute disease include splenomegaly, icterus, anemia, thrombocytopenia, hemoglobinuria, and fever.

Diagnosis. Initial diagnosis is made by examination of a blood smear.

- A large, clear, teardrop-shaped trophozoite organism in erythrocytes, sometimes seen in pairs, is representative of the three subtypes of *B. canis.*
- A much smaller, signet ring–shaped form occurring singularly and more frequently suggests subtypes of *B. gibsoni* or a Californian isolate genetically similar to *Theileria* species.
- An indirect fluorescent antibody (IFA) serum test is available but may be negative in early infections or display crossreactivity.
- A nested PCR test is most sensitive and can distinguish among canine babesial subtypes.
- A Coombs test is frequently positive in dogs with severe anemia related to a secondary immune-mediated disease.

Treatment. Treat babesiosis with one of the following drugs. The only drug approved in the United States is imidocarb. In general, the small *Babesia* species infections are considered more resistant to treatment and often develop a chronic carrier state.

- Imidocarb dipropionate (Imizol, Schering-Plough) (6.6 mg/kg SC or IM given twice 2 weeks apart)
- Diminazene aceturate (Berenil, Hoechst) (3.5 mg/kg SC or IM given once)
- Phenamidine isethionate (15 mg/kg SC q24h for 2 days)

Leptospirosis

Leptospira serovars can cause kidney disease, liver disease, hemolysis, icterus, and coagulopathies. Toxins released from proliferating organisms interfere with cellular metabolism and damage cells. The clinical findings, diagnosis, and treatment are discussed in Chapter 19.

Chemical or Toxic Injury of Erythrocytes

Oxidant-Induced (Heinz Body) Anemia

Heinz body anemia is produced by oxidant agents that cause precipitation of hemoglobin. Oxidative injury to the iron moiety of hemoglobin (methemoglobinemia) is discussed in a separate section later in this chapter. Accelerated red cell destruction involves intravascular fragmentation or extravascular phagocytosis by the spleen.

Etiology. Chemicals, drugs, or plants associated with Heinz body formation include acetaminophen, methylene blue, onions, vitamin K_3, dl-methionine, zinc, topical benzocaine (e.g., Cetacaine) sprayed on the larynx to aid intubation, and propylene glycol. Heinz body formation in cats also has been associated with ketoacidosis in diabetic cats, hyperthyroidism, and lymphoma.

▼ ***Key Point*** Cats are predisposed to oxidant damage and Heinz body formation because of their hemoglobin structure.

Clinical Signs. Acute hemolysis causes depression, hemoglobinemia, hemoglobinuria, moderate to severe anemia, and occasional icterus.

Diagnosis. Diagnosis is made by observation of a single, large, pale-staining area in erythrocytes of Romanowsky-stained blood smears. They also may appear as a single blunt projection by the Heinz body bulging from the membrane surface. These structures appear as dark blue spots when stained with new methylene blue in a direct wet mount procedure or after incubation of the stain with the blood.

- *Erythrocyte refractile bodies* are similar to Heinz bodies but are smaller, infrequent, and present in normal cats without presence of anemia. Contrast these to many large Heinz bodies with signs of a regenerative response.
- *Eccentrocytosis* is another erythrocyte change associated with oxidative damage resulting in hemolysis, which occurs from fusion of the erythrocyte membrane, producing a thin, colorless portion or hemighost on one side of the cell and a dense, hemoglobin portion on the opposite side. This has been associated with onion and garlic ingestion in dogs.

Treatment

- Remove the source of oxidant exposure. Use emetics if recent ingestion has occurred.
- Give blood transfusions or other forms of supportive care, as indicated.
- For acetaminophen-induced toxicity, give acetylcysteine (Mucomyst, Roxane Laboratories), 140 mg/kg of a 5% solution diluted with saline given IV as a loading dose, then give 70 mg/kg of a 5% solution every 4 hours for three to five treatments.

Snake Venom Toxicity

Snake venom toxicity has been recognized as a cause of hemolysis. Toxins, such as those produced from coral snakes, may be associated with spherocyte formation, in addition to neurologic and coagulation abnormalities.

- Diagnosis is based on the presence of a regenerative anemia and a bite wound with a history supporting recent exposure to a snake.
- For both coral snake and rattlesnake envenomation in dogs, a transient erythrocyte shape change of echinocytosis has been observed.
- Treatment involves use of a specific venom antidote and supportive care.

Zinc Toxicity

Zinc toxicity can produce intravascular hemolysis in dogs. Sources of the zinc include ingestion of galvanized wire or kennel cage nuts and pennies produced since 1983.

- Diagnosis involves the presence of a regenerative anemia and proof of zinc exposure. Spherocytosis and Heinz bodies have been noted in some cases on blood smear evaluation.
- Radiograph the abdomen to identify metallic foreign bodies in the GI tract and remove the source of zinc via surgery or endoscopy.

Mechanical Fragmentation of Erythrocytes

Heartworm Disease

Dirofilariasis may produce anemia after intravascular hemolysis as large numbers of adult heartworms *(Dirofilaria immitis)* obstruct blood flow, causing turbulence that mechanically disrupts erythrocytes.

- Clinical signs reflect the organs affected, such as the lungs, liver, or kidneys.
- Postcaval syndrome results from obstruction of the caudal vena cava causing, in addition to hepatic failure, erythrocyte fragmentation (schistocytosis), hemoglobinemia, and hemoglobinuria.

- Definitive diagnosis is based on detection of circulating microfilaria in the blood or on serologic detection of circulating antigens or antibodies (see Chapter 152).

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy may cause a microangiopathic hemolytic anemia because of fibrin deposition that result from damage to small blood vessels. Mechanical fragmentation of erythrocytes appears in blood smears as schizocytes or spherocytes.

- Etiology involves a variety of conditions, such as neoplasia, infections, necrosis, toxins, and immune complex formation. These can lead to massive tissue destruction and activation of clotting pathways.
- Diagnosis is based on consumption of platelets (thrombocytopenia), reductions in clotting factors (prolonged prothrombin time [PT], activated partial thromboplastin time [APTT], hypofibrinogenemia), and increased amounts of fibrin degradation products (see Chapter 23).
- Treatment is aimed at the inciting condition (see Chapter 23).

Hypophosphatemia

Cases of feline diabetes mellitus and hepatic lipidosis have been associated with hypophosphatemia-induced hemolysis. Heinz body formation may play a role in the development of hemolytic anemia in these cases.

Nonregenerative Anemia

Nonregenerative anemia generally is related to direct toxicity of erythroid precursors in the bone marrow or secondary suppression of erythropoiesis (Fig. 22-2). Often neutrophils and platelets also are affected (Fig. 22-3).

- Reduction in erythrocytes, leukocytes, and platelets in circulation is termed *pancytopenia.*
- The term *aplastic anemia* is used to describe bone marrow failure involving the three cell lines that leads to peripheral pancytopenia. The bone marrow in this condition is severely hypoplastic, with total or near complete replacement of hematopoietic elements by adipose tissue.
- In contrast, crowding from abnormal cellular infiltrates can suppress hematopoiesis, producing *myelophthisis.*

▼ ***Key Point*** Chronic, nonregenerative anemias may not require blood transfusion until the PCV falls below 15% in the dog and 12% in the cat.

Causes of nonregenerative anemia include infectious agents, nutritional disturbances, organic disease, endocrine abnormalities, toxic agents, myelophthisis, irradiation, and immune-mediated destruction.

Infectious Agents

Feline Leukemia Virus

FeLV-associated anemia is usually normochromic and normocytic to macrocytic. Nonregenerative anemia results from bone marrow suppression caused by both primary infection of hematopoietic stem cells and infection of the supporting stromal cells.

- Severe red cell hypoplasia is most common and is associated with depletion and arrest of maturation of erythroid precursors in the bone marrow.
- Approximately 10% of the cases are hemolytic with regeneration related to immune destruction of erythrocytes.
- One type of virus-induced anemia is associated with erythrocyte macrocytosis and is thought to be related to a defect in mitosis during erythrocyte maturation.

Diagnosis. Diagnosis is based on positive enzyme-linked immunosorbent assay (ELISA) or IFA test results (see Chapter 8). Bone marrow aspirate smears or core biopsy sections indicate decreased cellularity with increased fat infiltration when the infection is not associated with a proliferative leukemia.

Treatment. Treatment varies depending on concurrent conditions such as neoplasia, hemoplasmosis, FIV, or feline infectious peritonitis (FIP). Supportive care, in the form of blood transfusions (see "Principles of Transfusion Therapy"), antibiotics, appetite stimulants, and anabolic steroids, is often necessary (see Chapter 8 for additional information on FeLV).

Other Viruses

Other viruses, such as FIP, FIV, feline panleukopenia virus, canine parvovirus, and canine distemper virus, have been associated with suppression of erythropoiesis. The anemia is often mild to moderate and nonresponsive. Other cell lines, such as granulocytes or lymphocytes, are affected more severely. Diagnosis usually is determined by exposure history, clinical signs, virologic or serologic tests, characteristic histopathologic lesions, and identification of viral particles or inclusions within affected cells. In canine distemper virus, erythrocytes or leukocytes may contain one or more pale blue spots in the cytoplasm with Romanowsky-type stains. However, these inclusions stain a deep purple color with aqueous-based Wright stains (e.g., Diff-Quik).

Ehrlichiosis and Anaplasmosis

Ehrlichia spp. and *Anaplasma* spp. are tick-transmitted rickettsial infections that produce chronic polysystemic disease in dogs and cats associated with hyperglobulinemia, thrombocytopenia, mild to moderate nonregenerative anemia, and sometimes leukopenia or pancytopenia in the later stages. The epidemiology,

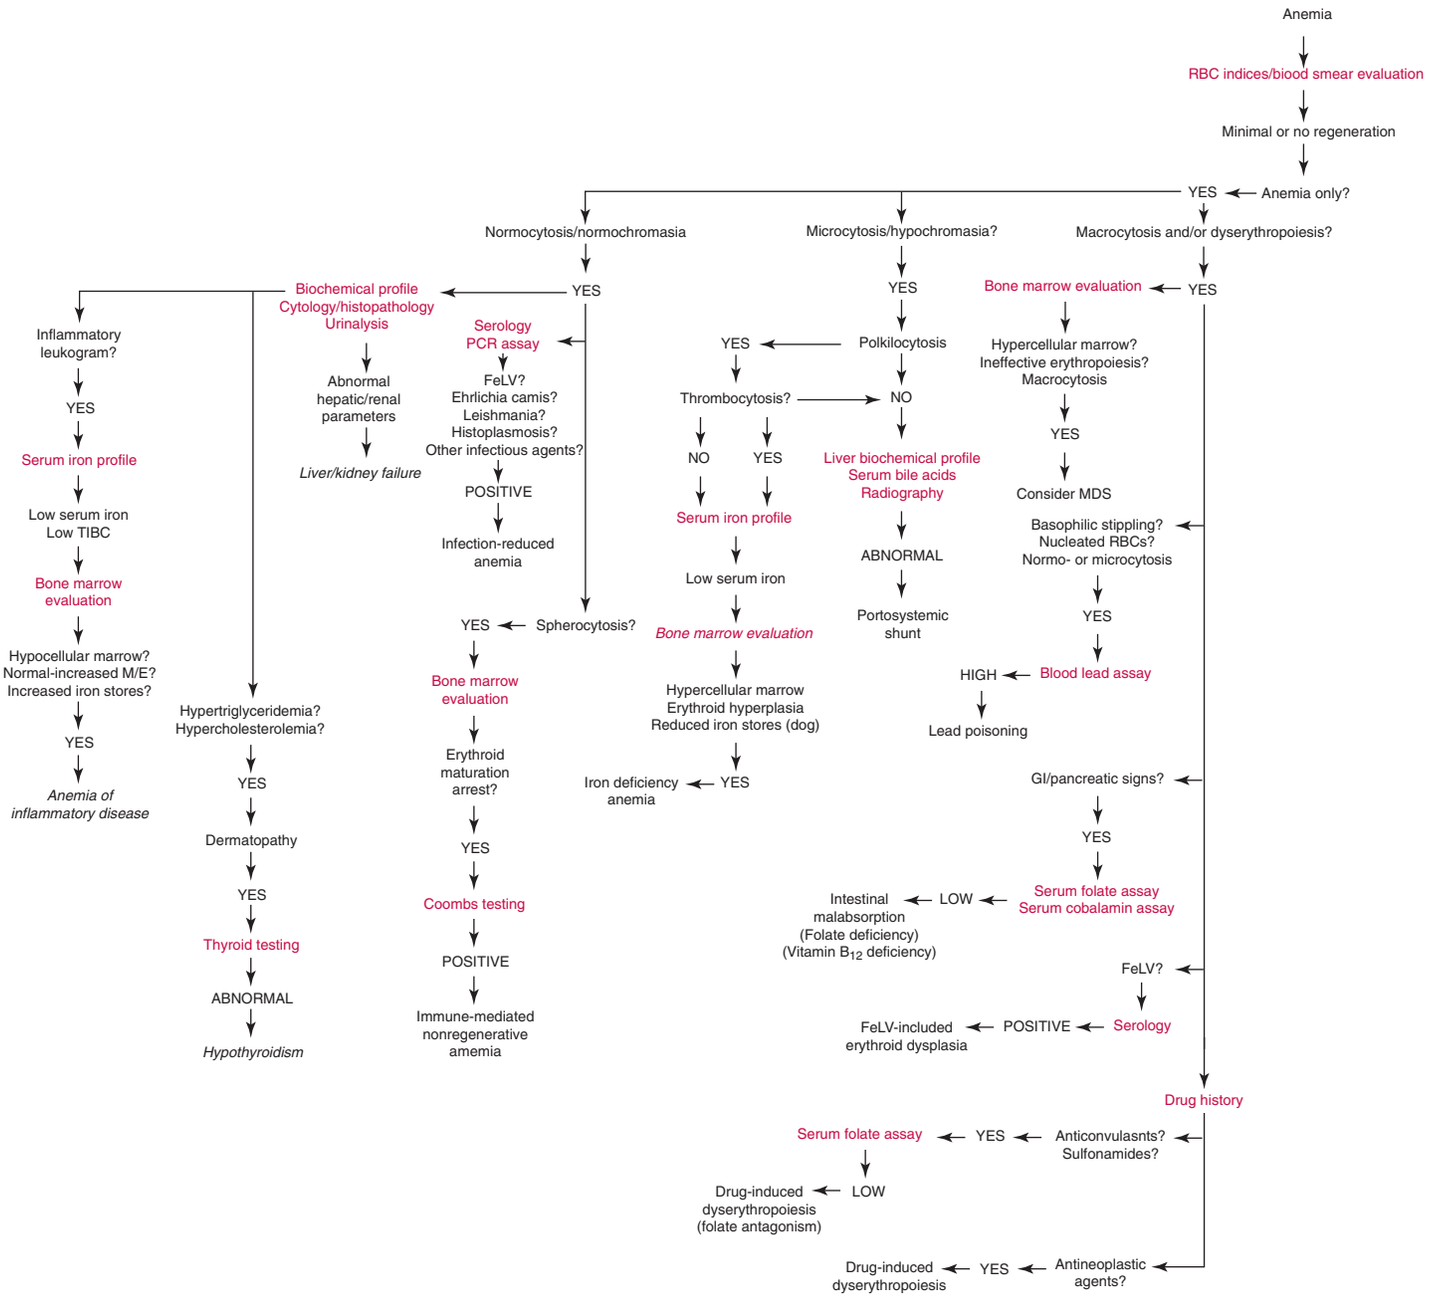

Figure 22-2. Diagnostic approach to common nonregenerative anemias in dogs and cats when only the erythrocyte line is involved. (FeLV, feline leukemia virus; MDS, myelodysplastic syndrome; M/E, myeloid-to-erythroid ratio; PCR, polymerase chain reaction; TIBC, total iron-binding capacity.)

clinical manifestations, diagnosis, and treatment of these infections are described in Chapter 17.

- Intracytoplasmic morulae are found infrequently in mononuclear cells *(E. canis, Ehrlichia chaffeensis)* or granulocytes *(Ehrlichia ewingii, Anaplasma phagocytophilum),* during the acute stage of the disease. Bone marrow, at this time, is often normocellular to hypercellular with increased numbers of megakaryocytes and plasma cells.
- In the chronic or late stages of monocytic ehrlichiosis, bone marrow cellularity decreases severely, with fat replacing hematopoietic elements.

Leishmaniasis

Leishmaniasis is an infrequent protozoal disease in dogs caused by *Leishmania* spp. The parasite, transmitted by sand flies, produces visceral or cutaneous manifestations. Organisms are present in macrophages of the

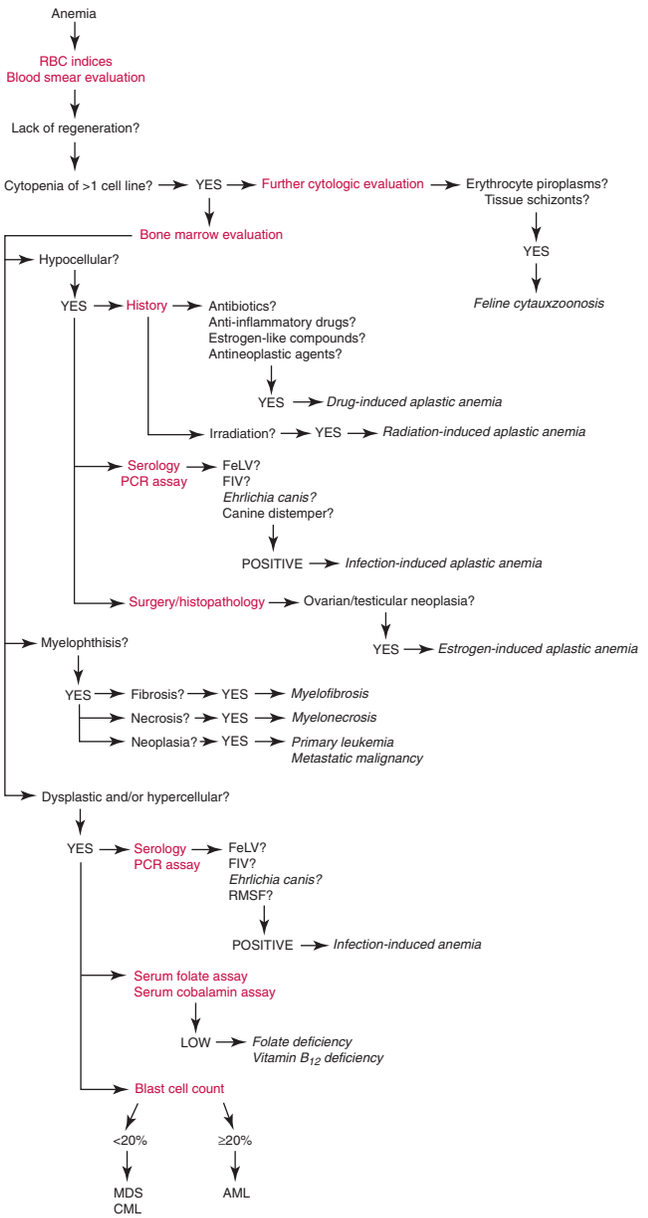

Figure 22-3. Diagnostic approach to common nonregenerative anemias in dogs and cats when multiple cytopenias are present. (AML, acute myeloid leukemia; CML, chronic myeloid leukemia; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; MDS, myelodysplastic syndrome; PCR, polymerase chain reaction; RMSF, Rocky Mountain spotted fever).

bone marrow, lymph nodes, spleen, and liver. The clinical signs, diagnosis, and treatment are discussed in Chapter 21.

- Leishmaniasis is endemic in many North American foxhound kennels. In other dogs, the history usually indicates travel outside the United States to endemic countries such as Greece, Spain, or Italy.
- Hyperglobulinemia and a mild to moderate normocytic, normochromic anemia may occur.

Cytauxzoonosis

Cytauxzoonosis is a highly fatal protozoal disease of cats caused by *Cytauxzoon felis*. It is a tick-borne infection, most prevalent in the wooded areas of the southern United States. The bobcat is the natural reservoir host.

Clinical Signs. Initial clinical signs include anorexia, dehydration, and lethargy, with gradual development of fever. This progresses rapidly to icterus, moderate anemia, leukopenia, thrombocytopenia, and splenomegaly. Cats usually die within a week after clinical signs are recognized.

Diagnosis. The diagnosis is generally made postmortem by histologic identification of large schizonts in endothelial cells of the lungs, liver, bone marrow, or spleen. Terminally, blood films may contain small (1 to 2 µm in diameter) ring or "safety pin" structures within erythrocytes.

Treatment. Treatment is usually unsuccessful despite the use of antibiotics and supportive care. Most reported cases have been fatal, except for several suspected to be infected with a less virulent strain of the organism.

Nutritional Deficiencies

Iron Deficiency

Iron deficiency produces a poorly regenerative anemia caused by deficient hemoglobin synthesis. It occurs with increased iron utilization, such as during growth or pregnancy, from decreased intestinal absorption of iron, and most commonly, when iron stores are reduced through hemorrhage or blood loss.

Etiology. Iron deficiency anemia is caused by neoplasia with tissue necrosis, trauma, internal or external parasites (hookworms, fleas), coagulopathies, and various GI diseases that cause hematemesis, melena, or hematochezia.

Diagnosis. Diagnosis is based on history and low serum iron levels.

- Erythrocytes in blood smears may appear normal in size but lighter in color, with increased central pallor (hypochromasia). Electronic cell counters report an MCV of less than 60 fl (microcytosis) in dogs.
- Poikilocytosis may be prominent in the form of schistocytes, keratocytes, codocytes, and elliptocytes.
- Thrombocytosis occurs in 50% of canine cases.
- Iron profiles have normal to increased level of transferrin (total iron-binding capacity) and decreased serum iron level (in cats <60 µg/dl, in dogs <8 µg/dl). The percentage of saturation of transferrin in iron-deficient animals is often less than 19% (normal is about 33%).
- Bone marrow examination is necessary to determine iron storage amounts, especially in the dog. It is less helpful in the cat, which typically lacks stainable iron in the bone marrow. Aspirate and core biopsies of the

bone marrow indicate hypercellularity with marked erythroid proliferation.

Treatment. Correct the inciting cause and treat with iron supplementation. Give ferrous sulfate at a dosage of 4 to 6 mg of iron per kilogram per day PO in divided doses. Continue therapy for several weeks to months until the PCV and MCV return to normal.

Cobalamin Deficiency

Cobalamin (vitamin B_{12}) deficiency may occur through acquired disorders such as small intestinal disease, exocrine pancreatic insufficiency, or bacterial overgrowth in dogs (see Chapter 69).

- Selective malabsorption of vitamin B_{12} has been described in giant schnauzers having an autosomal mode of inheritance. Clinical signs include weight loss, decreased appetite, and failure to thrive at 3 months of age.
- Laboratory findings involve chronic normocytic, normochromic, nonregenerative anemia with occasional erythroid dysplasia in peripheral blood or bone marrow.
- Serum cobalamin levels can be measured to determine affected animals (for normal values and additional information, see Chapter 69).
- Resolution of clinical and hematologic effects occurs with parenteral administration of cobalamin (initially 1 mg IM daily).

Folate Deficiency

Folate deficiency may produce macrocytic anemia in animals with neoplasia, intestinal malabsorption, liver disease, dietary imbalance, and severe anorexia or starvation. Drugs such as anticonvulsants (phenobarbital, primidone), sulfonamides (sulfasalazine, trimethoprim-sulfadiazine), and antineoplastic agents (methotrexate) may act as folate antagonists by impairing its absorption or production.

- Diagnosis is based on a history of drug exposure or concurrent disease. Serum folate levels can be measured to confirm the deficiency (for normal values and additional information, see Chapter 69).
- The hemogram may indicate a normochromic anemia with macrocytosis and megaloblastic changes in erythroid precursors.
- Treatment is aimed at the inciting cause, along with oral folate supplementation (5 mg/day in dogs, 2.5 mg/day in cats).

Inflammatory Disease

Anemia of inflammatory disease is a frequent cause of nonregenerative anemia. The mechanism may involve increased macrophage activity with cytokine release leading to decreased erythropoiesis, reduced iron availability through sequestration in macrophages, and decreased RBC survival. Primary infections and neoplasia are most often responsible for chronic inflammation. The animal may present with prolonged anorexia, weight loss, and weakness. Other clinical signs reflect the actual source of chronic inflammation or organ systems affected.

- Laboratory findings indicate a normocytic, normochromic anemia, inflammatory leukogram, low serum iron, low total iron-binding capacity, and increased bone marrow stores of iron.
- The bone marrow is usually hypocellular with a normal to increased myeloid-to-erythroid ratio.
- Treatment depends on the original cause. Iron supplementation does not effectively reverse this form of anemia.

Organic Disease

Kidney Disease

Chronic kidney disease may be associated with normocytic, normochromic, nonregenerative anemia.

- The mechanisms involved include reduced erythropoiesis, decreased erythrocyte survival, and blood loss.
- Diagnosis of renal failure involves the presence of azotemia and an abnormal urinalysis. For pathogenesis, diagnosis, and treatment, see Chapter 77.

Liver Disease

Chronic liver disease may be associated with normocytic, nonregenerative anemia. Blood smears often reveal poikilocytosis (acanthocytes, budding fragmentation). Pathogenic mechanisms include concurrent inflammation with iron sequestration, reduced erythropoiesis, and decreased erythrocyte survival.

- Blood loss may occur from coagulopathies related to decreased synthesis of clotting factors.
- Portosystemic shunts may develop erythrocyte microcytosis and poikilocytosis, with or without anemia, possibly related to a relative decrease in iron availability.
- Laboratory findings suggestive of hepatic disease include elevated serum liver enzymes (ALT, SAP, GGT), increased serum bile acid levels, hypoalbuminemia, and hyperbilirubinemia. Liver disease is discussed in Chapter 71.

Endocrine Disease

Hypothyroidism

Hypothyroidism may present with mild anemia in one-third of cases. Pathogenetic mechanisms include reduced tissue oxygen demand and depressed erythropoiesis at the stem cell level. Diagnosis is based on history, dermatologic signs, and hormone assay results (see Chapter 31).

Hyperestrogenism

Hyperestrogenism is associated with endogenous production by tumors (e.g., testicular Sertoli cell or ovarian granulosa cell) or exogenous administration of estrogenic compounds (see Chapters 51, 86, and 90). The mechanism of reduced erythropoiesis is thought to occur at the level of DNA transcription.

- Moderate to severe anemia may be accompanied by thrombocytopenia and leukopenia.
- Diagnosis of an estrogen-producing tumor may be confirmed by surgical removal with subsequent recovery of the cell lines.
- Supportive care, such as blood transfusion and anabolic steroids, may be necessary.

Hypoadrenocorticism

Hypoadrenocorticism may be a cause of nonregenerative anemia in a small percentage of cases. The anemia usually is discovered after fluid replacement for volume deficits associated with the disease (see Chapter 33).

Drug and Toxin-Induced Disease

Drug-Induced Anemia

Drugs (e.g., estrogens, phenylbutazone, antineoplastic agents, thiacetarsamide, quinidine, meclofenamic acid, and trimethoprim-sulfadiazine) are associated with reduced erythropoiesis and aplastic anemia in dogs.

- An idiosyncratic toxicosis caused by griseofulvin administration resulting in a nonregenerative pancytopenia has been reported in a cat.
- Exogenous estrogens are toxic in the dog, depending on the dose given and age of the animal (worse in older dogs). Initially, anemia and thrombocytopenia occur with leukocytosis, which is an inflammatory neutrophilia. Later, pancytopenia develops. After drug cessation, recovery begins in 1 month, starting with leukocytosis and followed by the return of the other cell lines.
- Chloramphenicol administration in cats causes a dose-dependent, reversible marrow suppression involving the erythroid series primarily. Dogs are much less sensitive to chloramphenicol.
- Treatment for drug-induced aplastic anemia often includes supportive care, such as blood transfusions (see "Principles of Transfusion Therapy"), anabolic steroids, and antibiotics in severe cases, once the drug has been stopped.

Lead Toxicity

Lead poisoning causes a mild anemia in some cases, possibly because of increased erythrocyte fragility and abnormal erythropoiesis. Lead primarily affects heme synthesis, causing defective maturation. Other clinical signs involve GI and neurologic disturbances.

Diagnosis

- The diagnosis of lead toxicity often is based on a history of exposure to lead in paint or automobile batteries. Heparinized blood samples are used to determine lead levels. Affected animals have levels greater than 0.06 mg/dl.
- The hemogram strongly suggests lead poisoning when large numbers of nucleated erythrocytes are present with a normal or slightly decreased PCV. The anemia is often normocytic and normochromic but may be microcytic and hypochromic.
- Basophilic stippling is best seen with Romanowsky-stained blood films prepared without EDTA anticoagulant. Polychromasia generally is rare.
- Bone marrow aspirates or core biopsies are characterized by maturation arrest at the metarubricyte stage.

Treatment. Treat lead toxicity in dogs and cats with calcium EDTA (100 mg/kg) diluted to 10 mg/ml in 5% dextrose and given SC, in four divided doses, daily for 5 days.

Myelophthisis

Neoplasia

Neoplasia of the bone marrow can occur with primary hemolymphatic tumors or metastatic tumors. Mild infiltrates or focal lesions within the bone marrow produce minimal peripheral blood changes. Cytopenias occur if the involvement is diffuse and severe. Approximately 57% of dogs with multicentric lymphoma have metastasis to the bone marrow at the time of diagnosis. Only half of these have evidence of abnormal cells in circulation. Diagnosis requires bone marrow examination by both aspirate and core biopsies (see discussion under "Leukemic Disorders").

Myelofibrosis

Myelofibrosis usually occurs as a result of marrow damage produced by inflammation, necrosis, neoplasia, and toxic agents and may be seen in the terminal stages of pyruvate kinase deficiency.

- Pancytopenia is observed in severe cases, along with poikilocytosis in the form of dacryocytes and schistocytes.
- Bone marrow aspiration attempts usually produce "dry taps" (i.e., blood alone without marrow particles). Bone marrow core biopsy evaluation is necessary to diagnose myelofibrosis.
- Myelofibrosis also is associated with myelodysplastic syndrome and acute myelogenous leukemia in cats (see discussion of dysplastic and leukemic disorders).
- Supportive care, including antibiotics, blood transfusions, anabolic steroids, and glucocorticoids, often is required in severe cases. Myelofibrosis may be reversible under some conditions.

Myelonecrosis

Myelonecrosis is an uncommon cause of nonregenerative anemia. It often is associated with neoplasia but may be related to infections or toxic agents. The mechanism likely involves occlusion of microcirculation or direct injury to endothelium.

- Diagnosis is based on bone marrow examination. Aspirate biopsies may contain peripheral blood, degenerative cells, increased macrophage activity, and amorphous stringy material representing necrotic bone marrow particles. Focal to diffuse regions of necrosis appear on histologic sections of bone marrow.
- Treatment includes removal of the inciting cause, along with supportive care. Prognosis is often poor.

Osteopetrosis

Osteopetrosis is an uncommon inheritable condition affecting the normal development of bone. It causes obliteration of the marrow cavities by bone and may be associated with refractory anemia, or pancytopenia in immature or young adult dogs.

- Clinical signs usually are related to anemia.
- Diagnosis is established by the inability to obtain bone marrow material on aspiration and by distinctive radiographic findings. Increased bone density is present and cortices are thickened, leaving a narrow medullary region. Histologic examination of medullary bone reveals thickened trabeculae, reduced marrow cavities, and an absence of osteoclasts.
- Despite supportive care, the prognosis is poor.

Irradiation

Irradiation acts as a local cytotoxic agent for cancer therapy. It also is used to treat hemolymphatic malignancies and genetic defects before bone marrow transplantation. High doses produce irreversible pancytopenia and aplastic bone marrow. Supportive care (e.g., blood transfusions, antibiotics, and immunosuppressive drugs) often is given after transplantation.

Immune-Mediated Destruction (Pure Erythrocyte Aplasia)

This uncommon condition is characterized by severe reduction of erythroid stem cells without affecting granulocytic or megakaryocytic lines. Both congenital and acquired forms have been reported in dogs. The myeloid-to-erythroid ratio is usually 10:1 to 20:1. Coombs testing has been positive in a few dogs. The mechanism is considered immune-mediated because the disease often responds to prednisolone and/or cyclophosphamide therapy (also see Chapter 24).

Polycythemia

Relative Polycythemia

Increase in erythrocytes (erythrocytosis) in relative polycythemia generally is related to fluid depletion (e.g., dehydration or hemoconcentration). However, excitement or fear may cause splenic contraction and a transient rise in PCV. Greyhounds normally have a high PCV of 60%.

- Clinical signs include dark red mucous membranes with slow capillary refill time.
- Diagnosis is based on a history of stress or fluid loss, elevated PCV, and increased erythrocyte and plasma protein concentrations. The erythrogram returns to normal after fluid replacement.
- If splenic contraction is suspected, the PCV should be retaken after the patient has relaxed.

Absolute Polycythemia

The erythrocytosis in absolute polycythemia may be primary or secondary, with a sustained increase in the circulating erythrocyte mass, based on erythropoietin production.

- *Primary erythrocytosis,* or *polycythemia vera,* has low serum erythropoietin that suggests the increased erythrocyte numbers are derived from an intrinsic stem cell defect (see "Leukemic Disorders").
- *Secondary erythrocytosis* involves overproduction of erythropoietin. Causes of secondary erythrocytosis include hypoxia (e.g., caused by high altitude, chronic pulmonary disease, or cardiac disease with right-to-left shunting), tumors that produce erythropoietin (e.g., renal lymphoma, renal carcinoma, and renal fibrosarcoma), and renal disease (e.g., pyelonephritis).

Diagnosis

Diagnosis of hypoxia is based on history and evidence of lung disease or right-to-left shunting heart disease. Renal disease, benign or malignant, can be excluded by urinalysis, radiography, ultrasonography, or biopsy. Serum erythropoietin levels currently are measured by radioimmunoassay and ELISA methods.

Treatment

Treatment of secondary erythrocytosis often involves removal of the inciting cause (e.g., nephrectomy).

Methemoglobinemia

Methemoglobinemia occurs from the oxidation of iron in hemoglobin. This form of oxidized hemoglobin is unable to bind and carry oxygen, producing a state of relative hypoxia. Clinically, the mucous membranes appear blue-gray or cyanotic if methemoglobin levels

exceed 30%. The patient is often dyspneic, weak, and ataxic.

Diagnosis

The appearance of dark red or chocolate-colored blood, even after exposure to air, is diagnostic for the condition. The color change, from dark to bright red in normal blood, is readily visible by a spot test on filter paper. The blood of affected animals shows no such color change if the methemoglobin content exceeds 15%.

- Severe disease is produced from oxidant drugs and chemicals, similar to those mentioned in the previous section on Heinz body formation. Both conditions present together, but methemoglobinemia tends to occur before Heinz bodies appear.
- Several breeds of dog and a domestic shorthaired cat were reported to have a rare enzyme (NADH-methemoglobin reductase) deficiency with a mild to moderate form of the disease.
- Quantitative measurement of methemoglobin content is performed by spectrophotometry at specialized laboratories.

Treatment

Treatment is similar to Heinz body anemia. In addition, methylene blue (1 mg/kg IV, as a 1% solution), if carefully administered, has been used to treat the condition caused by oxidant drugs. Caution is necessary to avoid potentiating a hemolytic crisis. Therapy usually is not required for animals with the reductase enzyme deficiency.

▼ ***Key Point*** A mild secondary polycythemia may develop in animals with methemoglobin reductase deficiency.

LEUKOCYTE DISORDERS

Congenital Disorders

Pelger-Huët Anomaly

Pelger-Huët anomaly is an inherited disorder in dogs and cats involving granulocyte maturation. Leukocyte function in dogs is not impaired, and there is no predisposition to infection or immunodeficiency. Chondrodysplasia has been recognized in a cat with a homozygous form of this disorder.

- Diagnosis is based on the appearance of mature leukocytes in blood that have nuclei with condensed, coarse, and patchy chromatin-lacking segmentation. The nuclear shapes often resemble those of bands, metamyelocytes, and myelocytes. The cytoplasm undergoes normal maturation. Abnormalities frequently are found during routine preoperative screening and may be mistaken as a severe left shift. Inflammatory conditions should be ruled out.
- No treatment is necessary.

Feline Chédiak-Higashi Syndrome

This is a rare, inheritable disorder seen in blue-smoke Persian cats with yellow eye color. Pathogenesis involves abnormal and enlarged lysosomal granule formation in granulocytes and monocytes. Affected cats may be photophobic with cataract formation. There is increased bleeding time because of platelet granule defects. With Romanowsky stains, neutrophils contain characteristic large, pink to magenta cytoplasmic inclusions that stain positive with peroxidase and Sudan black B. These cats do not exhibit an increased susceptibility to infection although neutropenia may occur.

Lysosomal Storage Diseases

Mucopolysaccharidosis and Gangliosidosis

These are inheritable lysosomal storage diseases reported in cats and dogs caused by an enzyme deficiency. Mucopolysaccharidosis (MPS) types VI and VII have been reported in cats and dogs and present with skeletal and ocular lesions. In cats with GM_2-gangliosidosis, neurologic deficits and corneal opacification are displayed.

- In all these diseases, neutrophils may contain coarse, red-purple granules when stained with Wright-Giemsa or toluidine blue. Cells must be distinguished from toxic neutrophils.
- A urine spot test is used to screen for glycosaminoglycans, whereas a cell enzyme activity test is diagnostic.
- Experimentally, bone marrow transplantation has been used to treat some of these disorders. Affected animals should not be bred.

Other Lysosomal Storage Diseases

Other lysosomal storage diseases in dogs and cats that present with progressive neurologic dysfunction or skeletal lesions involve a distinctive lymphocyte vacuolation abnormality. The specific lysosomal storage diseases that may display lymphocyte vacuolation include GM_1- and GM_2-gangliosidosis, Niemann-Pick disease, alpha-mannosidosis, MPS (types I, VI, and VII), and alpha-fucosidosis.

- Affected lymphocytes have multiple punctate cytoplasmic vacuoles on blood films. These vacuoles should not be confused with the artifactual changes seen with prolonged storage of blood in EDTA.
- These different diseases may be distinguished by special tests for enzyme activity from blood and/or affected tissues.
- Recently, genetic tests have been used for diagnosis.

Abnormal Granulation Syndrome in Birman Cats

This is a genetic anomaly recognized in Birman cats without associated clinical disease. Diagnosis is based on the presence of fine, pinkish-purple granules within the cytoplasm of neutrophils. These lysosomal granules have normal morphology, and neutrophil function is unaffected.

Neutrophilia

Neutrophilia is defined as more than 11,500 neutrophils per microliter in the dog and more than 12,500 neutrophils per microliter in the cat. Neoplastic neutrophilic conditions are discussed in the section on leukemic disorders.

Physiologic Neutrophilia

Epinephrine release as the result of stress, fear, or strenuous muscular exertion causes demargination of leukocytes, producing a rapid rise in neutrophils and lymphocytes. Within 30 minutes, the cell counts return to normal. The effect is more common and greater in cats than in dogs.

Corticosteroid-Induced Neutrophilia

Neutrophilia may be related to exogenous administration or endogenous release of glucocorticoids. Cells are released from marginating pools and bone marrow storage pools. The magnitude and duration of the effect depends on the type of corticosteroid given.

- Diagnosis is determined by the history and by the presence of concurrent lymphopenia, eosinopenia, or monocytosis, without a left shift.
- Neutrophil hypersegmentation is common because of a prolonged life span.

Inflammatory Neutrophilia

Evidence of inflammation is an increase in non-segmented forms of neutrophils, termed a *left shift*.

Etiology

Etiology involves infectious or non-infectious sources.

- *Infectious agents* include bacteria, systemic fungi, protozoa, or rickettsiae (see Section 2).
- *Non-infectious conditions* involve tissue necrosis, such as necrotizing pancreatitis, neoplasia, thrombosis, and burns.
- *Certain malignancies* (e.g., metastatic fibrosarcoma or renal tubular carcinoma) are reported to induce a leukemoid response, presumably as a paraneoplastic disorder, rather than come from tissue necrosis alone. Leukemoid counts range from 50,000 to 100,000 leukocytes per microliter with a left shift back to bands, metamyelocytes, and myelocytes.
- *Severe abscessation* (e.g., pyometra) can also cause this extreme degree of leukocytosis.
- *Immune-mediated reactions*, such as systemic lupus erythematosus, can result in a left shift with neutrophilia.
- *Granulocytopathy syndrome* in Irish setters is a congenital cause of inflammatory neutrophilia. Neutrophils appear morphologically normal but have impaired bactericidal activity related to a deficiency of adhesion proteins. Affected dogs have recurrent bacterial infections with extreme leukocytosis that can mimic chronic granulocytic leukemia (see "Leukemic Disorders").

Diagnosis

Diagnosis of inflammatory neutrophilia is based on a careful history and a CBC evaluation. A regenerative left shift requires a simultaneous neutrophilia.

- A left shift without neutrophilia is considered degenerative, especially if there is neutropenia (see the next section), or if more non-segmented forms are present compared with mature neutrophils.
- In addition to a significant shift toward immaturity (bands >1000/µl), neutrophils may exhibit toxicity. Toxins released from bacteria are mostly responsible for the focal or diffuse cytoplasmic basophilia and vacuolation found in mature or immature neutrophils.
- Antibiotic responsiveness suggests a bacterial cause.
- Tests for specific infectious agents and immune-mediated disorders may be indicated.

Treatment

Treatment depends on the inciting cause.

▼ ***Key Point*** Animals possessing neutrophil function defects present with neutrophilia and persistent and recurrent infections.

Neutropenia

Neutropenia is defined as less than 3000 neutrophils per microliter in the dog and less than 2500 neutrophils per microliter in the cat.

Congenital Cyclic Neutropenia

Cyclic neutropenia or cyclic hematopoiesis is an inherited disorder of gray collies. It is characterized by periodic fluctuations in neutrophils and, to a lesser extent, in monocytes, platelets, and reticulocytes as a result of the intrinsic bone marrow stem cell defect. Neutropenic cycles recur at 12-day intervals.

Clinical Signs

Clinical signs during neutropenic episodes include lethargy, pyrexia, anorexia, arthritis, keratitis, and respiratory or GI infections.

Diagnosis

Diagnosis is based on history, clinical signs, and cyclic decreases in cell counts. Carrier animals can be determined only by test mating.

Treatment

Antibiotics and supportive care are necessary during neutropenic cycles. Most affected dogs die within 6 months, after chronic recurrent infections. Experimental treatments involve bone marrow transplantation and administration of lithium carbonate (21–26 mg/kg/day) or recombinant canine granulocyte-colony stimulating factor (5 µg/kg/day).

Infectious Neutropenia

Consumption of neutrophils during severe systemic inflammation often produces neutropenia with an increase of immature forms, termed a *degenerative left shift*.

- Gram-negative bacteria usually are involved, as with septicemia, severe enteritis, or other severe bacterial infections.
- Systemic mycoses and protozoal infections (e.g., *Toxoplasma*) also can cause neutropenia.
- Reduced granulopoiesis may be associated with such viruses as FeLV, FIV, feline panleukopenia virus, and canine parvovirus. FeLV is associated with a cyclic neutropenia that may respond to lithium and prednisone.
- *E. canis* also may cause bone marrow suppression. Diagnosis of infectious causes is based on the history, CBC, and bone marrow findings, in addition to specific serologic or bacterial culture results.
- Neutropenia without a marked left shift may indicate peracute consumption without adequate time for bone marrow response. The lack of a left shift, if persistent, suggests an absolute reduction of neutrophilic precursors or myeloid hypoplasia of the bone marrow.

Drug- and Toxin-Induced Neutropenia

Drugs that cause neutropenia due to myelotoxicity include estrogens, antimicrobials, and cancer chemotherapeutic agents (see "Nonregenerative Anemia"), among others. Treatment requires cessation of the drug and supportive care, particularly antibiotics. The use of recombinant canine granulocyte colony-stimulating factor has shown promise in reducing the severity of drug-induced myelosuppression.

- *Antimicrobials* include chloramphenicol, trimethoprim-sulfadiazine, cephalosporins, and griseofulvin.
- *Antineoplastic agents* include cyclophosphamide, chlorambucil, busulfan, melphalan, cisplatin, cytosine arabinoside, methotrexate, mitoxantrone, doxorubicin, and hydroxyurea.
- *Nonsteroidal anti-inflammatory drugs* occasionally have been associated with myelotoxicity.
- *Endotoxins* from gram-negative sepsis produce a transient neutropenia. Mechanisms involve a shift of neutrophils from the circulation to the marginating pools and a shortened circulating half-life (normal is approximately 5.5–7.5 hours).

Immune-Mediated Neutropenia

Destruction of antibody-coated neutrophils by macrophages is a mechanism of neutropenia considered to occur in animals. As in immune-mediated hemolysis, the disorder may involve antibody directed against surface antigens of the cell itself or antibody directed toward drug antigens attached to neutrophils.

- Drugs responsible for suspected immune-mediated blood cell destruction include antithyroid drugs (e.g., thiouracil and methimazole) and cephalosporins.
- Definitive diagnosis requires detection of antineutrophil antibodies on the cells or in serum; however, such assays are not currently available for clinical usage.
- The bone marrow is expected to show myeloid hyperplasia, with a marked decrease in late-stage forms.
- In one suspected case in a dog, immunosuppressive doses of prednisone produced a positive response.

Paraneoplastic Syndrome

Neutrophilia was found to be associated with the presence of a benign rectal polyp in a dog. In a case of lung carcinoma in a dog and dermal adenocarcinoma in a cat, extreme neutrophilia occurred without clinically detectable inflammatory foci. In these two animals, hematopoietic growth factors or colony-stimulating factor concentrations were increased as demonstrated by PCR assays.

Myelophthisis

See the section on nonregenerative anemia.

Irradiation

See the section on nonregenerative anemia.

Monocytosis

Corticosteroid-Induced Monocytosis

Monocytosis, particularly in the dog, can be induced by glucocorticoid administration. Diagnosis is based on the history, but when it is unavailable, the presence of concurrent lymphopenia, eosinopenia, and mature neutrophilia should suggest the effects of corticosteroids.

Inflammatory Monocytosis

Acute and chronic inflammatory diseases that cause a high demand for macrophages may produce monocytosis. These include immune-mediated disorders, tissue necrosis, foreign body reactions, and mycobacterial or fungal infections. Diagnosis is based on the history, physical examination, immunologic testing, cytology, and histopathology.

Neoplastic Monocytosis

See the section on leukemic disorders.

Eosinophilia

Parasitic Eosinophilia

Peripheral eosinophilia may result from infiltration of the skin, respiratory tract, and alimentary tract by such parasites as *Ancylostoma* spp, *Trichuris vulpis, Toxocara canis, Dirofilaria immitis, Dipetalonema reconditum,* lungworms (*Aelurostrongylus abstrusus, Capillaria* spp., *Filaroides* spp.), and *Paragonimus kellicotti.* Definitive diagnosis of parasitism is determined by positive fecal examinations, tracheobronchial washes, thoracic radiographs, and heartworm serologic or concentration techniques.

Allergic and Inflammatory Eosinophilia

Hypersensitivity reactions can occur owing to the effects of fleas, food, grasses, and nonspecific allergens. The production of immunoglobulin E (IgE) causes mast cell degranulation and release of chemical mediators that attract eosinophils. Peripheral eosinophilia commonly is found in these conditions. The skin, respiratory, GI, and genitourinary systems often are affected.

- The history, physical examination, skin or food testing, and tracheobronchial lavage help locate the type of allergen and the system most affected.
- Eosinophilic granuloma is a localized infiltration of the dermis by eosinophils that occurs in the oral cavity or skin of dogs and cats. Impression smears and histopathology confirm the lesion. Clinical findings, underlying causes, and treatment are discussed in Chapter 53.
- Treatment usually involves elimination of the allergen, along with antihistamine and glucocorticoid administration.

Tumor-Associated Eosinophilia

Tumor-associated eosinophilia is a reported paraneoplastic syndrome in dogs with fibrosarcoma, anaplastic mammary carcinoma, and mast cell tumors. In cats, mast cell tumors and T cell lymphoma are the neoplasms most commonly associated with eosinophilia, although it may occur in other malignancies. Diagnosis depends on normalization or reduction of the eosinophil count in response to removal of the tumor.

Feline Hypereosinophilic Syndrome

Hypereosinophilic syndrome is an uncommon form of peripheral eosinophilia accompanied by severe infiltration of eosinophils into many organs, often including the GI tract (see Chapter 69), liver, spleen, lymph nodes, and lung. It resembles leukemia of well-differentiated eosinophils resulting from an apparent involvement of the bone marrow and may in fact be considered part of a continuum of a neoplastic disease. The cause is idiopathic. Clinical signs may include anorexia, weight loss, fever, vomiting, diarrhea, and lymphadenopathy. Death results from organ dysfunction caused by tissue infiltration.

Neoplastic Eosinophilia

See the section on leukemic disorders.

Eosinopenia

Endogenous release or exogenous administration of corticosteroids produces eosinopenia within a few hours. Levels will normalize in 1 day after a single dose is given. Mechanisms implicated are enhanced margination, decreased bone marrow release, and reduced bone marrow production. Absolute reductions in eosinophils or relative decreases from a previous eosinophilia suggest the effects of glucocorticoids. Elevated cortisol levels and an endocrine dermatopathy support hyperadrenocorticism (see Chapter 33).

Basophilia

Basophil granules in dogs and cats normally stain poorly. The cells frequently are mistaken for toxic neutrophils in dogs or faded eosinophils in cats.

Parasitic Basophilia

Heartworm infection, including occult disease, is a frequent cause of basophilia in dogs and cats. Dogs with hookworms also may have basophilia. Diagnosis often involves concurrent eosinophilia and positive proof of parasitic infestation.

Allergic Basophilia

Hypersensitivity reactions cause IgE production in such organs as the skin and lungs. The immune response leads to increased numbers of mast cells and basophils.

Basophilia Associated with Lipemia

Basophilia without eosinophilia has been associated with lipemia and is thought to be related to deficiency of heparin, which is found in basophils and is needed to activate lipoprotein lipase. This enzyme is necessary to clear lipemia. This has been associated with hypothyroidism but is observed infrequently.

Basophilia Associated with Mast Cell Neoplasia

Basophilia was found in 5 of 16 dogs with systemic mastocytosis. It is also reported in a cat with intestinal mastocytoma.

Neoplasia

See the discussion on leukemic disorders.

Lymphocytosis

Epinephrine-Induced Lymphocytosis

A transient rise in lymphocytes occurs with severe exertion or physiologic stress. This is especially significant in the young cat. Transient lymphocytosis that normalizes after a short time suggests epinephrine effects on the leukogram.

Infectious Lymphocytosis

- Lymphocytosis may be the result of antigen stimulation caused by FeLV, *E. canis, Rickettsia rickettsii,* and systemic fungi. In particular, lymphocytosis involving granular lymphocytes has been associated with *E. canis* infection in dogs.
- Modified live vaccines also may produce lymphocytosis, along with the morphologic appearance of reactivity, about 1 week after immunization.
- Slightly enlarged lymphocytes with deeply basophilic cytoplasm resembling plasma cells support the diagnosis of reactivity from antigen stimulation.
- Hyperglobulinemia due to a polyclonal gammopathy and plasma cell infiltration of tissues also may occur.

Neoplastic Lymphocytosis

Lymphocytosis resulting from metastatic lymphoma occurs in 20% of dogs and cats with lymphoma. Acute or chronic lymphoid leukemia often is characterized by lymphocytosis and atypical or immature lymphoid cells. However, rare blast cells may be found in non-neoplastic conditions such as immune-mediated hemolytic anemia and canine ehrlichiosis. Persistent hematologic abnormalities must be present to consider neoplasia and should be evaluated further with bone marrow aspiration and core biopsies (see Chapter 27).

Lymphopenia

Corticosteroid-Induced Lymphopenia

Endogenous or exogenous corticosteroids produce an absolute lymphopenia or a normal value reduced from a previous lymphocytosis. It is transient because cell counts return to normal within 1 to 3 days of drug withdrawal. Lymphopenia also may relate to redistribution of lymphocytes to other tissues (see "Neutrophilia"). Lymphopenia often accompanies the stress of many acute diseases.

Infectious Lymphopenia

Viral agents, such as canine distemper virus, FeLV, FIV, and canine or feline parvoviruses, may cause lymphopenia because of direct lymphocytolysis or lymphoid tissue destruction.

Lymphopenia in Lymphatic Injury

Rupture or malformation of lymphatic vessels (e.g., chylothorax or protein-losing enteropathy from lymphangiectasia) can cause lymphopenia because of a loss of lymph fluid into the pleural cavity or gut lumen, preventing recirculation (see Chapters 164 and 69). Destruction of normal lymph node architecture or blockage of lymph drainage, as in lymphoma, may also lead to lymphopenia (see Chapter 27).

Congenital Lymphopenia

Combined immunodeficiency of T and B lymphocytes occurs in basset hounds. It is associated with severe bacterial infections within the first few weeks of life. Diagnosis is based on the presence of low Ig levels, depressed T cell function, and histologic evidence of lymphoid cell depletion, as well as peripheral lymphopenia. Supportive therapy with antibiotics is suggested, but death may occur in severe cases.

Mastocytosis or Mastocythemia

See Chapter 28.

PLATELET DISORDERS

Thrombocytopenia: Overview

Platelets may be decreased in number through immune-mediated injury, increased consumption or utilization, sequestration, and decreased production. Clinical disease may not be present in certain dog breeds that may have a reference range for platelet numbers lower than that for other breeds, such as the cavalier King Charles spaniels and greyhounds.

Clinical Signs

- Petechial or ecchymotic hemorrhages involving the mucous membranes or skin are common manifestations of thrombocytopenia.
- Epistaxis, melena, hematuria, hyphema, or prolonged bleeding from venipuncture sites or wounds often occurs.
- Evidence of inciting conditions, such as infection, neoplasia, or splenomegaly, may be present.

General Diagnostic Considerations

- The history should determine the occurrence of trauma, surgery, drug or toxin exposure, and neoplasia, as well as the time period involved.

- Physical examination discloses sites of hemorrhage, presence of hepatosplenomegaly, and concurrent infections or neoplasia.
- Use CBC to screen for hematologic abnormalities including the adequacy of the platelet numbers.
- Perform platelet counts on fresh samples (within 1–2 hours). Thrombocytopenia is considered less than 100,000 platelets per microliter. However, clinical signs of bleeding are not expected until there are less than 20,000 platelets per microliter.
- Include both aspirate and core biopsies in bone marrow evaluation to check for adequate megakaryocyte numbers.
- Perform clotting profile, including fibrinogen, PT, and APTT or activated clotting time (ACT), to help rule out other coagulopathies (as described in Chapter 23). ACT may be slightly prolonged if platelet counts are less than 10,000/µl.
- Perform a von Willebrand factor assay if the breed and clinical signs suggest a deficiency (see Chapter 23).
- Bleeding time, a platelet function test, may be prolonged because of low platelet numbers.

▼ ***Key Point*** Examine the blood smear carefully, especially at the feathered edge, before making a diagnosis of thrombocytopenia.

Treatment

Supportive therapy may include fresh blood transfusions (administered within 8 hours of collection) if both platelets and erythrocyte numbers are low. If only platelets are needed, administer platelet-rich plasma (see Chapter 23).

Immune-Mediated Platelet Injury

This is one of the most frequent and important causes of thrombocytopenia manifested by clinically significant bleeding. The clinical findings, diagnosis, and treatment are discussed in Chapter 24.

Increased Platelet Consumption or Utilization

Infectious Agents

Thrombocytopenia produced by such agents as *E. canis, E. ewingii, Anaplasma platys,* and *A. phagocytophilum* presumably is the result of increased consumption and the presence of antiplatelet antibodies.

- Thrombocytopenia is the most frequent hematologic finding in canine ehrlichiosis. Bone marrow evaluation during the acute course of *E. canis* infection indicates megakaryocytic hyperplasia. The diagnosis of ehrlichiosis is based on a history of tick exposure and serologic and PCR tests (see Chapter 17).
- *A. platys* infection produces a cyclic thrombocytopenia occurring in 2-week cycles that may be diagnosed by direct observation of morulae within platelets or by serologic and PCR tests (see Chapter 17).

Modified Live Virus Vaccination

Canine distemper virus vaccine may induce thrombocytopenia within 1 week after vaccination. The effect is transient but may persist as long as 3 weeks. It is rarely of clinical significance unless surgery is performed during the platelet count nadir.

Hemorrhage

Bleeding can consume platelets. Consumption of platelets may occur through hemorrhage alone or in association with bacterial or viral infections that produce inflammation. Endotoxemia from gram-negative bacteria leads to endothelial damage and platelet activation.

- Diagnosis is based on history, physical examination, cytology, histopathology, and culture techniques.
- Treatment is aimed at the inciting agent. Whole blood or platelet transfusions may be necessary if thrombocytopenia is severe.

Disseminated Intravascular Coagulation

This condition leads to increased consumption of platelets, as well as clotting factors. It is associated most often with infections, neoplasia, heartworm disease, pancreatitis, and shock.

- Clinical signs involve petechial and ecchymotic hemorrhages. Organ dysfunction usually reflects the effects of the primary disease.
- Diagnosis is based on the findings in tests of coagulation, including hypofibrinogenemia, prolonged PT and APTT, increased fibrin degradation products, and decreased antithrombin III activity (see Chapter 23). Microthrombi formation is found on histopathology.
- Treatment is aimed at the inciting or underlying cause when possible. Supportive care, including fluids, is necessary to prevent shock. Replacement of platelets and coagulation factors using fresh plasma usually is indicated. Heparin rarely is effective, especially if the hemorrhagic stage already has occurred (see Chapter 23).

Platelet Sequestration: Splenomegaly

The spleen normally stores approximately one-third of the body's platelets. With enlargement of the spleen from any cause, there is an increase in blood volume that sequesters more platelets within endothelial passages, resulting in thrombocytopenia. Physical examination of an enlarged spleen without evidence of other conditions that induce thrombocytopenia supports the diagnosis. It is usually of little clinical significance if

associated with benign enlargements of the spleen (see Chapter 25).

Decreased Platelet Production

Congenital Thrombocytopenia

Cyclic hematopoiesis in gray collie dogs may exhibit thrombocytopenia of a cyclic nature (see under "Neutropenia").

Infectious Thrombocytopenia

Canine distemper virus, parvoviruses, FeLV, and *E. canis* may be associated with reduced thrombopoiesis. Approximately 20% of animals with ehrlichiosis have megakaryocytic hypoplasia of the bone marrow, especially in the late stages of the disease.

Drug-Induced Thrombocytopenia

Causes of drug-induced thrombocytopenia are similar to those that produce aplastic anemia (see "Nonregenerative Anemia"). Antineoplastic agents such as cisplatin, cyclophosphamide, chlorambucil, doxorubicin, and hydroxyurea produce significant thrombocytopenia.

Myelophthisic Thrombocytopenia

See the section on nonregenerative anemia.

▼ ***Key Point*** Thrombocytopenia associated with neoplasia occurs through several mechanisms including hemorrhage, microangiopathy, disseminated intravascular coagulation, myelophthisis, immune-mediated destruction, and chemotherapeutic drugs.

Thrombocytosis

Physiologic Thrombocytosis

Increased numbers of platelets are released from the spleen as a result of epinephrine release or during heavy exercise. Pulmonary stores of platelets also may be released during exercise. This is transient and of no clinical significance.

Reactive Thrombocytosis

Conditions associated with reactive or regenerative thrombocytosis include acute blood loss, iron deficiency anemia, trauma, surgery, inflammation, splenectomy, hyperadrenocorticism, and neoplasia.

- *Tumors* that may cause thrombocytosis are mast cell tumor, hemangiosarcoma, osteosarcoma, lymphoid and myeloid leukemias, and some carcinomas.
- *Vincristine* administration produces increased thrombopoiesis and cytoplasmic fragmentation of megakaryocytes because of a reduced maturation time.

Clinical Signs

There are no clinical signs directly related to transiently elevated platelet counts.

Diagnosis and Treatment

Diagnosis is supported by history, physical examination, platelet count greater than 600,000/µl (dog) or greater than 800,000/µl (cat), and mild to moderate megakaryocytic bone marrow hyperplasia without evidence of circulating megakaryoblasts.

- Pseudohyperkalemia can occur because of leakage of potassium from clotted platelets. Therefore, plasma is preferred for measurement of potassium levels in thrombocytotic samples.
- Treatment depends on the inciting cause.

Neoplastic Thrombocytosis

See the section on leukemic disorders.

DYSPLASTIC DISORDERS

Congenital Dysplasia

Inherited Erythrocyte Macrocytosis

An inherited disorder of toy and miniature poodles is associated with abnormal morphology of erythrocytes and their precursors.

- Affected animals present with no clinical signs of anemia, and the dysplastic findings are usually incidental.
- Diagnosis is based on the breed and on findings of a normal hematocrit, presence of macrocytosis (MCV > 80 fl), megaloblastosis in the blood and bone marrow, and absence of polychromasia or reticulocytosis. An asynchrony in maturation between the nucleus and the cytoplasm characterizes the RBC abnormalities. Neutrophil hypersegmentation and giantism also may occur but are less common.
- The condition persists and is not responsive to folate or cobalamin.

Inherited Macroplatelets

Macroplatelets as an inherited disorder have been reported in Cavalier King Charles spaniels without hemorrhages or clinical signs.

Infectious Causes of Dysplasia

Abnormal morphology of erythroid, granulocytic, and megakaryocytic lines occurs in cats infected with either FeLV or FIV.

- Macrocytosis, megaloblastosis, neutrophil giantism, hypersegmentation, and dwarf megakaryocyte for-

mation characterize the dysplastic changes found as a result of viral effects on nuclear development.
- Peripheral cytopenias arise from abnormal maturation of affected cell lines.
- Clinical signs often include concurrent bacterial or protozoal infections, neoplasia, and chronic wasting.
- Definitive diagnosis requires serologic testing.
- Treatment is supportive in nature. The median survival is 12 weeks.

Drug-Induced Dysplasia

Dyserythropoiesis characterized by macrocytosis, megaloblastoid changes, nuclear fragmentation, sideroblastosis, and siderocytosis may occur in animals treated with azathioprine, cyclophosphamide, cytosine arabinoside, vincristine, or chloramphenicol.

- These changes are not associated with folate deficiency.
- Diagnosis is based on blood and bone marrow samples taken during routine post-treatment hematologic evaluations.
- Normal morphology of hematopoietic cells returns several days after cessation of drug therapy.

Nutritional Dysplasia

- Erythroid dysplastic changes and neutrophil hypersegmentation may occur in giant schnauzers with an inherited selective malabsorption of vitamin B_{12} (described in this chapter under "Nonregenerative Anemia").
- A macrocytic nonregenerative anemia is found in acquired folate deficiencies such as intestinal malabsorption, neoplasia, liver disease, dietary imbalance, and severe starvation.
- Drugs such as anticonvulsants, antibiotics, and antineoplastic agents that inhibit folate metabolism produce megaloblastic changes in erythroid precursors (see under "Nonregenerative Anemia").

LEUKEMIC DISORDERS

Lymphoma or Lymphoid Leukemia

See Chapter 27.

Myeloid (Non-lymphoid) Malignancy

The etiology for this group of malignancy is generally unknown, although it is often associated with viral infection (e.g., FeLV), immunologic dysfunction, or irradiation.

Overview of Clinical Signs

Clinical signs include pale mucous membranes (except in polycythemia vera), fever, lethargy, weight loss, chronic infections, hepatosplenomegaly, mild lymphadenopathy, and hemorrhagic tendencies.

Diagnostic Principles

Myeloid leukemias are suggested by the history (e.g., FeLV infection), clinical signs of unexplained or frequent infections, and hematologic abnormalities that affect multiple cell lines. Definitive diagnosis is made from bone marrow aspirate and core examinations.

- *Acute myeloid leukemia* has been defined in the past as subtypes M_1 to M_7, which have blast cells in the bone marrow equal to or exceeding 30% of non-erythroid cells. However, to follow the current human classification, the percentage of myeloblasts may be defined as greater than 20% of non-erythroid cells. In general, survival involves weeks to months for patients with acute myeloid leukemia.
- *Chronic myeloid leukemia* subtypes have increased numbers of blast cells, but these cells account for less than 20% of non-erythroid cells of the bone marrow. A longer survival of months to years is expected for patients with chronic myeloid leukemia.
- Cytochemical staining or immunocytochemistry of blast cells from blood and bone marrow smears may be performed on unfixed slides submitted to special laboratories to determine the cell type primarily involved.
- Alternatively, flow cytometry may be helpful in some cases to define the cell type.

Treatment Principles

Treatment generally consists of supportive care (e.g., antibiotics, blood transfusions, and fluids).

- Antineoplastic agents, including corticosteroids, cytosine arabinoside, chlorambucil, busulfan, and hydroxyurea, have been used with limited success.
- Bone marrow transplantation has been attempted in the cat but is cost prohibitive for clinical application.

Myelodysplastic Syndrome

Myelodysplastic syndrome (MDS) is a clonal expansion of a hematopoietic stem cell abnormality characterized by persistent peripheral cytopenias in one or more hematopoietic cell lines together with features of abnormal maturation. This condition often precedes an overt leukemia by several weeks to months. Cats affected usually are seropositive for FeLV.

Several morphologic types exist relative to the numbers of myeloblasts present (e.g., MDS-RC [refractory cytopenia] or MDS-EB [excess blasts]) and a variant of MDS-RC with erythroid cells present (e.g., MDS-Er [erythroid predominance]). Cases of MDS-EB having 5% or greater marrow myeloblasts demonstrate shorter survival and poor response to treatment.

Clinical Signs

Clinical signs involve chronic infections, lethargy due to anemia, and hemorrhage.

Diagnosis

Despite the cytopenias, the bone marrow is usually hypercellular, with a mild increase in numbers of myeloblasts (<20% of all nucleated cells). Dysplastic changes in the blood or bone marrow include macrocytosis, megaloblastosis, nuclear fragmentation, abnormal cytoplasmic granulation, neutrophil hypersegmentation or hyposegmentation, micromegakaryocyte or macrothrombocyte formation, and cell giantism.

Treatment

Because the condition may persist for long periods without major clinical disease, treatment is usually supportive, including antibiotics and blood transfusions as needed.

- Antineoplastic agents, such as low-dose cytosine arabinoside, have been used to induce normal maturation and prevent conversion to a malignant state. Results with these agents have been mixed and therefore cannot be recommended as treatment.
- Dyserythropoiesis in dogs may respond to prednisone and recombinant human erythropoietin (100 U/kg SC q48h for 10 days).

Acute Myeloid Leukemia

Acute Myeloblastic Leukemia (M_1, M_2)

Acute myeloblastic leukemia (AML) is relatively common among leukemias and often is associated with FeLV in cats. It is characterized by a high percentage of myeloblasts in the bone marrow (>20% of non-erythroid cells). Acute promyelocytic leukemia (M_3) is recognized in people.

- These cells have pale basophilic cytoplasm that may contain several small, red granules. Nuclei are round, with prominent nucleoli. Intermediate- and late-stage forms of neutrophils are present to a variable degree.
- The CBC often indicates a severe nonregenerative anemia and thrombocytopenia. Total leukocyte counts usually are elevated.
- Cytochemical staining of blast cells is variably positive for peroxidase, Sudan black B, chloroacetate esterase, leukocyte alkaline phosphatase, and acid phosphatase.
- The bone marrow that is rebounding from neutropenia, such as that following feline panleukopenia infection, can appear neoplastic because of the presence of circulating myeloblasts. Persistent hematologic abnormalities must occur to confirm leukemia.

Acute Myelomonocytic Leukemia (M_4)

This is a common form of myeloid leukemia in dogs and cats. It involves the common stem cell for both granulocytes and monocytes.

- Cytochemical staining suggests the presence of both monoblasts and myeloblasts.
- The two blast cell types together are >20% of non-erythroid cells in the bone marrow.

Acute Monocytic Leukemia (M_5)

This condition has been reported in both dogs and cats. It is characterized by moderate to marked increases of monoblasts in the bone marrow, which are >20% of non-erythroid cells.

- These cells have basophilic cytoplasm that lacks any obvious granulation. Nuclei exhibit extreme irregularity, which gives the cell a folded appearance. Nucleoli are usually prominent.
- Cytochemical staining of the blast cells is generally positive for nonspecific esterases and acid phosphatase.

Erythroleukemia (M_6)

Erythroleukemia incorporates the varied manifestations of erythroid neoplastic cells. It frequently is associated with FeLV infection in cats.

- Rubriblasts may predominate or accompany neoplastic myeloblasts. Dysplastic changes are frequently prominent, such as megaloblastosis, neutrophil giantism, or hypersegmentation.
- Normochromic macrocytes and nucleated erythrocytes are found in the blood, without regenerative signs of polychromasia or reticulocytosis.
- Over time, this form of leukemia may change in appearance and progress to involve predominantly granulocytic precursors.

Megakaryoblastic Leukemia (M_7)

This is a rare type of leukemia reported in dogs and cats. It may be associated with irradiation in the dog.

- Laboratory findings indicate severe nonregenerative anemia, leukopenia, and often thrombocytopenia, although platelet counts are variable.
- Megakaryoblasts may appear in the circulation, and platelet morphology is often bizarre, characterized by giantism and abnormal granulation.
- Hemolymphatic organs usually are infiltrated by the neoplastic population, which rules out a benign proliferation.
- Immunocytochemical stains are used to determine the megakaryocytic origin of the blast cells.

Chronic Myeloproliferative Diseases

Chronic Granulocytic (Neutrophilic) Leukemia

This disorder is characterized by a low percentage of myeloblasts in the bone marrow (<20% of all nucleated cells), with increased numbers of early forms such as progranulocytes to metamyelocytes in the blood and bone marrow.

- Leukocytes often are elevated markedly (40,000–200,000/µl). Anemia is mild to moderate, and platelet counts are variable.
- The elevated leukocyte count distinguishes this condition from MDS because both conditions have a similar bone marrow presentation. The marrow myeloid-to-erythroid ratio is 4:1 to 25:1.
- This form of leukemia must be differentiated from leukemoid reactions caused by highly suppurative infections such as pyometra (see "Neutrophilia").
- Death often occurs months after detection and may be associated with a blast cell crisis, severe anemia, and thrombocytopenia.

Eosinophilic Leukemia

This type of leukemia is rare, but it has been documented in the cat associated with FeLV infection and in the dog.

- It is characterized by a high eosinophil count (often >50,000/µl) with a shift toward immaturity. A moderate anemia may be present. It may be difficult to differentiate this malignancy from reactive hypereosinophilic conditions (e.g., allergies, parasitism, eosinophilic inflammatory diseases, mast cell tumors, and certain lymphomas) (see "Eosinophilia").
- Leukemic eosinophils spread from the bone marrow and infiltrate other tissues, such as the lymph nodes, liver, and spleen.

Basophilic Leukemia

This disorder is rare, and most cases have been reported in the dog. Mature and immature basophils are increased in the blood or bone marrow, and tissue infiltration may occur. It has been associated with thrombocytosis and anemia.

- Cytochemical staining with omega-exonuclease is helpful in identifying basophil precursors when cytoplasmic granulation is inapparent.
- Basophilic leukemia must be differentiated from mast cell leukemia.
- Treatment is suggested using hydroxyurea (Hydrea, Squibb) at 50 mg/kg/day in dogs for 3 days a week until cell counts are reduced sufficiently. Survival has been reported up to 21 months.

Polycythemia Vera

Polycythemia vera occurs rarely in dogs and cats.

Clinical Signs

Clinical signs differ from other myeloid leukemias because they relate to increased erythrocyte mass and blood hyperviscosity.

- Mucous membranes are dark red because of hematocrits of 65% to 82%. Splenomegaly usually is not present.
- Polyuria, polydipsia, hemorrhage, and neurologic disorders occur in 50% of canine cases.

Diagnosis

Rule out other causes of erythrocytosis (see "Polycythemia"). Arterial blood gas evaluations are normal, with no evidence of hypoxia. Erythropoietin levels are absent or reduced when measured at specialized laboratories. Leukocyte and platelet counts are normal to mildly elevated. Bone marrow examination indicates hyperplasia of the erythroid line, with normal morphology and maturation. Myeloblasts make up less than 20% of nucleated cells.

Treatment

Use phlebotomy for immediate relief (10–20 ml/kg/day).

- Survival of at least 1.5 years is possible with hydroxyurea given at 30 mg/kg/day for 1 week then 15 mg/kg once daily until remission; then taper to the lowest effective frequency of administration based on monitoring hematocrit. Monitor cats more closely because of greater risk of myelotoxicity.
- Radiophosphorus ^{32}P (2.4–3.3 mCi/m^2) has been used with encouraging results.

Primary Thrombocythemia

Primary, or essential, thrombocythemia is a rare neoplastic proliferation of platelets reported in the dog and cat. It is not related to transient or reactive increases (see "Thrombocytosis").

- Clinical signs include splenomegaly and platelet function abnormalities, such as spontaneous bleeding and thromboembolism.
- Platelet counts are persistently greater than 600,000/µl and are usually greater than 1 million/µl. Neutrophilia or basophilia also may be present.
- Treatment may include melphalan (2–4 mg/m^2), hydroxyurea (500 mg/m^2), or radiophosphorus ^{32}P (2.4–3.5 mCi/m^2). Therapy produces a survival of up to 32 months.
- Transformation to chronic myelogenous leukemia has been reported.

Idiopathic Myelofibrosis

This chronic myeloproliferative disease is also known as agnogenic myeloid metaplasia or chronic megakaryocytic-

granulocytic myelosis. It is an uncommon condition that results in intramedullary and extramedullary hematopoiesis accompanied by a reactive or secondary marrow fibrosis late in the course of the disease. The hematopoietic precursors most involved are granulocytic and megakaryocytic forms, which infiltrate the spleen and liver. Some cases may be mistaken for acute myeloid leukemia of megakaryocytic origin.

- The peripheral blood often has concurrent immature granulocytes and erythroid cells, termed a *leukoerythroblastic reaction*. Erythrocytes may display poikilocytosis with a teardrop appearance (dacryocytosis).
- Bone marrow aspiration is often difficult related to the presence of myelofibrosis, so core biopsy is recommended to confirm the diagnosis.
- Survival varies from months to years depending on the response to treatment for the nonregenerative anemia.

Chapter

23 Coagulation Diseases

Marjory B. Brooks

Coagulation disorders comprise a group of bleeding diatheses caused by dysfunction of the clotting cascade and subsequent failure of fibrin clot formation. Included in this discussion of coagulation disorders are von Willebrand disease and the complex syndrome of disseminated intravascular coagulation. Common bleeding diatheses that are not coagulation disorders include thrombocytopenia and acquired platelet dysfunction (platelet disorders are discussed in Chapter 22). Initial examination should aim to differentiate bleeding caused by localized blood vessel injury or vessel disease from bleeding due to a systemic platelet or coagulation defect.

ETIOLOGY

Categories of bleeding disorders are listed in Table 23-1 and include coagulation factor deficiencies, von Willebrand disease, and disseminated intravascular coagulation.

Coagulation Factor Deficiencies

Acquired Deficiencies

Acquired deficiencies of functional coagulation factors are common disorders and are caused by decreased production of coagulation factors, release of inactive factors, or inhibition of factor activity.

Production Defect

Coagulation factors are proteins synthesized primarily or exclusively in the liver. Clinically significant reduction in these factors most often accompanies acute fulminant necrosis, chronic cirrhosis, and portosystemic shunting diseases; each of these causes severe liver failure and marked reduction in functional hepatic mass.

Inactive Factors

Vitamin K Deficiency

- The prothrombin group of coagulation factors (factors II, VII, IX, and X) require vitamin K for post-translational carboxylation. This modification allows the factors to assume an active conformation and participate in the coagulation cascade.
- The most common vitamin K deficiency state in small animal medicine occurs after ingestion of anticoagulant rodenticides. These poisons prevent intrahepatic vitamin K recycling, which depletes vitamin K from body stores. Potency and duration of effect vary for different poisons. Overdose of the anticoagulant drug warfarin causes bleeding via the same mechanism.
- Posthepatic biliary obstruction and infiltrative bowel disease also cause vitamin K deficiency by reducing its intestinal absorption.
- Occasionally, bleeding due to vitamin K deficiency is seen in neonatal puppies. Typically, these puppies are born prematurely or are delivered by cesarean section.

Factor Inhibition

Heparin

- Heparin inhibits fibrin clot formation by enhancing the activity of the plasma anticoagulant protein, antithrombin III, several thousand-fold.
- Bleeding due to iatrogenic factor inactivation results from overdose of heparin for treatment of thrombotic disorders or excessive heparinization of transfused blood products.
- Release of heparin from mast cell tumor granules often causes local tissue hemorrhage and edema. In rare cases, massive degranulation of disseminated tumor causes systemic anticoagulation.

Pathologic Inhibitors

- High plasma concentration of fibrin(ogen) degradation products can interfere with mature fibrin clot formation.
- Autoantibodies and alloantibodies directed against specific coagulation factors have been reported in human patients and should be included in the differential of acquired coagulopathy in animals.
- Antibodies directed against phospholipid-binding proteins, referred to as “lupus anticoagulants,” cause prolongation of in vitro clotting times but are associated with clinical thrombotic syndromes.

Table 23-1. CLASSIFICATION AND CAUSES OF COAGULATION DISORDERS

Category	Cause
Coagulation factor deficiency	
Acquired (multiple) factor deficiencies	Decreased factor production
	Liver failure (acute necrosis, chronic cirrhosis, portosystemic shunts)
	Decreased factor activation
	Vitamin K deficiency (anticoagulant rodenticide toxicity, biliary obstruction, malabsorption, neonatal)
	Heparin excess (iatrogenic, mast cell tumor)
	Pathologic inhibitors (fibrin degradation products, anti-factor antibodies)
Inherited (single) factor deficiencies	X-linked traits—Males affected
	Hemophilia A—Factor VIII deficiency (most common defect in dogs and cats; German shepherd breed has high prevalence)
	Hemophilia B—Factor IX deficiency (especially Airedale and Bichon, but any purebred and mixed-breed dogs and cats)
	Autosomal traits—Males and females affected
	Dysfibrinogenemia and hypofibrinogenemia (borzoi, French bulldog, DSH cats)
	Prothrombin deficiency (boxer, English cocker)
	Factor VII deficiency—Mild bleeding (beagle), moderate to severe bleeding (malamute)
	Factor X deficiency—Severe bleeding (American cocker spaniel, Jack Russell terrier, DSH cat)
	Factor XI deficiency—Severe bleeding (English springer spaniel, Kerry blue terrier, DSH cat)
	Factor XII deficiency—No abnormal bleeding (common in cats, DSH and purebred)
von Willebrand disease	Inherited—Autosomal trait; 3 subtypes
	Type 1—Variable severity in affected dogs, high prevalence (Doberman pinscher, golden retriever, standard poodle, Pembroke corgi, Bernese mountain dog, miniature pinscher, dachshund, others)
	Types 2 and 3—Severe bleeding in affected dogs (German wirehaired and shorthaired pointer, Scottish terrier, Shetland sheepdog, Chesapeake retriever, others)
Disseminated intravascular coagulation	Factor depletion and systemic fibrinolysis
	Neoplasia (hemangiosarcoma, prostatic and mammary carcinoma, lymphoid tumors)
	Sepsis
	Liver disease
	Pancreatitis
	Intravascular hemolysis
	Severe tissue injury (burns, crush wounds)

DSH, domestic shorthair.

Inherited Deficiencies

Inherited factor deficiencies are caused by mutations in genes coding for specific coagulation proteins or vitamin K recycling enzymes. These defects are typically found in certain lines of purebred dogs and cats and are often propagated when asymptomatic carriers are bred. Hereditary bleeding disorders may also arise from new, spontaneous mutations in previously unaffected families of purebred or mixed-breed animals. Inheritance patterns vary for different factor deficiencies.

X-linked Traits

Hemophilia is by far the most common severe coagulation factor deficiency and is inherited as an X-linked recessive trait. Spontaneous mutations causing hemophilia arise frequently in dogs and cats.

- Males inheriting one abnormal gene from their mother express the trait, whereas females inheriting one abnormal gene from either parent are asymptomatic carriers.
- Mutations in the factor VIII gene cause hemophilia A and arise about 5 times as often as those in the factor IX gene. Hemophilia B is a specific deficiency of factor IX.
- German shepherds, especially those with European dogs in their pedigree, have the highest breed prevalence of canine hemophilia A.

Autosomal Traits

Males and females express these traits with equal frequency.

- Clinically significant bleeding disorders due to inherited deficiencies of factors XI, X, VII, and II and fibrinogen have been described.
- Factor XII deficiency is common in cats but does not cause a clinical bleeding diathesis.
- A combined deficiency of vitamin K-dependent factors (II, VII, IX, and X) has been reported in Devon Rex cats and Labrador retriever dogs.

Von Willebrand Disease

Von Willebrand (vWD) disease is the most common hereditary bleeding disorder in dogs. Bleeding in affected individuals is caused by deficiency or dysfunc-

tion of von Willebrand factor (vWF), a plasma protein critical for normal platelet function in the primary phase of hemostasis.

- The trait is autosomal; both males and females can transmit and/or express vWD.
- Exacerbation of the bleeding tendency of vWD may be seen in association with concurrent thrombocytopenia, infection, hormonal fluctuation, or endocrinopathy (especially thyroid insufficiency). Avoid giving drugs with antiplatelet effects, such as aspirin and other nonsteroidal anti-inflammatory drugs, plasma expanders, and heparin, to vWF-deficient patients.
- Breeds with high prevalence or severe forms of vWD include Doberman pinscher, Scottish terrier, Shetland sheepdog, German wirehair and shorthair pointer, Pembroke Welsh corgi, Chesapeake retriever, and Australian shepherd. The vWD trait can occur in any breed and is occasionally diagnosed in mixed-breed dogs.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a dynamic disease process caused by systemic activation of the coagulation cascade. The loss of localized clot formation results in thrombotic occlusion of small and midsize vessels, with compromise to tissue blood supplies and secondary activation of fibrinolytic pathways.

- Disorders that trigger the DIC process cause widespread damage to vascular tissue, platelet aggregation and consumption, or intravascular release of tissue factor.
- DIC most often accompanies severe inflammatory disease syndromes and diseases causing severe tissue injury such as sepsis, neoplasia (especially hemangiosarcoma, hepatic neoplasia, lymphoma, and prostatic and mammary carcinoma), burn or crush wounds, pancreatitis, and intravascular hemolysis.
- Bleeding may develop in patients with DIC as coagulation factors, platelets, and regulatory hemostaticproteins are depleted in the systemic thrombotic process.

CLINICAL SIGNS

Coagulation disorders are characterized by spontaneous hemorrhage and/or excessive bleeding after surgery or trauma. Hemorrhage into the central nervous system (CNS) may cause acute onset of neurologic dysfunction or sudden death. Thrombocytopenia (see Chapter 22), rather than coagulation factor deficiency, is by far the most common cause of petechiae in small animals. Hemorrhagic macules, papules, and ecchymoses are lesions most characteristic of primary or secondary vasculitic diseases and rarely are caused by coagulopathy.

- *Coagulation factor deficiencies* tend to cause spontaneous bleeding into the chest, abdomen, or muscles, and subcutaneous hematoma formation.
- *vWD* is associated most often with spontaneous hemorrhage from mucosal surfaces of oral and nasal cavities or from intestinal and genitourinary tracts. Excessive or prolonged bleeding occurs after injury or surgery.
- *Bleeding in association with DIC* is usually severe and occurs from mucosal surfaces and into body cavities; in addition, signs of the underlying disease are usually present.
- *Bleeding from venipuncture sites* most often accompanies severe deficiencies of multiple coagulation factors or fulminant DIC. Absence of this sign does not rule out a clinically significant coagulation disorder.

DIAGNOSIS

▼ ***Key Point*** The first consideration when evaluating bleeding patients is to differentiate a blood loss due to injury of a single or local group of blood vessels from a systemic bleeding diathesis. This distinction is usually apparent after thorough history, physical examination, and evaluation of quick assessment tests.

History

The history should include specific questions to identify previous episodes of spontaneous bleeding or excessive hemorrhage after surgery or trauma.

- Gingival bleeding from tooth eruption and bleeding from docking or dewclaw removal are common signs of inherited coagulation factor deficiency and vWD. Conversely, history of severe trauma or invasive surgical procedure without excessive hemorrhage rules out an inherited hemostatic defect.
- Patients with histories of hepatic disease or disorders associated with DIC are at risk for acquired coagulation defects and should be further evaluated before invasive procedures.

Physical Examination

Physical examination should define as thoroughly as possible the nature, severity, and precise anatomic source of hemorrhage. In patients with a single obvious site of external blood loss, ophthalmoscopy, digital anorectal examination, careful auscultation, and joint palpation may identify additional sites of hemorrhage that would be suggestive of a systemic hemostatic defect.

Radiographic Examination

Radiography of the thorax and abdomen can detect fluid densities indicative of bleeding in pleural, peritoneal, or retroperitoneal spaces. Intrapulmonary

hemorrhage causes an alveolar pattern on thoracic films. Epistaxis, hematuria, and gastrointestinal hemorrhage may be difficult to differentiate as being signs of local vessel trauma versus signs of systemic coagulation disorder. Contrast radiography, ultrasonography, and computed tomography (CT) scan can non-invasively identify erosive, infiltrative, or mass lesions causing vessel damage. CT scan is especially useful for evaluating the nasal cavity to identify focal lesions early in the disease process before they extend into the CNS.

Quick Assessment Tests

Quick assessment tests (QATs) are useful for identifying hemostatic defects and evaluating hemostatic function prior to performing invasive procedures. Table 23-2 presents additional diagnostic ruleouts and procedures, based on results of QATs, for differentiating coagulation disorders from other hemostatic defects. Table 23-3 lists expected results of the following QATs for categories of common coagulation disorders.

Slide Estimate of Platelet Number

Thrombocytopenia can be ruled out if examination of a stained blood film under oil immersion reveals at least 7 to 10 platelets per field for dogs and 10 to 15 platelets per field for cats.

Activated Clotting Time

Most of the common acquired and inherited coagulation factor deficiencies can be detected by prolongation of activated clotting time (ACT), a functional test of the intrinsic clotting system.

- Procedure
  - Collect 2 ml of whole blood directly into a test tube, maintain the needle (Vacutainer, Becton-Dickinson) in the vein, remove the first tube, and replace it with a second evacuated tube containing siliceous earth (Vacutainer, Becton-Dickinson) to withdraw a second 2-ml sample.
  - Warm the evacuated tube to 37°C before sampling.
  - Immediately after blood collection, gently invert the second tube several times to mix the blood with the siliceous activator then place it in a heating block calibrated at 37°C.
  - After incubation for 45 seconds, remove the tube from the block at 5- to 10-second intervals, gently tilt it, and evaluate for clot formation.
- ACT is the time elapsed from sampling to clot formation.
- Normal range of canine ACT is 60 to 120 seconds; feline range is 60 to 70 seconds.
- ACT may be technically difficult to perform in cats and small dogs.
- Sampling from the jugular vein is not recommended in patients with severe hemorrhagic disorders because iatrogenic hematoma formation and subsequent upper respiratory obstruction might occur.

Bleeding Time Tests

Bleeding time tests are in vivo measures of hemostatic function performed by making a standard wound and timing the interval to cessation of blood flow. These tests should be performed only on patients with platelet counts greater than 100,000/µl because significant thrombocytopenia prolongs bleeding time.

Buccal Mucosa Bleeding Time Test

- Procedure
  - Evert the lip, then hold it in place with gauze that encircles the muzzle and causes the buccal veins to engorge slightly.

Table 23-2. DIAGNOSTIC CHECKLISTS BASED ON RESULTS OF QUICK ASSESSMENT TESTS

QAT	Result; Interpretation	Checklist
Platelet estimate	Low; thrombocytopenia	See Chapter 22
Bleeding time	Prolonged; defect of primary hemostasis	History (drug exposure, familial bleeding) CBC/metabolic profile, endocrine profile Radiography vWF:Ag Fibrin degradation product or D-dimer titer Platelet function testing
Activated clotting time	Prolonged; defect of intrinsic and/or common coagulation system	History (toxin exposure, familial bleeding) Coagulation screening assays Coagulation factor analysis CBC/metabolic profile Liver function Radiography Fibrin degradation product or D-dimer titer Response to vitamin K therapy

CBC, complete blood count; QAT, quick assessment test; vWF:Ag, von Willebrand factor antigen.

Table 23-3. EXPECTED RESULTS OF QUICK ASSESSMENT TESTS FOR COAGULATION DISORDERS

Category	Tests			
	Platelet Count	ACT	TBT	BMBT
Coagulation factor deficiency				
Acquired deficiencies	N	A	A	N
Inherited deficiencies				
Hemophilia (A and B)	N	A	A	N
Dysfibrinogenemia	N	A	A	N/A
Prothrombin and Factor X, XI deficiencies	N	A	A	N
Factor VII deficiency	N	N	N	N
Factor XII deficiency	N	A	N	N
vWD	N	N	A	A
DIC (hemorrhagic phase)	A	A	A	N/A

A, abnormal; ACT, activated clotting time; BMBT, buccal mucosal bleeding time; DIC, disseminated intravascular coagulation; N, normal; QAT, quick assessment test; TBT, toenail bleeding time; vWD, von Willebrand disease.

- Use a template device (Simplate II, Organon Teknika) to make two parallel incisions in mucosa of the upper lip.
- Collect hemorrhage from the wounds on filter paper applied underneath, but not directly to, bleeding sites.

- Buccal mucosa bleeding time (BMBT) is the average time elapsed from triggering the device until blood stops flowing from both incisions.
- Normal BMBT is 2 to 4 minutes for dogs and cats.
- BMBT is prolonged for patients with acquired and inherited platelet dysfunction and vWD but is normal for patients with coagulation factor deficiencies and for some patients with DIC.
- Cats require sedation for BMBT testing, but some dogs tolerate this procedure without chemical restraint.

Toenail Bleeding Time Test

- Procedure
  - Using a guillotine-type toenail clipper, make a clean transection at the tip of the nail cuticle.
  - Allow blood to flow freely from the injury.
- The time from transection until blood ceases to flow is the toenail bleeding time (TBT).
- Normal TBT is 5 to 6 minutes; accuracy depends on technique and immobilization of the patient's digit during the procedure.
- TBT is less specific than BMBT and is prolonged for patients with clinically significant coagulation factor deficiencies, vWD, platelet dysfunction, and bleeding due to DIC.
- The TBT test should only be performed on sedated or anesthetized patients.

Definitive Tests

Definitive tests to diagnose coagulation disorders depend on correct sampling technique and test systems that are validated specifically for canine and feline patients. Table 23-4 lists coagulation factors of the intrinsic, extrinsic, and common pathways, a classification system useful for in vitro diagnosis of bleeding disorders. Table 23-5 presents expected results of diagnostic tests for categories of common coagulation disorders.

Coagulation Screening Assays

These tests measure the time, in seconds, for in vitro fibrin clot formation. Prolongation of screening assay times beyond the laboratory's reference range for the species is indicative of coagulation factor deficiency or inhibition.

- *Activated partial thromboplastin time (aPTT)* is sensitive to deficiencies of intrinsic and common coagulation pathways.

Table 23-4. COAGULATION FACTORS OF THE INTRINSIC, EXTRINSIC, AND COMMON PATHWAYS

Intrinsic	Extrinsic	Common
Contact factors (kininogen, prekallikrein)	Tissue factor	Factor X
Factor XII	Factor VII	Factor V
Factor XI		Factor II (prothrombin)
Factor IX		Factor I (fibrinogen)
Factor VIII		

Table 23-5. DEFINITIVE DIAGNOSTIC TESTS FOR COAGULATION DISORDERS

Category	Tests	Results
Coagulation Factor Deficiency		
Acquired deficiencies		
Liver disease	aPTT, PT, TCT	Prolonged
	Fibrinogen	Low
	Factor assays	Low activity for most factors
Vitamin K deficiency	aPTT, PT	Prolonged
	TCT, Fibrinogen	Normal
	Factor assays	Low factors II, VII, IX, X
Heparin excess	aPTT, PT, TCT	Prolonged (PT least affected)
	Fibrinogen	Normal
	anti-Xa activity	High (>1 U/ml)
Hereditary deficiencies		
Hemophilia	aPTT	Prolonged
	PT, TCT, fibrinogen	Normal
	Factor assays	Low factor VIII (Hemophilia A) or IX (hemophilia B)
Hypo/dysfibrinogenemia	aPTT, PT, TCT	Prolonged
	Fibrinogen	Low
Prothrombin or factor X deficiency	aPTT, PT	Prolonged
	TCT, fibrinogen	Normal
	Factor assays	Low factor II or X
Factor VII deficiency	aPTT, TCT, fibrinogen	Normal
	PT	Prolonged
	Factor assays	Low factor VII
Factor XI or XII deficiency	aPTT	Marked prolongation
	PT, TCT, fibrinogen	Normal
	Factor assays	Low factor XI or XII
von Willebrand Disease		
	aPTT, PT, TCT, fibrinogen	Normal
	Buccal bleeding time	Prolonged
	vWF:Ag	Low (type 1 & 2), absent (type 3)
	vWF collagen binding, multimers	abnormal (type 2)
Disseminated Intravascular Coagulation		
	aPTT, PT, TCT	Normal to marked prolongation
	Fibrinogen	High or normal (thrombotic DIC)
	Platelet count and antithrombin	Low (hemorrhagic DIC)
	FDPs and D-dimer	Low
	Red cell morphology	High
		Schistocytes

aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; FDP, fibrin or fibrinogen degradation product; PT, prothrombin time; TCT, thrombin clotting time; vWF:Ag, von Willebrand factor antigen.
Reference ranges author's laboratory 2004: Canine: aPTT (10–17 sec); PT (14–18 sec); TCT (5–9 sec); fibrinogen (147–479 mg/dl). Feline: aPTT (14–18 sec); PT (18–22 sec); TCT (5–8 sec); fibrinogen (76–270 mg/dl). Both species: Bleeding time < 4 minutes; vWF:Ag > 50%; antithrombin > 75%; FDP < 5 µg/ml; D-dimer < 250 ng/ml.

- *Prothrombin time (PT)* detects deficiencies in extrinsic and common pathways.
- *Fibrinogen* concentration (mg/dl) is a quantitative measure of plasma fibrinogen.
- *Thrombin clotting time (TCT)* detects both deficiency and dysfunction of fibrinogen.
- Based on the pattern of abnormalities detected in coagulation screening assays, individual clotting factor analyses identify specific single or multiple coagulation factor deficiencies.

Specific von Willebrand Factor Assays

Specific tests must be performed to establish diagnosis of vWD. Clotting time tests, coagulation assays, and platelet count do not detect abnormal vWF. Three subtypes of vWD occur in dogs: Type 1 vWD is a mild to moderate form characterized by low vWF concentration and normal vWF structure. Type 2 vWD causes a severe bleeding diathesis, with low vWF concentration and abnormal structure. Type 3 vWD is a severe form caused by a complete lack of vWF.

- Measurement of vWF antigen is a specific measurement of plasma vWF concentration.
- Patients with vWF below the normal range (established at each testing laboratory) are considered at risk for carrying and/or expressing the vWD trait.
- In addition to low or absent plasma vWF, affected individuals have prolonged *in vivo* bleeding time.

Diagnosis of Disseminated Intravascular Coagulation

Definitive diagnosis of DIC cannot be based on one diagnostic test but depends on a combination of clinical signs and laboratory abnormalities. The DIC process is dynamic, and an early thrombotic or pro-coagulant phase may be followed by later signs of hemorrhage. Serial evaluations are useful to monitor response to therapy and determine prognosis.

- The presence of high plasma concentration of fibrin or fibrinogen degradation products or of cross-linked fibrin fragments (D-dimer) is compatible with ongoing systemic fibrinolysis usually caused by DIC.
- Additional laboratory criteria of DIC include the following:
  - Falling platelet count
  - Low antithrombin activity
  - Low or high fibrinogen
  - Prolongation of coagulation screening assays (aPTT, PT, TCT)
  - Presence of schistocytes on stained peripheral blood smears
  - Elevated values of plasma-soluble fibrin monomer and thrombin-antithrombin complex are believed to be sensitive tests of DIC; however, these assays are not readily available in clinical human or veterinary practice

TREATMENT

▼ ***Key Point*** Successful management of patients with coagulation disorders requires establishing an accurate diagnosis and then administering appropriate transfusion and non-transfusion support. Pretreatment samples are invaluable for establishing definitive diagnosis early in the course of disease.

Transfusion Therapy

Transfusion therapy to supply active factors is required for patients with severe, inherited coagulation factor deficiencies and severe vWD and for patients with acquired disorders that are not responsive to correction of an underlying disease process. Table 23-6 lists blood product(s) and dosages for treating specific coagulation disorders (see Chapter 22 for a description of cross-matching protocol).

- Transfusion of whole blood, administered within 4 to 6 hours of collection, supplies active coagulation factors and vWF, as well as red blood cells (RBCs).
- Transfusion of plasma products (fresh plasma, fresh frozen plasma, plasma concentrate), rather than whole blood, reduces the risk of immunologic transfusion reactions, most importantly RBC sensitization. Plasma components also can be transfused preoperatively and repeatedly in 1 day without causing volume overload.
- Stored whole blood and packed red cells do not contain replacement levels of coagulation factors or vWF, but the administration of red cells is indicated for patients with signs of acute or chronic blood loss anemia. Packed cells, in combination with an appropriate plasma product, are the therapeutic equivalent of fresh whole blood. The use of blood components, rather than fresh whole blood, provides a more convenient, rapid, and often safer means of transfusion support.
- Do not routinely pretreat with antihistamine or corticosteroid before transfusion of any blood product. Acute immune reactions directed against RBCs can be prevented in cats by using donors that are blood type and cross-match compatible with the recipient. Anti-RBC reactions are prevented in dogs by using type-compatible or "universal donor"–type dogs. Dogs negative for dog erythrocyte antigen (DEA) 1 (1.1 and 1.2) and negative for DEA 7 are unlikely to

Table 23-6. GUIDELINES FOR TRANSFUSION*

Product	Volume	Frequency	Indications
Fresh whole blood†	12–20 ml/kg	q24h	Signs of anemia accompanying coagulation factor deficiencies, von Willebrand disease, disseminated intravascular coagulation
Packed red cells	6–10 ml/kg	q12–24h	
Fresh plasma†	6–12 ml/kg	q8–12h	Coagulation factor deficiencies, von Willebrand disease, hemorrhagic disseminated intravascular coagulation
Fresh frozen plasma‡			
Plasma cryoprecipitate§	1 U¶/10 kg	q4–12h (as needed)	Hemophilia A (factor VIII deficiency), fibrinogen deficiency, von Willebrand disease
Cryosupernatant§	6–12 ml/kg	q8–12h	Hemophilia B (factor IX deficiency); Factor VII, X, and XI deficiency; vitamin K deficiency

*Transfuse at a rate of 1–2 ml/min for cats and puppies, 3–6 ml/min for adult dogs.
†Collected in citrate anticoagulant, transfused within 4–6 hours of collection.
‡Frozen within 4–6 hours of collection, stored below –20°C.
§Supernatant remaining after thawing fresh frozen plasma for separation of cryoprecipitate.
¶1 unit = cryoprecipitate produced from 200 ml of fresh frozen plasma.

sensitize recipients and can be considered universal donors.
- Cross-species transfusions of any blood product are contraindicated because fatal anaphylaxis can result.

Nursing Care

Nursing care practices that reduce hemorrhage include the following:

- Confinement to limit activity
- Feeding soft food
- Avoidance of neck leads and intramuscular injections
- Use of peripheral veins for sampling or intravenous catheter placement

Do not give platelet inhibitory drugs, including sulfas and nonsteroidal anti-inflammatory agents.

Wound Management

Good management reduces the need for transfusion in some patients with coagulation disorders and mucosal or cutaneous hemorrhage. The best treatment, for even small wounds, is usually suture and/or pressure bandages. Application of tissue adhesive (Vetbond, 3M Co.) to focal areas of bleeding also can limit local blood loss.

Drug Therapy

Vitamin K Therapy

Vitamin K therapy improves hemostasis only in vitamin K-deficient patients. It often is initiated pending test results, but maintenance of vitamin K therapy is not indicated when diagnosis of inherited factor deficiency, non-obstructive liver disease, vWD, or DIC is made. Anticoagulant rodenticide toxicities are the most common cause of vitamin K deficiency in dogs and cats. Vitamin K reverses the anticoagulant effect of rodenticides over a period of 24 to 48 hours from initiation of therapy.

Treatment for Warfarin Toxicity

Warfarin is a relatively short-acting poison, and treatment for a total of 1 week usually is adequate. Standard treatment is as follows:

- Administer an initial dose of vitamin K_1 (AquaMephyton, Merck, Sharp, Dohme), 2.2 mg/kg subcutaneously (SC).
- Follow with a dose of 1.1 mg/kg SC or by mouth (PO), q12h, until active bleeding subsides.
- Continue therapy with an oral preparation (Mephyton) at the same twice-daily dosage for a total of 1 week.

Treatment for Long-acting Rodenticide Toxicity

The following steps are taken to treat toxicity from second-generation or long-acting rodenticides (diphacinone, pindone, bromadiolone, and brodifacoum):

- Give transfusions for patients with severe anemia, pulmonary, or CNS hemorrhage at presentation (see Table 23-6).
- Initiate parenteral vitamin K_1 as for warfarin (2.2 mg/kg SC).
- Administer vitamin K_1 at 1.1 mg/kg SC, q12h, until the hematocrit value stabilizes and active bleeding subsides.
- Maintain oral vitamin K_1 at 1.1 mg/kg PO, q12h, for a total of 2 weeks.
- Taper the maintenance dose by one-half every 2 weeks during treatment.
- To prevent relapse, continue therapy for 4 to 6 weeks.

▼ ***Key Point*** Subcutaneous injection of vitamin K is the preferred parenteral route of administration because intravenous vitamin K can cause anaphylaxis, and hematomas may form at intramuscular injection sites. Vitamin K_3 (Synkayvite) is not effective for treating rodenticide toxicity because of its delayed onset of action.

Hormonal Therapy

Endocrine imbalance (hypercortisolism or hypocortisolism, hypothyroidism, and hyperestrogenism) can impair hemostasis and complicate the management of acquired or hereditary platelet and coagulation disorders. Diagnosis and correction of the endocrinopathy can prevent or minimize transfusion requirements.

Thyroxin

Thyroid insufficiency (see Chapter 31) is common in many breeds with the vWD trait, including Doberman pinscher, Bernese mountain dog, golden retriever, and standard poodle.

- Treat hypothyroid dogs with L-thyroxine at a standard replacement dosage of 0.02 mg/kg PO q12–24h, with post-pill monitoring to ensure attainment and maintenance of normal T_4 values.

Desmopressin Acetate

Desmopressin acetate (DDAVP, USV Pharmaceutical), a vasopressin analogue, has shown efficacy in transiently improving hemostasis in some dogs affected with type 1 vWD.

- Its activity probably is the result of release of vWF from intracellular stores, and its effectiveness depends on the patient's ability to produce functional vWF protein.
- Duration of action, after a dose of 1 µg/kg SC, is 3 to 4 hours; repeated dosage within 24 hours does not prolong response time. The onset of action is 15 to 30 minutes.
- Desmopressin is often given as preoperative prophylaxis to dogs with mild to moderate type 1 vWD.

Plasma products should be available in case the patient does not respond.

Heparin Therapy

- Unfractionated heparin therapy (100–300 U/kg SC q6–8h) is often used to manage thrombotic DIC and other acute thrombotic syndromes. Because of extensive protein and cell binding, unfractionated heparin (UFH) anticoagulant effect varies widely among patients and requires close monitoring to prevent overdosage and iatrogenic bleeding. Prolongation of aPTT to approximately 1.5 to 2 times the patient's baseline or the assay's mean value is a common therapeutic target.
- Low molecular weight heparins are newer anticoagulant drugs with a more predictable pharmacologic profile than UFH. Safe and effective dosage guidelines have not yet been developed for dogs and cats. The target therapeutic range for high-dose anticoagulant effect in human patients is 0.5 to 1.0 Units of anti-Xa activity per milliliter.
- Transfusion therapy with fresh blood or blood products to replace active coagulation factors, fibrinogen, and platelets is more likely than heparin therapy to benefit patients presenting with severe hemorrhage in association with DIC.

▼ ***Key Point*** The critical factor for successfully managing all patients with DIC is identification and correction of the underlying disorder.

Chapter 24

Systemic Immune-Mediated Diseases

Michael Stone

Immune-mediated diseases may affect multiple body systems; for example, polyarthritis may be associated with thrombocytopenia or proteinuria. A CBC, platelet count, chemical profile and urinalysis are considered the minimum database for any suspected immune-mediated disease. The diagnosis of "idiopathic immune-mediated disease" remains a diagnosis of exclusion. Infectious/parasitic, neoplastic, and toxic causes must always be excluded with appropriate testing and/or therapeutic trials.

Since many immune-mediated diseases are treated similarly, this chapter begins with a general discussion of treatment and commonly used drugs. This is followed by a discussion of immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, and systemic lupus erythematosus.

TREATMENT OF IMMUNE-MEDIATED DISEASES

Corticosteroids

Corticosteroids are effective immunosuppressive agents. Many animals tolerate their administration with only mild side effects, or the disease goes into remission and the corticosteroid treatment may be stopped. For many animals with immune-mediated disease, single agent therapy with corticosteroids is adequate.

- *Prednisone* is always included initially in immunosuppressive protocols. The dosage is approximately 2.2 mg/kg once daily in most cases; however 1 mg/kg/day may be used in less severe diseases. The dose may be divided into twice daily administration, but there is no obvious benefit from the division. Some dogs are intolerant to prednisone and will develop side effects (polyuria, polydipsia, polyphagia, panting, and/or lethargy) that are unacceptable to the owner.

▼ ***Key Point*** Therapy with an equipotent dose of a different steroid (prednisolone, methylprednisolone, triamcinolone, or dexamethasone) often resolves unacceptable side effects of prednisone (Table 24-1).

▼ ***Key Point*** Some cats do not effectively respond to prednisone. These cats may be "poor converters" that cannot metabolize inactive prednisone to the active form, prednisolone. Thus, when cats don't respond well to prednisone, try using an alternate steroid (see Table 24-1).

- Corticosteroids are generally administered at full doses until the disease is in complete remission. Complete remission may be defined as resolution of signs of disease along with radiographic or laboratory changes that were initially present. After remission is attained the dose is cut, generally in half, for 4 weeks. Reevaluation is then performed, and if signs of disease are absent (on physical or laboratory data), the dose is again halved. This protocol is followed monthly until the animal either relapses or stops medication.

▼ ***Key Point*** The minimum duration of therapy for any immune-mediated disease is 6 months.

- Many patients will experience a relapse as the dose is tapered. Relapse is treated with return to full dose administration, again with monthly tapering, but as the dose is approached that previously allowed relapse, the dosage may then either be held constant or tapered more slowly. If signs of relapse are mild, the dose may instead be increased to the most recently effective dose and held there for a few months before it is tapered again.

Combination Immunosuppression Therapy

Combination immunosuppression therapy is very useful, because the addition of another agent may allow a lower dose of corticosteroid to be used (prednisone-sparing effect). Additional medications may also increase the strength of immunosuppression because they work by different mechanisms. The drug most frequently used in combination with corticosteroids in dogs is azathioprine.

▼ ***Key Point*** Combination immunosuppressive therapy is often more effective and has less side effects than prednisone therapy alone.

Table 24-1. INITIAL IMMUNOSUPPRESSIVE DOSES OF CORTICOSTEROID AND THEIR AVAILABLE STRENGTHS IN THE UNITED STATES

	Available Oral Strengths	Initial Feline Dose (Oral)	Initial Canine Dose (Oral)
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/5 ml syrup	10 mg/day	2.2 mg/kg/day
Prednisolone	5, 20 mg tablets; 15 mg/5 ml syrup	10 mg/day	2.2 mg/kg/day
Methylprednisolone	2, 4, 8, 16, 24, 32 mg tablets	8 mg/day	2.2 mg/kg/day
Triamcinolone	4, 8 mg tablets	2–4 mg/day	0.4 mg/kg/day
Dexamethasone	0.25, 0.5, 0.75, 1, 1.5, 4, 6 mg tablets	1–2 mg/day	0.2 mg/kg/day

Azathioprine

- Azathioprine (Imuran) is administered orally. Adverse side effects are infrequent in dogs. The dose is approximately 2.2 mg/kg once daily until remission occurs, then the same dose is administered every other day.
- A potential side effect is bone marrow suppression, and a complete blood count (CBC) should be evaluated after 7 days, and then every 2 weeks while the patient is receiving daily treatment. Once the patient is receiving every other day therapy, a CBC should be evaluated every 3 months, but bone marrow suppression is unusual at this dose.
- Prednisone and azathioprine are frequently used in combination. The drugs are administered together once daily and then tapered after remission is attained. The method of tapering is somewhat arbitrary; if signs of prednisone intolerance are experienced then the prednisone is tapered first; if bone marrow disease is encountered the azathioprine should be tapered or discontinued first. If the disease was difficult to get into remission then only one drug should be tapered at a time; if the disease easily went into remission, then both drugs may be tapered concurrently. Tapering should be performed every 4 weeks, with the minimum duration of therapy being 6 months. It is important to have a therapeutic plan to follow. Notations in the medical record should include the intended date of recheck, with the tests to be performed and the expected decrease of dose if tests return results within normal limits. Relapse is treated with the administration of full dosage of both medications with gradual taper to the lowest effective dose. As the dose that allowed relapse is approached, the dosage may then either be held constant or tapered more slowly.
- Cats often develop life-threatening neutropenia with the use of azathioprine, and its use in this species is not recommended. Instead, the use of chlorambucil is recommended for cats that require immunosuppression in addition to prednisolone.

Chlorambucil

- Chlorambucil (Leukeran) is an oral drug, used in cats at 15 mg/m^2 (4 mg total dose for most cats) once daily for 4 days, repeated every 3 weeks.
- Potential side effects include anorexia and bone marrow suppression. A CBC should be evaluated 5 to 7 days after the last dose. If after two or more evaluations the CBC remains normal (no leukopenia), further monitoring may not be necessary. If leukopenia is detected (absolute neutrophil count < 3,000/µl), the dose of the next administration should be decreased by 25%. Signs of infection (loss of appetite along with fever) during the expected white blood cell count (WBC) nadir (3–10 days after administration) should be aggressively treated. Physical examination, CBC, and treatment with amoxicillin and enrofloxacin are indicated if severe neutropenia (<1,000/µl) and fever are present.
- In cats, the dosage of chlorambucil should be tapered before the dose of prednisolone is tapered.

Monitoring of Immunosuppressive Therapy

Side effects of immunosuppressive medications often lead to significant morbidity; treatment of any immune-mediated disease involves balancing the control of disease against the side effects of immunosuppressive therapeutics. Obesity related to prednisone is very common, and owners should be specifically counseled about its prevention. Body weight should be recorded and weight management discussed at each recheck. Long-term immunosuppressive therapy may also allow the development of asymptomatic infection, especially in the urinary system. Urine culture is recommended

every 3 to 4 months regardless of the absence of clinical signs.

▼ ***Key Point*** Many patients are euthanized due to side effects of prednisone. Strategies to decrease prednisone-induced side effects include: avoidance of obesity, exchanging equipotent doses of an alternate steroid, use of additional immunosuppressive agents, and routinely scheduled monitoring.

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

The diagnosis of immune-mediated hemolytic anemia (IMHA) is suspected upon discovering severe anemia in the presence of normal serum protein levels (Figure 24-1). IMHA may be classified as regenerative or nonregenerative with red cell destruction in the bone marrow prior to the release of reticulocytes. Red cell destruction may be mild (low grade) or rapidly progressive.

Etiology

- Specific causes of IMHA are not known. However, genetic factors may play a role and certain breeds, such as cocker spaniels, poodles, and old English sheep dogs, show higher incidence of IMHA. Initiating events, such as vaccination, stress, or infectious agents can trigger IMHA in patients with the appropriate predisposing genes.
- In animals presenting with hemolytic anemia, IMHA must be differentiated from other causes of hemolytic anemia, both in dogs (Table 24-2) and in cats (Table 24-3). These are described in Chapter 22.

Clinical Signs

- Historical findings may include weakness, collapse, pale gums and/or discolored urine.
- Physical examination may reveal fever, pale or icteric gums, systolic heart murmur, hepatosplenomegaly (sites of red cell phagocytosis), tachycardia and/or tachypnea.

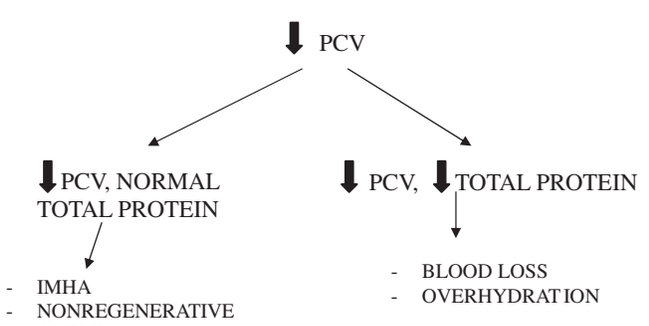

Figure 24-1. Classification of anemia. PCV, packed cell volume; IMHA, immune-mediated hemolytic anemia.

Table 24-2. CAUSES OF HEMOLYTIC ANEMIA IN THE DOG

Hereditary causes (pyruvate kinase deficiency, phosphofructokinase deficiency)
Toxins (onions, zinc, copper)
Babesia canis, B. gibsoni, Mycoplasma hemocanis (formerly *Hemobartonella canis*)
Recent vaccination
Drug reaction (cephalosporins, penicillins, sulfa-drugs, nonsteroidal antiinflammatory drugs, levamisole, Vit K_3)
Neoplasia (hematopoietic, hemangiosarcoma, histiocytic)
Splenic torsion
Hypophosphatemia
Bee sting envenomation
Microangiopathic (disseminated intravascular coagulation, heartworm caval syndrome)
Idiopathic, immune-mediated hemolytic anemia

Table 24-3. CAUSES OF HEMOLYTIC ANEMIA IN THE CAT

Hereditary: pyruvate kinase deficiency (Abyssinian, Somali)
Feline leukemia virus, feline immunodeficiency virus
Mycoplasma hemofelis, Mycoplasma haemiminutum (formerly *Hemobartonella felis*)
Cytauxzoon felis
Toxins (zinc, copper, onion, methylene blue, acetaminophen, D-L-methionine, benzocaine, propylene glycol)
Drug reaction (propylthiouracil, others)
Incompatible blood transfusion
Neonatal isoerythrolysis
Neoplasia (hemangiosarcoma, histiocytic)
Hypophosphatemia
Microangiopathic (disseminated intravascular coagulation)
Idiopathic, immune-mediated hemolytic anemia

Diagnosis

- Perform a CBC with manual differential count, platelet count, reticulocyte count, chemistry profile, urinalysis, thoracic and abdominal radiographs, coagulation profile, Coombs' test and abdominal ultrasonography. Serology for *Babesia canis* and *B. gibsoni* is indicated in endemic areas. Bone marrow cytology is indicated if the anemia is nonregenerative or if infiltration with hemolytic histiocytes is suspected (hemophagocytic syndrome).
- Cats should be tested for feline leukemia virus (FLV) and feline immunodeficiency virus (FIV) as well as hemoplasmosis (microscopic blood examination, polymerase chain reaction).
- Typical CBC findings include anemia, reticulocytosis, spherocytosis, and leukocytosis with left shift. Hemolysis can cause a severe granulocytic response that should not be confused with infection.
- Coombs' (direct antiglobulin) test results are usually, but not invariably, positive, with both false-positive

and false-negative results possible. Spontaneous autoagglutination of red blood cells may occur when blood is placed on a slide, however, rouleaux formation must be excluded. Rouleaux tend to disperse when one drop of anticoagulated blood is diluted in three to four drops of saline, whereas antibody-mediated autoagglutination remains.

▼ ***Key Point*** Spherocytosis is present in most cases of IMHA, and strongly supports the diagnosis of immune-mediated hemolytic anemia.

- Biochemistry may reveal increased liver enzymes (thought to reflect hypoxic damage) and hyperbilirubinemia.
- Coagulation profile results are often abnormal in patients with severe hemolysis. Thromboembolism and disseminated intravascular coagulation are recognized as common complications of hemolytic anemia.
- Consider thoracic radiographs to screen for evidence of neoplasia or pulmonary thromboembolism. Abdominal imaging commonly reveals mild hepatosplenomegaly (representing hyperactivity of the mononuclear-phagocytic cell system), however, consider biopsy for nodular irregularities or lymphadenopathy.

Concurrent Diseases

IMHA may coexist with other immune-mediated disease, the most common of which is immune-mediated thrombocytopenia. Interpretation of test results must be cautious, because low platelets may also indicate systemic thrombosis or disseminated intravascular coagulation.

Treatment

- Intravenous fluids are recommended for most cases and supplemental oxygen is essential for dyspneic patients.
- Red cell transfusion is indicated if the packed cell volume (PCV) drops to less than 15%.
- Due to a high incidence of pulmonary thromboembolism in cases with a rapid rate of hemolysis, use prophylactic therapy with heparin (initially 200 units/kg SC q6h and adjust the activated partial thromboplastin time (aPTT) to 1.5 to 2 times normal values through daily monitoring) or aspirin (0.5–5 mg/kg PO q24h).
- Mild cases with PCV >22% and bilirubin <3 mg/dl: treatment with prednisone alone or prednisone with azathioprine may be effective.
- Aggressive hemolytic cases (PCV rapidly dropping or bilirubin >3 mg/dl): treatment with intravenous fluids, heparin, prednisone or dexamethasone, and azathioprine is indicated. More aggressive therapy may be considered: intravenous human immunoglobulin (0.5g/kg IV once daily for 3 days), cyclosporine (Sandimmune 10 mg/kg IV or PO twice daily; Neoral or Atopica 5 mg/kg PO twice daily), or methylprednisolone sodium succinate pulse therapy (11 mg/kg IV once daily for 3 days).
- Monitor blood counts daily until stabilization occurs, then at least weekly until the PCV is >25%. Full doses of immunosuppressive medications are administered until the hematocrit normalizes, and then they are tapered as discussed in the Treatment section. It is not necessary to normalize the hematocrit to eliminate clinical signs of disease, and in some cases it may be preferable to allow a low grade of anemia to persist in order to decrease medications to tolerable levels. The minimum length of treatment is 6 months.

Prognosis

▼ ***Key Point*** Mild IMHA may respond well to treatment, whereas rapidly progressive cases are associated with a high rate of mortality.

The prognosis is guarded to fair for mild cases and very guarded for aggressively hemolytic cases. Many patients are able to taper completely off medications, however, relapses occur unpredictably. Relapses may be associated with immune stimulation due to vaccination, infection, or stress, and avoidance of these causes may be prudent. Monitoring for control, recurrence, and infection should be performed at least 3 to 4 times per year for the life of the patient.

IMMUNE-MEDIATED THROMBOCYTOPENIA

Immune-mediated thrombocytopenia (IMT) is usually suspected when cutaneous petechiae or bleeding from mucosal surfaces are discovered in an otherwise healthy-appearing animal. Severe thrombocytopenia associated with other causes is more often associated with overt clinical illness.

Etiology

A specific cause of IMT is not known. Many other causes of thrombocytopenia exist (Table 24-4) that must be differentiated from IMT; these are usually associated with less severe thrombocytopenia (>25,000/µl). Any drug the patient is receiving must be considered as a potential cause of hapten-mediated thrombocytopenia and stopped, if possible.

Clinical Signs

- Epistaxis, oral cavity hemorrhage, cutaneous petechiation or ecchymoses, hematuria, hematochezia and/or melena are common presenting complaints. Hematomas, hemothorax, hemoperitoneum and

Table 24-4. CAUSES OF THROMBOCYTOPENIA IN THE DOG AND CAT

Sequestration in spleen (splenic neoplasia, torsion, hematoma, thrombosis/infarction)
Drugs (cytotoxic, antibiotics, estrogen, nonsteroidal antiinflammatory drugs, albendazole, griseofulvin, propylthiouracil, ketoconazole, others)
Neoplasia (hematopoietic, histiocytic, hemangiosarcoma)
Infectious agents (*Ehrlichia canis, E. ewingii, E. chafeensis, Anaplasma phagocytophila, A. platys, Rickettsia rickettsii*, parvovirus, distemper, feline leukemia virus, feline immunodeficiency virus, cytauxzoonsis, systemic mycoses, leptospirosis, *Babesia canis, B. gibsoni*, sepsis, endotoxemia)
Bone marrow disease (myelofibrosis, myelodysplasia, necrosis, myelophthesis)
Recent vaccination
Vasculitis
Disseminated intravascular coagulation/systemic thrombosis (thoracic, abdominal, peripheral)
Hemolytic uremic syndrome
Severe hemorrhage (anticoagulant rodenticide, trauma)
Idiopathic, immune-mediated thrombocytopenia

hemarthroses are more commonly associated with anticoagulant poisonings or hemophilia.

- Physical examination may reveal pale gums, splenomegaly, and cutaneous, mucosal, or ocular hemorrhages. Fever is occasionally present. Fundic examination may reveal retinal hemorrhages. Rectal examination may reveal melena or hematochezia.

Diagnosis

- The presence of severe thrombocytopenia (<25,000/µl) in an otherwise healthy-appearing animal is most likely to be caused by immune-mediated, rather than infectious disease. The diagnosis of infectious thrombocytopenia is more likely if fever or other systemic signs are also present.
- Perform a CBC with manual differential, platelet count, coagulation profile, chemistry profile, urinalysis (voided only to avoid iatrogenic hemorrhage), thoracic radiographs and abdominal ultrasound. Bone marrow cytology may be safely performed despite low platelet counts, but is usually not helpful unless bicytopenia or pancytopenia is found. Tick titers (*Ehrlichia canis, Anaplasma phagocytophila* [formerly *E. equi*], *E. ewingii, Rickettsia rickettsii*) and/or treatment with doxycycline may be indicated.
  - CBC should reveal a platelet count of less than 25,000/µl. If bleeding occurs with platelet counts greater than 25,000/µl, consider other causes (anticoagulant, hemophilia, bleeding neoplasm, vasculitis, thrombopathia).
  - Biochemistry is typically normal. Coagulation profile is typically normal although fibrin degradation products and d-dimers may be mildly elevated due to hemorrhage. Abdominal imaging commonly reveals mild hepatosplenomegaly (representing hyperactivity of the mononuclear-phagocytic cell system).
  - Bone marrow evaluation is not routinely necessary, but may reveal increased or decreased megakaryocytes and mild plasmacytosis. Tests for detection of antiplatelet antibodies are not necessary in most cases.

Concurrent Diseases

IMT may coexist with other immune-mediated diseases. Anemia may be caused by blood loss or concurrent IMHA. The presence of spherocytosis, or severe anemia in the face of normal blood protein levels, is suggestive of concurrent IMHA (see Figure 24-1).

Treatment

- Most cases of IMT respond to immunosuppressive therapy with prednisone alone or with prednisone combined with azathioprine.
- Vincristine (0.5 mg/m^2 IV once weekly) may be administered concurrently. Vincristine is not typically considered to be immunosuppressive, but it appears to work synergistically to raise the platelet count. Vincristine is often administered once and only repeated if relapse or lack of response is seen. Side effects of vincristine are uncommon, however, great care must be used to avoid extravasation.
- Avoid Cyclophosphamide (Cytoxan), since an episode of hemorrhagic cystitis, which may occur after only a single dose, may be fatal.
- Platelet transfusions are impractical, instead, either whole fresh blood (supplying at least some platelets) or packed red cells are administered as needed.
- Monitor platelet counts daily until above 25,000/µl and then weekly. Full doses of immunosuppressive medications are administered until the platelet count normalizes, and then tapered as discussed above. It is not necessary to normalize the platelet count to eliminate clinical signs of disease, and in some cases it may be preferable to allow a low grade of thrombocytopenia to persist in order to decrease medications to tolerable levels. The minimum length of treatment is 6 months.

Prognosis

A guarded prognosis should be given until the platelet count begins to rise. Bleeding into the brain or spinal cord may be fatal. Once the platelet count rises, the prognosis is often good. Many patients are able to taper completely off medications; however, relapses occur unpredictably. Relapses may be associated with immune stimulation due to vaccination, infection, or stress, and avoidance of these factors may be prudent. Monitoring for control, recurrence, and infection should be performed at least 3 to 4 times per year for the life of the patient.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an uncommon disease of young to middle aged patients. The disease may affect multiple organs, the most frequently of which are joints, kidneys, and integument. See Chapter 48 for additional discussion of the cutaneous aspects of SLE. A complete diagnostic workup is indicated for patients with waxing and waning signs of illness along with suspicion of immune-mediated disease.

Etiology

- Genetic factors are important and experimental colonies of dogs with SLE have been established.
- SLE patients produce antibodies directed against a broad range of nuclear, cytoplasmic, and cell membrane molecules. Autoantibodies may directly damage tissues or cause damage through the formation of immune complexes. When there is continued production of autoantibody to a self-antigen, overload of the mononuclear phagocyte system may occur. Circulating immune complexes will deposit in walls of blood vessels where there is physiological outflow of fluid, such as glomeruli, synovia, and the choroid plexus.
- Infectious agents and/or environmental triggers (such as sunlight) can worsen SLE in patients with the genetic predisposition.

Clinical Signs

Almost any organ may be affected in SLE, including joints, kidneys, skin, blood cells, muscles, the brain, and the heart (Table 24-5). The most commonly recognized syndrome is immune-mediated polyarthritis, in combination with immune-mediated skin disease, glomerulonephritis, hemolytic anemia and/or thrombocytopenia. Signs may exist concurrently or different manifestations may develop over time.

- Cutaneous manifestations may include erythema, scaling, crusting, depigmentation, and alopecia (see Chapter 48). Ulcers may develop in the skin, mucocutaneous junctions and oral cavity.
- In cats, reported central nervous system (CNS) involvement has included twitching of the ears, tail, and hindlimbs; generalized seizures; hyperesthesia along the dorsum; restless crying; disorientation; ataxia; nystagmus; and ventroflexion of the neck.
- Polymyositis has been suspected in several dogs and cats.
- Neutrophilic myocarditis has been reported in several dogs.

Diagnosis

Criteria for Diagnosis

Patients with SLE must demonstrate at least two separate manifestations of autoimmunity along with positive antinuclear antibody (ANA) test results. Patients with three or more separate manifestations of autoimmunity may also be considered to have SLE despite the absence of detectable ANA. Different manifestations may develop over time. For example, a patient with immune-mediated polyarthropathy and positive ANA that later develops thrombocytopenia, may be considered to have SLE.

Diagnostic Evaluations

Diagnostic testing should include CBC with manual differential, platelet count, biochemistry, urinalysis,

Table 24-5. CLINICAL MANIFESTATIONS IN DOGS AND CATS WITH SYSTEMIC LUPUS ERYTHEMATOSUS

Clinical Sign	Dogs (Incidence*)	Dogs (Percentage)	Cats (Incidence*)	Cats (Percentage)
Nonerosive polyarthritis	236/302	78	9/25	36
Fever	186/275	68	11/21	52
Renal disorders	167/302	55	10/25	40
Dermatologic lesions	138/302	46	15/25	60
Lymphadenopathy/ splenomegaly	66/175	38		
Leukopenia	54/302	18		
Hemolytic anemia	45/302	15	6/25	24
Thrombocytopenia	40/302	13	2/25	8
Myositis	16/275	6		
CNS disorders	16/302	5	6/25	24
Neuropathy	7/302	2		

*Number of cases with clinical finding/number of reported cases (from Stone, 2004).

imaging, joint fluid cytology, histopathology of the skin and/or kidney, and serum ANA. Cats should also be tested for FeLV and FIV. Infectious and neoplastic disease must be excluded through imaging, culture of urine, blood and/or joint fluid, serology for tickborne and fungal disease, and therapeutic antibiotic trials. In tick-infested areas, a 3 to 7 day course of doxycycline should be considered prior to concluding the presence of immune-mediated disease.

Treatment

- Avoid sunlight to prevent photosensitization. Dogs with mild lameness may require only intermittent nonsteroidal anti-inflammatory therapy such as carprofen (4.4 mg/kg once daily), etodolac (15 mg/kg once daily), or meloxicam (0.1 mg/kg once daily).
- More severe signs necessitate corticosteroid with or without azathioprine administration. Medication should be administered at full dosages until remission is obtained, and then tapered slowly as described in the Treatment section. The minimum duration of therapy is 6 months.

Prognosis

The prognosis is generally good; however, waxing and waning of signs may occur. Signs may disappear never to reappear, signs may recur, or new manifestations may develop over time. Progressive renal damage may occur due to deposition of circulating immune complexes, and renal function should be carefully monitored. Periodic (every 3 to 4 months) reevaluation of the CBC, biochemical profile, and urinalysis is indicated to detect and monitor occult disease.

Chapter 25

Diseases of the Spleen

William C. Kisseberth / Margaret C. McEntee

The spleen can be the site of primary disease, or it can be affected by disease elsewhere as an active or passive participant. The spleen has hematopoietic, reservoir, filtering, and immunologic functions. The spleen may be affected by a variety of neoplastic and non-neoplastic disorders. It has an important role in responding to a number of infectious diseases through phagocytosis, antibody production, and modulation of hemoparasitic infections.

Splenic disorders usually are identified by a change in shape, size, and function of the spleen. Splenomegaly is defined as a localized or diffuse splenic enlargement. Splenomegaly generally can be detected on physical, radiographic, or ultrasonographic examination.

ANATOMY AND HISTOLOGY

- The spleen is located in the left cranial abdomen, attached to the greater curvature of the stomach by the greater omentum. Anatomically, the spleen consists of a capsule, trabeculae, and parenchyma that include the white pulp, marginal zone, and red pulp. The blood vessels of the spleen are the splenic artery, a branch of the celiac artery, and the splenic vein, which drains into the gastrosplenic vein. Blood enters the spleen through approximately 25 splenic branches that enter the capsule through the hilus and then enter the trabeculae. The vessels branch repeatedly, then leave the trabeculae and enter the white and red pulp. Blood from the venous sinuses coalesce into veins of the red pulp and merge to become the trabecular veins. The canine spleen is considered to be sinusoidal, while that in the cat is non-sinusoidal. Blood cells in the canine spleen extravasate by moving between adjacent endothelial cells in order to enter the red pulp sinuses; however, in the feline spleen large gaps are present between adjacent endothelial cells, permitting passage into the sinuses without deformation of cell shape.

Capsule and Trabeculae

- A capsule rich in elastic and smooth muscle fibers surrounds the spleen. Fibromuscular trabeculae form a complicated network within the organ. The muscular capsule and trabeculae in the dog and cat spleen permits a several-fold increase in size in the relaxed versus contracted state. The smooth muscle component allows contraction and distension of the spleen.

White Pulp

- The white pulp consists of diffuse and nodular lymphoid and reticuloendothelial cells. Nodules are usually less than 1 mm in diameter. White pulp lymphocytes and reticuloendothelial cells are associated with the splenic arterial circulation; forming periarteriolar lymphatic sheaths (PALS) rich in T lymphocytes. B lymphocytes are located in nodules along these sheaths and represent areas of B lymphocyte proliferation and antibody production.

Marginal Zone

- The marginal zone separates the white pulp from the red pulp. Arterial vessels terminate either in the marginal zone or in the red pulp. The marginal zone is not well developed in the dog and cat. In other species, the marginal zone is functionally important as a major area of circulatory interchange, cell-to-cell interaction, and cell sorting. The marginal zone is where the distribution of blood flow between slow and fast transit pathways is controlled. The slow pathways permit prolonged exposure of blood cells and particles to phagocytic cells.

Red Pulp

- The red pulp consists of the venous sinuses, pulp cords, and the terminal branches of the arterial system. Together, these elements filter the blood. The periarterial lymphatic sheath is lost as arteries enter the red pulp and is replaced by the periarteriolar macrophage sheath. Particles, cells, and plasma pass through gaps between endothelial cells in the terminal arterial capillaries. The red pulp culls abnormal blood cells and processes particulate antigens for presentation to the white pulp where an immune response is mounted.

PHYSIOLOGY AND FUNCTION

Filtration Function

▼ ***Key Point*** The primary function of the spleen is to filter the peripheral blood.

- The filtering capability of the spleen is significantly enhanced in animals with splenomegaly. In the dog, approximately 2.0 L/kg body weight of blood passes through the spleen each minute. The spleen has a unique vascular structure through which the blood circulates in close contact with the reticuloendothelium, allowing ample biologic filtration of cells and particles. Filtration occurs primarily in the marginal zone of the white pulp and by macrophages. Splenic filtration involves three processes: culling, pitting, and erythroclasis.
- *Culling* refers to the destruction of erythrocytes, or other circulating blood cells, physiologically as they age or in pathologic conditions involving increased red cell destruction. These pathologic changes may be associated with blood cell abnormalities or primary splenic changes. Culling is also the process by which other circulating cells and particulate material, such as bacteria, are removed.
- *Pitting* describes the removal of inclusions from erythrocytes with their return to the circulation. These inclusions may include remnants of nuclear material (Howell-Jolly bodies), denatured hemoglobin (Heinz bodies), and hemoparasites such as *Mycoplasma* and *Babesia* spp. Pitting does not occur in the cat because of larger gaps in the walls of the pulp venule.
- *Erythroclasis* involves the destruction of erythrocytes by fragmentation. In contrast to culling, cellular fragments are returned to the peripheral blood and are removed in subsequent passage. Associated diseases include immune-mediated hemolytic anemia and hemoglobinopathies.

Immunologic Function

▼ ***Key Point*** The white pulp of the spleen is the single largest lymphoid organ in the body.

- The spleen reacts primarily to disseminated blood-borne antigens such as circulating bacteria in septicemia. The white pulp is relatively compartmentalized into B and T cell zones. The periarterial lymphoid sheath is composed primarily of T lymphocytes. The marginal zone contains both B and T lymphocytes. The majority of B lymphocytes are located in the germinal center and mantle zones. Circulating lymphocytes enter the spleen and home to the white pulp. Lymphocytes first enter the marginal zone and then migrate to the PALS and lymphoid follicles. If antigen is present, the lymphocytes undergo activation and proliferation; if no antigen is present, lymphocytes return to the circulation.
- The slow circulation of the spleen enhances contact time and resulting phagocytosis of microorganisms. The spleen plays a key role in the defense against polysaccharide-encapsulated bacteria and other circulating particulate antigens. The liver is more effective than the spleen at removing blood-borne bacteria in the presence of a specific antibacterial antibody; however, in the absence of a specific antibody, the spleen becomes crucial for removal of bacteria. The spleen appears to be the primary organ responsible for the production of an early-appearing antibody in response to intravenous particulate antigens.
- Red blood cells acquire surface immunoglobulins as part of the normal aging process and in immune-mediated hemolytic anemia. Splenic macrophages remove the portion of the erythrocyte membrane coated with immunoglobulin G, resulting in spherocyte formation. Because spherocytes are less deformable, they are culled.

Reservoir Function

- Blood cells of all hematopoietic lineages are stored in the spleen. The dog has a muscular spleen that functions as an expansible organ capable of holding a large volume of blood. Of the red blood cell mass, 90% passes quickly through the spleen; 9%, representing 50% of the total number of red cells in the spleen at one time, take about 8 minutes to transit; and the remaining 1% have a transit time of 1 hour. Normally, the spleen stores from 10% to 20% of the total blood volume.

▼ ***Key Point*** The canine spleen is able to store one-third of the dog's red blood cell mass. This reservoir can be rapidly released, increasing the packed cell volume 10% to 20% in dogs and cats. The spleen also concentrates platelets. Up to one-third of the total body platelets are sequestered in the spleen.

Vigorous exercise results in a transient increase in the circulating platelet count. Margination of granulocytes occurs in the spleen as well.

Hematopoietic Function

- The role of the spleen in hematopoiesis varies considerably with different species. In mammals, the major site of hematopoietic activity is the bone marrow. The spleen is a hematopoietic organ during fetal development, but the normal adult spleen in the dog and cat has no hematopoietic activity. The red pulp retains the ability for extramedullary hematopoiesis (EMH) on demand.
- A wide variety of disorders have been associated with splenic EMH in dogs, including splenic and

extrasplenic hemangiosarcoma, splenic and extrasplenic lymphomas, multiple myeloma, leukemias, immune-mediated hemolytic anemia, eosinophilic gastroenteritis, estrogen-induced bone marrow hypoplasia, pyometra, and ehrlichiosis.
- EMH does not appear to be as common in cats as it is in dogs.
- The hemograms of dogs and cats with EMH may be characterized by the presence of immature red-cell and white-cell precursors.

Miscellaneous Functions

Other functions of the spleen include the following:

- Storage and activation of factor VIII
- Regulation of the formation, liberation, and degradation of angiotensin-converting enzyme
- Modulation of plasma norepinephrine concentrations and/or prostaglandin E2 (PGE2) activity
- Iron storage and recycling of iron to the bone marrow

ETIOLOGY

Splenic disorders can be separated into two categories, localized or asymmetrical splenomegaly and generalized or symmetrical splenomegaly.

Causes of localized splenomegaly (Table 25-1) include the following:

- Primary or metastatic neoplasia
- Nodular hyperplasia
- Hematoma
- Abscess

Generalized splenomegaly (Table 25-2) may result from the following:

- Inflammatory or infectious diseases
- Hyperplastic splenomegaly
- Congestive splenomegaly
- Infiltrative diseases

Localized Splenomegaly

The term *localized splenomegaly* refers to a localized palpable enlargement of the spleen. Most splenic masses are round and irregular and can be found in the left cranial or mid-abdomen. Localized splenomegaly may have a neoplastic or non-neoplastic cause.

Table 25-1. LOCALIZED SPLENOMEGALY

Non-neoplastic	Neoplastic
Nodular hyperplasia	*Primary*
Hematoma	Hemangiosarcoma
Abscess	Hemangioma
	Sarcoma
	Metastatic

Neoplasia

▼ ***Key Point*** Hemangiosarcoma is the most common neoplastic splenic mass occurring in the dog but is rare in the cat.

- Hemangiomas also occur. Hemangiosarcoma occurs predominantly in older, large-breed dogs. German shepherds, golden retrievers, and Labrador retrievers appear to be over-represented. Most other neoplastic splenic masses are sarcomas, including fibrosarcoma, leiomyosarcoma, leiomyoma, osteosarcoma, chondrosarcoma, rhabdomyosarcoma, myxosarcoma, liposarcoma, myelolipoma, fibrous histiocytoma, lipoma, mesenchymoma, and undifferentiated sarcoma. Although lymphoma usually has an infiltrative growth pattern in the spleen, it can have a nodular appearance.
- The most common malignant neoplasms of the spleen in cats, systemic mastocytosis and lymphoma, generally have a symmetrical infiltrative pattern of growth (see below).
- Metastasis to the spleen may occur from different sites; however, metastatic carcinoma to the spleen is rare.

Nodular Hyperplasia

- Splenic nodular hyperplasia can be single or multiple nodules that are benign accumulations of lymphoid cells, hematopoietic cells, and plasma cells. The stimulus for hyperplasia may be known in some instances, such as chronic antigenic stimulation; in other cases the cause is not known.
- Nodular hyperplasia is a common incidental ultrasonographic finding in older dogs and is a common finding in dog and cat spleens at necropsy. Nodular hyperplasia and hematoma accounted for 53% of canine splenectomies in one case series.

Hematoma

- Trauma can result in subcapsular hematoma formation, causing a mass effect in the spleen. In the majority of cases, no underlying cause predisposing to intrasplenic hemorrhage is found. Splenic hematoma has been reported in association with splenic lymphoma.

▼ ***Key Point*** Splenic hematomas cannot be distinguished from hemangiomas or hemangiosarcoma on the basis of size, shape, or other morphologic criteria. Aspiration cytology or biopsy is required to make a presumptive or definitive diagnosis.

- Splenic rupture associated with trauma or tumor rupture (hemangiosarcoma) may require surgical intervention.

Table 25-2. GENERALIZED SPLENOMEGALY

Inflammatory	Hyperplastic	Congestive	Infiltrative
Suppurative	Bacterial endocarditis	Pharmacologic	***Neoplastic***
Penetrating abdominal wounds	Brucellosis	Portal hypertension	Acute and chronic leukemia
Migrating foreign body	Discospondylitis	Splenic torsion	Systemic mastocytosis
Bacterial endocarditis	Immune-mediated disease	Thrombosis	Malignant histiocytosis
Septicemia	Autoimmune hemolytic anemia		Lymphoma
Splenic torsion	Immune-mediated thrombocytopenia		Multiple myeloma
Toxoplasmosis	Systemic lupus erythematosus		Metastatic neoplasia
Mycobacteriosis			
Infectious Canine Hepatitis (Acute)	***Hypersplenism***		***Non-neoplastic***
	Primary (idiopathic)		Extramedullary hematopoiesis
Necrotizing	Secondary		Hypereosinophilic syndrome
Splenic torsion			Amyloidosis
Splenic neoplasia			
Infectious canine hepatitis			
Salmonellosis			
Eosinophilic			
Eosinophilic gastroenteritis			
Hypereosinophilic syndrome			
Lymphoplasmacytic			
Infectious canine hepatitis (chronic)			
Ehrlichiosis (chronic)			
Rocky Mountain spotted fever			
Pyometra			
Brucellosis			
Hemobartonellosis			
Granulomatous			
Histoplasmosis			
Mycobacteriosis			
Leishmaniasis			
Pyogranulomatous			
Blastomycosis			
Sporotrichosis			
Feline infectious peritonitis			

- Splenic rupture also can lead to splenosis, the disseminated development of "daughter" spleens throughout the abdominal cavity.

Abscess

- Splenic abscesses can form from hematogenous spread of microorganisms but are rare in the dog and cat. The most common isolate in the dog is *Staphylococcus*. Splenic abscess has been associated with cholangiohepatitis in cats.

Generalized Splenomegaly

Generalized splenomegaly refers to diffuse enlargement of the spleen. Four major categories of generalized splenomegaly exist: inflammatory and infectious, hyperplastic, congestive, and infiltrative.

Inflammatory and Infectious Disease

- Inflammatory changes within the spleen usually result in diffuse enlargement. A wide range of infectious diseases can result in diffuse splenomegaly. A partial list of disorders that may be associated with generalized splenomegaly is provided in Table 25-2 (see the various chapters in this book on infectious diseases for details concerning these disorders). The various types can be classified based on the primary type of cellular infiltrate (suppurative, necrotizing, eosinophilic, lymphoplasmacytic, granulomatous, or pyogranulomatous splenitis). Different etiologic agents are associated with the different cellular infiltrates.

Hyperplastic Splenomegaly

- The spleen commonly reacts to blood-borne antigens and red blood cell destruction with hyperplasia of the reticuloendothelial and lymphoid cells.
- Hyperplastic splenomegaly is common in dogs with immune-mediated disease including immune-mediated hemolytic anemia or thrombocytopenia.
- It commonly occurs in dogs with subacute bacterial endocarditis and chronic bacteremic disorders such as discospondylitis or brucellosis.
- It has been seen in association with systemic lupus erythematosus.

- The same occurs in certain other hemolytic disorders, including hemophagocytic syndrome, drug-induced hemolysis, pyruvate kinase deficiency anemia, phosphofructokinase deficiency anemia, familial non-spherocytic hemolysis in poodles, Heinz body hemolysis, and *Mycoplasma haemofelis* infection (hemobartonellosis).

Congestive Splenomegaly

- Splenic enlargement resulting from congestion can occur through a number of different mechanisms. Splenic distension occurs as a result of smooth muscle relaxation in the splenic capsule and trabeculae. Phenothiazine tranquilizers and barbiturates increase blood pooling. Pooling of blood in an enlarged spleen may account for up to 30% of the total blood volume. Consider these changes when evaluating red blood cell parameters from anesthetized or tranquilized patients.
- Portal hypertension also can lead to congestive splenomegaly; however, splenic congestion secondary to portal hypertension does not appear to be a common cause of congestive splenomegaly in dogs and cats. Right-sided congestive heart failure, caudal vena cava obstruction (e.g., congenital anomalies, neoplasia, and heartworm disease), and intrahepatic obstruction may cause splenic congestion. Ultrasonography usually reveals markedly distended splenic, portal, and/or hepatic veins.
- Splenic torsion, either isolated or associated with gastric dilatation-volvulus syndrome, commonly results in marked splenomegaly due to congestion. A high percentage of dogs with splenic torsion have hemoglobinuria. The treatment of choice for dogs with splenic torsion is splenectomy (see the description in this chapter).

Infiltrative Splenomegaly

Neoplastic Infiltration

- Infiltration of the spleen with neoplastic cells constitutes one of the most common causes of splenomegaly in small animals. Splenomegaly is common in patients with acute and chronic leukemia. Other neoplastic conditions that result in diffuse splenomegaly include lymphoma, mastocytosis (most commonly in cats), multiple myeloma, and malignant histiocytosis (in dogs). EMH may contribute to the splenomegaly caused by the presence of neoplastic cells.

Non-neoplastic Infiltration

- EMH is common in dogs but by itself rarely results in detectable splenomegaly. EMH can be associated with neoplastic infiltrations and also has been observed in dogs with immune-mediated hemolysis, immune-mediated thrombocytopenia, bone marrow hypoplasia, pyometra, and infectious diseases.
- Hypereosinophilic syndrome of cats can lead to infiltration of the spleen with mature eosinophils. This syndrome is characterized by peripheral blood eosinophilia, bone marrow hyperplasia of eosinophil precursors, and multiple organ infiltration by mature eosinophils.
- Splenic amyloidosis can cause splenomegaly but is rare.

Hypersplenism

Hypersplenism is characterized by the following:

- Cytopenias
- Bone marrow hyperplasia of the affected cell line or a normocellular bone marrow
- Splenomegaly
- Resolution of the cytopenia in response to splenectomy

Hypersplenism results mainly from the filtering and phagocytic functions of the spleen.

- *Primary hypersplenism* occurs when the splenic dysfunction is idiopathic.
- *Secondary hypersplenism* occurs as the result of an underlying disease process that has resulted in splenomegaly.

Hyposplenism

- Hyposplenism, or decreased splenic function, can occur secondary to a wide range of disease processes. A number of hematologic changes are recognized in association with hyposplenism (Table 25-3). These changes are also seen in splenectomized animals.

CLINICAL SIGNS

- Clinical signs of splenic disease typically are nonspecific or related to the underlying disease process.
- Clinical signs may include anorexia, weight loss, weakness, abdominal distension, vomiting, diarrhea, and polyuria or polydipsia.
- Acute collapse and pale mucous membranes are common clinical signs in patients with splenic rupture.

Table 25-3. HEMATOLOGIC ABNORMALITIES IN DOGS AND CATS WITH SPLENOMEGALY

Hypersplenism	Hyposplenism/Asplenia
Regenerative anemia	Target cells
Neutropenia	Acanthocytes
Thrombocytopenia	Howell-Jolly bodies
Bicytopenias	Nucleated red blood cells
Pancytopenia	Reticulocytosis
	Thrombocytosis

DIAGNOSIS

History

- The history and clinical signs for many patients with splenic disease are nonspecific; however, the history can aid the diagnosis of patients with certain types of splenic disease.
- Periodic weakness or collapse, often accompanied by mucous membrane pallor, raises the suspicion of splenic hemangiosarcoma with intermittent hemorrhage, particularly in certain breeds (e.g., golden retrievers and German shepherds).
- Patients presenting with a relatively acute onset of abdominal distension and retching may have splenic torsion in conjunction with gastric dilatation-volvulus. A history of tick exposure in patients with splenomegaly can aid in the diagnosis of ehrlichiosis and Rocky Mountain spotted fever.
- Travel history to endemic disease areas, vaccination history, and reported drug exposures may aid in the diagnosis of underlying infectious diseases or pharmacologic causes of splenic disease.

Physical Examination

- The spleen is located in the left cranial abdominal quadrant. The dorsal extremity of the spleen is relatively fixed near the midline ventral to the left crus of the diaphragm, but the remainder is freely movable and oriented longitudinally along the left flank.
- The normal spleen is palpable in many dogs and cats. Splenomegaly often can be detected with careful abdominal palpation. Position of the spleen and ease of identification can vary depending on a variety of factors including breed conformation, presence of ingesta in the stomach, and body weight. However, not all enlarged spleens are palpable and not every palpable spleen is abnormal. Imaging of the spleen with radiography, ultrasonography, or computed tomography may be required to identify an enlarged spleen.
- Other physical examination findings may be directly or indirectly related to the underlying cause of the splenic disease. These findings may include abdominal distension, peritoneal effusion, pain on abdominal palpation, petechiae, ecchymoses, pale mucous membranes, and fever.
- Peripheral lymphadenopathy can occur in conjunction with underlying neoplastic diseases such as leukemia or lymphoma and infectious diseases such as ehrlichiosis or systemic mycoses.

Hematologic and Serum Biochemical Findings

- The hemogram is often helpful in the diagnosis of splenic disorders. Two patterns of hematologic changes are recognized in dogs and cats with splenomegaly: hypersplenism and hyposplenism (or asplenia). The hematologic abnormalities in patients with splenomegaly are summarized in Table 25-3.
- Hyposplenism is more common and results in hematological changes similar to those in splenectomized patients.
- Spherocytes are common in patients with autoimmune hemolytic anemia.
- Patients with immune-mediated thrombocytopenia may have splenomegaly and thrombocytopenia with no other hematologic abnormalities.
- Common hematologic findings in dogs with hemangiosarcoma include anemia (regenerative or nonregenerative), poikilocytosis, nucleated red blood cells, presence of acanthocytes and schistocytes, presence of Howell-Jolly bodies, thrombocytopenia, and neutrophilia.
- A coagulation profile can aid in the diagnosis of acute or chronic disseminated intravascular coagulation (DIC), which occurs in some patients with splenic disease. DIC is a common complication of hemangiosarcoma, splenic torsion, and autoimmune hemolytic anemia.
- Perform biochemical profile and urinalysis in all patients with splenic disease. Biochemical abnormalities usually are a consequence of the primary underlying disease process rather than of splenic enlargement or other pathology. Hemoglobinemia and resultant hemoglobinuria are common findings in dogs with splenic torsion.

Abdominal Radiography

- In most dogs, the tail of the spleen is visible on the lateral view just caudal to the stomach along the ventral body wall. The head of the spleen usually is seen on ventrodorsal radiographs between the fundus of the stomach, the cranial pole of the left kidney, and the body wall, appearing as a triangular structure. The entire spleen is best seen on the ventrodorsal view along the left lateral body wall.
- In dogs, splenic size is variable. Causes of diffuse splenic enlargement are listed in Table 25-2.
- The most reliable radiographic indicator of splenic enlargement is rounded or blunted margins. Generalized splenic enlargement may result in caudal and dorsal displacement of the small intestine viewed on lateral radiographs.
- In dogs, a splenic mass is the most likely cause of a mid-abdominal mass visible in a lateral abdominal radiograph.
- Splenic size is less variable in cats and is always much smaller than dogs. It usually is seen on the ventrodorsal radiograph along the left lateral body wall.
- The tail of the spleen is visible on lateral radiographs only if the spleen is enlarged.

- Severe splenomegaly develops following torsion. Torsion of the spleen occurs most commonly in large and giant deep-chested dogs. The spleen may have a characteristic C-shaped appearance on the lateral view; however, accompanying peritoneal fluid may obscure this shape. The fundus of the stomach may be displaced caudally and medially due to tension on the gastrosplenic ligament. Torsion may occur as a consequence of gastric volvulus (see Chapter 67).

Abdominal Ultrasound

- Ultrasonographic examination of the spleen is useful for determining size, location, and presence of parenchymal abnormalities when a pathologic condition is suspected (also see Chapter 4).
- Primary indications for ultrasonographic examination include generalized splenomegaly, abdominal or splenic mass, trauma, and hemoperitoneum.

▼ ***Key Point*** The primary value of ultrasonography over radiography is its ability to determine whether focal or non-focal parenchymal disease is present, to differentiate cavitary from solid lesions, and to provide guidance for biopsy procedures.

Generalized Splenomegaly

- The size of the normal spleen is variable and must be assessed subjectively. The normal canine spleen appears hyperechoic and finely textured when compared with the liver bounded by a thin, hyperechoic capsule.
- In most instances, ultrasonography by itself is not helpful in establishing a specific diagnosis in cases of diffuse splenomegaly. Ultrasound-guided aspiration biopsy is usually indicated.
- Passive congestion usually results in splenomegaly with normal or slightly reduced echogenicity.
- Splenic torsion produces a markedly enlarged spleen with diffuse anechoic areas and multiple parallel echogenic lines within the parenchyma. Doppler evaluation of the splenic parenchyma indicates an absence of blood flow. Larger vessels may be thrombotic.
- Diffuse neoplastic disease (e.g., lymphoma, leukemia, malignant histiocytosis, and mastocytosis) may reduce or increase echogenicity, or the parenchyma may appear normal.
- Splenitis is occasionally seen, usually with abnormally hypoechoic and coarsely textured parenchyma. Focal or multifocal hypoechoic areas or nodules may be present concurrently with diffuse changes.

Lymphoma of the spleen may have a wide variety of appearances and may produce diffuse increased or decreased echogenicity, a honeycomb pattern, a moth-eaten appearance, or focal or multifocal hypoechoic nodules or complex mass lesions.

Localized Splenomegaly

- Focal lesions of the spleen are easily detected, but findings must be correlated with history and laboratory findings. Ultrasonography is useful for guided aspiration biopsy of focal lesions to obtain representative cytologic material for analysis.
- Splenic hematomas result from abdominal trauma, clotting disorders, nodular hyperplasia, and neoplasia. The ultrasonographic appearance of a hematoma is extremely variable, depending on its age.
- Focal splenic infarcts occur secondary to embolism or thrombosis. The appearance of infarcts is variable and depends on the time since the infarct occurred. Initially, infarcts appear as poorly marginated hypoechoic or complex lesions, which appear echogenic if there is postinfarctive hemorrhage.
- Abscesses, although uncommon, produce focal or multifocal splenic lesions. Their appearance is variable from poorly marginated hypoechoic lesions to complex lesions with variable cystic and solid components.
- Nodular hyperplasia of the spleen may appear as isoechoic, hypoechoic, hyperechoic, or complex lesions that usually are very vascular.
- Focal or multifocal neoplastic lesions of the spleen commonly result from sarcomas, in the dog most commonly hemangiosarcoma. The specific type of neoplasia cannot be determined from its ultrasonographic appearance alone. Neoplastic lesions are commonly poorly defined, anechoic, hypoechoic, or complex in appearance. Hemoperitoneum is often present with hemangiosarcoma of the spleen. Lymphoma may produce poorly marginated, anechoic to hypoechoic focal or multifocal lesions. Focal lymphomatous masses may distort the splenic contour or cavitate. Mesenteric lymphadenopathy often is seen with splenic lymphosarcoma.

Fine-Needle Aspiration

▼ ***Key Point*** Fine-needle aspiration (FNA) cytology often is the diagnostic technique of choice following abdominal radiography and ultrasound for the evaluation of splenic disease.

FNA is perhaps most useful in the diagnosis of diffuse splenic disease. The radiographic and ultrasonographic appearance of most splenic diseases, with the exception of splenic torsion, is relatively nonspecific. FNA cytology can aid in the selection of patients for exploratory surgery, splenic biopsy, and splenectomy. A cytologic diagnosis of neoplastic (e.g., lymphoma, hemangiosarcoma, and mastocytosis) and non-neoplastic (e.g., EMH and nodular hyperplasia) is often possible. Though this procedure can be done "blindly," it preferably is done using ultrasound guidance.

Contraindications

Aspiration cytology may be contraindicated in patients with large cavitary lesions, which may rupture during aspiration, although this is a rare occurrence. More importantly, aspiration of these lesions is often nondiagnostic, and surgery may be recommended in these cases. In patients with hemangiosarcoma, aspiration can theoretically result in tumor seeding along the needle tract or rupture and seeding of the abdominal cavity. Given the high incidence of spontaneous splenic rupture and seeding in this disease, even without FNA, it probably should not be a practical contraindication to performing the procedure when needed.

Technique

- Position the patient in right lateral or dorsal recumbency.
- Mild sedation may be required in some patients but is usually not necessary.

▼ ***Key Point*** Avoid phenothiazine tranquilizers; they cause splenic enlargement from vascular stasis and may dilute the sample with blood.

- Cleanse the area with alcohol, or do a surgical prep.
- Insert a 25- or 22-gauge, 1- to 1.5-inch needle without a syringe attached using ultrasound guidance to avoid overlying organs and large splenic blood vessels. In obese patients, use a stylet type of needle, removing the stylet once you have entered the parenchyma. This prevents inadvertent sampling of the near-field tissues.
- Avoid penetrating the opposite (far field) capsule to reduce hemorrhage.
- A pincushion sampling technique usually results in less hemodilution of the sample than does an aspiration technique. Without a syringe attached, make multiple penetrations of the needle into the spleen using one hole and without pulling the tip of the needle out of the spleen with each jab.
- Repeat 2 to 3 times, smearing each sample onto a new, clean slide.
- In high-risk cases, reassess the patient sonographically in 2 to 4 hours for evidence of hemorrhage (rare).

Complications

Potential complications include splenic rupture, hemorrhage, damage to other organs, peritonitis, and abdominal seeding of a splenic neoplasm; however, two reports describing the use of this technique reported no complications. Thrombocytopenia is not considered a contraindication for this procedure.

Needle Biopsy

- Considerations are similar to those for aspiration of the spleen.
- Use ultrasound guidance.
- Use 18- (cats), 16-, or 14-gauge biopsy needles.
- Avoid penetrating the opposite splenic capsule to reduce chance of hemorrhage.
- Obtain two to three samples.
- In general, biopsies and aspirates are more commonly performed for diffuse or nodular disease, and surgery is preferred for mass lesions.

Miscellaneous Tests

Bone Marrow Aspiration Cytology

- Bone marrow aspiration cytology or core bone marrow biopsy is indicated in patients with splenomegaly and cytopenias (see Chapter 22 for details on bone marrow biopsy technique).
- Splenectomy may be contraindicated in a patient with splenomegaly due to EMH secondary to bone marrow hypoplasia or aplasia.
- Bone marrow aspiration cytology may support or confirm the underlying disease process.

Lymph Node Aspiration Cytology

- Lymph node needle aspiration cytology or biopsy is indicated in patients with lymphadenopathy.
- Marked peripheral lymphadenopathy usually is associated with lymphoma. Mild or moderate lymphadenopathy can be seen in lymphoma and in a number of different diseases, including infectious and immune-mediated disorders.
- Ultrasound guided biopsy procedures may be needed to aspirate enlarged lymph nodes within the abdomen or other sites.

Serologic Tests and Polymerase Chain Reaction

- Serologic tests for specific infectious and immune diseases can be performed. Rickettsial titers or polymerase chain reaction (PCR) for ehrlichiosis or *Mycoplasma haemofelis* infection (hemobartonellosis), Coombs test for immune-mediated hemolytic anemia, and antinuclear antibody test for systemic lupus erythematosus may be indicated for some patients. Test cats with splenomegaly for feline leukemia virus and feline immunodeficiency virus.

Other Tests

- Thoracic radiographs or computed tomography (CT) may be useful in patients with suspected neoplastic disease and some infectious diseases (e.g., blastomycoses).
- Diagnosis of lymphoma based on FNA cytology of the spleen often must be made with caution, especially in those patients with minimal lymphadenopathy. Demonstration of a monoclonal lymphocyte population using PCR, or assessment of cell immunophenotype using flow cytometry, can be useful for arriving at a diagnosis of lymphoma.

TREATMENT

Splenectomy

Preoperative Considerations

- Splenectomy is indicated for patients with splenic rupture, splenic torsion, or splenic masses and for symptomatic patients.
- Splenectomy in cats with systemic mastocytosis can significantly prolong life expectancy even if mast cells are present in the peripheral circulation.

Splenic Hemangiosarcoma

- Because of the potential for splenic rupture and death in patients with hemangiosarcoma, perform splenectomy. Prior to splenectomy, evaluate a complete blood count, coagulation panel, and thoracic and abdominal radiographs. If available, abdominal ultrasound and echocardiography provide a more thorough assessment of potential metastatic sites. Dogs with hemangiosarcoma typically are not cured by surgery alone and usually have evidence of recurrence within 4 months; however, even dogs with gross evidence of metastatic disease may have favorable responses to splenectomy combined with adjuvant chemotherapy (Table 25-4). Doxorubicin containing protocols, using doxorubicin as a single agent or in combination with cyclophosphamide (AC) or cyclophosphamide and vincristine (VAC), have been shown to be beneficial in dogs with splenic hemangiosarcoma. The relative efficacy of these different protocols appears to be similar; however, they have not been directly prospectively compared.

Table 25-4. TREATMENT PROTOCOLS FOR HEMANGIOSARCOMA

VAC Protocol (21-Day Cycle)
Doxorubicin[*†]: 30 mg/m^2 (or 1 mg/kg if <10 kg), IV, day 1
Vincristine[‡]: 0.75 mg/m^2, IV, days 8, 15
Cyclophosphamide: 200–300 mg/m^2, day 10
Sulfa-trimethoprim: 15 mg/kg, q12h

AC Protocol (21-Day Cycle)
Doxorubicin: 30 mg/m^2 (or 1 mg/kg if <10 kg), IV, day 1
Cyclophosphamide[†]: 200–300 mg/m^2, day 10
Sulfa-trimethoprim: 15 mg/kg, q12h

Doxorubicin (Monotherapy)
Doxorubicin: 30 mg/m^2 (or 1 mg/kg if <10 kg), IV, q21 days

[*]Doxorubicin is potentially cardiotoxic. Perform cardiac evaluation prior to treatment and monitor throughout treatment. The recommended maximum cumulative dose is 180–240 mg/m^2 or 6–8 doses, but it must be applied to each patient individually.
[†]Cyclophosphamide can cause hemorrhagic cystitis. If it occurs, discontinue cyclophosphamide immediately and usually limit therapy to oral antibiotics and corticosteroids. Resolution of signs usually occurs within 8 weeks.
[‡]Evaluate a complete blood count before each doxorubicin or vincristine treatment to check for bone marrow suppression. Monitor patient progress every two cycles (radiographs of thorax, abdominal radiographs or ultrasound, and echocardiography if indicated). Allow completion of two to three cycles of treatment before making a decision about response to therapy.
AC, Adriamycin (doxorubicin)-cyclophosphamide; VAC, vincristine-Adriamycin (doxorubicin)-cyclophosphamide.

Other Splenic Sarcomas

Most other histopathologic types of splenic sarcomas warrant a poor prognosis and are associated with a high rate of metastasis. Adjuvant chemotherapy probably is warranted postoperatively for these patients as well, although limited information is available on the efficacy of therapy.

Other Splenic Disorders

- Splenectomy is contraindicated in patients with immune-mediated hemolytic anemia or thrombocytopenia, except as a last resort after medical therapy has failed, and in patients with bone marrow hypoplasia or aplasia, because the spleen is the major hematopoietic organ in these patients.
- Splenectomy may be a therapeutic option in selected patients with lymphoma and leukemia, notably in patients with massive splenomegaly and/or disease localized to the spleen. In these cases, multimodality therapy combining surgery with systemic chemotherapy should be considered. In humans with non-Hodgkin's lymphoma, the indications for splenectomy are massive splenomegaly, hypersplenism syndrome, and autoimmune complications.

▼ ***Key Point*** Generalized splenomegaly often is not a surgical disease. Attempt to diagnose and treat the underlying disorder before performing a splenectomy.

Technique

Partial Splenectomy

1. Prepare the ventral abdomen for aseptic surgery.
2. Make a ventral midline abdominal incision from the xiphoid to 2 to 4 cm cranial to the pubis or more caudally if necessary.
3. Place a Balfour retractor to expose the abdominal viscera.
4. Examine the spleen and other abdominal organs for evidence of abnormalities.
5. Gently pull the spleen out of the abdominal cavity.
6. Doubly ligate the splenic branches of the splenic artery and vein to the affected area of the spleen with absorbable suture. Divide the vessels among the ligatures. Alternatively, use the ligate-and-divide stapling instrument (LDS).
7. Place two non-crushing clamps (e.g., Doyen) on the spleen between the healthy and the diseased areas.
8. Divide between the clamps and remove the splenic tissue.

9. Oversew the splenic capsule on the remaining spleen (3-0 or 4-0 polydioxanone [PDS], simple continuous suture).
10. Alternatively, use the thoraco-abdominal stapler (TA) (55- or 90-mm cartridge) to staple the splenic parenchyma prior to excision.
11. Check vessels and splenic incision for bleeding. Close the abdomen routinely.

Total Splenectomy

1. to 5. These steps are the same as for partial splenectomy.
6. Doubly ligate all the splenic branches of the splenic artery and vein with absorbable suture. Ligate the vessels close to the hilus of the spleen. Usually, two or three vessels can be included in each ligature. If possible, preserve the left gastroepiploic artery and vein (Fig. 25-1); this may not be possible when removing large splenic tumors.
7. Divide each vessel among the ligatures and remove the spleen.
8. An alternative and more rapid procedure for total splenectomy is to place vascular clamps across the vessels before ligation. Include two or three of the vessels in each clamp. Divide the vessels between each pair of clamps and then place the next pair of clamps (see Fig. 25-1). After all vessels have been clamped and divided, remove the spleen. Ligate all vessels with absorbable sutures.
9. Alternatively, use the LDS to ligate and divide the vessels.
10. When splenic torsion is present, do not untwist the spleen because release of tissue breakdown products and bacteria may result. Ligate the entire vascular pedicle with two or three absorbable ligatures. Consider placing a transfixing ligature in large dogs. Place two clamps across the vascular pedicle, divide between them, and remove the spleen. Remove the remaining clamp and check the pedicle for hemorrhage.
11. Check the vessels for hemorrhage. Close the abdomen in a routine fashion.

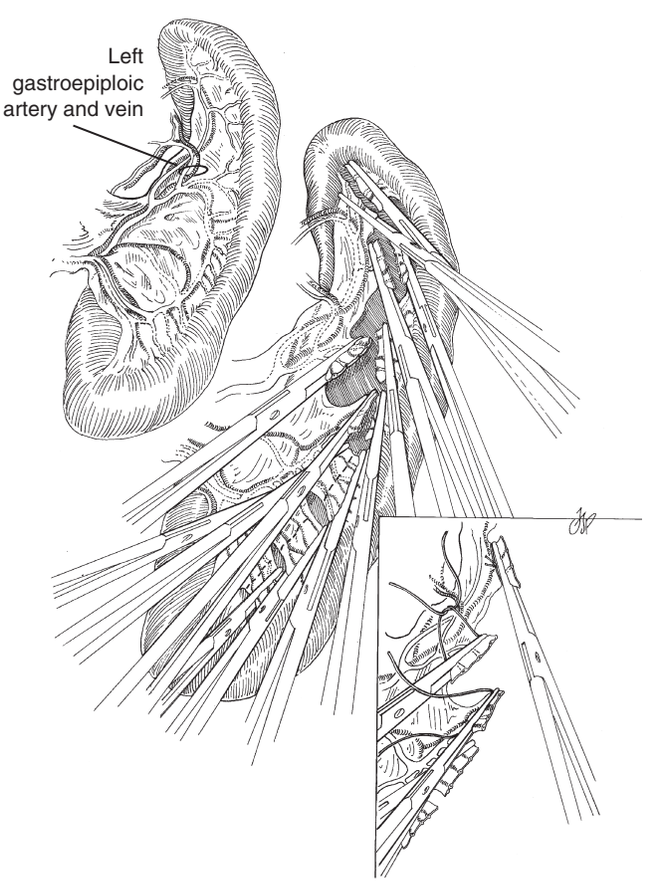

Figure 25-1. General procedure for total splenectomy. See text for details.

Postoperative Care and Complications

- The gross appearance of the spleen cannot be used to differentiate hematoma, hemangioma, and hemangiosarcoma. A histopathologic diagnosis is crucial for determining postoperative treatment and prognosis.
- Postsplenectomy sepsis is a serious complication in humans and can be fatal. Although this is a rare complication in dogs and cats, partial splenectomy or splenic biopsy may be advisable in certain animals. Partial splenectomy is a viable option for those animals with localized masses unless malignancy is suspected.
- Other possible complications of splenectomy include exacerbation of certain diseases such as hemobartonellosis and babesiosis in animals that are latent carriers and cytopenia(s) in patients with EMH secondary to a primary bone marrow disorder.

Treatment of the Underlying Disease Process

- Treat infectious diseases with appropriate antibiotic therapy and supportive care.
- Treat immune-mediated diseases (immune-mediated hemolytic anemia and immune-mediated thrombocytopenia) as follows:
  - Use immunosuppressive doses of corticosteroids and other drugs as necessary (e.g., cyclophosphamide).
  - Use blood component therapy if indicated (as described in Chapters 22 and 23).
- Chemotherapy alone or in conjunction with the necessary supportive care is recommended for patients with acute and chronic leukemia and lymphoma (see Chapter 27) and for dogs with systemic mastocytosis (see Chapter 28) and hemangiosarcoma (Table 25-4).

Chapter 26

Principles of Oncology

Stephen D. Gilson / Rodney L. Page / Rance M. Gamblin

Cancer management in animals has evolved considerably over the past 3 decades as the result of several significant factors. Improved health care of animals has increased the age distribution of pets and hence their likelihood of developing cancer; clients are more aware of aggressive treatment choices; and there have been significant improvements in treatment success. There remains some controversy and confusion over the best course of treatment for many tumor types, and more studies are needed to provide the necessary data. However, clinicians can use a generic framework for evaluation and treatment management of many tumor types. This chapter provides an outline useful for clinical management of an animal with cancer.

INITIAL CLINICAL PRESENTATION

Signalment

Many neoplasms more commonly affect animals of a certain age, sex, or breed, and such knowledge often aids diagnosis. Table 26-1 is a partial list of specific breeds and characteristics of dogs and cats predisposed to certain types of neoplasia.

History

The onset and duration of a mass, its growth rate, the presence of other masses, signs of paraneoplastic syndromes, and knowledge of prior treatments further help narrow diagnostic and treatment options and define the behavioral characteristics of a neoplasm.

Physical Examination

Examination is used to define the extent of tumor burden and identify concurrent diseases that may limit treatment or affect survival. Tumor characteristics such as *size* (measure with calipers to determine objectively), *location* (e.g., oral melanoma is more malignant than cutaneous melanoma), *invasiveness* (is mass fixed to adjacent tissue), and presence of *ulceration* or *necrosis* of the tumor is important to determine tumor behavior and to plan adequately an appropriate biopsy and treatment regimen. Regional lymph nodes are evaluated for size, consistency, and fixation to adjacent tissues. To complete the clinical evaluation, a list of differential diagnoses is made and a diagnostic and staging plan is determined.

Client Counseling

A diagnosis of cancer can evoke considerable emotional response from owners. For many clients, the diagnosis implies pain, discomfort, and impending death of their pet. Proper counseling on the part of the veterinarian should include the following:

- Listen to the needs of the client and mutually determine a set of realistic goals for treatment.
- Explain treatment procedures, discussing risks, benefits, toxicity, and costs. It is helpful to provide written material for home review of information.
- Provide a realistic and *unbiased* view of all treatment options available and the animal's likely prognosis.
- Beware of the tendency for clinicians untrained in oncology to prematurely recommend euthanasia.
- Consider consultation with or referral to a specialist when appropriate.

DIAGNOSIS

Laboratory Evaluation

Assess general health status to identify concurrent disease or paraneoplastic syndromes that may adversely affect prognosis and limit or alter therapy. After a thorough physical examination, perform screening laboratory evaluations, including a complete blood count, serum biochemistry panel, and urinalysis. Perform other special laboratory tests as indicated to aid diagnosis (e.g., feline leukemia virus, feline immunodeficiency virus, bone marrow aspirate, adrenal or thyroid function tests, etc.).

Diagnostic Imaging

- Obtain survey radiographs to detect metastases (on the thorax, abdomen, or skeleton), to evaluate orthopedic soundness before amputation or limb-sparing

Table 26-1. SOME FACTORS PREDISPOSING DOGS AND CATS TO SPECIFIC NEOPLASMS

Factor	Predilection For
Age	
Histiocytoma	Young dogs
Viral papilloma	Young dogs
Sex	
Malignant melanoma	Males
Perianal adenoma	Males
Anal Sac AdenoCA	Females
Adrenal tumor	Females
Meningiomas	Females (dog), males (cat)
Color	
Squamous cell carcinoma	Nonpigmented regions
Malignant melanoma	Darkly pigmented regions
Breed	
Skin tumors	Basset, boxer, bull mastiff, Scottish terrier, weimaraner
Mast cell tumor	Brachycephalic breeds, Retrievers
Bone tumors	Large/giant breeds
Thyroid tumor	Boxer, beagle, golden retriever
Hemangiosarcoma	Retrievers, German shepherd
Lymphoma	Retrievers, boxers, mastiffs
Histiocytic malignancies	Burnese Mountain Dogs, retrievers, rottweillers

surgery for dogs with osteosarcoma, and to determine bone margins of oral or nasal masses. When taking thoracic radiographs, remember to take both right and left laterals as well as a ventrodorsal/dorsoventral view, to avoid missing metastatic lesions (see Chapter 4).

- Contrast radiography may be helpful for defining the extent of disease in hollow viscera (see Chapter 4).
- Computed tomography and magnetic resonance imaging are useful to delineate deep masses of the body cavities and axial skeleton (see Chapter 4).
- Ultrasound is useful to image abdominal viscera. It can determine accurately the parenchymal nature of a mass and tumor proximity to large vessels, and evaluate for intra-abdominal metastases to lymph nodes or organs. Additionally, it can be used for direction of fine needle aspiration or minimally invasive biopsy procedures (see Chapter 4).

Cytology

Cytology is useful to evaluate fine-needle aspirates of masses and lymph nodes, bone marrow aspirates, and buffy coat and peripheral blood smear preparations. It can provide rapid and inexpensive diagnostic and staging information. Do not over-interpret cytologic preparations. Base treatment decisions on cytologic diagnosis only when a definitive diagnosis can be made by a pathologist, as with lymphoma and mast cell tumors. Although a diagnosis may be accomplished with cytologic preparations, histologic assessment is usually necessary to determine prognosis (i.e., grade of malignancy).

Biopsy

Many techniques are available for tumor biopsy. The method selected should safely and simply procure an adequate tissue sample to provide an accurate diagnosis without making definitive treatment more difficult or invasive.

General Considerations

- In general, larger tissue samples are more likely to provide an accurate diagnosis. Avoid traumatic tissue handling, electrocoagulation, and other tissue damage to provide a histologically useful sample.
- Fix tissue samples for routine histopathologic analysis in 10% buffered formalin (10:1 formalin-to-tissue ratio).
- Obtain samples for culture or other special analyses at the same time to avoid a second biopsy procedure if histologic analysis identifies an inflammatory or other nonneoplastic process.
- Include a complete history and description of the clinical and surgical findings with the biopsy specimen submission.
- If unsure of the most appropriate biopsy technique, consult with or refer the animal to a specialist.

Excisional Biopsy

- Complete removal of a tumor and submission for histologic diagnosis is most useful for cutaneous, mammary, and central nervous system (CNS) tumors and easily resectable masses found during laparotomy or thoracotomy.
- Ideally, an excisable mass is small and freely movable without significant adjacent tissue invasion.
- Excise the mass with a histologically confirmed complete resection margin of normal tissue. Use suture tags to identify areas of possible inadequate resection that require closer histologic scrutiny. Inking of all surgical margins can also aid the pathologist in determination of the completeness of the excision.

Nonexcisional/Incisional Biopsy

- Remove only a portion of a tumor (e.g., cutting needle, endoscopic, punch, or incisional biopsy) when definitive diagnosis or grading would influence treatment decisions.
- Take deep biopsies of superficial ulcerated masses to avoid sampling only overlying necrotic debris on the surface.
- Incisional and needle biopsy tracts are considered contaminated by tumor cells and must be completely within the future field of surgical resection or radiation treatment.
- Ideal histologic samples contain a margin of normal and neoplastic tissue. This allows assessment of tumor invasiveness, and margins are frequently the site of greatest tumor cell activity. Biopsy at the margin is often undesirable, however, because it disrupts the

natural tumor margin and effectively extends it. This necessitates a wider resection or larger radiation field for definitive treatment. Therefore, if biopsies include marginal tissues, collect from areas where there is adequate tissue for wider excision.

▼ ***Key Point*** Improper biopsy technique can significantly alter treatment, increase treatment morbidity, and sometimes adversely affect prognosis.

Evaluation of Pathology Reports

The pathology report should include:

- Histologic diagnosis and, where appropriate, histologic grade (e.g., mast cell tumor, soft tissue sarcoma, osteosarcoma)
- Complete description of cellular characteristics and degree of anaplasia
- Mitotic index
- Identification of lymphatic or vascular invasion
- Evaluation of resection margins

If aspects of the report are questionable or do not match your clinical judgment, always discuss the results with the pathologist.

Tumor Staging

Accurate staging requires understanding the biologic behavior of different tumor types, combined with the results of a thorough diagnostic workup based on this expected behavior. Tumor staging is used to do the following:

- Determine the extent of neoplastic disease
- Provide a framework for rational treatment planning
- Facilitate communication between clinicians
- Allow for uniform comparison and evaluation of treatment results
- Aid in establishing a prognosis

Several staging systems are available. Most are based on assessment of local, regional, and distant disease involvement. Some systems include other factors, such as presence or absence of clinical signs (e.g., lymphomas), tumor histologic grade (e.g., mast cell tumors), or tumor location (e.g., squamous cell carcinoma of mouth, tonsil, pinna, or digit). The TNM staging system (T, tumor size or extent; N, lymph node involvement; M, metastasis) devised by the World Health Organization is the standard system for most tumors in veterinary medicine. Table 26-2 describes this staging scheme and gives an example. Staging systems should be revised as new prognostic information is acquired.

Table 26-2. WORLD HEALTH ORGANIZATION TNM CLASSIFICATION OF TUMORS

T = Tumor Size or Extent

T_1–T_4 represent specific size categories designated for each tumor type and define the extent of local tumor involvement.

N = Lymph Node Involvement

N_1–N_3 (± a, b) describes regional lymph node characteristics for presence or absence of neoplasia, number and location of enlarged lymph nodes, and occurrence of adjacent tissue adhesion.

M = Metastasis

M_0 or M_1 indicates absence or presence of distant metastasis.

Example—TNM Classification of Tumors of the Oral Cavity in Dogs or Cats:

T: Primary Tumor

T_{is} = Preinvasive tumor (in situ)
T_0 = No evidence of tumor
T_1 = Tumor <2 cm diameter
T_2 = Tumor 2–4 cm diameter
T_3 = Tumor 3 cm diameter
subclassification of a (no bone invasion) or b (bone invasion) can be added.

N: Nodes

N_0 = No evidence of lymph node enlargement
N_1 = Movable ipsilateral nodes enlarged
N_2 = Movable contralateral/bilateral nodes enlarged
N_3 = Fixed nodes

M: Metastasis

M_0 = No metastasis
M_1 = Metastasis detected

Example of Stage Grouping for Oral Tumors:

Stage	*T*	*N*	*M*
I	T_1	N_0, N_{1a}, N_{2a}	M_0
II	T_2	N_0, N_{1a}, N_{2a}	M_0
III	T_3	N_0, N_{1a}, N_{2a}	M_0
	Any T	N_{1b}	M_0
IV	Any T	N_{2b}, N_3	M_0
	Any T	Any N	M_1

From Owen LN: Classification of Tumours in Domestic Animals. Geneva: WHO, 1980.

PRINCIPLES OF THERAPY

Rational treatment planning requires an accurate diagnosis, complete staging, and knowledge of expected tumor behavior with regard to local growth and propensity for developing regional and distant metastases. Many treatment options are available for the management of cancer, and each has its advantages and disadvantages. Become familiar with the strengths and weaknesses of each treatment modality and develop a treatment plan that addresses each aspect of expected tumor behavior (i.e., local, regional, and distant disease). Currently, multidisciplinary treatment is employed most commonly to maximize treatment results while minimizing toxicity. Combinations of surgery, chemotherapy, and radiation often can more effectively eradicate cancer, especially multifocal cancer, than any one modality alone. The goal of treatment is to maintain the highest quality of life for the longest period of time.

▼ ***Key Point*** The probability of long-term tumor control is greatest when aggressive therapy is instituted early, before the tumor is disturbed by previous failed therapeutic attempts.

Surgery

Surgery is primarily useful for localized neoplasms. In select cases, en bloc dissection of regional lymph nodes and the primary mass is used for treatment of regional disease, and surgery can be useful for treatment of metastatic disease that is slow growing or causing clinical morbidity.

Applications

Surgery is the most widely applied modality for control of localized cancer. Surgery can also be used for prevention (e.g., ovariohysterectomy before 2.5 years of age for mammary cancer in dogs), diagnosis (see section on Biopsy), staging (see section on Staging), and treatment (cure or palliation). Surgery also is used for treatment of oncologic emergencies (e.g., obstruction or perforation) and for complications related to chemotherapy or radiotherapy (e.g., drug extravasation, radionecrosis).

Principles of Surgery

A special technique is used to prevent surgical spread of cancer cells and to ensure complete tumor resection.

▼ ***Key Point*** Aggressive initial surgical management of neoplasia may be the most important principle for improved cancer control. The best chance for complete resection and cure is with the first surgery.

- Decide resection margins in advance of the surgery based on tumor type, expected behavior, extent of local invasion, and the barrier provided by surrounding tissues (Fig. 26-1). Vascular-poor, collagen-rich tissue (e.g., cartilage and fascia) are most impermeable to tumor invasion. Other tissues (e.g., fat and subcutaneous tissue) provide less of a barrier.
- Resect all neoplastic tissue; if necessary, use skin flaps or grafts to close large defects (see Chapter 57). If uncertain about achieving complete resection or wound closure, consider referral to a specialist.
- Protect healthy tissues from tumor cell contamination by use of barrier drapes and laparotomy sponges. Employ glove, instrument, and drape changes as necessary to prevent contamination of normal tissue with cancer cells. Copious lavage of surface wounds also may reduce the likelihood of residual tumor.
- Minimize tumor manipulation. Handle tumors by placing stay sutures in normal margin tissues.
- Ligate vascular and lymphatic vessels early, and always before severing, to prevent shedding of tumor emboli.

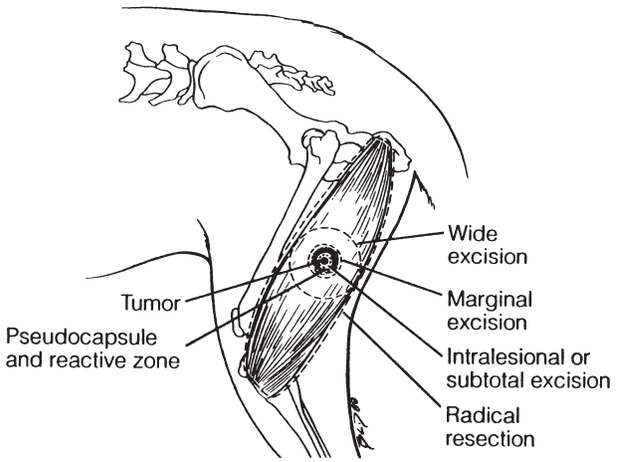

Figure 26-1. Surgical options for removal of a neoplasm. Wide excision or a more radical, compartmental resection is recommended for tumors that are not superficial or are infiltrative. Additional therapy may be indicated from histologic evaluation of tumor specimen. (Reprinted with permission from Gilson SD, Stone EA: Compend Contin Educ Pract Vet 12:1047, 1990.)

- Fulgurate or electrocoagulate any exposed tumor surfaces.
- When en bloc resection is performed, maintain adequate margins and dissect from the most peripheral affected lymph node toward the primary mass.
- When postoperative radiotherapy is used, all surgically exposed tissues plus a margin of normal tissue are irradiated. Position tissue grafts, flaps, and drains to minimize treatment fields. Use of hemoclips or other metallic markers are helpful in radiographically establishing the margins of manipulated tissues for radiation treatment planning.
- Submit all resected specimens for histologic analysis and evaluation of margins.

▼ ***Key Point*** A pseudocapsule made up of compressed cancer cells surrounds most tumors. Although seemingly a convenient plane for dissection, it is not a true capsule and provides no barrier to tumor invasion. A properly excised tumor is encased completely in an envelope of normal tissue.

If histopathology of the excised tumor reveals incomplete excision, promptly plan and perform a re-excision if possible.

Sources of Failure

Treatment failures result from surgery-related morbidity and mortality, local or regional tumor recurrence, and tumor seeding or metastatic disease. Most failures can be minimized by use of proper surgical technique and appropriate patient selection.

Radiotherapy

Radiotherapy is primarily useful for local and regional neoplasia (Table 26-3). In selected cases, it is used for palliation of painful disseminated tumors.

Applications

Radiotherapy is administered as a single modality or is combined with surgery, chemotherapy, or hyperthermia. It can be administered:

- As the initial form of therapy (neoadjuvant radiotherapy)
- Concurrent with other therapies (intraoperative radiation, concurrent chemotherapy)
- As postoperative therapy (adjuvant radiotherapy)

Advantages of Neoadjuvant Radiotherapy (Preoperative)

- Reduced tumor size, requiring less surgery and increasing the effectiveness of adjuvant chemotherapy
- Tumor vasculature is unaltered, decreasing local tumor hypoxia
- Viability of any surgically disseminated tumor cells is decreased
- Peripheral subclinical disease is eliminated

Advantages of Concurrent Therapy (Intraoperative or Combined with Chemotherapy)

- Improved radiation effectiveness by chemotherapy-induced radiosensitization
- Decreased radiation toxicity to normal tissues with intraoperative radiation

Table 26-3. RELATIVE RADIATION SENSITIVITY OF SELECTED CANINE TUMORS

Tumor Type	Site	Response
Squamous carcinoma	Gingiva	Good
	External nose	Poor
	Tonsil	Fair–poor
	Nasal cavity	Fair–poor
Malignant melanoma	Oral	Fair
Acanthomatous epulis	Gingiva	Excellent
Fibrosarcoma	Nasal cavity	Fair–good
Chondrosarcoma	Nasal cavity	Fair–good
Adenocarcinoma	Nasal cavity	Fair–good
Transmissible venereal tumor	Variable (usually penis and vulva)	Excellent
Soft tissue sarcoma	Peripheral	Poor–good
Mast cell tumor	Cutaneous	Fair–excellent
Perianal adenoma	Perianal	Excellent
Meningioma	Brain	Fair–good
Osteosarcoma	Any site	Fair (palliation only)
Solitary lymphoproliferative disease	Any site	Excellent

Advantages of Adjuvant Radiation (Postoperative)

- Improved effectiveness of radiation against smaller tumor burden
- More accurate radiotherapy planning based on information gained from surgery
- No delays in other therapy from radiation-related complications

Principles of Radiotherapy

- Irradiate all potentially affected tissues (such as regional lymph nodes and the tumor itself) and a margin of normal tissue.
- Radiation is more effective against a small tumor burden and well-oxygenated tumor cells.
- Higher energy radiation sources (linear accelerator, cobalt therapy), result in deeper, more uniform radiation penetration and greater sparing of skin and superficial tissues.
- Frequent small doses of radiation (e.g., 3 Gy daily or every other day) are preferable to allow for reoxygenation of tumor cells, repair of normal cells, and decreased late effects of radiation toxicity.
- Damage to normal tissue is minimized by judicious treatment planning and use of multiple treatment portals and shrinking field techniques.
- Administer radiation doses to the maximum dose tolerated by adjacent normal tissues. Radiation-induced tissue changes are permanent; however, re-irradiation of recurrent tumors is possible in some situations.
- Radiation-induced normal tissue effects may be classified as *acute,* occurring during the last portion of therapy or in the first few weeks after irradiation (e.g., mucositis, moist desquamation of skin, hair loss, tissue inflammation), or *late,* occurring many months or years after treatment (e.g., contraction and fibrosis, bone necrosis, cataract formation).
- After treatment, tumor volume may not change and biopsy samples can show the presence of nonviable neoplastic cells. Only gross evidence of active tumor growth indicates tumor recurrence.

Sources of Failure

Treatment failures result from radiation-related toxicity to normal tissues and from tumor- or treatment-related factors. Meticulous technique and the use of advanced radiotherapy planning technology minimize these errors.

Tumor-Related Factors

- Histologic tumor type (some tumor cells are inherently more radioresistant)
- Tumor volume (a larger volume increases the likelihood of radioresistant cells and tumor hypoxia)

Table 26-4. COMMON CHEMOTHERAPEUTIC AGENTS USED IN VETERINARY MEDICINE

	Indication	Recommended Dosages	Toxicity
Alkylating Agents			
Cyclophosphamide (Cytoxan; Mead-Johnson)	Lymphoproliferative disorders, mast cell tumors, hemangiosarcoma, miscellaneous carcinomas	50 mg/m^2 PO q48 hr 50 mg/m^2 PO q24h for 4d weekly 100–300 mg/m^2 IV q3wk	BM, GI, hemorrhagic cystitis
Chlorambucil (Leukeran; Burroughs-Wellcome)	Lymphoproliferative disease, macroglobulinemia	2–4 mg/m^2 q24–48 h	BM
Melphalan (Alkeran; Burroughs-Wellcome)	Multiple myeloma	2–4 mg/m^2 PO q24–48 h	BM
Lomustine/CCNU	Lymphomas, mast cell tumors	60–90 mg/m^2 PO q21–28 d	BM, GI, Liver
Cisplatin (Platinol; Bristol)	Osteosarcoma, transitional cell carcinoma, squamous cell carcinoma	50–70 mg/m^2 IV q3wk (vigorous hydration)	BM, GI, renal; DO NOT USE IN CATS!
Carboplatin (Paraplatin; Bristol)	Similar to cisplatin	250–300 mg/m^2 IV q3wk	BM, GI
Antimetabolites			
Methotrexate (Lederle)	Lymphoproliferative disorders	2.5 mg/m^2 PO q24–48 h 15–20 mg/m^2 IV q3wk	BM, GI, renal
5-Fluorouracil (Roche)	Gastrointestinal and hepatic carcinoma	150–200 mg/m^2 IV q7d	BM, GI, CNS; DO NOT USE IN CATS!
Cytosine Arabinoside (Cytosar-U; Upjohn)	Lymphoproliferative disorders, myeloproliferative disorders	100 mg/m^2 IV or SC for 4 days q3–4wk	BM, GI
Plant Alkaloids			
Vincristine (Oncovin; Eli Lilly)	Lymphoproliferative disorders, sarcomas, carcinomas	0.5–0.7 mg/m^2 IV q7d	GI, vesicant
Vinblastine (Velban; Eli Lilly)	Mast cell tumors	2 mg/m^2 IV q7–14d	GI, BM, vesicant
Antibiotics			
Doxorubicin (Adriamycin; Adria Labs)	Lymphoproliferative disorders, soft tissue sarcoma, carcinomas	20–25 mg/m^2 IV q3wk for dogs ≤l0 kg and cats; 30 mg/m^2 IV q3wk for dogs >10 kg; maximum cumulative dose = 180–240 mg/m^2	BM, GI, cardiac; severe vesicant; urticaria, alopecia
Mitoxantrone (Novantrone; Lederle)	Lymphoproliferative disorders	4–6 mg/m^2 IV q3wk	BM
Hormones			
Prednisone	Lymphoproliferative disorders, mast cell tumors, brain tumors	20–50 mg/m^2 q24–48h	Iatrogenic Cushing's syndrome
Miscellaneous			
l-Asparaginase (Elspar; Merck, Sharp & Dohme)	Lymphoproliferative disorders	10,000 IU/m^2 IM, SC	Anaphylaxis

BM, bone marrow; CNS, central nervous system; GI, gastrointestinal; IM, intramuscularly; IP, intraperitoneally; IV, intravenously; m^2, body surface area in square meters (see Table 26-4); PO, per os; SC, subcutaneously;

Treatment-Related Factors

- Inadequate radiation dose
- Geographic miss (i.e., a portion of the tumor is outside the treatment field)

Chemotherapy

Chemotherapy is most useful for regional and disseminated neoplasms. It is used primarily for palliation; few cures are achieved. Some cancer types are notably chemosensitive. Lymphoid neoplasms and transmissible venereal tumors often are treated effectively; most other nonlymphoid tumors are only moderately sensitive. Chemotherapy is useful, however, for treatment of many tumor types as an adjunct therapy to other treatments or for palliation. Table 26-4 lists the most common neoplastic agents used in veterinary medicine. Indications and major toxicity also are listed. Table 26-5 is a conversion schedule for estimating body surface area for dogs and cats based on body weight. Cytotoxic agents must be used safely to avoid exposure in health care workers. General guidelines for handling cytotoxic agents are given in Table 26-6.

Applications

Most chemotherapeutic agents are administered intravenously or orally. This is convenient and relatively

Table 26-5. CONVERSION FROM BODY WEIGHT (KG) TO BODY SURFACE AREA IN SQUARE METERS (M^2) FOR DOGS*

kg	m^2	kg	m^2
0.5	0.06	29.0	0.94
1.0	0.10	30.0	0.96
2.0	0.15	31.0	0.99
3.0	0.20	32.0	1.01
4.0	0.25	33.0	1.03
5.0	0.29	34.0	1.05
6.0	0.33	35.0	1.07
7.0	0.36	36.0	1.09
8.0	0.40	37.0	1.11
9.0	0.43	38.0	1.13
10.0	0.46	39.0	1.15
11.0	0.49	40.0	1.17
12.0	0.52	41.0	1.19
13.0	0.55	42.0	1.21
14.0	0.58	43.0	1.23
15.0	0.60	44.0	1.25
16.0	0.63	45.0	1.26
17.0	0.66	46.0	1.28
18.0	0.69	47.0	1.30
19.0	0.71	48.0	1.32
20.0	0.74	49.0	1.34
21.0	0.76	50.0	1.36
22.0	0.78	51.0	1.38
23.0	0.81	52.0	1.40
24.0	0.83	53.0	1.41
25.0	0.85	54.0	1.43
26.0	0.88	55.0	1.45
27.0	0.90	56.0	1.47
28.0	0.92	57.0	1.48

*Specific values can be calculated using the following formula:

$$\text{Body surface area } (m^2) = \frac{(k) \times (Wt)^{2/3}}{10^4}$$

where (k) = 10.1 for dogs and 10.0 for cats

Table 26-6. PRACTICAL RECOMMENDATIONS FOR SAFE HANDLING OF CYTOTOXIC ANTINEOPLASTIC AGENTS

1. Designate a specific hospital location for drug handling (reconstitution, preparation, disposal).
2. Use an absorbent, disposable, plastic-backed sheet to cover work surface; change it regularly.
3. Wear latex, non-powdered, non-permeable gloves when handling all cytotoxic agents.
4. Reduce exposed skin surfaces by wearing laboratory coats, gowns, and other protective wear. Wear particulate respiratory filtration masks to prevent inhalation of aerosolized drug particles.
5. Reconstitute all materials carefully and safely, avoiding potential contamination of materials or aerosolization.
6. Clean reconstituted material of any contamination and properly label concentration and date.
7. Dispose of contaminated materials in leak-proof, puncture-resistant containers. Proper disposal by health regulatory officials is necessary.
8. Wash hands thoroughly after removing gloves.

non-invasive. Chemotherapy also is given by intra-arterial or intra-cavitary routes to increase tumor/drug exposure. Drugs can be given before (neoadjuvant) or after surgery (adjuvant); the optimal sequence for most tumors is not yet known.

Advantages of Neoadjuvant Chemotherapy (Preoperative)

- Tumor size is reduced, necessitating less surgery or radiotherapy
- Tumor vasculature is not altered by surgery or radiation, ensuring more uniform delivery of drug
- Drug therapy can be evaluated by monitoring tumor response

Advantages of Adjuvant Chemotherapy (Postoperative)

- Resection of primary mass decreases the tumor burden; chemotherapy is more effective against a smaller tumor burden.
- Recruitment of dormant tumor cells into a more chemosensitive cell cycle phase increases tumor susceptibility to cytotoxic agents.

A preplanned protocol, regardless of sequence, is important for proper management of tumors that are likely to recur after single-modality treatment. Chemotherapy must be used appropriately to maximize treatment results and minimize toxicity.

Principles of Chemotherapy

- Use only drugs with documented activity against the specific tumor type.
- Administer all drugs at maximum tolerated doses and intervals.
- Some protocols are administered in two phases: an initial phase of intensive therapy *(induction),* followed by a period of less frequent drug administration *(maintenance).*
- Combination chemotherapy using agents with different mechanisms of action and no overlap in toxicity results in enhanced cancer cell destruction, reduced induction of drug resistance, and reduced toxicity.
- Continue chemotherapy past the time of complete remission because a microscopic tumor remains after the clinically detectable tumor has resolved.

Sources of Failure

Treatment failures result from excessive chemotherapy-related side effects (e.g., renal, hepatic, or myocardial toxicity or sepsis) or from progressive tumor growth because of intrinsic or acquired drug resistance. Intrinsic resistance results from molecular or biological adaptations or mutations within cancer cells that provide mechanisms for circumventing drug effects. The larger the tumor is, the more likely the existence of resistant

cells. Clinically detectable tumors are likely to have multiple resistant cell lines.

Intrinsic Drug Resistance

Causes of intrinsic resistance include the following:
- Inherent genetic mechanisms of cell protection
- Sanctuary sites (site where cells are protected, such as the CNS)
- Tumor cell dormancy, or insensitivity to specific action of a drug
- Insufficient drug delivery

Acquired Drug Resistance

Acquired resistance arises from selection pressure induced by sublethal drug doses. It occurs when cancer cells survive long enough to do the following:
- Develop alternate metabolic pathways
- Change drug transport mechanisms
- Initiate cellular repair
- Inhibit drug activation

Pleiotropic (Multiple) Drug Resistance

Resistance can develop to a single drug, a group of drugs, or many classes of drugs (pleiotropic resistance). Pleiotropic resistance is associated most commonly with the anthracyclines and vinca alkaloids.

Miscellaneous Therapy

Hyperthermia

Heat is an effective adjunct therapy because it enhances the cytotoxic effect of radiation and many chemotherapy agents. Hyperthermia is induced locally by ultrasound or radio waves or implemented as whole-body hyperthermia induced by a humidified chamber or radiant heat device.

Immunotherapy

Immunotherapy has emerged with renewed potential. Because neoplastic cells may be immunologically different from healthy cells, selective or nonselective induction of the host immune system by various biologic response modifiers (e.g., bacterial agents, interferons, monoclonal antibodies, lymphokines, and tumor vaccines) may enhance elimination of tumor cells. Immunotherapy appears to have the greatest potential as an adjunct to other therapies to eliminate microscopic residual tumor.

Photodynamic Therapy

Many tumor cells selectively accumulate certain systemically administered photoactive chemicals. Tumors then are exposed to light of selected wavelengths (laser light), and the photoactive substances become cytotoxic. Various photoactive drugs and light sources currently are being tested. Early results indicate that photodynamic therapy may be useful for treatment of localized solid tumors and in palliation of tumor-associated signs (esophageal or urethral obstruction, etc.).

Post-Treatment Monitoring

Patient monitoring after therapy is important to assess toxicity, adjust subsequent treatment, and monitor tumor response.

- Reevaluate animals at regular intervals
- Tailor follow-up schedule and appropriate diagnostic tests to each patient and the particular stage and expected behavior of the tumor.
- The goal of follow-up evaluation is to detect tumor recurrence or metastasis at the earliest possible time and to maximize the response to any additional alternate therapies.

ADJUNCT CLINICAL CONSIDERATIONS

Nutritional Management

Many animals with cancer have alterations of metabolism that result in malnutrition. When severe, these alterations result in the clinical syndrome of *cancer cachexia*. Malnutrition impairs the immune system, inhibits wound healing and normal cell repair, and increases treatment morbidity and mortality.

- Factors contributing to malnutrition include the following:
  - Anorexia
  - Decreased nutrient intake
  - Metabolic or digestive abnormalities that cause inefficient or inappropriate use of nutrients
  - Treatment-related factors such as therapy-induced nausea and vomiting
- Proposed mechanisms of cachexia include:
  - Tumor-produced anorexigenic substances
  - Alterations in brain neurotransmitter and anabolic hormone function
- Treatment is directed toward early elimination of the cachexia syndrome (by elimination of neoplasia) and supportive care to minimize its effects during the interim. Nutritional support is provided by enteral or parenteral feeding (see Chapter 3), and should be provided when patients do not eat for more than 5 days or have more than 10% acute loss of body weight. Laboratory parameters indicative of malnutrition include hypoalbuminemia, lymphopenia, and anemia.

Pain Management

Clinical management of pain in cancer patients is an important aspect of care to reduce morbidity and improve the quality of life.

- Pain can be:
  - Acute or chronic
  - Treatment- or tumor-related
  - Visceral, somatic, or neurogenic in origin
- Pain can contribute significantly to development of inappetence, weight loss, reduced mobility, depression, and poor interaction with the owner. Presence of pain is determined by changes, often subtle, in normal behavior patterns (see Chapter 6).
- The severity is determined and a treatment protocol implemented to provide adequate analgesia with minimal sedation and other side effects. Prevention or early treatment of pain is more effective than trying to resolve established significant or chronic pain signs. Therapy is by use of local or regional anesthesia, or with systemic treatment using transdermal delivery of narcotic-based pain medication, or parenterally administered nonsteroidal anti-inflammatory agents, and narcotics (see Chapter 6). Continual reassessment and modification of therapy is necessary.

Euthanasia

When treatment options fail and an animal's disease is progressing, consideration of euthanasia is appropriate. Encourage owners in advance to establish limits for their pet's level of deterioration. When the decision for euthanasia is reached by an owner, it should be supported by the veterinarian. For many owners, euthanasia is the last humane "treatment" they can give to their pet. Review the details of the euthanasia process in advance with owners and options for them to remain present or not. For clients having difficulty coping, provide assistance to help them find bereavement counseling. Condolence cards, telephone calls, or other forms of communication afterward are useful to provide closure. A positive experience with the euthanasia process often leaves clients with a positive feeling about the whole cancer treatment process.

Chapter 27

Lymphoid Neoplasia

David M. Vail

The lymphoproliferative disorders presented here are characterized by neoplasia involving cells or cell lines of lymphoid origin, including lymphoma, lymphoid leukemia, multiple myeloma, and plasmacytoma. Because of differences in diagnosis, therapy, and prognosis among these conditions, they are discussed here as separate entities.

LYMPHOMA

Lymphoma (lymphosarcoma) is defined as a lymphoid neoplasm primarily affecting lymph nodes or other solid visceral organs such as the liver or spleen. It is the most common of the lymphoproliferative disorders in small animals. Middle-aged to older dogs primarily are affected without sex predilection. Although lymphoma can occur in any purebred or mixed-breed dog, it may be more prevalent in golden retrievers, German shepherds, boxers, poodles, bassets, and Saint Bernards.

No breed predilection exists for cats; however, several reports have observed a 1.5:1 male-to-female ratio. Affected cats that are feline leukemia virus (FeLV) antigenemic tend to be younger (median age 3–5 years) than FeLV-negative cats (median age 7–10 years).

Etiology

Retrovirus

A retroviral etiology for certain forms of lymphoma has been demonstrated in a variety of species, including cats, chickens, and humans. In the cat, evidence exists for direct induction of lymphoma by FeLV and indirect induction by the feline immunodeficiency virus (FIV). Before 1985, most cats with lymphoma (>70%) were FeLV antigenemic. Since then, the general availability of FeLV vaccination and testing has increased and FeLV-positive cats currently make up a minority of lymphoma cases (<25%). This shift is likely due directly to vaccination and to FeLV antigen testing before vaccination, which allowed separation of potentially infective cats from the susceptible population. In either situation, the result is a reduction in the number of FeLV-associated lymphomas. Conclusive evidence of a viral etiology has not been established in the dog.

Genetic

A genetic predisposition for the development of certain forms of lymphoma may exist.

Carcinogenic Agents

Exposure to chemical, physical, and viral carcinogens may play a role in the development of many tumor types. Weak associations with herbicide use and exposure to high tension wires have been reported.

Classification and Clinical Signs

Traditionally, lymphoma is classified based on anatomic site. Clinical signs vary with the sites involved. In cats, the frequency of anatomic forms associated with FeLV antigenemia (i.e., mediastinal and multicentric forms) has declined along with the declining frequency of FeLV-associated lymphomas. Whereas these sites made up the bulk of cases observed in cats before 1985, they are now in the minority. Currently, the alimentary form, which only rarely is associated with FeLV antigenemia, makes up the bulk of lymphomas in cats. Other less common forms occurring in cats include renal, hepatic, and miscellaneous extranodal sites.

World Health Organization (WHO) clinical staging of lymphoma also can be used to classify the extent of the disease (Table 27-1).

Multicentric Lymphoma

This is the most common form in the dog. It usually manifests as increased lymph node size with nonspecific signs such as inappetence, weight loss, polyuria or polydipsia, and lethargy. Hepatic and splenic involvement, manifested as diffuse organ enlargement, also is common in multicentric lymphoma.

Alimentary Lymphoma

This type of lymphoma often is associated with vomiting, diarrhea, and nonspecific signs such as weight loss and lethargy.

Table 27-1. WORLD HEALTH ORGANIZATION CLINICAL STAGING FOR LYMPHOMA*

Stage†	Criteria
I	Involvement limited to single lymph node or lymphoid tissue in a single organ (excluding bone marrow)
II	Involvement of many lymph nodes in regional area (with or without tonsils)
III	Generalized lymph node involvement
IV	Liver and/or spleen involvement (with or without stage III)
V	Manifestations in blood and involvement of bone marrow and/or other organ systems (with or without stages I–IV)

*Reprinted with permission from World Health Organization: Owen LN: *TNM Classification of Tumors in Domestic Animals*. Geneva: WHO, 1980.
†Each stage is subclassified into (a) without systemic signs and (b) with systemic signs.

Mediastinal Lymphoma

This form of lymphoma often causes respiratory signs secondary to pleural effusion, the mass effect of the tumor, or precaval syndrome (i.e., facial and forelimb edema caused by reduced venous and/or lymphatic drainage). Approximately 40% to 50% of mediastinal lymphomas in the dog are associated with hypercalcemia, which can cause polyuria or polydipsia, anorexia, and weakness.

Cutaneous Lymphoma

Cutaneous lymphoma involves single or multiple skin lesions that can vary greatly in appearance. It may mimic other skin disorders such as seborrhea, pemphigus, and pyoderma. The cutaneous lesions can begin as a mild eczematous pruritic plaque and progress to nodular tumors. Approximately half of the reported cases of cutaneous lymphoma are pruritic.

Extranodal Forms

Miscellaneous extranodal forms of lymphoma include lymphoma of the eyes, central nervous system (CNS), bones, heart, kidneys, urinary bladder, and nasal cavity. Their presentations vary with respect to the site of involvement.

Classification by Immunophenotype

Lymphomas also can be classified by immunophenotype, that is, whether they are of B lymphocyte or T lymphocyte origin. Most (70–80%) lymphomas in dogs are composed of B cells. T cell origin lymphoma in dogs is associated more commonly with hypercalcemia and cranial mediastinal involvement. In cats, most FeLV-associated lymphomas are T cell in origin. The breakdown of B versus T cell lymphoma is less clear cut in cats.

Diagnosis

The diagnosis of lymphoma is based on a complete history, physical examination, tissue diagnosis, and clinical staging. Clinical staging should include a complete blood count (CBC), platelet count, bone marrow aspiration or core biopsy, biochemistry profile, and thoracic and abdominal radiographs. Abdominal ultrasound can be added to the workup if indicated based on presentation.

History

The history should include an evaluation of past and present water intake and urination frequency because they may reflect hypercalcemia of malignancy and subsequent renal disease.

Physical Examination

Perform a complete physical examination for all animals with lymphoma.

- Palpate all lymph nodes (including rectal palpation of sublumbar nodes) and abdominal viscera.
- Because bone marrow involvement can result in hematologic abnormalities, closely examine mucous membranes for signs of pallor or petechiae.
- Visceral involvement can lead to organ failure; therefore, look for any physical signs that may be indicative of liver or kidney disease (e.g., icterus and uremic ulcers).
- Ophthalmic abnormalities are present in more than one-third of dogs with lymphoma and include uveitis, hemorrhage, and ocular infiltration. Therefore, optic and fundic examinations should be conducted.

▼ ***Key Point*** Canine lymphoma usually is a disease of middle-aged and older animals; thus, it is essential to perform a complete examination to identify concomitant problems in other systems.

Laboratory Evaluations

Hematologic Abnormalities

- Hematologic abnormalities occur in most dogs and cats with multicentric lymphoma. Common abnormalities, in decreasing frequency, include atypical immature lymphocytes in the circulation, thrombocytopenia, eosinopenia, anemia, and nucleated erythrocytes.
- The anemia is usually that of chronic disease (normocytic, normochromic, and nonregenerative); however, a small percentage of animals have indices compatible with blood loss or hemolysis. FeLV-positive cats are more likely to be anemic than cats that are not infected.
- Bone marrow aspirate or core biopsy may reveal an altered bone marrow myeloid-to-erythroid ratio and bone marrow infiltration with neoplastic lymphocytes.

Biochemical Abnormalities

▼ ***Key Point*** Serum calcium is elevated in 15% to 20% of dogs with lymphoma. The likelihood of hypercalcemia is greatest in dogs with the mediastinal form.

- Paraneoplastic hypercalcemia (i.e., elevated serum calcium) may serve as a marker for response to therapy and, although uncommon, may cause hypercalcemic nephropathy, a potentially irreversible cause of renal failure (see Chapters 32 and 77).
- Elevations in blood urea nitrogen and serum creatinine may result from neoplastic infiltration of the kidneys, hypercalcemic nephrosis, or dehydration.
- Increased serum concentration of liver enzymes or bilirubin may indicate neoplastic infiltration of the liver.
- Abnormally elevated serum globulins may be noted in some B cell lymphomas.

Feline Leukemia Virus Status

Approximately 80% of cats with mediastinal and multicentric lymphoma are FeLV-positive, in contrast to 50% with renal lymphoma, 5% to 10% with alimentary lymphoma, and a minority with cutaneous forms.

Radiography and Ultrasonography

Radiography and ultrasonography (see Chapter 4), although not diagnostic for lymphoma, are often useful for staging or determining the extent of disease.

- Half of all dogs with lymphoma have evidence of enlarged sternal and sublumbar lymph nodes, spleen, and liver.
- Thoracic radiographs are important for identification of thoracic masses that are due to mediastinal lymphoma and are recommended for any dog with hypercalcemia of unknown etiology.
- Abdominal ultrasonography and contrast studies of the upper gastrointestinal (GI) tract are abnormal in most animals with GI lymphoma.

Histopathology and Cytology

Histopathologic and cytologic evaluation of affected tissues is necessary for confirmation of lymphoma.

- Fine-needle aspiration cytology of lymph nodes, visceral organs, and other involved sites can be suggestive of neoplastic disease; however, conclusive histologic diagnosis is often recommended.

▼ ***Key Point*** In the cytologic evaluation of lymph nodes in cats, neoplastic involvement is difficult to distinguish from benign lymphadenopathy syndromes. For this reason, only histopathologic examination is definitive.

- Avoid sampling lymph nodes draining reactive areas of the body (e.g., submandibular lymph nodes in the presence of periodontal disease) because reactive lymphoid hyperplasia can mask (or mimic) the true neoplastic condition.
- In addition to confirming a diagnosis of lymphoma, histologic and cytologic samples can be analyzed by various immunohistochemical and histochemical techniques to determine immunophenotype (B vs. T cell), tumor proliferation rates, and histologic subtype (high-, intermediate-, or low-grade tumors). The availability of such analysis is growing; however, at present only immunophenotype is consistently predictive of prognosis in dogs.

Additional Diagnostic Tests

Additional tests may be necessary to confirm the diagnosis of the extranodal forms of lymphoma.

- Stage the disease by performing a CBC, bone marrow evaluation, and thoracic and abdominal radiography. Staging is important in animals with extranodal lymphoma to ensure that the disease is not a sequela of the more common multicentric forms and to determine whether the disease is localized to a solitary extranodal site.
- Perform exploratory laparotomy and full-thickness biopsy or fine-needle aspiration to diagnose most cases of alimentary lymphoma. Endoscopic biopsies of the mucosa may be too superficial to diagnose GI lymphoma because lymphoma usually originates in the submucosa. In addition, GI lymphoma often is accompanied by lymphocytic/plasmacytic mucosal infiltrations that may be misdiagnosed as a benign condition. However, improved endoscopic sampling techniques may reduce the likelihood of misdiagnosis.
- Cytological evaluation of cerebrospinal fluid (CSF) may be helpful in the diagnosis of CNS lymphoma in the dog, but CSF is rarely abnormal in feline spinal lymphoma because the tumor is usually extradural. Magnetic resonance imaging, computed tomography, and myelography may be helpful.

Differential Diagnosis

The differential diagnosis (DDx) varies with the anatomic form of the disease.

- *DDx for lymphadenopathies* includes infectious diseases (e.g., bacterial, viral, rickettsial, parasitic, and fungal; see Section 2, Infectious Diseases), immune-mediated diseases (e.g., systemic lupus erythematosus; see Chapter 24), and other types of metastatic neoplasia.
- *DDx for alimentary lymphoma* includes lymphocytic/plasmacytic enteritis, other types of intestinal neoplasia, granulomatous and infiltrative bowel disease, and hypereosinophilic syndrome (see Chapter 69).

- *DDx for mediastinal lymphoma* includes ectopic thyroid tumors, heart base tumors, thymoma, and pulmonary lymphomatoid granulomatosis.
- *DDx for cutaneous lymphoma* includes pyoderma, immune-mediated and parasitic skin disorders, and other neoplastic dermatopathies.

Treatment

▼ ***Key Point*** Lymphoma is the most chemoresponsive malignancy encountered in veterinary medicine.

Most dogs and cats with lymphoma have multicentric systemic disease and therefore require systemic chemotherapy to improve quality of life and survival time. Untreated, dogs and cats with malignant lymphoma live an average of only 4 to 6 weeks once a diagnosis has been established. With standard-of-care combination chemotherapy, 75% to 90% of dogs and 60% to 70% of cats go into remission and survive a median of 7 (cats) to 12 (dogs) months with an excellent quality of life. With most combination protocols, approximately 25% of patients survive 2 years or more. Cures are still uncommon. Cost is within the financial reach of many clients, especially with the availability of generic brands of cytotoxic drugs.

Many combination chemotherapy protocols have an "induction" period designed to place a dog or cat into a remission, followed by a less intensive "maintenance" treatment period intended to sustain a remission. Current data suggest that intensive "up front" therapy to induce a sound remission is as effective as less intense protocols with continuously administered maintenance therapy for most cats and dogs (see below).

Complete remission is more difficult to achieve in cats; however, if a remission can be achieved and maintained for approximately 6 months, cats are more likely to experience prolonged survivals compared with dogs. Cats are generally more resistant to the adverse effects of chemotherapy than dogs. The exception to this rule is cats who receive doxorubicin as part of their protocol. Most dogs tolerate doxorubicin every 21 days at a dosage of 30 mg/m^2; however, cats appear to be more sensitive to the drug and therefore are treated at a dosage of 25 mg/m^2 (or 1 mg/kg) given every 21 days. Cats with preexisting azotemia should not receive doxorubicin.

Criteria for Choosing Chemotherapy

When choosing a chemotherapy protocol, several points must be discussed with the companion animal owner.

- *Cost:* Many chemotherapeutic agents are generally affordable. The additional costs of blood work, office visits, and catheters and the potential cost of treating toxicity also must be considered. Combination chemotherapy protocols, although often more effective, are also more expensive.
- *Time:* Time commitments can be more important to some clients than the cost of the therapy. In general, the more elaborate the protocol, the more time invested in the care of the patient.
- *Efficacy:* As a general rule, the more complex the protocol, the longer the duration of remission and of survival time. Conversely, single-agent chemotherapy is generally less effective than combination chemotherapy.
- *Toxicity:* The toxicity of most protocols is designed to be acceptable to the general public; however, the potential risks and benefits of each protocol must be discussed with each owner. Complex protocols increase the potential for toxicity and increase the importance of client education.
- *Experience of the attending clinician:* The successful application of any chemotherapy treatment requires experience and confidence because the effective dosage is very near the toxic dosage.

Induction Chemotherapy Protocols

Several chemotherapy protocols for dogs and cats have been reflecting that cures are still uncommon, and several investigators are continually attempting to improve on previous outcomes. Listing dosage and timing of all available protocols is beyond the scope of this chapter; therefore, I have chosen to elaborate on three protocols of varying cost, time commitment, and effectiveness: the University of Wisconsin-Madison CHOP-based combination protocol, the single-agent doxorubicin protocol, and single-agent prednisone therapy.

Dosages of chemotherapeutic agents are based on body surface area expressed in square meters (m^2). Refer to Chapter 26, Table 26-5, for conversion of body weight to body surface area.

University of Wisconsin-Madison Short Protocol

Most combination protocols are variations on the so-called CHOP-based protocols (C = cyclophosphamide; H = hydroxydaunorubicin [doxorubicin]; O = oncovin^R [vincristine]; P = prednisone). The University of Wisconsin-Madison protocol is one such protocol (Table 27-2). This protocol is complex but gratifying because the majority of dogs and cats achieve remissions and survive for medians of 12 and 7 months, respectively. This is a no-maintenance protocol, and dogs and cats are off all medication after 19 weeks. Notice the absence of L-asparaginase from this protocol, a drug often included in earlier versions. Several studies have shown that the addition of L-asparaginase does not increase the length of remissions and survivals; I reserve the use of this drug for "rescue" situations (see below).

Table 27-2. UNIVERSITY OF WISCONSIN-MADISON LYMPHOMA PROTOCOL

A: Combination Chemotherapy Protocol for Dogs with Lymphoma

Treatment Week	Drug, Dosage, and Route	Treatment Week	Drug, Dosage, and Route*
1	Vincristine, 0.5–0.7 mg/m^2, IV

8	Vincristine, 0.5–0.7 mg/m^2, IV	23	Vincristine, 0.5–0.7 mg/m^2, IV
9	Doxorubicin, 25 mg/m^2, IV	25‖	Doxorubicin, 25 mg/m^2, IV

*Refer to Chapter 26, Table 26-5, for conversion of body weight to body surface area.
†Cyclophosphamide is always delivered concurrently with 1 mg/kg of furosemide, IV, to decrease the incidence of sterile hemorrhagic cystitis.
‡If in complete remission at week 19, therapy is discontinued and monthly reevaluations are instituted.
§If renal lymphoma or CNS lymphoma is present, substitute cytosine arabinoside at 600 mg/m^2 divided SC bid over 2 days at these treatments.
¶Prednisone is continued (1 mg/kg, PO) every other day from this point on.
‖If in complete remission at week 25, therapy is discontinued and cat is rechecked monthly for recurrence.

Single-Agent Doxorubicin

Doxorubicin is one of the most effective single-agent treatments for lymphoma in dogs. Of the dogs treated with doxorubicin (30 mg/m^2 IV q21d for five to six total treatments), approximately 70% achieve a complete or partial remission. The duration of remission varies depending on the published report but is approximately 6 to 9 months.

Prednisone Only

When more aggressive or expensive chemotherapy is declined by clients, an inexpensive, although only transiently effective, alternative is prednisone alone. With prednisone therapy, the average dog or cat lives 2 months. One-third of dogs and cats treated with prednisone achieve a complete remission, one-third go into partial remission, and one-third do not respond at all. Similar responses are seen in cats. Dogs and cats that receive high-dose prednisone for a significant period before traditional chemotherapy is initiated may develop resistance to the cytotoxic effects of other chemotherapy agents.

Chemotherapy in the Presence of Cytopenia

Drug therapy for multicentric lymphoma may have to be altered in the presence of thrombocytopenia (<75,000/µl) and neutropenia (<1500/µl). Chemotherapeutic regimens that tend to spare bone marrow and are usually safe in the presence of low white blood cell (WBC) and platelet counts include prednisone, L-asparaginase, and vincristine. If myelosuppression is attributed to chemotherapy, discontinue treatment for 5 to 7 days and repeat the CBC and the platelet count. When the platelet and WBC counts have rebounded, reinstitute therapy at a decreased dose or frequency. However, if the neutropenia, the thrombocytopenia, or both are secondary to myelophthisis (i.e., tumor infiltration into bone marrow) aggressive chemotherapy is required despite the cytopenia to allow normalization of marrow cellular constituents.

Reinduction and Rescue Therapy

Reinduction therapy is defined as therapy instituted when a patient has recrudescence of lymphoma following discontinuation of chemotherapy that had resulted in a successful remission. In those cases, cycle the patient back through the same induction protocol as was used initially. The length of remission following reinduction is generally half that of the initial induction; however, several cases have been known to have equally or more durable second remissions.

Rescue therapy is defined as therapy instituted when either induction or reinduction fails to achieve a remission and other drugs not previously used are initiated. Several rescue protocols have been published and include non-CHOP drugs, including mitoxantrone, L-asparaginase, lomustine (CCNU), and actinomycin D. In general, remissions can be achieved with rescue; however, they are rarely durable and last approximately 1 to 2 months.

Future goals for the treatment of lymphoma in companion animals include increasing the remission time while decreasing cost, toxicity, and time involved to treat the patient. The future role of biologic-based therapies, including signal transduction modification, immunotherapeutics, and staged adjuvant radiotherapy, is under investigation. The question of whether cats benefit from long-term maintenance therapy has yet to be answered.

Small Cell Variant Lymphoma

This less common form of lymphoma is a "low-grade" variant. In represents a moderately common form of GI or hepatic lymphoma in cats and a rare multicentric form in dogs. It tends to be less chemoresponsive than intermediate or high-grade lymphoma; however, it has a more protacted course and patients can survive a long time with their disease. In my practice, small cell lymphoma is initially treated with continuous chlorambucil (20 mg/m^2, by mouth [PO], q14 days) and prednisone therapy.

Extranodal Lymphoma Therapy

Therapy unique to extranodal lymphoma depends on the site of involvement and the extent of disease. Extranodal lymphoma that is determined, after thorough staging, to be a local disease can be treated locally (e.g., excisional surgery or radiotherapy) without the necessity for systemic chemotherapy. Follow diligent reevaluation schedules to identify recurrence or systemic spread of disease. Initiate systemic chemotherapy once systemic involvement has been documented.

Therapy for CNS lymphoma depends on location, the capacity of drugs to cross the blood-brain barrier, and the presence of disease outside the CNS. Surgical intervention can be used for diagnosis or removal of accessible CNS tumors, but usually this is not feasible or practical. More commonly, surgery is combined with adjuvant chemotherapy or radiotherapy. Of the chemotherapeutic agents commonly used in veterinary medicine, only prednisone and cytosine arabinoside consistently cross the blood-brain barrier in therapeutic concentrations. Radiotherapy also has been used successfully for the treatment of CNS lymphoma.

Cutaneous Lymphoma Therapy

Cutaneous lymphoma, if solitary and confined, can be treated with local radiotherapy or surgery; however, the likelihood of ultimate systemic spread is high. Generalized, cutaneous lymphoma tends to be less responsive to chemotherapy than multicentric lymphoma, and clinical signs can wax and wane considerably over time. CCNU (lomustine), cis-retinoic acid therapy, and L-asparaginase have all proven effective in approximately 40% to 60% of dogs with cutaneous lymphoma, although long-term survival is uncommon.

Therapy for Hypercalcemia

Treatment of hypercalcemia secondary to lymphoma is accomplished best by attaining tumor remission. If necessary, diuresis with high sodium crystalloids (0.9% NaCl) delivered at twice the maintenance rate (see Chapter 32) is often sufficient along with initiation of chemotherapy. If hypercalcemia is severe, calcitonin therapy can be initiated. The addition of prednisone also decreases serum calcium levels; initiate only after a histologic or cytologic diagnosis.

Prognosis

Prognostic Indicators for Dogs with Lymphoma

- WHO clinical stage V (see Table 27-1) is associated with shorter survival times, especially when the bone marrow involvement results in significant cytopenias.
- WHO substage b (i.e., presenting ill, with significant clinical signs) is strongly predictive of shorter remission and survival times.
- The presence of a T cell origin lymphoma is strongly predictive of shorter remission and survival times.
- In some reports, female dogs have significantly longer remission and survival times than males.
- Hypercalcemia and mediastinal involvement have been reported to worsen prognosis; however, this has been shown to be due to their T cell association rather than a direct effect.
- Anatomic site of involvement can have prognostic significance. Alimentary, disseminated cutaneous, and leukemic forms have a poorer prognosis than multicentric forms.

Prognostic Indicators for Cats with Lymphoma

- A higher clinical stage is associated with lower remission rates and survival times (approximately 90%

complete remission rate in stage I versus 50% in stage III or higher)
- FeLV status is strongly predictive of remission and survival times. FeLV-antigenemic cats and the anatomic forms of lymphoma associated with them (mediastinal, multicentric) have a poorer prognosis than FeLV-negative cats (most often alimentary form).
- Leukemia, anemia, neutropenia, and sepsis negatively affect response to therapy and survival times.
- Response to therapy is strongly predictive of outcome. Cats that achieve a complete remission early in their treatment often go on to have a prolonged and durable remission. This indicator cannot be assessed before therapy, however, and therefore is not clinically useful at initial diagnosis.

LYMPHOID LEUKEMIA

Leukemia is defined as the proliferation of neoplastic cells in the bone marrow; such cells may or may not be circulating in the peripheral blood. There are two major categories of lymphoid leukemia: acute lymphoblastic leukemia and chronic lymphocytic leukemia. Both forms are relatively rare in dogs; however, they may constitute up to one-third of feline lymphoid neoplasms.

Acute Lymphoblastic Leukemia

Acute lymphoblastic leukemia (ALL) is defined as an abnormal proliferation of morphologically immature lymphoblasts in the bone marrow or peripheral blood. This form of leukemia is rapidly progressive and responds poorly to therapy.

Epidemiology and Clinical Signs

- No sex, breed, or weight predilection exists. Most affected dogs are of late middle age; the mean age in cats with ALL tends to be younger, owing to an association with FeLV.
- Clinical signs can include fever, generalized or abdominal pain, anorexia, splenomegaly, and pale mucous membranes.
- Anemia occurs in nearly half of ALL patients, and one-fourth are thrombocytopenic.
- Most cats with ALL are FeLV-positive.

Diagnosis

- Diagnosis depends on documentation of abnormal lymphocytes in the bone marrow or peripheral blood.
- The presence of 30% or more abnormal cells in the bone marrow is diagnostic.
- Most patients have absolute leukocytosis with circulating abnormal lymphocytes; 10% are classified as having aleukemic leukemia (bone marrow involvement without peripheral blood involvement).
- In some forms, the neoplastic lymphoid cells are very undifferentiated, making special histochemical stains necessary to differentiate them from other forms of leukemia and myeloproliferative conditions.
- ALL may be clinically differentiated from late stages of lymphoma by the following:
  - More acute progression of ALL
  - Less likelihood of lymphadenopathy (<50%)
  - Poor response to therapy
  - Shorter survival times

Treatment and Prognosis

- Most published reports utilize CHOP-based protocols (see earlier discussion in this chapter). Strict attention to treatment of secondary infection and symptomatic care are mandatory.
- A poor prognosis resulting from a meager short-lived response to therapy generally is the rule. Exceptions do exist.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is defined as an abnormal proliferation of morphologically mature lymphocytes in the bone marrow or peripheral blood. It occurs primarily in older dogs and cats.

Clinical Signs

- Presenting complaints for the most part are nonspecific and include lethargy, inappetence, polyuria or polydipsia, bleeding diathesis, intermittent lameness, and episodes of collapse.
- Two-thirds of dogs have lymphadenopathy and splenomegaly; pale mucous membranes and fever are common.

Hematologic Abnormalities

- Most animals are anemic (normocytic, normochromic, and nonregenerative), and approximately half are thrombocytopenic.
- One-third of dogs are hyperproteinemic, and half have monoclonal gammopathies on serum electrophoresis, often with Bence Jones proteins in the urine, indicative of a B cell origin; however, recent evidence suggests the majority of CLL in dogs is of T cell origin.
- All reported cases in cats are FeLV-negative.

Treatment and Prognosis

- Therapy for CLL is recommended only if the patient is symptomatic, if significant cytopenias exist (e.g., anemia, thrombocytopenia, and neutropenia), or if splenomegaly or lymphadenopathy is present.
- Prednisone and chlorambucil are the drugs most commonly used, and nearly 75% of animals respond, with median survivals of nearly 1 year.

- Chlorambucil (Leukeran), 20 mg/m^2 PO given every 1 to 2 weeks or 6 mg/m^2 daily, has provided excellent results.
- The prognosis for CLL is much better than that for ALL. Most dogs respond well to therapy, and quality of life is good.

PLASMA CELL NEOPLASMS

There are three primary clinical forms of plasma cell neoplasms: multiple myeloma (MM), solitary plasmacytoma of bone, and extramedullary plasmacytoma. MM is the most common form; the other two occur rarely. Plasma cell neoplasms are rare in cats.

Multiple Myeloma

Epidemiology and Clinical Signs

- MM occurs primarily in aged dogs and has no sex predilection.
- Clinical signs include nonspecific anorexia, listlessness, and polyuria or polydipsia.
- Most dogs present with lameness secondary to paresis or bone pain.
- Bleeding diathesis (epistaxis or gingival bleeding) secondary to hyperviscosity syndrome or thrombocytopenia develops in approximately 50% of affected dogs.

Hematologic Abnormalities

- Three-fourths of animals with MM have associated monoclonal gammopathy, either the immunoglobulin G or immunoglobulin A subtype. A rare immunoglobulin M-secreting primary macroglobulinemia (Waldenström's disease) also exists.
- Light-chain (Bence Jones) proteins may be detectable in the urine. These proteins cannot be detected by routine urine dipstick analysis and require phoretic technique to be identified.
- Dogs with MM often have nonregenerative, normocytic, or normochromic anemia. Approximately 30% are thrombocytopenic, and 10% have circulating abnormal plasmacytes.
- Approximately 15% to 20% of MM patients are hypercalcemic secondary to bone resorption caused by osteoclast-activating factors or other substances released by the tumor.

Diagnosis

Diagnosis involves identification of the following triad of abnormalities:

- Bone marrow plasmacytosis (>20–30% plasma cells).
- Radiographic evidence of osteolytic bone lesions, often observed in dorsal spinous vertebral processes. Approximately 50% of dogs with MM have radiographic evidence of bone lesions, whereas skeletal lesions are rare in cats with MM.
- Serum or urine myeloma proteins, as revealed by immunoelectrophoresis.

Histological confirmation may be necessary for those cases that do not meet all three criteria.

Differential Diagnosis

- DDx for monoclonal gammopathy includes ehrlichiosis (see Chapter 17) and benign hypergammaglobulinemia syndrome, which has been described in the dog.
- DDx for plasmacytosis includes carcinomas, connective tissue disorders, liver disease, hypersensitivity states, and infections, especially ehrlichiosis (see Chapter 17).

Treatment and Prognosis

- The short-term prognosis for MM in dogs is normally good, and long-term remissions are the rule. In cats, the prognosis is poor, and durable remissions after therapy are the exception.
- Extensive bone lesions, light-chain proteinuria, hypercalcemia, and anemia have been reported to be negative prognostic indicators.
- Combination chemotherapy using melphalan (Alkeran, Burroughs Wellcome) (0.1 mg/kg daily for 10 days, then 0.5 mg/kg daily) and prednisone (0.5 mg/kg q24h for 10 days, then every other day) has resulted in published remission rates of 90% and median survival times of 540 days in dogs.
- Serum protein levels should normalize within 2 to 3 months.
- Fractures accompanying MM can be treated by surgical reduction in combination with chemotherapy or radiotherapy. Healing normally accompanies remission of the MM; however, it may take many months and may not be complete.
- Rescue therapy is not well documented once remission is lost. Doxorubicin, vincristine, and dexamethasone combinations appear to work well in humans and may be beneficial in dogs.

Solitary Plasmacytoma of Bone

Solitary plasmacytoma of bone is rare. It usually is not accompanied by a secretory protein but tends to progress to systemic MM. Localized lesions can be treated with surgery or radiotherapy; however, careful clinical staging and a strict reevaluation schedule should be established because of the propensity for the development of systemic disease. Melphalan and prednisone are initiated once systemic involvement is documented.

Extramedullary Plasmacytoma

Two general categories of extramedullary plasmacytoma (EMP) exist, each with a very different biological behavior.

- Solitary cutaneous and oral EMP is generally a benign condition in dogs that is curable with complete surgical excision or local radiotherapy.
- Conversely, GI EMP in the dog tends to behave in a malignant fashion. It rarely is associated with monoclonal gammopathies. Thorough staging (e.g., bone marrow) is necessary to ensure that the disease is localized initially. If that is the case, local excision can be attempted. The likelihood of eventual systemic spread is high, and once documented, combination chemotherapy is initiated.

Chapter 28

Soft Tissue Sarcomas and Mast Cell Tumors

Joanne C. Graham

SOFT TISSUE SARCOMAS

Soft tissue sarcomas are tumors that arise from mesodermal tissue. They make up 14% to 17% of all malignancies in the dog and approximately 7% to 9% in the cat. These tumors are non-epithelial and extraskeletal and may arise from fibrous tissue, adipose tissue, muscle, synovial tissue, and from blood and lymph vessels. Schwannomas, nerve sheath tumors, or neurofibrosarcomas arise from primitive ectodermal tissues but are included in the soft tissue sarcoma category because of similarities in location, clinical presentation, and clinical behavior. Soft tissue sarcomas are classified histologically according to the specific tissue of origin. However, some tumors are so undifferentiated that this classification is difficult. These tumors are appropriately named undifferentiated sarcomas.

Etiology

The etiology of most soft tissue sarcomas remains unknown. Several causes and predisposing factors have been suggested. These include genetic predisposition, viral agents, chemical carcinogens, ionizing radiation, foreign body implantation, trauma, parasites, and injections of vaccines or medication.

Genetic Predisposition

This is suspected to play a role in tumor development because certain breeds of dogs have a higher incidence of sarcomas. These breeds include boxers, German shepherds, Great Danes, Saint Bernards, golden retrievers, basset hounds, and flat-coated retrievers.

Viral Agents

Viruses have been implicated as causes of sarcoma development in rodents, poultry, non-human primates, and cats. Feline sarcoma viruses (FeSVs) are replication-defective variants of the feline leukemia virus (FeLV). These retroviruses together induce formation of multicentric fibrosarcomas in young cats (see Chapter 8). In contrast, solitary fibrosarcomas found in older cats usually are not associated with FeSV.

Chemical Carcinogens

Chemical carcinogens and environmental contaminants have been shown to induce sarcomas in rodents and humans. Although this has not been documented in dogs and cats, it likely occurs.

Ionizing Radiation

X-rays, gamma rays, and particulate radiation have been shown to cause sarcoma development. In dogs, sarcomas have been reported to occur at treatment sites after orthovoltage radiotherapy of acanthomatous epulides.

Chronic Tissue Inflammation

- Sarcomas have developed at sites of chronic tissue inflammation. Implants, particularly metallic orthopedic implants, are known to cause sarcoma development at the implant site. It is believed that this is the result of a foreign body reaction in the tissues rather than a direct carcinogenic effect of the implant. Most of these tumors are osteosarcomas, although fibrosarcomas and undifferentiated sarcomas have been reported.
- Both single and chronic traumatic episodes have been associated with intraocular sarcomas in the cat.
- Chronic inflammation caused by the parasite *Spirocerca lupi* has resulted in sarcoma development in the esophagus of infected dogs.
- Recently, certain soft tissue sarcomas in cats have been associated with the administration of vaccinations and medication (lufenuron). The exact incidence is unknown but may be greater than 1 in 10,000 vaccinated cats. The mechanism behind injection-associated sarcoma development is under investigation but may involve chronic inflammation

induced by the injection combined with predisposing host factors.

Biologic Behavior

In general, soft tissue sarcomas are locally invasive and infiltrative along fascial planes, resulting in poorly defined tumor margins. The metastatic rate varies according to tumor grade, with low-grade tumors often slow to metastasize. Metastasis is usually via hematogenous spread to the lungs and liver. Regional lymph node metastasis is uncommon. A brief description of various soft tissue sarcomas follows.

Liposarcoma

Malignant tumor of adipocytes

- Rare in dogs and cats
- Invasive and aggressive
- Location may be a prognostic indicator (appendicular and visceral locations worse)
- Metastasis is uncommon except with the visceral location
- "Infiltrative lipomas," believed by some to be well-differentiated liposarcomas, frequently occur on the extremities

Hemangiopericytoma

Tumor of pericytes, spindle-shaped, contractive cells that surround precapillary arterioles

- Common in dogs (German shepherds at risk)
- Slow growing
- Encapsulated appearance but quite infiltrative, and recurrence after excision is common
- Frequently occurs on extremities
- Metastasis is rare

Fibrosarcoma

Tumor of fibrocytes

- Common in dogs and cats
- Locally invasive and slow growing
- Metastasis is uncommon except in injection-site sarcomas (20% to 30%)

▼ ***Key Point*** Multicentric fibrosarcomas of young cats (less than 5 years) may be caused by FeSV. These cats are always FeLV-positive.

Hemangiosarcoma

Tumor of blood vessel endothelium

- Common in dogs (German shepherds at risk); rare in cats
- Very invasive and rapid growing
- Spleen, heart, and skin are common primary sites
- Metastasis is common

Schwannoma, Neurofibrosarcoma, or Peripheral Nerve Sheath Tumor

Tumor of the nerve sheath or Schwann cell

- Invasive and slow growing
- May occur anywhere but frequently occurs in the brachial or lumbosacral plexuses
- Progressive lameness is possible
- Metastasis is rare with grade 1 and 2 tumors

Myxosarcoma

Fibrosarcoma-like tumor with a mucinous matrix

- Rare in dogs and cats
- Infiltrative; no site predilection
- Metastasis is uncommon

Rhabdomyosarcoma

Tumor of striated muscle

- Uncommon in dogs and cats
- Infiltrative
- Heart, bladder, and appendicular muscles are possible sites
- Metastasis is possible
- Botryoid rhabdomyosarcomas (grape-like appearance) is found in bladders of young, large-breed dogs

Leiomyosarcoma

Tumor of smooth muscle

- Rare in dogs and cats
- Solitary, infiltrative, and slow growing
- Spleen, liver, gastrointestinal, and genitourinary tracts are the most common sites
- Metastasis is possible (common with primary liver site)
- Gastrointestinal (GI) obstructive signs or perforation are possible with gastrointestinal sites

Synovial Cell Sarcoma

Tumor of periarticular mesenchymal tissue, not the synovial membrane

- Uncommon in dogs; few reports in cats
- Large-breed dogs are at risk
- Aggressive tumor
- Bones on both sides of major joints may be involved
- Metastasis is possible (22% at time of diagnosis)

Lymphangiosarcoma

Tumor of lymphatic endothelial vessels

- Rare in dogs and cats
- May be invasive
- Metastasis is rare
- Draining tracts on skin or edema are possible presenting signs

Malignant Fibrous Histiocytoma

Tumor containing a mixture of fibroblast-like cells and histiocyte-like cells

- Uncommon in dogs and cats
- Invasive (may cause bone lysis)
- Usually found in subcutaneous tissue
- Metastasis is uncommon

Feline Injection-Site Sarcomas

Most are fibrosarcomas, but the category also includes rhabdomyosarcomas, leiomyosarcomas, chondrosarcomas, osteosarcomas, malignant fibrous histiocytomas, and undifferentiated sarcomas

- The number of giant cells in the histopathology sample may correlate with the grade (higher number of cells = higher grade)
- Aggressive, highly invasive tumors
- Cervical or interscapular area and hind limbs are the most common sites
- Metastasis is possible (20–30% of cases)

Clinical Signs

Clinical signs depend on the location, size, and degree of invasiveness of the tumor as well as on the presence and degree of metastatic disease.

- Soft tissue sarcomas are more common in older animals (mean age 9 years).
- Because of the widespread distribution of mesodermal tissues in the body, soft tissue sarcomas may occur in almost any anatomic location, including the abdomen.
- Tumors may become quite large before any clinical signs are apparent. They often are noticed first by the owner, either by observation or by handling the animal.
- Certain types of sarcoma may invade bone, causing lameness, or may obstruct lymphatics, causing edema.
- GI leiomyosarcomas may cause signs of GI obstruction (vomiting) or melena.
- Smooth muscle sarcomas of the bladder may cause hematuria, pollakiuria, or dysuria.
- Hemangiosarcomas may cause a variety of clinical signs, including collapse due to tumor rupture and hemorrhage.
- Injection-site sarcomas arise in injections sites.

Diagnosis

The goals of diagnosis are to identify the histologic type and grade of the primary tumor, to delineate the extent of the tumor, and to determine whether metastatic disease is present. Although history, physical examination, laboratory evaluation, and diagnostic imaging provide valuable information, the only way to obtain a definitive diagnosis is through biopsy and histopathologic evaluation of the tumor. Histologic grade is useful in predicting tumor behavior and prognosis for dogs with soft tissue sarcomas.

History

The history helps determine how long the mass has been present and the rate of growth. Also important is information regarding exposure to carcinogens, recent vaccination, and past traumatic incidents. Concurrent systemic disorders may be present if metastatic disease or paraneoplastic syndromes have developed.

Physical Examination

Perform a thorough examination to determine the number of masses and their physical characteristics.

- In general, benign neoplasms are well delineated, slow growing, and freely moveable. They seldom are ulcerated or inflamed.
- Malignant tumors are often rapid-growing, fixed masses with ill-defined borders. However, some low-grade sarcomas are slow growing and appear well demarcated. The appearance of these masses can be misleading and should not preclude biopsy.
- Search for evidence of metastasis. Palpate the regional lymph nodes for size and mobility. Look for hepatomegaly, splenomegaly, and increased respiratory sounds or dyspnea as signs of systemic involvement.

Clinical Pathology

Evaluate a complete blood count (CBC), platelet count, serum biochemical profile, and urinalysis in animals with soft tissue sarcomas. Although results are often unremarkable, in some cases these may suggest the presence of metastatic disease, paraneoplastic syndromes, or other concurrent disease. The values obtained also provide a baseline for future therapy. Abnormalities may include the following:

- Anemia of chronic inflammatory disease
- Leukocytosis
- Thrombocytopenia (may be associated with disseminated intravascular coagulation)
- Hypoglycemia
- Increased serum concentrations of alanine transferase (ALT), alkaline phosphatase (ALP), and gamma-glutamyl transpeptidase (GGT)

Diagnostic Imaging

Radiography

- Radiograph the mass to aid in determining the extent of the sarcoma and assess for underlying bone invasion.
- Radiograph the thorax and abdomen to help identify metastatic disease.
- Dystrophic calcification caused by some anaplastic sarcomas may be seen on radiographs.

Ultrasonography

- Use this technique to help determine the character, consistency, and extent of the primary mass.
- Ultrasound procedures are especially useful in the examination of abdominal masses and to examine the internal organs for intra-abdominal metastasis.

Computed Tomography

- This modality, when available, is particularly useful for determining the precise localization and extent of a mass. It is also an ideal test to detect the presence of lung metastasis.

Biopsy

Biopsy is essential to obtain a definitive diagnosis and grade of the tumor.

- Plan carefully to ensure that a representative sample of the mass is obtained.
- Submit all biopsies for histopathologic evaluation.
- Immunohistochemical stains may be necessary to determine the cell of origin.

Several methods for biopsy are available.

Fine-Needle Aspiration Biopsy

- For fine-needle aspiration (FNA), use a 22- or 25-gauge needle and a 6- or 12-ml syringe.
- Because soft tissue sarcomas do not exfoliate well, FNA is limited in value.
- FNA, however, is useful for the diagnosis of lipomas, lymphoma, and inflammatory masses that may appear similar to soft tissue sarcomas.

Needle Punch Biopsy

- For needle punch biopsy (NPB), use a Franklin-modified Vim-Silverman needle (V. Mueller Co., Chicago) or Tru-Cut biopsy needle (Travenol Laboratories, Deerfield, IL).
- NPB is useful for externally palpable masses. A larger sample of tissue can be obtained than with FNA. NPB usually can be performed using local anesthesia with or without sedation.

Incisional Biopsy

- Incisional biopsies yield an even larger sample than NPB samples.
- Plan the biopsy site so that it can be excised later when definitive resection is done.
- Include some normal tissue in the sample when possible.

Excisional Biopsy

- Excisional biopsies are indicated when knowledge of the histologic type of the tumor does not change the treatment and/or total excision is no more invasive than other types of biopsy.

Clinical Staging

Stage all patients with soft tissue sarcomas. Clinical staging is based on the classification system developed by the World Health Organization (WHO) (Table 28-1). In general, the higher the stage, the more guarded the prognosis. Recommended staging tests include CBC, biochemical profile, urinalysis, thoracic radiographs, abdominal radiographs or ultrasound (preferable), and imaging (radiographs, ultrasound, and computed tomography scan) of the primary mass.

Treatment

The goal of treatment is to remove the primary tumor in its entirety, when possible, and to treat microscopic disease and metastasis. In the case of benign and some

Table 28-1. WORLD HEALTH ORGANIZATION CLINICAL STAGING SYSTEM FOR CANINE SOFT TISSUE SARCOMAS

T = Primary Tumor	N = Regional Lymph Node	M = Distant Metastasis
T_0—No evidence	N_0—No evidence	M_0—No evidence
T_1—Tumor < 2 cm	N_1—Movable ipsilateral	M_1—Metastasis present
T_2—Tumor > 2 and <5 cm; minimal invasion	N_2—Movable contralateral	
	N_3—Fixed	
T_3—Tumor > 5 cm	a—Metastasis absent	
T_4—Invasive	b—Metastasis present	
	Stage	
I	$T_1N_0M_0$, $T_2N_0M_0$	
II	$T_1N_1M_0$, $T_2N_1M_0$	
III	$T_1N_{2,3}M_0$, $T_2N_{2,3}M_0$, $T_3N_{0-3}M_0$, $T_4N_{0-3}M_0$, any N_b	
IV	any M_1	

From Owen LN: Classification of tumours in domestic animals. Geneva, Switzerland: World Health Organization, 1980.

malignant tumors, surgical resection can be curative. In animals with non-resectable malignant tumors, attempt to prolong survival time and provide good quality of life.

Surgery

Surgical excision remains the mainstay of therapy for soft tissue sarcomas (see Chapter 26 for principles of oncologic surgery). However, many of these tumors recur because of inadequate resection. A well-planned, aggressive initial surgery has the greatest likelihood of success.

▼ ***Key Point*** Excise soft tissue sarcomas with 3-cm margins in all planes. Remove one fascial plane deep to the tumor if 3-cm margins are not possible.

- Remove overlying subcutaneous tissues and skin as well as underlying tissues to which the mass is fixed. In some cases, limb amputation is indicated.
- Include all previous biopsy sites in the excision.
- Remove the tumor intact to prevent seeding of normal tissues with malignant cells.
- Have the specimen margins histologically evaluated for completeness of excision and grade.
- Do not remove regional lymph nodes unless they are involved.

Radiation Therapy

Soft tissue sarcomas are variably responsive to radiation therapy depending upon the histologic type and grade of the tumor.

- Radiation therapy is used most frequently to irradiate incompletely excised tumor fields or reduce tumor volume preoperatively. Tumor control rates of 95% at 1 year and 91% at 2 years post-radiation therapy have been reported for patients with incompletely excised, well-differentiated sarcomas.
- High-dose (8 Gy) weekly radiation has been reported to be successful for palliative control of soft tissue sarcomas in dogs.
- Repeat irradiation of previously irradiated tumors is possible. A 38% local control rate after 1-year repeat irradiation has been reported. Unfortunately, if the regrowth of tumors is within 4 to 5 months of the first treatment, the chance of complications from additional radiation is much higher.

Hyperthermia

Hyperthermia involves electromagnetic radiation or ultrasound to heat tissues.

- Hyperthermia is cytotoxic when used alone; however, the best results are seen when it is used as a combined modality with radiation or chemotherapy.
- A 91% response rate has been reported in dogs with hemangiopericytoma treated using orthovoltage irradiation in combination with hyperthermia.
- Unfortunately, hyperthermia requires training and equipment found in few hospitals and thus is of limited accessibility.

Chemotherapy

Chemotherapy has been used with some success to treat patients with soft tissue sarcomas.

- Agents most often used are vincristine, doxorubicin, cyclophosphamide, mitoxantrone, dacarbazine, carboplatin, and lomustine. Response rates range from 15% to 50%. Commonly used protocols are outlined in Table 28-2.
- Chemotherapy is not likely to be efficacious in treating patients with large tumor burdens. Rather, it is best used to treat patients with microscopic disease following incomplete excision, metastatic disease, micrometastatic disease, or patients with grade 3 sarcomas.

MAST CELL TUMORS

Mast cell tumors (MCTs) comprise approximately 7% to 20% of cutaneous neoplasms in the dog and 20% in the cat. MCTs may develop in almost any location but are found most commonly in the skin and subcutaneous tissues of the dog, and in the skin, spleen, liver, and intestines of the cat. Mast cells are a normal component of the immune system and are important in the inflammatory response to tissue trauma as well as in allergic reactions. Cytoplasmic granules found in mast cells contain biologically active substances such as heparin, histamine, platelet-activating factor, prostaglandins, cytokines, and leukotrienes. The quantity and type of granules in MCTs depends on the degree of differentiation. Well-differentiated tumors contain more heparin than undifferentiated tumors, which have a higher histamine content.

Etiology

The cause of MCTs is unknown; however, breed predisposition, chronic inflammation, and viruses may play a role.

Breed Predisposition

Boxers, Boston terriers, English bulldogs, English bull terriers, Sharpeis, and Labrador and golden retrievers are at risk. However, MCTs in boxers are more likely to be well differentiated and may have a more favorable prognosis. Siamese cats younger than 4 years of age have been reported to have a higher incidence of cutaneous histiocytic-like MCTs that may spontaneously regress.

Table 28-2. CHEMOTHERAPEUTIC PROTOCOLS FOR SOFT TISSUE SARCOMAS*

Drug (Trade Name)	Dosage**	Route	Day
Doxorubicin (Adriamycin)	30 mg/m^2 (dogs > 10 kg) 1 mg/kg (cats and dogs < 10 kg)	IV	1
Repeat cycle every 21 days for 4–6 treatments; do not exceed 8 treatments			
Mitoxantrone (Novantrone)	5–6 mg/m^2 (dogs) 5.5–6.5 mg/m^2 (cats)	IV	1
Repeat cycle every 21 days for 4–6 treatments			
Carboplatin (Paraplatin)	260–300 mg/m^2 (dogs) 220–260 mg/m^2 (cats)	IV	1
Repeat cycle every 21 days for 4–6 treatments			
Lomustine (CeeNU)	50–70 mg/m^2 (dogs and cats)	PO	1
Repeat cycle every 21 days for 4–6 treatments			
AC Protocol			
Doxorubicin	As above	IV	1
Cyclophosphamide (Cytoxan)	100–150 mg/m^2	IV	1
	or 50 mg/m^2	PO	3–6
Repeat cycle every 21 days for 4–6 treatments; do not exceed 8 treatments			
VAC Protocol (Dogs Only)			
Vincristine (Oncovin)	0.5–0.7 mg/m^2	IV	8 & 15
Doxorubicin	As above	IV	1
Cyclophophamide	As above	IV	1
	or as above	PO	3–6
Repeat cycle every 21 days for 4–6 treatments; do not exceed 8 treatments. Very myelosuppressive protocol; may need prophylactic antibiotics.			
ADIC Protocol (Dogs Only)			
Doxorubicin	As above	IV	1
Dacarbazine (DTIC)	800–1000 mg/m^2	IV	1
	or 200 mg/m^2	IV	2–5
Repeat cycle every 21 days for 4–6 treatments; do not exceed 8 treatments			

*Caution: The use of chemotherapeutics requires careful handling and knowledge of potential toxicities.
**See Chapter 26 (Table 26-5) for conversion of body weight to body surface area in square meters (m^2).

Chronic Inflammation

Chronic inflammatory sites in the dog have been reported to give rise to MCTs.

Topical carcinogens have been suspected to be involved in MCT development because these tumors are so prevalent in the skin. No definitive proof of this exists.

Viruses

The speculation that viruses may have a role in MCTs stems from experimental studies in which dogs developed MCTs after being given injections of cell-free tumor extracts. However, no specific viruses have been identified as causative agents.

Biologic Behavior

The biologic behavior of MCTs is extremely variable.

▼ ***Key Point*** Because it is often difficult to histologically differentiate benign from malignant tumors, all MCTs should be considered potentially malignant.

Dog

- Approximately 30% to 55% of patients have well-differentiated (grade 1) tumors and are cured with complete surgical excision. The behavior of intermediate-grade tumors is less predictable.
- Undifferentiated tumors (grade 3) are found in 20% to 40% of patients and are aggressive. Most dogs with grade 3 tumors die of their disease within 6 months of surgery.
- Tumor location and rate of growth may help predict behavior. Tumors in preputial, inguinal, perineal, oral, and aural areas may be more aggressive.
- Slow-growing localized MCTs may have a better prognosis. In one study, tumors that were present for 28 weeks or longer before removal had a more favorable prognosis.
- Regional lymph nodes, the spleen, and the liver are the most common sites of metastasis. Bone marrow involvement is uncommon (4.5% of patients in one study). Pulmonary metastasis also is uncommon.

Cat

Controversy exists about the frequency and biologic behavior of MCTs in cats. There are two forms of the disease: cutaneous and visceral.

- Most cutaneous MCTs are well-differentiated and do not display malignant behavior.
- A subset of cutaneous MCTs that appear histologically more diffuse and pleomorphic are behaviorally more aggressive.
- A third type of cutaneous MCT, histiocytic, is seen in young cats and has a benign course, often regressing spontaneously.
- The visceral form (splenic or intestinal) of the disease is aggressive, and widespread metastasis is common.

Clinical Signs

Clinical signs depend on the location, the size and number of the tumors, and the secondary systemic complications caused by the MCT.

- In the dog, most MCTs are observed as solitary masses in the skin of the trunk and perineal area (50%), followed by the extremities (40%) and the head and neck (10%).
- In the cat, 40% to 60% of cutaneous MCTs are solitary masses on the head and neck. At least 20% of cats will have tumors in multiple sites.
- Dermal MCTs are usually well-defined, raised masses that can be hairless, ulcerated, and erythematous. Dermal MCTs may be diffuse, erythematous thickenings in the skin.
- Subcutaneous MCTs may resemble lipomas.
- Mechanical manipulation of MCTs may cause degranulation, resulting in erythema and wheal formation (Darier's sign).
- Visceral MCTs arise in the spleen, small intestine, liver, and visceral lymphatics. Cats with visceral MCTs may present with anorexia, vomiting, or diarrhea.
- Gastroduodenal ulcers have been reported in up to 80% of dogs with MCTs and are thought to be related to histamine release. These animals may have anorexia, vomiting, diarrhea, and melena.
- Heparin and proteolytic enzyme release by MCTs at the time of surgery may prolong coagulation times and delay wound healing.

Diagnosis

History, physical examination, clinical pathology, tumor and bone marrow cytology, radiography, ultrasonography, and histopathology are useful in the diagnosis and staging of MCTs. Stage all patients with MCTs to determine prognosis and therapeutic decisions. Recommended staging tests include CBC, biochemical profile, urinalysis, buffy coat cytology or bone marrow aspiration (controversial), regional lymph node aspirate, abdominal radiographs or ultrasound (preferable), and thoracic radiographs (low yield). A classification system for staging has been developed by the WHO (Table 28-3).

Table 28-3. WORLD HEALTH ORGANIZATION CLINICAL STAGING SYSTEM FOR CANINE MAST CELL TUMORS

Stage	Criteria
I	One dermal tumor without regional lymph node involvement
II	One dermal tumor with regional lymph node involvement
III	Multiple dermal tumors or a large infiltrative tumor with or without regional lymph node involvement
IV	Any tumor with distant metastasis or recurrence with metastasis
Stages are subdivided into the following:	
a	Without systemic signs
b	With systemic signs

History

The history can determine the length of time the mass has been present and the rate of growth.

MCTs present for months without worsening in clinical appearance may be associated with a favorable prognosis.

Physical Examination

Thoroughly examine the animal to detect the location and number of masses. Palpate carefully for hepatomegaly, splenomegaly, and lymph node enlargement as signs of metastasis.

Clinical Pathology

Routine laboratory evaluations may be unremarkable. Examine a CBC for evidence of systemic dissemination. Circulating mast cells, eosinophilia, and basophilia are more common in the dog than in the cat (except with the visceral form). Microcytic-hypochromic anemia may suggest gastrointestinal hemorrhage. The significance of mast cells in buffy coat smears is controversial as patients with non-neoplastic diseases may have increased numbers in smears.

Bone Marrow Aspiration

This is a more sensitive indicator of bone marrow involvement than a buffy coat smear. The presence of greater than 10 mast cells per 1000 nucleated cells is abnormal. However, less than 5% of dogs with cutaneous MCTs will have bone marrow involvement.

Radiography and Ultrasonography

Perform abdominal radiography or ultrasonography (preferable) to detect hepatomegaly, splenomegaly, and intra-abdominal lymph node enlargement. FNA of

enlarged organs (especially the spleen) can be helpful in confirming metastatic MCT. Thoracic radiographs are seldom helpful.

Fine-Needle Aspiration

MCTs exfoliate well and usually can be diagnosed by FNA. Aspirates generally contain numerous discrete round cells with abundant basophilic granules (mast cells). Occasionally, the granules may not stain well with Diff-Quik stains.

Histopathology

Histopathology is important to evaluate completeness of excision and histologic grade. Special stains (toluidine blue, Giemsa) are sometimes needed to identify undifferentiated MCTs. Other stains or immunohistochemical assays that can be performed on histopathology samples and may aid with prognosis are agyrophilic nucleolar staining organizing regions (AGNORs), proliferating cell nuclear antigen (PCNA), and Ki-67 staining. The higher the counts, the poorer the prognosis.

Grading of Tumors

The most reliable predictor of MCT behavior and prognosis in dogs is tumor grade. The most widely used grading system (Patnaik) assigns grades I, II, and III to well, moderately, and poorly differentiated tumors, respectively (based on histologic appearance).

- Low-grade tumors are less likely to recur or metastasize, and dogs with low-grade tumors have increased survival times.
- The Patnaik grading system has not been found useful in determining prognosis in cats.

Treatment of Canine Cutaneous Mast Cell Tumors

Treatment of MCTs may include surgery, radiation therapy, chemotherapy, or some combination of the three. The type of treatment instituted depends primarily on the histologic grade of the tumor and the clinical stage of the patient.

Surgery

Wide surgical excision is the treatment of choice for canine MCTs.

▼ ***Key Point*** Although they appear to be discrete masses, MCTs may extend deep into surrounding tissues, making wide surgical excision imperative (especially for grade 3 tumors)

- Administer an antihistamine (e.g., diphenhydramine; 2 mg/kg IM or IV) just before surgical excision of large tumors to decrease the effects of histamine release from the tumor.
- Excise the mass with 3-cm margins on all sides and one fascial plane deep to the tumor.
- Remove regional lymph nodes if enlarged or if metastasis is detected.
- Have the specimen margins histologically evaluated for completeness of excision and grade. If the tumor extends to the margins, plan a second wider excision (if possible).
- If tumors are excised incompletely or are non-resectable, proceed with radiation therapy and/or chemotherapy.
- Wound complications, such as excessive inflammation, edema, and dehiscence, can occur after MCT excision.

Radiation Therapy

Radiation therapy alone or in combination with other treatment modalities may be used to treat incompletely excised or non-resectable MCTs.

- Patients with grade 1 and 2 tumors respond better than those with grade 3. In one study, tumor-free survival rates of 94% at 1 year and 86% at 5 years post-radiation therapy were reported in dogs with incompletely excised grade 1 and 2 MCT.
- Radiation is most effective against microscopic disease.
- Irradiate involved regional lymph nodes, if necessary.

Chemotherapy

Chemotherapy is indicated for patients with systemic mastocytosis, grade 3 tumors, non-resectable tumors, or incompletely excised tumors when a second surgery or radiation therapy is not possible.

- Glucocorticoids (prednisone and prednisolone) are commonly used but are effective in less than 25% of dogs when used alone.
- Vinblastine, cyclophosphamide, and lomustine are chemotherapy drugs reported to have efficacy against MCTs (Table 28-4 shows dosages). Combination therapy is thought to be superior to single-agent use.

Ancillary Drug Therapy

Patients with grade 3 tumors, systemic mastocytosis, or gastrointestinal hemorrhage should receive ancillary drug therapy.

- Use H_2-antagonists to reduce gastric acid secretion and help decrease the incidence and severity of gastrointestinal ulcers in MCT patients. Administer one of the following H_2-blockers:
  - Cimetidine (Tagamet), 5 to 10 mg/kg PO q8h
  - Ranitidine (Zantac), 1 to 2 mg/kg PO q12h
  - Famotidine (Pepcid), 0.5 to 1 mg/kg PO q24h
- When an active gastrointestinal ulcer is suspected in an animal with MCT, also administer the following:
  - Sucralfate (Carafate), 250 to 1000 mg PO q6–8h

Table 28-4. CHEMOTHERAPEUTIC PROTOCOLS FOR MAST CELL TUMORS

Drug (Trade Name)	Dosage*	Route	Day
CVP			
Cyclophosphamide (Cytoxan)	250–300 mg/m^2 divided	PO	8–11
Vinblastine (Velban)	2 mg/m^2	IV	1
Prednisone	1 mg/kg	PO	q24h
Repeat cycle every 21 days			
VLP (Dogs)			
Vinblastine (Velban)	As above	IV	1
Lomustine (CeeNU)	60–70 mg/m^2	PO	14
Prednisone	2 mg/kg Gradually taper to 0.5 mg/kg	PO	q24h
Repeat cycle every 28 days			
Lomustine (CeeNU)	50–70 mg/m^2	PO	1
Repeat cycle every 21 days			
Prednisone	1 mg/kg	PO	q24h

*See Chapter 26 (Table 26-5) for conversion of body weight to body surface area in square meters (m^2).

- Use an H_1-antagonist (diphenhydramine) as needed to reduce inflammation and pruritis associated with histamine release.

Treatment of Feline Mast Cell Tumors

Cutaneous

- Wide surgical excision is the treatment of choice.
- Chemotherapy and radiation therapy have not been well evaluated but may be helpful in recurrent or metastatic tumors. One study found a 57% response rate to lomustine in cats with MCTs.

Visceral

- Splenectomy may ameliorate clinical signs and prolong survival in cats with splenic MCT even when other organs are involved. Median survival times following splenectomy was 19 months in one study of 43 cats.
- Treat intestinal MCTs by wide surgical excision (5- to 10-cm margins). However, the prognosis for cats with intestinal disease is poor.
- Chemotherapy has not been critically evaluated.

Chapter 29

Mammary Gland Neoplasia

Kechia M. Davis / Elizabeth A. Stone

The mammary gland tumor (MGT) is the most common tumor in the female dog and the third most common neoplasm in the female cat. MGTs have been reported in the male dog and cat but are rare.

ETIOLOGY AND RISK FACTORS

- The cause of mammary gland neoplasia is unknown.
- Predisposing risk factors proposed but incompletely established include dietary intake of red meat and obesity at 1 year of age.
- A genetic etiology has been suggested in one colony of beagles.
- Although virus-like particles have been identified in feline and canine MGTs, their role as a causative agent has not been established.
- Routine administration of medroxyprogesterone acetate, proligestone, or other progestins for estrus prevention or dermatologic therapies increases the risk of MGTs in dogs and cats.
- About 50% of canine mammary carcinomas have estrogen and progesterone receptors at levels lower than in benign or normal mammary gland tissues. Only benign and well-differentiated adenocarcinomas appear to be hormonally sensitive in female dogs.
- Dogs with benign MGTs have more than a threefold risk of subsequently developing a mammary malignancy of a different cell type.
- Dogs that are spayed before their first estrus have almost no risk of developing MGTs.

CLINICAL SIGNS

- A mass or swelling develops in the ventral thoracic or abdominal region. The mass is typically associated with the mammae but may appear distant to the mammary gland.
- Metastatic lesions in the lungs may cause dyspnea.
- Metastatic lesions in the axial skeleton or proximal long bones may cause pain or lameness.
- Anorexia and weight loss may be noted in cats with inflammatory mammary carcinoma (IMC).
- MGTs can be seen concurrent with uterine neoplasms in cats.

DIAGNOSIS

Establish a definitive diagnosis, determine local invasion, and determine the stage of the MGT.

Signalment

Dogs

- In dogs, the risk of developing MGTs increases markedly after 6 years of age.
- Most MGTs are reported in sporting breeds (pointers, English setters, and spaniels), poodles, Boston terriers, and dachshunds.
- Consider predisposing risk factors (see prior section).

Cats

- Feline carcinomas occur most often in intact female cats 8 to 12 years of age.
- Siamese cats are reported to have twice the risk of developing mammary carcinoma as all other breeds combined.

History

- The owner may have noticed the tumor or it may have been an incidental finding during routine examination.
- The owner may have delayed seeking veterinary assistance. Median time from owner observation of mammary masses in cats to presentation to a veterinarian is 5 months.

Physical Examination

- In dogs, MGTs develop most frequently in the caudal mammary glands.

- Depending on the time of recognition, the tumors may be small and movable, lobular and firm, fixed to the body wall, and ulcerated.
- Dogs with inflammatory carcinoma have diffusely swollen glands with poor demarcation between normal and abnormal tissue, which may be confused with mastitis. In mastitis, the swelling is more localized and occurs after estrus, whelping, or false pregnancy.
- Hindlimb edema, popliteal lymphadenopathy, and ulceration may be noted in cats with IMC up to 4 months after mammary mass excision.
- In young, intact female cats, mammary hypertrophy can be mistaken for MGT. Mammary hypertrophy resulting from either endogenous or exogenous progesterone stimulation can be differentiated readily by case history and, if necessary, histologic examination.
- In cats, infiltrated lymphatics may look like linear beads.
- Superficial cervical, axillary, popliteal, and inguinal lymph nodes may be enlarged.
- Carefully examine dogs for evidence of lameness and bony swelling. If these signs are present, radiograph the affected area and obtain a nuclear bone scan if needed. Mammary carcinoma is one of the most common primary tumors with metastases to the skeleton.
- In advanced disease, cachexia may be noted due partially to altered carbohydrate metabolism.

Diagnostic Imaging

▼ ***Key Point*** In cats, mammary adenocarcinoma has been reported as the most common tumor to metastasize to the lungs.

- The radiographic appearance is frequently diffuse or ill-defined pulmonary infiltrates.
- If caudal mammary glands are involved, use abdominal ultrasonography or abdominal radiographs to evaluate the iliac lymph nodes.
- Magnetic resonance imaging with gadolinium contrast has been shown to detect metastatic lymph nodes in canine mammary tumors.

Cytologic Evaluation

- Cytology is generally not recommended for the diagnosis of MGTs.
- Varying degrees of epithelial atypia and inflammation make definitive diagnosis and tumor grading difficult.
- Cytology may be useful to differentiate inflammatory carcinoma from mastitis in dogs and mammary hypertrophy from mammary carcinoma in cats.
- Fine needle aspiration of enlarged inguinal or axillary lymph nodes is recommended.

Histologic Evaluation

Submit all excised mammary masses for histopathologic evaluation. Although about 50% of MGTs are benign, many dogs can have multiple tumors often of different tumor types, both benign and malignant.

- Tumors are graded by cell type (epithelial, mesenchymal, or mixed) and by degree of differentiation. High-grade tumors are typically poorly differentiated.
- Histopathologic evaluation is the preferred method of definitively diagnosing and grading mammary masses. The histopathologic diagnosis does not alter current treatment recommendations for MGT (except for IMC, as explained in "Contraindications"). Thus, surgical excision is performed for both diagnostic and therapeutic purposes. A wide excision is essential to ensure complete removal of tumor cells.
- Regional lymph nodes should be removed as well and submitted for histopathology. Dogs with lymph node metastasis have been shown to have a significantly shorter disease-free interval and a poorer prognosis than those without lymph node involvement.

Other Diagnostic Tests

- If the animal is to undergo surgery, perform a complete blood count, biochemical profile, and urinalysis. These animals are typically older and may have concurrent disease that may need to be addressed.
- Perform thoracocentesis with cytologic analysis if pleural fluid is evident on thoracic radiographs.

TREATMENT: SURGICAL

The primary surgical goal is to excise all of the neoplastic tissue while maintaining quality of life.

Preoperative Considerations

Indications

Surgical excision is beneficial in dogs because it does the following:

- Provides a histologic diagnosis
- Can modify disease progression
- Can improve quality of life
- Can be curative

Contraindications

Preoperative diagnosis of IMC is a contraindication for surgery. Mean survival of dogs with IMC is 25 days with palliative treatment. Cats have lived up to 45 days after diagnosis of IMC. Delayed diagnosis may partially explain the short survival time. Treatment for IMC

should be palliative using anti-inflammatory drugs and antibiotics. Surgery is not recommended for IMC for the following reasons:

- It is impossible to remove all affected tissue.
- Disseminated intravascular coagulation often is induced by surgery.
- Incisions may dehisce as the disease progresses.
- The following discussion excludes inflammatory carcinoma.

▼ ***Key Point*** Radical mastectomy has not been shown to be more effective than excision of only affected glands for dogs with MGTs.

Resection Margins

Determine resection margins before surgery. Dissect only healthy tissues during surgery. Do not disrupt the tumor itself. The margins should be at least 1 cm from the neoplastic tissue.

Gland Excision in Dogs

Past recommendations have suggested regional mastectomy for all MGTs in dogs. These recommendations were based on the lymphatic drainage in normal dogs. However, MGTs have been shown to disrupt normal drainage and open new channels between other glands. Thus, the number of excised glands should be based on having adequate resection margins of normal tissue around the tumor.

Gland Excision in Cats

In cats, removal of all glands on an affected side decreases local recurrence compared with a lumpectomy. However, this may not prolong survival time.

Other Recommendations

- If the tumor has invaded the subcutaneous tissue beneath the gland, include the ventral fascia of the underlying muscle in the excision.
- If the tumor has invaded the body wall, remove a wide section of the body wall en bloc with the tumor.
- Remove the inguinal lymph node routinely during mastectomy of gland 5.
- Axillary lymph nodes usually are not removed with gland 1 unless there is palpable or cytologic evidence of an abnormality.

Surgical Procedures

The choice of surgical procedures for MGTs include lumpectomy, simple mastectomy, regional mastectomy, complete unilateral mastectomy, and one-stage or two-stage complete bilateral mastectomy. Ovariohysterectomy can be combined with any of these.

Lumpectomy

Removal of the tumor and 1 cm of normal tissue without removal of surrounding glandular tissue *(lumpectomy)* is adequate if the tumor is small (<5 mm), circumscribed, and non-invasive.

Simple Mastectomy

In many instances, removal of the entire mammary gland *(simple mastectomy)* is easier than lumpectomy, and this avoids milk and lymph leakage into the wound.

Regional Mastectomy

When the incision must extend into the adjacent gland or glands to obtain adequate margins, the adjacent gland or glands are also removed *(regional mastectomy)*. Consider the blood supply to individual mammary glands when planning and executing the mastectomy. When two or more glands are neoplastic, choose the most efficient approach. Involvement of two or three adjacent glands necessitates a regional mastectomy.

Complete Unilateral Mastectomy

When multiple glands contain tumors, all the ipsilateral glands and intervening tissues are removed *(complete unilateral mastectomy),* rather than excising each gland separately and leaving tissue between glands.

Removal of Tumors in Contralateral Glands

Tumors in contralateral glands may be excised by bilateral simple, regional, or complete mastectomy. The limiting factor is the amount of skin that will be available after excision for closure. In cats and in relatively flat-chested dogs, such as Yorkshire terriers or Pekingese, bilateral complete mastectomy is possible.

In deep-chested dogs, such as Irish setters or pointers, often it is not possible to excise contralateral cranial glands with adequate margins of healthy tissue and still be able to close the skin. In this type of dog, perform a staged bilateral mastectomy. Operate on one side and then, after 2 to 4 weeks, operate on the other side.

Surgical Technique

1. Prepare the affected mammary glands and surrounding skin for aseptic surgery.
2. After skin and subcutaneous tissues are incised, suture drapes or towels to the normal wound edges to protect skin from tumor implantation.
3. Place stay sutures in the margin tissues.
4. Use blunt and sharp dissection to remove mammary glands and underlying subcutaneous tissue. Avoid handling the tumor with instruments or fingers.
5. Use meticulous hemostasis with point electrocautery and vessel ligation.
6. Lavage the wound with 0.5 to 1 L of warm sterile normal saline to remove exfoliated tumor cells.

7. Replace contaminated gloves and surgical instruments before beginning closure.
8. Meticulously close the subcutaneous tissues to relieve tension across the incision and prevent problems associated with dead space.
9. Close skin routinely.
10. Consider a light bandage on the incision after extensive mastectomy to protect from trauma.

Ovariohysterectomy

Ovariohysterectomy (OHE) at the time of mastectomy remains controversial. One study found that dogs spayed less than 2 years before mastectomy survived significantly longer than those spayed more than 2 years prior to surgery. The investigators theorized that MGTs that develop in the presence of reproductive hormones are less aggressive than those that develop in spayed dogs. Another study failed to demonstrate such a difference. OHE does result in atrophy of the remaining glands, which may make it easier to detect new tumors. However, with aggressive MGTs, death from metastatic disease may occur before new tumors become problematic.

If OHE is planned during the same surgery, perform the OHE before the mastectomy to avoid seeding the abdomen with tumor cells. If MGT extends across the midline, perform the mastectomy first, lavage the area, and use new gloves and instruments for the OHE.

Biopsy Preparation

Because multiple tumor types can be present, submit each mass for histopathologic examination. Mark the edges of the tissue with suture material or India ink to help the pathologist maintain proper orientation.

Pain Control

Use perioperative pain control on patients undergoing tumor excision, considering options such as nonsteroidal anti-inflammatory agents (NSAIDs), narcotic analgesics, and local anesthetics (see Chapter 6). For extensive tumor resections involving the body wall or entire chains of mammary glands, use single, preoperative epidural injections or epidural catheters in addition to other modalities of pain control.

TREATMENT: MEDICAL

Chemotherapy, anti-estrogen therapy, and biologic response modifiers have been used to treat MGTs in conjunction with surgery and to treat metastic or unresectable tumors. In general, efficacy remains to be established, and surgery is the treatment of choice whenever possible.

Chemotherapy

Efficacy of chemotherapeutic agents has not been established for canine MGTs. A recent study cited an increase in survival time in dogs treated with cyclophosphamide and 5-fluorouracil after surgery. Cyclophosphamide and doxorubicin may induce a short-term partial or complete response in cats with metastatic or nonresectable local disease. However, these drugs cause severe anorexia and mild myelosuppression.

Anti-Estrogen Therapy

A response of MGTs to anti-estrogen therapy (e.g., tamoxifen) has not been proven. Estrogenic side effects (e.g., vaginal bleeding, vulval swelling, and attractiveness to male dogs) are common.

Biologic Response Modifiers

Biologic response modifiers such as levamisole and bacilli Calmette-Guerin (BCG) have not been proven to be beneficial for MGT.

PROGNOSIS

Dogs

In dogs, histologic grade and stage appear to be important prognostic factors. Various studies in dogs have concluded the following:

- Poorly differentiated or invasive MGTs have a worse long-term prognosis than other types.
- Ductular carcinomas metastasize more frequently and result in a threefold increase in death rate compared with adenocarcinomas.
- Approximately 26% of dogs with benign tumors develop new mammary masses within 2 years of tumor excision regardless of OHE.
- Cancer mortality rate after excision of mammary carcinomas is reportedly 22%, with most deaths occurring within 1 year of surgery.
- The mortality rate for dogs with invasive or metastatic carcinomas is 80%. Invasive carcinomas also recur more often (44%) than benign and non-invasive carcinomas (12%).

▼ ***Key Point*** Dogs with tumors <3 cm in diameter have a better prognosis than dogs with tumors >3 cm in diameter.

Cats

In cats, histologic grade and tumor size appear to be prognostic but cell type is not.

- Cats with mammary adenocarcinomas and carcinomas >3 cm have a poorer prognosis and shorter 12-month median survival time.

- Survival may be decreased in cats with multiple tumors and tumors >8 cm^3.
- Vascular endothelial growth factor expression is an important prognostic indicator in cats.

PREVENTION

▼ ***Key Point*** The risk of MGT is less than 0.5% in dogs that are spayed before their first estrus and less than 8% in those spayed before their second estrus.

- After 2.5 years, OHE has no protective effect on MGT development. In dogs spayed at any age, risk of MGT is reduced if dogs were thin at 9 to 12 months of age.
- Spayed cats have a 0.6% risk for developing mammary carcinoma compared with intact cats.

Chapter 30

Tumors of the Skin and Subcutaneous Tissues

Janet L. Peterson

The skin and subcutis are the most common sites of neoplasia in the dog, accounting for approximately 30% to 40% of all tumors. In the cat, only 20% of all tumors originate in the skin and subcutis, making it the second most common site of origin. Most canine skin tumors are benign, whereas most feline skin tumors are malignant. Owners often discover skin tumors while petting or grooming their animals.

▼ ***Key Point*** Skin tumors should not be ignored. Advising owners to "watch" the tumor rather than to seek a diagnosis could be life-threatening to their dog or cat.

The most common skin tumors in the dog and cat are shown in Table 30-1.

Dog breeds at an increased risk for skin tumors include the basset hound, boxer, bull mastiff, Scottish terrier, and Weimaraner; there is no apparent breed predilection in the cat. In general, skin and subcutaneous tumors are more common in older dogs and cats. Common tumors in younger dogs are shown in Table 30-1. The etiology of most canine and feline tumors is unknown; however, some tumors have been associated with defined etiologic agents, such as those listed in Table 30-2.

Physical examination may assist the clinician in formulating a list of potential tumors in the small animal patient. A basic working knowledge of the anatomic location and tissue of origin of various tumors can assist the clinician in making educated decisions. Additionally, fine-needle aspiration helps make a definitive diagnosis without requiring an incisional or excisional biopsy.

TUMOR CLASSIFICATION

Skin tumors can be classified by tissue of origin (Table 30-3), anatomic location (Table 30-4), and stratum of origin (Table 30-5). Miscellaneous tumors affecting the skin are listed in Table 30-6.

DIAGNOSIS

General Principles

- Diagnosis and characterization of a skin mass is important for several reasons. Knowledge of the tumor type before surgical excision allows the clinician (1) to plan an appropriate surgical approach (e.g., in a mast cell tumor that requires 3-cm margins beyond the tumor edges), (2) to consider radiation therapy (e.g., non-resectable mast cell tumors), or (3) to institute medical treatment (e.g., vincristine chemotherapy is usually curative for transmissible venereal tumors).
- To detect the presence of metastatic disease before surgery, evaluate every enlarged regional lymph node cytologically (fine-needle aspiration) or histologically. Additionally, consider lymph node excisional biopsy at surgery for more accurate staging.
- Perform thoracic radiographs (three views) on all animals with suspected (or confirmed) malignant tumors to detect potential pulmonary metastases. Perform abdominal radiography and/or abdominal ultrasonography in those cases in which dissemination to the abdominal organs, cavity, or multicentricity is suspected (e.g., mast cell tumor or hemangiosarcoma). Evaluate skeletal structures on thoracic and abdominal radiographs for metastatic disease.

▼ ***Key Point*** Diagnosis and staging of a skin tumor before surgery are critical to ensure complete excision and to determine appropriate additional treatment.

Fine-Needle Aspiration Cytology

Equipment

- 12-ml syringe
- 22- or 25-gauge needle
- Glass slides
- Diff-Quick or Wright-Giemsa stain

Epidermal inclusion cyst (epidermoid, epidermoid cyst)
Dermoid cyst

Technique

- Isolate and hold the mass firmly while inserting the needle into it.
- Apply negative pressure to the syringe to obtain cells.
- Release the negative pressure before withdrawing the needle from the mass.
- Remove the needle from the syringe and fill the syringe with air.
- Replace the needle and expel the contents (within the hub of the needle) onto a glass slide or cover slip.
- Prepare the smear by placing the two slides together and pulling them apart in a parallel motion (“horizontal pull-apart” technique).

- An alternative technique is to insert the needle several times without a syringe into the mass ("pass-through" technique). The contents of the needle are expelled using a syringe and are prepared as aforementioned.

Cytologic Classification of Neoplasia

Cytology can be used to classify masses as neoplastic or non-neoplastic. If the mass is not neoplastic, then the decision must be made as to whether it is inflammatory or non-inflammatory. Masses also can be classified as mixed, as in the case of a neoplastic mass with a necrotic center and associated inflammation. Infectious agents also may be identified cytologically (e.g., bacteria, fungi, or protozoa).

Cytologic examination may allow classification of tumors into one of three categories: epithelial, mesenchymal, or round cell neoplasm (includes epithelial, mesenchymal, and melanocytic tumors).

Epithelial Tumors

Epithelial cells cluster because of desmosomes. Aspiration cytology reveals round to polygonal cells with basophilic cytoplasm (with and without vacuoles) and cell-to-cell association. The latter may be absent in squamous cell carcinomas.

Mesenchymal Tumors

Mesenchymal tumors arise from connective tissue, including fibrous tissue, muscle, fat, and blood vessels. They do not exfoliate well on fine-needle aspiration; however, when they do exfoliate, they appear as individual cells or in small groups of cells, with a spindle to polygonal shape.

Round Cell Tumors

On fine-needle aspiration, round cell tumors tend to exfoliate as single cells with the exception of transmissible venereal tumor cells, which usually clump. The cells have distinct cell membranes like epithelial cells. Some cells may have cytoplasmic granules (i.e., mast cells, melanoma cells, and large granular lymphocytes).

Round cell tumors include lymphoma, melanoma, histiocytoma, transmissible venereal tumor, mast cell tumor, and plasma cell tumor. Additionally, squamous cell carcinomas and basal cell tumors can resemble round cell tumors cytologically.

Incisional Biopsy

Punch Biopsy

The skin punch biopsy using the Baker biopsy punch is a relatively simple technique for obtaining a sample of superficial masses. The advantage of skin punch biopsies is that they can be done quickly, using only local anesthetic. See Chapter 37 for skin biopsy technique.

Needle Biopsy

Tru-cut or spring-loaded needle biopsies can be used to obtain representative samples of larger or subcutaneous masses using only local anesthesia.

Wedge Biopsy

A routine surgical procedure is used to obtain a "wedge" biopsy (see Chapter 26).

Excisional Biopsy

Excisional biopsy implies that all or most of the tumor or mass is removed and submitted for histopathologic examination. This approach is indicated for small, easily excisable masses. Margins of excised tissue should be at least 1 cm in all cases. All excised tumors must be properly fixed. Label each tumor by location if there are multiple tumors, and finally, send all tumors to a qualified veterinary pathologist for examination. Principles of surgical biopsy of tumors are described in Chapter 26.

▼ ***Key Point*** Perform histopathologic examinations on all excised skin masses, no matter how "benign" they appear. Appropriate treatment necessitates a definitive diagnosis.

Staging

Clinical staging is helpful in characterizing the extent of the disease. Obtain thoracic radiographs (left and right lateral and ventrodorsal views) when malignancy is suspected. Perform abdominal radiography or ultrasonography for tumors such as cutaneous hemangiosarcoma and mast cell tumor to evaluate for splenic and hepatic involvement (metastases or primary tumor).

SELECTED TUMORS OF THE SKIN AND SUBCUTANEOUS TISSUE

Epithelial Neoplasia

Papilloma

Origin and Etiology

Papillomas (squamous papillomas, squamous cell papillomatosis, warts, and cutaneous papillomatosis) originate from the squamous epithelium. Papillomas have a DNA viral etiology in puppies (see Chapter 16), but the etiology is unknown in older dogs.

Description

Papillomas may appear as cauliflower or wart-like growths that are usually well encapsulated. They can be sessile or pedunculated and may bleed if traumatized.

They can occur as a single tumor (usually non-viral etiology) or as multiple tumors (usually viral etiology) in the skin, mucous membranes, or mucocutaneous regions.

Epidemiology and Biologic Behavior

Papillomas are common in dogs but rare in cats. The virally induced papillomas found in young dogs often appear as multiple or occasionally single masses on the head, eyelids, feet, or mouth. These tumors are contagious to other dogs and have an incubation period of approximately 30 days. In older dogs, non-viral papillomas tend to appear as solitary dermoepidermal masses. Some papillomas in older dogs can transform into squamous cell carcinomas.

Treatment

Papillomas tend to regress spontaneously in younger dogs (usually within 1–2 months) and therefore do not require treatment. Surgically remove viral papillomas that do not regress and non-viral papillomas that cause a clinical problem.

Sebaceous Gland Tumors

Origin and Etiology

Sebaceous gland adenoma, hyperplasia, and adenocarcinoma originate from the epithelium of the sebaceous glands.

Description

These tumors are common in dogs (especially spaniels) and rare in cats. Hyperplasia usually appears as pink, smooth, lobulated, and wart-like growths that are firm, dermoepidermal, and well-circumscribed masses with an alopecic surface. They may be pigmented and can occur anywhere on the body. These tumors are frequently multiple. They often appear as bleeding and ulcerated masses. Sebaceous gland adenocarcinoma is poorly circumscribed, large, invasive, and frequently ulcerated. These are extremely rare.

Cytology

Cytologic examination of sebaceous gland hyperplasia reveals mature secretory epithelial cells, frequently with a "signet-ring appearance" because of the accumulation of secretions within the cell. Sebaceous adenocarcinoma cells exhibit typical features of epithelial malignancy.

Epidemiology and Biologic Behavior

Sebaceous gland hyperplasia tends to be multiple lesions. Sebaceous gland adenomas can occur as single tumors; however, they frequently occur in multiple sites. They occur in older female dogs, especially poodles and cocker spaniels. When metastases from sebaceous gland adenocarcinomas occur, they generally spread to the regional lymph nodes and subsequently to the lungs.

Treatment

Surgical excision of sebaceous gland hyperplasia lesions may not be necessary unless they occur in an area that is easily traumatized. Perform wide surgical excision on all sebaceous adenocarcinomas. Adjunct treatment with radiotherapy and/or chemotherapy may be indicated (Table 30-7).

Perianal Tumors

Origin and Etiology

Perianal adenomas, hyperplasia, and adenocarcinomas originate from the perianal (hepatoid) glands. These are sebaceous glands that encircle the anus of the dog and also are located in the skin of the tail, prepuce, and thigh and over the dorsum of the back. The growth and maintenance of these cells are dependent on the presence of testosterone.

Description

Perianal adenoma and hyperplasia can occur as solitary or multiple nodules. These are most common in *older* intact male dogs, and their behavior is usually benign. They can be found wherever perianal glands are located (see "Origin and Etiology"), but they are most common in the perineal region. Perianal adenocarcinomas are usually larger, ulcerative, and invasive.

Cytology

Cytologic examination usually reveals large hepatoid cells. It is impossible to differentiate perianal adenoma from hyperplasia. Malignancy can be difficult to assess solely on the basis of cytology.

Epidemiology and Biologic Behavior

Perianal adenocarcinomas metastasize to the local lymphatics, especially the iliac lymph nodes, and to the lungs. These tumors occur primarily in male dogs.

Treatment

Perianal adenoma and hyperplasia usually regress with castration because of their testosterone dependency. Castration therefore is recommended for all dogs in which perianal adenoma or hyperplasia constitutes a problem. Perform aggressive surgical excision on all resectable perianal adenocarcinomas and those perianal adenomas that fail to respond to castration. Other treatment options are radiation therapy or chemotherapy using carboplatin, mitoxantrone, and doxorubicin (see Table 30-7 for dosages).

Table 30-7. CHEMOTHERAPY PROTOCOLS

Soft Tissue Sarcoma

1. *ADIC protocol* (*dogs*)
   Doxorubicin (Adriamycin): 30 mg/m^2 BSA, IV, q3 weeks
   DTIC (Dacarbazine): 1000 mg/m^2 BSA, IV drip for 6–8 hours; repeat q3 weeks
2. *VAC protocol* (*21-day cycle*) (*dogs*)
   Vincristine (Oncovin): 0.75 mg/m^2 BSA, IV, days 8, 15
   Doxorubicin (Adriamycin): 30 mg/m^2 BSA, IV, day 1 (dogs)
   Cyclophosphamide (Cytoxan): 100–200 mg/m^2 BSA, IV, day 1
   Tribrissen: 14 mg/kg, PO, q12h
3. *VAC protocol* (*21-day cycle*) (*cats*)
   Vincristine (Oncovin): 0.5 mg/m^2 BSA, IV days 8, 15
   Doxorubicin (Adriamycin): 20 mg/m^2 BSA, IV, day 1
   Cyclophosphamide (Cytoxan): 100–200 mg/m^2 BSA, IV, day 10
   Tribrissen: 14 mg/kg, PO, q12h

Carcinoma—Dog

1. *CMF protocol*
   5-Fluorouracil (5-FU): 150 mg/m^2 BSA, IV, once a week
   Cyclophosphamide (Cytoxan): 50 mg/m^2 BSA, PO, 4 days a week or qod
   Methotrexate: 2.5 mg/m^2 BSA, PO, 2 or 3 times a week
2. *VAF protocol*
   Vincristine (Oncovin): 0.75 mg/m^2 BSA, IV, days 8, 15
   Doxorubicin (Adriamycin): 30 mg/m^2 BSA, IV, day 1
   5-Fluorouracil (5-FU): 150 mg/m^2 BSA, IV, days 1, 8, 15
3. *VAC protocol*
4. *Cisplatin* (*Platinol*)*:* 50–70 mg/m^2 BSA, IV drip, 3 weeks; prior intensive diuresis is required
5. *FAC protocol*
   5-Fluorouracil (5-FU): 150 mg/m^2 BSA, IV, days 8, 15
   Doxorubicin (Adriamycin): 30 mg/m^2 BSA, IV, day 1
   Cyclophosphamide (Cytoxan): 100–200 mg/m^2 BSA, IV, day 1
   Tribrissen: 14 mg/kg, PO, BID
6. *Carboplatin* (*Paraplatin*)*:* 300 mg/m^2 BSA, IV, q21d
7. *Mitoxantrone* (*Novantrone*)*:* 6 mg/m^2 BSA, IV, q21d

Carcinoma—Feline

1. *Vincristine* (*Oncovin*)*/Cyclophosphamide* (*Cytoxan*)
   Vincristine (Oncovin): 0.5 mg/m^2 BSA, IV, once a week
   Cyclophosphamide (Cytoxan): 50 mg/m^2 BSA, PO, 4 days a week or qod
2. *As above, plus methotrexate:* 2.5 mg/m^2 BSA, PO, 2 or 3 times a week
3. *VAC protocol* (*28-day cycle*)
4. *Mitoxantrone* (*Novantrone*)*/Cytoxan Protocol* (*21-day cycle*)
   Mitoxantrone: 3–5 mg/m^2, IV over 45 minutes, day 1
   Cyclophosphamide (Cytoxan): 200–300 mg/m^2 BSA, PO, day 15
5. *Carboplatin* (*Paraplatin*)*:* 150–250 mg/m^2 BSA, IV, q21d
6. *Mitoxantrone* (*Novantrone*)*:* 6.5 mg/m^2 BSA, IV, q21d

Transmissible Venereal Tumor

Vincristine (Oncovin): 0.5 mg/m^2 BSA, IV, once weekly until and at least 1 week beyond resolution of the tumor

Anal Sac or Apocrine Gland Adenocarcinoma

1. *FAC protocol*
2. *Melphalan* (*Alkeran*)
   Melphalan (Alkeran): 2 mg/m^2 BSA, PO, q24h × 1 week; then qod, i.e., 6–8 mg/m^2 PO q24h × 5 days; repeat q3 weeks
3. *Carboplatin* (*Paraplatin*)*:* 300 mg/m^2 BSA, IV, q21d
4. *Mitoxantrone* (*Novantrone*)*:* 6.0 mg/m^2 BSA, IV, q21d

Extramedullary Plasmacytoma

Melphalan (Alkeran): 2 mg/m^2 BSA, PO, q24h × 1 week; then qod

Basal Cell Tumors

Origin and Etiology

Basal cell tumors (basal cell carcinoma, basal cell epithelioma) originate from the basal cells of the epidermis and adnexa.

Description

Basal cell tumors commonly occur as solitary nodules. They can be sessile or pedunculated, firm, and well demarcated from the underlying tissues. These tumors frequently are pigmented, contain cystic spaces, and occasionally are ulcerated (in cats). Basal cell tumors tend to be found more frequently on the head, neck, and shoulder of the dog. They can be found almost anywhere in the cat, in which they represent the most common skin tumor.

Cytology

Cells may be arranged in cords or palisades. "Palisading" clusters and uniform nuclei generally are seen on cytologic examination. The cells usually appear malignant on cytologic and histopathologic examination.

Epidemiology and Biologic Behavior

Basal cell tumors are common in older dogs and cats. Cocker spaniels and poodles may be at increased risk for these tumors. The tumors usually are benign and may have been present from months to years before diagnosis. However, when these tumors are identified histologically as basal cell carcinoma, this is generally a reliable diagnosis, and their behavior must be considered very aggressive.

Treatment

Wide surgical excision is the treatment of choice for basal cell tumors. Complete excision is curative. Nonresectable or invasive tumors can be treated successfully with radiation therapy and/or chemotherapy (see Table 30-7).

Ceruminous Gland Tumors

Origin and Etiology

Ceruminous gland adenomas and adenocarcinomas originate from the epithelium of the ceruminous glands in the ear canal.

Description

They are usually brown tumors associated with cerumen production, which may resemble chronic otitis. Ceruminous gland adenomas are small, pedunculated masses that frequently are located near the tympanic membrane and extend exteriorly. Adenocarcinomas

are similar to adenomas; however, they are frequently invasive.

Cytology

Cytologic examination reveals mature or immature (ceruminous gland adenocarcinoma) secretory cells with epithelial characteristics.

Epidemiology and Biologic Behavior

This is the most common external ear tumor in older dogs and cats but appears to be more common in cats.

Treatment

Total ear canal ablation may be necessary to completely excise these tumors (see Chapter 60). Surgical removal may be sufficient in animals with ceruminous gland adenomas; however, external beam irradiation is highly recommended for dogs and cats with ceruminous gland adenocarcinomas with incomplete resection after an aggressive ear canal ablation and for recurrent or non-excisable adenomas. Chemotherapy also may be considered for patients with incomplete tumor resection or metastases using protocols that contain cisplatin, carboplatin, mitoxantrone, and doxorubicin (see Table 30-7 for dosages).

Squamous Cell Carcinoma

Origin and Etiology

Squamous cell carcinoma may occur secondary to ultraviolet light exposure in cats and dogs with hypopigmented areas. It originates from stratified squamous epithelium. The cell of origin is the keratinocyte.

Description

These tumors frequently appear as ulcerated, necrotic, non-healing lesions. Common sites in dogs include the ventral abdomen, digits (especially nail bed), limbs, scrotum, lips, and nose. In the cat, they include the ear pinnae, lips, nose, and eyelids. Proliferative tumors may resemble a red, firm plaque or a cauliflower-like lesion. Digital squamous cell carcinoma can be proliferative, ulcerative, locally aggressive, and erosive. It also can appear as a non-healing wound. Multiple nail bed squamous cell carcinomas have been observed in black dogs.

Cytology

These epithelial cells are polygonal and may keratinize as they mature. Typical epithelial cells mixed with keratinizing cells frequently are noted. Aging squamous epithelial cells tend to be more angular or polyhedral, with a pyknotic nucleus and bluer cytoplasm. Abundant neutrophils and other inflammatory cells frequently are observed.

Epidemiology and Biologic Behavior

These tumors occur more frequently in cats, especially in white cats or in those with hypopigmented areas that are more likely to be exposed to sunlight, especially ear tips and nose. Dogs have an increased frequency of these tumors in the ventral abdomen (especially), trunk, scrotum, and lips. They are locally invasive with late metastases to the local lymph nodes and lungs.

Treatment

Perform complete surgical excision for squamous cell carcinomas if they are in an easily accessible location. Perform complete pinna resection for tumors of the ear (see Chapter 60) and digital amputation for squamous cell carcinoma of the digit (see Chapter 114). Consider radiation therapy and photodynamic therapy for dogs and cats with non-resectable or incompletely excised squamous cell carcinomas. Retinoids may be considered for those animals with preneoplastic lesions. Consider chemotherapy for non-resectable or metastatic tumors, using cisplatin, carboplatin, bleomycin, mitoxantrone, and doxorubicin (see Chapter 26, Table 30-7 for dosages).

Anal Sac or Apocrine Gland Adenocarcinoma

Origin and Etiology

Apocrine gland adenocarcinomas are derived from the apocrine glands that secrete into the anal sac.

Description

These tumors can vary from very small masses that can be located only after careful rectal and perirectal palpation to large masses protruding from the rectum. They may cause ulceration of the overlying skin.

Cytology

Cytologic examination reveals large cells with abundant cytoplasm and eccentric round nuclei.

Epidemiology and Biologic Behavior

Apocrine gland adenocarcinomas are most commonly found in older female dogs. A paraneoplastic syndrome of hypercalcemia is frequently associated with these tumors (see Chapter 32). Metastases are common (90% of cases) and most frequently involve to the regional (i.e., iliac) lymph nodes.

Treatment

Surgical excision offers the best option for a cure. Chemotherapy also may be considered, using carboplatin or mitoxantrone (see Table 30-7). Hypercalcemia generally resolves after remission of this tumor.

Intracutaneous Cornifying Epithelioma (Keratoacanthoma)

Origin and Etiology

This tumor is derived from the superficial epithelium between hair follicles.

Description

Intracutaneous cornifying epitheliomas may be located on the skin of the neck, the dorsal thorax, the legs, and occasionally on the ventral abdomen. A toothpaste-like material may be expressed from these masses.

Cytology

Cytologic evaluation may reveal keratin associated with inflammatory cells.

Epidemiology and Biologic Behavior

These are benign tumors that can occur in a solitary form in many breeds of dogs and in a multicentric form in Norwegian elkhound and keeshond dogs.

Treatment

Surgical excision is the treatment of choice, although it may not be required. Consider retinoid therapy for the multicentric form (see "Drug Dosage Guidelines Appendix" for dosages).

Dermoid and Epidermal Inclusion Cyst

Origin and Etiology

Dermoid and epidermal inclusion cysts originate from the dermis and epidermis. Epidermal inclusion cysts are frequently secondary to an occluded hair follicle, whereas dermoid cysts may be developmental defects.

Description

Dermoid cysts contain epidermal appendages, hair, and sebaceous and sweat gland secretions, in addition to the keratin that is in the epidermal inclusion cysts. A semisolid material frequently is contained within these cysts.

Cytology

A clear to brown fluid frequently is obtained for cytologic examination.

Epidemiology and Biologic Behavior

These are benign tumors.

Treatment

Surgical excision is the treatment of choice, although it is not always required.

Mesenchymal Neoplasia

Lipomas and Liposarcomas

Origin and Etiology

Lipomas, infiltrative lipomas, and liposarcomas originate from adipocytes or fat cells.

Description

Lipomas can occur either as single or multiple masses and are located over the thorax, sternum, abdomen, and proximal limbs of dogs. These masses are usually subcutaneous; well circumscribed, although not necessarily well encapsulated; fluctuant; soft; and sometimes multilobulated. Infiltrative lipomas infiltrate the deep tissue and are extremely difficult to excise. Liposarcomas are uncommon and usually solitary tumors that tend to be very infiltrative, firm, and poorly circumscribed.

Cytology

Fatty-appearing material or oil droplets usually are present on the slide before staining. Most cells from aspirates of lipomas are "washed off" by the methanol in the fixative. Occasionally, oily material with a few intact adipocytes or fatty cells remains on the slide or cover slip. Cytology of liposarcoma reveals immature mesenchymal cells with vacuoles and round, indented nuclei. Variation in cell size is common, and occasionally, multinucleation is noted.

▼ ***Key Point*** Evaluate all "lipomas" cytologically because they are indistinguishable from mast cell tumors in physical appearance and clinical presentation.

Epidemiology and Biologic Behavior

Lipomas are benign tumors that appear to be more common in older spayed female dogs. They are the most common mesenchymal tumor in the dog but are extremely rare in the cat. Infiltrative lipomas are also benign; however, because of their highly infiltrative nature, they may require extensive surgical excision, including amputation of the affected limb. Liposarcomas are extremely rare tumors in both dogs and cats but are found most often in dogs older than 10 years of age. They are locally invasive and may metastasize to the lungs and/or liver.

Treatment

It may or may not be necessary to remove lipomas, depending on their size, location, and owner preference. If surgery is considered, remove these lipomas while they are small and before they become too large and difficult to resect. Treat infiltrative lipomas with aggressive surgery and radiation therapy if indicated.

Treat all liposarcomas with complete surgical excision and radiation therapy if incomplete margins are obtained.

Fibrosarcoma

Origin and Etiology

These tumors typically originate in the subcutaneous fibrous connective tissue from fibrocytes or fibroblasts. In cats, fibrosarcomas can occur in association with feline sarcoma virus or feline leukemia virus, as vaccine-associated sarcomas (see also Chapter 28), and as sporadic non-retrovirus-induced tumors. Retrovirus-induced fibrosarcomas occur in young cats, are rare, and do not respond to any form of treatment (see Chapter 6). Fibrosarcomas generally occur on the head, trunk, or limbs. There is a strong association between the administration of inactivated vaccines (e.g., feline leukemia virus, rabies, and certain herpes-calici-panleukopenia [FVRCP] vaccines) and subsequent development of soft tissue sarcomas (primarily fibrosarcomas) at the vaccination site.

Description

Fibrosarcomas can occur as solitary or multiple masses. They are frequently firm, lobulated, and infiltrative into underlying tissues.

Cytology

Cytology reveals typical spindle or mesenchymal cells, although cells from these tumors tend not to exfoliate well.

Epidemiology and Biologic Behavior

Most fibrosarcomas occur as solitary tumors in older dogs and cats (i.e., non-retrovirally induced). In contrast, fibrosarcomas associated with feline sarcoma virus tend to occur in younger cats and are multiple. Vaccine-associated fibrosarcomas have an overall prevalence of between 1 and 3 cases per 10,000 vaccinated cats. Other types of fibrosarcoma are very locally invasive but usually metastasize late in their course (less than 10% of cats and dogs with solitary fibrosarcoma have metastases at presentation).

Treatment

Wide and deep surgical excision is recommended, although this can be difficult because the invasive nature of this tumor causes widespread infiltration of adjacent tissues. Histologic evaluation of margins is very important because complete excision is usually curative. Consider amputation in patients with tumors on the extremities.

Response to chemotherapy is variable. Histologically, poorly differentiated fibrosarcomas and fibrosarcomas with giant cells in cats appear to be more responsive to chemotherapy. Chemotherapy could include doxorubicin or mitoxantrone (see Table 30-7 for dosages). Other treatment options include radiation therapy and hyperthermia.

Nerve Sheath Tumors

Neurofibromas, neurofibrosarcomas, schwannomas, and neurilemomas are discussed in Chapter 129.

Hemangiosarcomas

Origin and Etiology

These tumors (also known as malignant hemangioendotheliomas and angiosarcomas) originate from the vascular endothelium.

Description

Hemangiosarcomas generally are solitary masses found on the limbs, flank, or neck. They can occur in the skin and/or subcutaneous tissue. Those in the subcutaneous tissue also may infiltrate the underlying muscle. Hemangiosarcoma must be differentiated from hemangioma.

Cytology

Cytology reveals spindle-shaped or polygonal cells with large nuclei and a lacy chromatin pattern; one or more nucleoli; and a bluish, usually vacuolated cytoplasm. Hemangiosarcomas also can exfoliate cells in sheets similar to those of epithelial cells.

Epidemiology and Biologic Behavior

Hemangiosarcomas of the skin can be either primary or metastatic. Hemangiosarcomas are much more common in dogs, especially German shepherds and golden retrievers, than in cats. The prognoses for these tumors are variable depending on location. Those patients in which the tumor is confined to the dermis have an excellent prognosis, whereas subcutaneous tumors have a poor prognosis, especially if there is muscular involvement.

Treatment

Perform complete surgical excision when feasible. Chemotherapy probably is not necessary for those tumors involving only the dermis, whereas those involving the subcutaneous tissue with or without muscular involvement usually require chemotherapy using doxorubicin.

Hemangiopericytoma

See Chapter 28.

Histiocytoma

Origin and Etiology

The origin of canine cutaneous histiocytomas is the monocyte-macrophage cells in the skin.

Description

These are dermoepidermal tumors frequently located on the head and neck and less commonly on the extremities. They are round, alopecic, and sometimes pink or erythematous, and they occasionally ulcerate. Because of their gross appearance, they also are referred to as "button tumors."

Cytology

Cytology reveals a round cell tumor with a moderate amount of cytoplasm and, possibly, an eccentrically located nucleus. Histiocytomas also tend to be highly pleomorphic and moderately vacuolated. Lymphocytes are abundant. These tumors can appear inflammatory.

Epidemiology and Biologic Behavior

These tumors generally exhibit benign behavior and are found mostly in young dogs (approximately 1 to 3 years). Histiocytomas usually regress spontaneously within 4 to 8 weeks of diagnosis. This tumor does not occur in cats.

Treatment

Observation alone may be appropriate for most histiocytomas because the majority regress with age. Perform surgical excision if this tumor does not regress in a reasonable period; in older dogs, for cosmetic reasons; and finally, to avoid an erroneous diagnosis and further growth of the tumor.

Mast Cell Tumor

Mastocytoma, mast cell sarcoma, and mastocytosis are discussed in Chapter 28.

Extramedullary Plasmacytoma

See Chapter 27.

Cutaneous Lymphoma

Dermal lymphoma, mycosis fungoides, and histiocytic lymphoma are discussed in Chapter 27.

Transmissible Venereal Tumor

Origin and Etiology

Transmissible venereal tumors frequently are transmitted at coitus or through close contact. The cell of origin is considered to be from the monocyte-macrophage system. See also Chapters 88 and 92.

Description

Transmissible venereal tumors tend to occur on the external genitalia and the face and frequently appear as ulcerated, friable, cauliflower-like masses that can be solitary or multiple.

Cytology

Cytology reveals round to ovoid cells with round nuclei and numerous mitotic figures. The cytoplasm is blue or transparent, contains distinct clear vacuoles, and is surrounded by a distinct cell membrane.

Epidemiology and Biologic Behavior

This tumor is transmitted by mucocutaneous transplantation of tumor cells through coitus, licking, biting, and scratching. It occurs more frequently in areas where dogs are free roaming. No breed or sex predilections have been observed. These tumors have a low metastatic potential.

Treatment

Transmissible venereal tumors can be cured with single-agent vincristine chemotherapy, surgery, and/or radiation therapy (see Table 30-7).

Malignant Fibrous Histiocytoma (Extraskeletal Giant Cell Tumors)

See Chapter 28.

Melanocytic Tumors (Melanomas)

Origin and Etiology

Melanomas originate from melanocytes (melanin-producing cells) or melanoblasts, which are cells of neuroectodermal origin.

Description

These are typically brown to black pigmented nodules (although they may be non-pigmented) that occur more frequently on the face, trunk, feet, mucocutaneous regions, and nail beds.

Cytology

Cytologic examination may reveal cells that vary from round to spindle shaped. They frequently contain brown to black granules.

Epidemiology and Biologic Behavior

Melanomas are considerably more common in dogs than in cats. Tumors originating in the skin tend to be benign, whereas tumors of the mucocutaneous regions (e.g., oral cavity and nail beds) tend to be malignant.

Treatment

Local recurrence and distant metastases are very common. Surgery is the treatment of choice. Results of chemotherapy have been unrewarding; however, DTIC, carboplatin, and cisplatin may be the drugs of choice (see Table 30-7 for dosages). Palliative radiation therapy may be another option in some cases.

Chapter

31 Diseases of the Thyroid Gland

David L. Panciera / Mark E. Peterson / Stephen J. Birchard

HYPOTHYROIDISM IN DOGS

Hypothyroidism is a common, multisystemic disease in dogs. Thyroid hormone deficiency affects virtually all body systems, resulting in a wide array of clinical signs. It occurs predominantly in middle-aged, pure-breed dogs, including the golden retriever, Doberman pinscher, Irish setter, boxer, miniature schnauzer, dachshund, and cocker spaniel. There is no strong sex predilection.

Etiology

Primary Hypothyroidism

Primary hypothyroidism, resulting from gradual destruction of the thyroid gland, is responsible for over 95% of cases.

Lymphocytic Thyroiditis

- Immune-mediated destruction
- Circulating antithyroglobulin antibodies in most cases
- Lymphocytic infiltration in the thyroid gland

Idiopathic Thyroid Gland Atrophy

- Replacement of thyroid parenchyma by adipose tissue without inflammation
- Unknown cause
- Not associated with antithyroglobulin antibodies

Other Causes

- Uncommon causes of primary hypothyroidism include congenital types (e.g., dyshormonogenesis and thyroid dysgenesis), replacement of thyroid gland parenchyma by nonfunctional neoplastic tissue, surgical thyroidectomy, and radioiodine treatment.

Secondary (Pituitary) Hypothyroidism

Secondary (pituitary) hypothyroidism is caused by impaired secretion of thyroid-stimulating hormone (TSH). This etiology accounts for less than 5% of cases.

- Pituitary tumors: Destruction of normal pituitary thyrotrophs by neoplastic invasion.
- Cystic Rathke pouch: This form occurs in German shepherd pituitary dwarfs and is associated with concurrent hormone deficiencies including growth hormone deficiency, hypoadrenocorticism, and hypogonadism (see also Chapter 36).

Tertiary (Hypothalamic) Hypothyroidism

Tertiary (hypothalamic) hypothyroidism resulting from deficient production or release of thyrotropin-releasing hormone (TRH) has not yet been documented in dogs.

▼ ***Key Point*** The majority of hypothyroid dogs have primary disease due to lymphocytic thyroiditis or atrophy.

Clinical Signs

The clinical signs of hypothyroidism are insidious in onset because of the gradual destruction of the thyroid gland. Signs are diverse and range from mild to severe (Table 31-1).

General Appearance and Behavior

- Weight gain (mild to marked obesity)
- Lethargy, dullness, and exercise intolerance
- Cold intolerance and hypothermia (uncommon)

Integument

- The majority of hypothyroid dogs have dermatologic abnormalities.
- Excessive scaling and dry haircoat are often the earliest changes.
- Excessive shedding.
- Alopecia.
  - Often begins on the tail and neck (areas of friction).
  - May progress to bilaterally symmetric truncal alopecia sparing the head and extremities.
- Cutaneous hyperpigmentation.
- Recurrent otitis externa or pyoderma.
- Myxedema: Thickening of the skin, especially facial, secondary to glycosaminoglycan accumulation, leading to a "tragic" facial expression.
- Pruritus is not present except when associated with secondary pyoderma, seborrhea, or *Malassezia* infection.

Table 31-1. CLINICAL SIGNS AND LABORATORY FINDINGS IN DOGS WITH HYPOTHYROIDISM

Common Findings	Uncommon Findings
Dermatologic Abnormalities	Neuropathy
Seborrhea	Vestibular
Alopecia	Facial
Pyoderma	Generalized
Myxedema	Laryngeal paralysis
Obesity	Myopathy
Lethargy	Megaesophagus
Weakness/exercise intolerance	Central nervous system abnormalities
Low-voltage ECG complexes	Dwarfism
Bradycardia	Reproductive abnormalities (anestrus)
Hypercholesterolemia	Insulin-resistant diabetes mellitus
Nonregenerative anemia	Ocular abnormalities
	Myxedema stupor or coma

ECG, electrocardiographic.

Nervous System and Muscle

- Uncommon finding in hypothyroidism.
- Peripheral neuropathy.
  - Generalized neuropathy can cause weakness, ataxia, and abnormal proprioception.
  - Vestibular neuropathy.
  - Facial neuropathy, often concurrent with vestibular signs.
  - Unilateral forelimb lameness with pain in the glenohumeral joint.
- Megaesophagus is very rare and may occur secondary to myopathy, neuropathy, or concurrent myasthenia gravis.
- Nonspecific weakness and exercise intolerance may be caused by myopathy or mild neuropathy.
- Behavioral abnormalities including aggression have been reported with hypothyroidism.

Cardiovascular System

- Bradycardia, weak apex beat, and weak pulses.
- Decreased amplitude of R wave or first-degree atrioventricular block on electrocardiogram.
- Atrial fibrillation may occur rarely in dogs with hypothyroidism.
- Decreased myocardial contractility (mild and subclinical).

Reproductive System

- No clinically significant effects on male reproduction.
- Anestrus, infertility, and abortion are possible in females.
- Inappropriate galactorrhea in intact females.

Eyes

- Ocular manifestations of hypothyroidism are rare and appear to be associated with hyperlipidemia.
- Corneal lipid deposits.
- Chronic uveitis.

Bleeding Disorders

- Bleeding tendencies are not caused by hypothyroidism.
- Thyroid hormone administration does not increase the von Willebrand factor in dogs with congenital von Willebrand disease.

Congenital Hypothyroidism

- Lethargy, mental dullness, weak nursing, and constipation.
- Disproportionate dwarfism, broad skull, macroglossia, delayed dental eruption, hypothermia, distended abdomen, retention of puppy haircoat, dry skin, and gait abnormalities.
- Some abnormalities (e.g., short stature, osteoarthritis, and impaired mental function) may persist despite treatment.

Myxedema Stupor and Coma

- Most severe and rarest form of hypothyroidism
- Stupor or coma, hypothermia without shivering, bradycardia, hypotension, and hypoventilation, in addition to the more common signs of hypothyroidism
- Hypercholesterolemia, hyponatremia, hypoglycemia, and high creatine kinase level

▼ ***Key Point*** Dogs may develop various clinical signs of hypothyroidism. Although one sign may predominate, cutaneous abnormalities, lethargy, and/or weight gain are present in most cases.

Diagnosis

Because of the diverse clinical signs and difficulty in interpreting thyroid function tests, hypothyroidism is often diagnosed inappropriately.

▼ ***Key Point*** Many non-thyroidal factors can influence thyroid function tests, resulting in low serum thyroid hormone concentrations in euthyroid dogs.

Diagnosis is dependent on both compatible clinical signs and abnormal thyroid function tests, not either alone.

Screening Laboratory Tests

- Complete blood count shows normocytic, normochromic anemia in 30% of cases.
- Serum biochemical analysis shows hypercholesterolemia in 75% of cases. Hypertriglyceridemia is also common.

Basal Total Thyroid Hormone Concentration (T_4 and T_3)

- Normal serum thyroxine (T_4) concentration infrequently occurs in the hypothyroid dog.
- Serum T_4 is in the low-normal range in about 10% of hypothyroid dogs.
- Serum triiodothyronine (T_3) concentration is unreliable in the diagnosis of hypothyroidism since it is often within the reference range in hypothyroid dogs.
- Serum T_4 is often below normal in euthyroid dogs for the following reasons:
  - Normal daily fluctuation can result in low serum T_4 on repeated sampling of normal dogs.
  - Breed differences result in low serum T_4 in greyhounds, deerhounds, Alaskan sled dogs, and probably other breeds.
  - Non-thyroidal illness (e.g., hyperadrenocorticism, renal disease, or neoplasia) causes a decrease in total T_4 and T_3.
  - Administration of various drugs, including glucocorticoids, sulfonamides, anticonvulsants, non-steroidal anti-inflammatory drugs, and radiocontrast agents, lowers serum T_4 and T_3.

▼ ***Key Point*** Low total T_4 concentration is almost always present in hypothyroidism. If total T_4 is normal, hypothyroidism is very unlikely.

Free Thyroxine Concentration

- Free T_4 is the portion of T_4 that is not bound to plasma carrier proteins (normally 0.1% of total T_4).
- Free T_4 is not affected by most non-thyroidal illnesses and drugs.
- Equilibrium dialysis is the only reliable method for measurement of free T_4 in dogs with non-thyroidal illness. Free T_4 by equilibrium dialysis is the most accurate single test for diagnosing hypothyroidism (see the Endocrine Diagnostic Laboratory of the Michigan State University website: www.ahdl.msu.edu).
- Hypothyroid dogs rarely have a normal serum, free T_4 concentration.

Serum Endogenous Canine Thyroid-Stimulating Hormone Concentration

- Serum TSH concentration is increased in most cases of primary hypothyroidism due to loss of negative feedback of T_4 and T_3 on the pituitary gland.
- High serum TSH and low serum T_4 or free T_4 are diagnostic of hypothyroidism.
- Serum TSH concentration is normal in 20% to 40% of hypothyroid dogs.
- Serum TSH concentration may occasionally be increased in euthyroid dogs with non-thyroidal illness.

Thyroid-Stimulating Hormone Stimulation Test

- The most reliable method of confirming the diagnosis of hypothyroidism in dogs is by demonstrating a low resting T_4 that fails to increase following TSH administration.
- Test protocol: Collect blood for measurement of serum T_4 before and 4 hours after IV administration of 100 μg human recombinant TSH.
- Human recombinant TSH is very expensive, making this test impractical in most cases. Use should be reserved for cases in which the diagnosis cannot be made by measurement of baseline serum hormones.

Thyrotropin-Releasing Hormone Stimulation Test

- TRH administration results in a small and inconsistent increase in serum T_4 and free T_4 in dogs, making this test inadequate for routine use.

Antithyroglobulin Antibodies

- Autoimmune thyroiditis is associated with serum antibodies directed against thyroglobulin.

- Antithyroglobulin antibodies can be present in euthyroid dogs, and they do not indicate hypothyroidism.
- This assay may be useful to identify dogs affected with autoimmune thyroid disease prior to development of hypothyroidism to help plan breeding, but it is not clear if the antibodies predict hypothyroidism in the future.

Thyroid Hormone Autoantibodies

- Antibodies occasionally form against T_3 and T_4 that interfere with radioimmunoassay of these hormones.
- These antibodies cause a false increase in T_3 or T_4 in most assays, with apparent elevation of the hormone into the normal or hyperthyroid range.
- Dogs with thyroid hormone autoantibodies may or may not have signs of hypothyroidism.
- Measurement of free T_4 by equilibrium dialysis is not affected by T_4 autoantibodies.

▼ ***Key Point*** The most reliable method of confirming a diagnosis of hypothyroidism in a dog with compatible clinical signs is the demonstration of decreased serum total T_4 or free T_4 by equilibrium dialysis combined with elevated serum endogenous TSH.

Treatment

Treat dogs with hypothyroidism with daily administration of thyroid hormone. Response to treatment is usually noted within 1 to 2 weeks with an increase in activity and improvement in attitude. Weight loss and neurologic abnormalities usually begin to resolve within 1 to 4 weeks of initiating treatment, whereas dermatologic changes may require 4 to 6 weeks to improve and months to completely resolve. Failure to respond within 6 to 8 weeks of initiating treatment should prompt reevaluation of the diagnosis and reasons for possible therapeutic failure.

Synthetic L-Thyroxine

Synthetic L-thyroxine (levothyroxine) is the treatment of choice in all cases of hypothyroidism. Synthetic L-triiodothyronine (L-T_3), combinations of synthetic L-T_4 and L-T_3, and desiccated thyroid gland preparations or extracts are not indicated in the treatment of canine hypothyroidism.

- The initial dosage of L-T_4 is 0.022 mg/kg q12h PO. Once-daily treatment at the same dose is usually adequate for resolution of clinical signs and can be used initially or after twice-daily treatment has resulted in a good clinical response.
- Decrease the dosage slightly in dogs over 30 kg.
- Reevaluate after 6 to 8 weeks of treatment by examining for resolution of clinical signs and measuring serum T_4.
- A serum T_4 concentration collected 4 to 6 hours after pill administration should be near the upper limit or slightly above the reference range; T_3 concentration may be low despite normal or high T_4.
- If signs of hyperthyroidism occur, such as polyuria, polydipsia, tachycardia, weight loss, diarrhea, or tachycardia, measure serum T_4 and T_3, stop treatment for 1 to 2 days, and reduce the dosage based on this evaluation.
- Treatment for myxedema stupor and coma consists of IV administration of L-T_4 (0.66 mg/kg), passive warming, judicious fluid therapy, glucocorticoid supplementation, and mechanical ventilation if necessary. The prognosis is guarded.

HYPOTHYROIDISM IN CATS

▼ ***Key Point*** Spontaneous hypothyroidism is extremely uncommon in cats.

Most clinical cases of feline hypothyroidism occur as a rare complication of treatment for hyperthyroidism. Non-iatrogenic feline hypothyroidism has been reported primarily in kittens with dwarfism. Cretinism is the most common cause of endocrine congenital dwarfism in cats (growth hormone deficiency has not been reported in cats). Adult onset spontaneous hypothyroidism has been proven in only one cat.

Etiology

- *Congenital hypothyroidism* is associated with thyroid gland atrophy or defective thyroid hormone biosynthesis. In many kittens, this may go undetected and may result in early death.
- *Primary iatrogenic hypothyroidism* results from surgical removal of thyroid glands or their destruction by radioactive iodine in the treatment of feline hyperthyroidism.

Clinical Signs

Congenital Hypothyroidism

- Disproportionate dwarfism (stunted growth of long bones, enlarged head).
- Lethargy and mental dullness.
- Hypothermia.
- Bradycardia.
- Bilaterally symmetric alopecia does *not* occur.

Primary Iatrogenic Hypothyroidism

- History of treatment for hyperthyroidism.
- Lethargy.
- Seborrhea sicca and dry haircoat.
- Obesity is common.
- Bilaterally symmetric alopecia does *not* occur.

Diagnosis

- Strong index of suspicion based on history and clinical signs.
- Confirmed by finding subnormal resting serum T_4 concentration that fails to increase 4 to 6 hours after IV administration of TSH (see "Hypothyroidism in Dogs").
- Can also be confirmed by finding low serum concentrations of total T_4 and free T_4 (see "Hypothyroidism in Dogs").
- Determination of serum TSH concentration is not generally useful in diagnosis of hypothyroidism in cats, inasmuch as most available TSH assays do not measure feline TSH.

Treatment

- Treatment for congenital cretinism is not very rewarding because growth abnormalities and mental deficiencies may not be reversible.
- Treat iatrogenic hypothyroidism with daily T_4 supplementation using an initial dosage of T_4 of 0.01 to 0.02 mg/kg/day (10–20 µg/kg/day) PO.
- Adjust the dosage based on resolution of clinical signs and on postpill serum T_4 concentrations.

HYPERTHYROIDISM IN CATS

Feline hyperthyroidism, a multisystemic metabolic disorder resulting from excessive circulating concentrations of thyroid hormone, is the most common endocrinopathy of middle-aged and older cats. First described in 1979, hyperthyroidism has emerged as the most common endocrine disorder of this species and a disease frequently diagnosed in small animal practice. There is no breed or sex predilection. The clinical signs of the disease are the result of increased basal metabolic rate and the body's inability to meet excessive metabolic demands.

Etiology

Adenomatous Hyperplasia

Functional adenomatous hyperplasia of one or both lobes of the thyroid gland, causing high circulating concentrations of T_4 and T_3, is the most common cause. Both lobes are enlarged in approximately 70% of cases. The pathogenesis of this adenomatous hyperplasia is unknown.

- In cats, the disease most closely resembles toxic nodular goiter in human patients, which is caused by hyperfunctioning adenomatous thyroid nodules.
- Hyperthyroidism in cats is not analogous to the autoimmune disorder Graves disease, the most common form of hyperthyroidism in human patients.

Thyroid Carcinoma

Thyroid carcinoma occurs in only 1% to 2% of cats with hyperthyroidism.

Clinical Signs

All of the clinical manifestations of hyperthyroidism are due to the effects of excessive thyroid hormone. These effects are generally stimulatory. They cause increased heat production and heightened protein, carbohydrate, and lipid metabolism in virtually all body systems and tissues. Clinical signs can range from mild to severe (Table 31-2).

▼ ***Key Point*** The classic clinical signs of feline hyperthyroidism include weight loss despite an increase in appetite.

General Appearance and Behavior

- Weight loss.
- Restlessness, hyperexcitability, and difficulty in examining.
- Impaired stress tolerance. The hyperthyroid cat is prone to respiratory distress and weakness when stressed. Cardiac arrhythmias or arrest can occur in extreme cases.
- Unkempt haircoat, excessive shedding, and matting of hair, especially in long-haired cats.

Thyroid Gland

- Enlargement of one or both lobes of the thyroid gland is palpable in >90% of cats with hyperthyroidism. To palpate the thyroid gland, extend the cat's neck and tilt the head back slightly. Using the

Table 31-2. FREQUENCY OF HISTORICAL AND CLINICAL SIGNS IN CATS WITH HYPERTHYROIDISM

Clinical Finding	Percentage of Cats
Weight loss	95–98
Hyperactivity/difficult to examine	70–80
Polyphagia	65–75
Tachycardia	55–65
Polyuria/polydipsia	45–55
Cardiac murmur	20–55
Vomiting	33–50
Diarrhea	30–45
Increased fecal volume	10–30
Decreased appetite	20–30
Lethargy	15–25
Polypnea (panting)	15–30
Muscle weakness	15–20
Muscle tremor	15–30
Congestive heart failure	10–15
Dyspnea	10–15

thumb and forefinger, gently palpate the tissues on either side of the trachea, starting at the larynx and moving caudally to the thoracic inlet (see Fig. 1-3 in Chapter 1).
- A small percentage of cats have intrathoracic thyroid nodules that evade palpation.

Nervous System and Muscle

- Hyperactivity
- Weakness and increased fatigability

Gastrointestinal System

- Increased appetite is due to increased energy utilization and high metabolic demands. The increased caloric intake observed in most cats is, however, inadequate to compensate for increased demand.
- Approximately 5% of cats with hyperthyroidism experience periods of decreased appetite. The cause is unclear but usually is associated with concurrent disease (e.g., renal or cardiac disease).
- Vomiting, often secondary to rapid polyphagia, occurs shortly after eating.
- Diarrhea and increased volume and frequency of defecation are due to polyphagia, intestinal hypermotility, and decreased fat absorption.

Renal System

- Polyuria and polydipsia. Thyroid hormones may have a diuretic action. Alternatively, a hypothalamic disturbance associated with hyperthyroidism might cause primary polydipsia, with secondary renal medullary solute washout.

Respiratory System

- Dyspnea, panting, and hyperventilation at rest are attributable to any of the following: respiratory muscle weakness, increased tissue carbon dioxide production and inability to meet tissue oxygen demand, and/or congestive heart failure (CHF) (see subsequent discussion).

Cardiovascular System

- Tachycardia, systolic murmurs, gallop rhythm, and arrhythmias may be attributable to the catecholamine-like effects of thyroid hormone and increased tissue oxygen demand, or they may be associated with other signs of CHF secondary to hyperthyroidism.
- Signs of CHF (e.g., dyspnea, muffled heart sounds, tachycardia, and ascites) may develop, especially in cats with severe or advanced hyperthyroidism. Electrocardiographic and echocardiographic findings are often suggestive of hypertrophic or, much less commonly, dilative cardiomyopathy. Hyperthyroidism results in a high-output cardiac state in which vascular resistance is low and cardiac output is high due to increased tissue metabolism and oxygen requirements. The cardiac compensatory mechanisms are dilation (in response to volume overload) and hypertrophy (in response to dilation). There also appears to be a direct myopathic effect of thyroid hormones on cardiac muscle.

Apathetic Hyperthyroidism

- In about 5% of cats with hyperthyroidism, the predominant clinical signs are depression, lethargy, anorexia, and weakness rather than the hyperexcitability, restlessness, and polyphagia observed in 95% of cases.
- Weight loss and cardiac abnormalities are common findings in these cats.
- In most of these cats, a severe concurrent disease is also present, including CHF, renal failure, or cancer.

Diagnosis

- The diagnosis of hyperthyroidism in cats is made on the basis of clinical signs, palpable goiter (thyroid enlargement), screening laboratory testing, and, except in cases of occult hyperthyroidism (see subsequent discussion), high serum T_4 concentrations. Serum T_3 concentrations are less useful in the diagnosis of hyperthyroidism in cats.
- The differential diagnoses for cats with clinical signs of hyperthyroidism include diabetes mellitus, renal disease, gastrointestinal lymphoma, and chronic inflammatory bowel disease. Cardiac manifestations of hyperthyroidism can be confused with cardiomyopathy. Hyperthyroid cats with high serum liver enzyme levels can be difficult to distinguish from cats with primary liver disease.

Screening Laboratory Tests

Complete Blood Count

- Mature leukocytosis and eosinopenia are common findings.
- A slight elevation in packed cell volume is found in more than half of cats with hyperthyroidism. Macrocytic erythrocytes may cause an elevated mean corpuscular volume.

Serum Biochemical Analysis

- High alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase activity occur singly or in combination in 50% to 75% of cats with hyperthyroidism.

Urinalysis

- Urinalysis is generally unremarkable but useful in differentiating other diseases with similar clinical signs such as diabetes mellitus. Urine specific gravity is variable.

Radiography and Cardiac Ultrasonography

- In approximately 50% of cats, there is evidence of mild to severe cardiac enlargement on thoracic radiography.
- Common echocardiographic abnormalities include left ventricular hypertrophy (approximately 70% of cases), left atrial and ventricular dilation (70% and 45%, respectively), and interventricular septum hypertrophy (4%). Myocardial hypercontractility, as evidenced by an increased shortening fraction and velocity of circumferential fiber shortening, is also common.
- These cardiovascular changes resolve or improve following successful treatment of the hyperthyroidism.

Basal Total Thyroid Hormone Concentration (T_4 and T_3)

The diagnosis of hyperthyroidism is confirmed by demonstrating increased production of the thyroid hormones. In cats, T_4 is the main secretory product of the thyroid gland. T_3 is 3 to 5 times more potent than T_4, but approximately 60% of circulating T_3 is produced by extrathyroidal 5'-deiodination of T_4. Over 99% of circulating T_4 is protein-bound, while approximately 0.1% is free and metabolically active. Overall control of thyroid hormone production is provided by a negative feedback mechanism of circulating T_4 and T_3 on TRH from the hypothalamus and TSH from the anterior pituitary. In hyperthyroid cats, there is autonomous and excessive secretion of thyroid hormones from the abnormally functioning thyroid gland.

▼ ***Key Point*** High resting serum concentrations of total T_4 and, less reliably, T_3 are the biochemical hallmarks of hyperthyroidism in the majority of cats with the disease.

- Over 30% of cats with hyperthyroidism maintain normal serum T_3 concentration despite elevation in T_4. These cats generally have milder disease; serum T_3 concentration in these cats is expected to increase eventually.
- Most hyperthyroid cats exhibit a clearly high circulating total T_4 concentration. However, a proportion of hyperthyroid cats (approximately 10% of all cases and 40% of cases with mild hyperthyroidism) have serum total T_4 concentration within the reference range. Such values are usually within the middle to high end of the reference range. Thus hyperthyroidism cannot always be excluded in cats by demonstration of a single total T_4 concentration within the normal reference range.
- Thyroid hormone concentrations in some cats are subject to a degree of fluctuation. In cats with mild disease, serum T_4 concentrations have been shown to fluctuate in and out of the normal range. The finding of a single normal serum T_4 concentration in a cat with clinical signs of hyperthyroidism does not rule out the diagnosis of this disease, especially if an enlarged thyroid can be palpated.
- Severe concurrent, systemic non-thyroidal illness (e.g., primary hepatic disease, renal disease, or diabetes mellitus) can cause serum thyroid hormone concentrations to decrease. Because non-thyroidal illness is expected to reduce the serum thyroid hormone concentration into the subnormal range in a euthyroid cat, concomitant hyperthyroidism should be suspected in any middle-aged to old cat with high-normal serum T_4 concentration in the face of severe non-thyroidal illness, especially if clinical signs of hyperthyroidism are also present.

▼ ***Key Point*** In most cats with hyperthyroidism, the diagnosis can be confirmed by a high serum total T_4 concentration alone.

Free T_4 Concentration

- Determination of the serum concentration of free T_4 by dialysis (Free T_4 kit, Nichols Institute) is useful in the diagnosis of hyperthyroidism in cats, especially in those cats with clinical signs of the disease and a palpable thyroid nodule in which the basal total T_4 value is normal or only slightly elevated.
- Serum free and total T_4 concentrations are highly correlated in hyperthyroidism. However, serum free T_4 concentrations, as measured by equilibrium dialysis, are more consistently (over 98% of cases) elevated in hyperthyroid cats. More significantly, serum free T_4 concentrations are high in 95% of hyperthyroid cats with total T_4 values in the normal reference range as a result of mild disease and hormone fluctuation or of the suppressive effect of concurrent non-thyroidal illness.
- Euthyroid cats with non-thyroidal disease usually maintain normal free T_4 concentrations; however, a false-positive elevation of free T_4 concentration also occurs in approximately 10% of these sick cats without hyperthyroidism. Based on reported clinical studies, the following recommendations can be made regarding the use of free T_4 as a diagnostic test to identify cats with hyperthyroidism:
  - In all hyperthyroid cats with a high serum total T_4 concentration, free T_4 concentration is concurrently high and its measurement adds no further diagnostic information. Given the expense of free T_4 measurement coupled with the necessity for interpretation with a total T_4 estimation, and the high prevalence of high total T_4 values in hyperthyroid cats, it is more cost effective to initially measure total T_4 concentration alone. If a diagnosis is not confirmed, consideration can be given to measurement of the corresponding free T_4 concentration.

- Always measure free T_4 in conjunction with a total T_4 determination. In cats with occult hyperthyroidism, the total T_4 concentration is expected to be in the middle to high end of the reference range limits (i.e., 2.5–4.0 µg/dl; 25–50 nmol/L).
- Never use free T_4 as the sole screening test for hyperthyroidism because high free T_4 concentrations also occasionally are found in cats with non-thyroidal diseases that do not have hyperthyroidism. The reason for high free T_4 concentrations in these cats with non-thyroidal disease is unclear, but almost all of these cats have serum total T_4 concentrations that are below or at the low end of the reference range.
- Free T_4 by dialysis is a useful diagnostic test for hyperthyroidism and eliminates the need for provocative testing (T_3 suppression test or TRH stimulation test; see the following section) in most cases. However, in order to interpret the test result, the cat *must* have clinical signs (i.e., weight loss despite a good appetite) and physical exam findings (i.e., a palpable thyroid nodule) that are consistent with hyperthyroidism.
- If a high free T_4 concentration is found in a cat without classic clinical signs of hyperthyroidism, and especially if a thyroid nodule cannot be palpated, repeat the tests (total and free T_4 determinations) in 2 to 4 weeks. Alternatively, use one of the provocative tests (T_3 suppression or TRH stimulation; see the following section) to confirm hyperthyroidism.

Provocative Thyroid Tests

In the majority of hyperthyroid cats with reference-range total T_4 concentration, identification of concurrent disease, repeat total T_4 analysis, or simultaneous measurement of free T_4 allows confirmation of the diagnosis. Further diagnostic tests are rarely required. However, dynamic thyroid function tests have been recommended in the past as helpful in confirming a diagnosis of hyperthyroidism. Currently, the T_3 suppression or TRH stimulation tests should only considered in cats with clinical signs suggestive of hyperthyroidism when repeated total T_4 concentration remains within the reference range or free T_4 analysis is unavailable or inconclusive.

Triiodothyronine Suppression Test

Administration of exogenous T_3 causes suppression of pituitary TSH secretion and a subsequent drop in thyroidal T_4 secretion in the normal cat. In cats with autonomously hyperfunctioning thyroid adenomas, TSH secretion has been chronically suppressed and exogenous T_3 administration does not appreciably affect the pituitary-thyroid axis. The protocol for the T_3 suppression test is as follows:

- Collect a blood sample for T_4 and T_3 measurements.
- Administer oral T_3 (liothyronine: Cytomel, SmithKline Beecham) starting the next morning at a dosage of 25 µg/cat q8h for 2 days.
- On the morning of the third day, give the cat a final 25-µg dose of T_3 before returning to the veterinarian for blood sampling.
- Measure serum T_4 and T_3 in the same assay run on both basal and post-exogenous T_3 blood samples.
- In cats with hyperthyroidism, minimal, if any, suppression of serum T_4 occurs. A rise in serum T_3 concentration confirms owner compliance in administering the drug to the cat.

Thyrotropin-Releasing Hormone Stimulation Test

Administration of TRH stimulates pituitary TSH secretion and produces a subsequent rise in thyroidal T_4 secretion in the normal cat. In cats with autonomously hyperfunctioning thyroid adenomas, TSH secretion has been chronically suppressed and exogenous TRH administration does not appreciably affect the pituitary-thyroid axis. The protocol for the TRH stimulation test is as follows:

- Collect a blood sample for serum T_4 measurement.
- Administer TRH at a dosage of 0.1 mg/kg IV.
- Collect another blood sample for serum T_4 measurement 4 hours later.
- Although the effects are transient, TRH administration causes hypersalivation, tachypnea, and vomiting in most cats. However, this test is less time consuming than the T_3 suppression test and does not rely on owner compliance.
- Interpretation:
  - Administration of TRH to normal cats and cats with non-thyroidal disease causes a twofold or greater increase in serum T_4 concentrations at 4 hours.
  - In contrast, serum T_4 concentration in cats with mild hyperthyroidism generally increases little, if at all, after administration of TRH.

Thyroid Radionuclide Uptake and Imaging

- Increased thyroidal uptake of radioiodine after the administration of a small tracer dose of radionuclide is a characteristic finding in cats with hyperthyroidism. However, the relative lack of nuclear medicine facilities available to small animal practitioners limits the usefulness of this diagnostic modality to referral hospitals.
- Thyroid imaging (scanning) can be performed using either radioiodine or pertechnetate and is useful in delineating hyperfunctioning thyroid tissue. This technique is a helpful adjunct in the diagnosis of hyperthyroidism in cats and provides valuable preoperative information. The disadvantages are that nuclear medicine facilities are required and that the cat generally needs to be sedated for the procedure.

Treatment

Treatment of hyperthyroidism in cats is usually rewarding and is aimed at reducing circulating concentrations of thyroid hormone. This is accomplished by blocking production of thyroid hormone from the thyroid gland or by destroying or removing hyperfunctioning adenomatous thyroid tissue. Antithyroid drugs can be used effectively to block thyroid hormone synthesis but are not curative. Adenomatous thyroid tissue can be removed by surgical thyroidectomy or destroyed by radioiodine therapy. On return to euthyroidism, the clinical manifestations of thyrotoxicosis, including cardiac abnormalities, generally resolve completely.

▼ ***Key Point*** Azotemia may occur following treatment of hyperthyroidism by any method due to normalization of renal blood flow.

Medical Management

Medical management is a practical treatment option for many cats. It requires no special facilities and is readily available. There is a rapid return to euthyroidism (usually within 2 weeks), which may be desirable in severely affected cases. Anesthesia is avoided as are the peri-operative and postoperative complications associated with surgical thyroidectomy and the hospitalization necessary after radioactive iodine administration. However, medical management is not curative, is highly dependent on adequate owner and cat compliance, and requires regular biochemical monitoring to ensure the efficacy of treatment. In addition, adverse effects are relatively common. It is therefore often reserved for cats of advanced age, for those with concurrent diseases, and for when owners refuse, or facilities are not available for, either surgery or radioactive iodine.

Antithyroid Drugs

- Methimazole (Tapazole, Lilly) and propylthiouracil (PTU) are the two thiourylene antithyroid drugs available in the United States. Both are supplied in oral tablet form and act by inhibiting synthesis of thyroid hormones.
- Carbimazole, a third thiourylene antithyroid drug available in many European countries and Japan, is not available in the United States. After oral administration to cats, carbimazole has been shown to be immediately converted into methimazole.
- Do not use PTU in cats. This drug produces a high incidence of mild to serious adverse effects, including anorexia, vomiting, lethargy, immune-mediated hemolytic anemia, thrombocytopenia, and development of serum antinuclear antibodies in both normal and hyperthyroid cats.
- Methimazole is better tolerated and safer than PTU in the cat and can be considered the antithyroid drug of choice for hyperthyroidism.
- Initially, administer methimazole at a dose of 2.5 to 10 mg/day PO, depending on the severity of the hyperthyroid state. Ideally, the methimazole dose is divided q8h to q12h. Some cats have been effectively managed by giving methimazole once a day. However, results of one study suggested that once-daily administration of methimazole was not as effective as twice-daily administration in cats with hyperthyroidism.
- While antithyroid dugs are routinely administered orally, compliance can be problematic, particularly in fractious cats or in cats that vomit or develop inappetence on the drug. Recent studies have shown that methimazole when applied transdermally to the inner pinnae of the ear is effective in most hyperthyroid cats and is associated with fewer gastrointestinal side effects. Therefore, the use of transdermal methimazole is a viable alternative in the treatment of hyperthyroidism in cats in which the oral route is not efficacious or feasible.
- Perform complete blood counts, including platelet count, and serum T_4 determinations every 2 weeks during the first 3 months of drug therapy.
- Increase or decrease the daily drug dosage by 2.5 to 5 mg and continue further testing at 2- to 3-week intervals until the lowest daily dose is found that effectively maintains serum T_4 concentrations within the low-normal range.
- Mild clinical side effects associated with methimazole treatment are relatively common (approximately 15% of cats) and include anorexia, vomiting, and lethargy. Self-induced excoriations of the face and neck also may develop in a few cats within the first few weeks of therapy.
- A variety of hematologic abnormalities may develop in cats during treatment with methimazole. Those abnormalities that do not appear to be associated with any adverse clinical effects include eosinophilia, lymphocytosis, and transient leukopenia with normal differential count. More serious hematologic reactions that develop in a few cats treated with methimazole include severe thrombocytopenia, agranulocytosis (panleukopenia), and hemolytic anemia.
- If serious hematologic reactions develop during methimazole therapy, stop the drug and give supportive care. These adverse reactions should resolve within 5 days after the methimazole is withdrawn. Most life-threatening side effects usually develop quickly after beginning the drug again. If they occur, consider alternative therapy with surgery or radioiodine.
- Long-term antithyroid drug treatment has some advantages over surgery and radioiodine, including the absence of certain complications such as postsurgical hypoparathyroidism. Unlike surgery and radioiodine, antithyroid drug therapy requires no advanced skills, training, or special licensing and is a practical treatment option for most practitioners.

▼ ***Key Point*** Daily antithyroid drugs can block T_4 secretion and control hyperthyroidism, but surgery or radioiodine can cure the disorder.

Propranolol and Atenolol

- Propranolol and atenolol are the most frequently used β-adrenoceptor blocking agents in hyperthyroid cats. These drugs have no discernable effect on serum thyroid hormone concentrations but are used to symptomatically control the tachycardia, tachypnea, hypertension, and hyperexcitability associated with hyperthyroidism.
- Propranolol is a non-selective β-adrenoceptor blocker and is contraindicated in cats with pre-existing uncontrolled asthma or congestive cardiac failure. Administer the drug at a dose of 2.5 to 5 mg PO q8h.
- Atenolol is often preferred because it is a selective β_1-adrenoceptor blocking agent. Administer the drug at a dose of 6.25 to 12.5 mg PO q12–24h.

Cholecystographic Agents

Cholecystographic agents are a feasible alternative to methimazole for medical treatment of some cats with hyperthyroidism, particularly those that cannot tolerate methimazole and are not candidates for surgery or radiotherapy.

A number of oral cholecystographic agents have been used to decrease T_4 production, an effect presumably mediated by the drugs' effect to inhibit peripheral T_4 to T_3 conversion. In the United States, both ipodate and iopanoic acid have been discontinued by the manufacturer and are no longer available. Iopanoic acid is still available from some compounding pharmacies, but the drug is still of limited availability. Diatrizoate (brand name, Hypaque) is still available for use in the United States and also has shown promise as a viable replacement.

- The drugs' mechanism of action is inhibition of outer-ring 5′-deiodination of T_4 to the more active T_3, as well as some direct inhibitory effects on thyroid hormone secretion. Therefore, use of these drugs induces a rapid, marked decrease in serum T_3 concentration. Serum T_4 concentration usually does not change.
- The initial dosage of iopanoic acid or diatrizoate is 100 mg PO q24h. Monitor the drug's effects on clinical signs, body weight, heart rate, and serum T_3 concentrations. Increase the dosage of these drugs to 150 to 200 mg/day if serum T_3 remains high or a good clinical response is not observed at the lower dose.
- Adverse clinical signs attributable to iopanoic acid or diatrizoate treatment are uncommon.
- Cats with severe hyperthyroidism are less likely to respond to these drugs than are cats with mild or moderate disease. Cats in which serum T_3 concentration does not normalize are unlikely to have an adequate improvement in clinical signs.

Surgical Thyroidectomy

See under "Thyroidectomy" for a detailed description of this surgery.

- Usually successful.
- Preoperative thyroid nuclear imaging is useful if available.
- The modified extracapsular method is most effective for removal of all diseased tissue.

▼ ***Key Point*** Use methimazole for 2 to 4 weeks preoperatively (if possible) to restore euthyroidism and to reduce the anesthetic and surgical risks, especially in cats with severe hyperthyroidism.

- Monitor for postoperative hypocalcemia secondary to removal or damage of the parathyroid glands (only a risk following bilateral thyroidectomy).
- Postoperative laryngeal paralysis due to recurrent laryngeal nerve damage occurs uncommonly.
- After bilateral thyroidectomy, serum T_4 concentration is often below normal but thyroid hormone supplementation is rarely needed longer than 2 to 3 months. Permanent, surgically induced hypothyroidism in cats is rare. Long-term T_4 replacement is needed only in those cats that develop clinical signs of hypothyroidism (e.g., lethargy, weight gain, and dermatopathy) or azotemia with persistently low serum T_4 concentrations.

Radioactive Iodine Therapy

- Treatment with radioactive iodine (^{131}I) is simple, safe, and effective and is the best treatment for most hyperthyroid cats.
- No medical preparation with antithyroid drugs is needed.
- ^{131}I can be administered IV or orally, but the subcutaneous route is preferred. It is equally effective, not associated with gastrointestinal side effects, safer for personnel, and can be performed under light sedation if necessary, thereby avoiding anesthesia.
- There are few complications of ^{131}I therapy. Persistent hyperthyroidism, more common in severely affected cats with large goiters and extreme elevations in serum total T_4 concentration, can be successfully managed with a repeat injection. Permanent hypothyroidism is rare, as is recurrence after successful treatment, and other side effects are minimal.
- The main disadvantage is the long hospitalization time required (generally 1–2 weeks). Adherence to strict radiation safety regulations is required.
- The long-term prognosis for cats treated with radioiodine is excellent. In the largest study of 534 cats,

the median survival time was 24 months and 89%, 72%, 52%, and 34% of cats were alive at 1, 2, 3, and 4 years after treatment, respectively.

Effect of Treatment on Renal Function

- Hyperthyroidism is known to increase glomerular filtration rate (GFR), decrease circulating creatinine concentration, and mask underlying renal disease. All treatments for hyperthyroidism have been associated with a decrease in GFR capable of unmasking latent renal disease. Therefore renal dysfunction should always be considered a potential adverse reaction of treatment and assessed if clinical signs develop.
- Predicting those cats in which renal failure is likely to develop is difficult. In the absence of methods for accurately measuring GFR in practice, serum urea and creatinine concentrations and urine specific gravity should be carefully evaluated in individual cases. If any parameter is considered abnormal, then renal failure may develop upon treatment of the hyperthyroidism.
- Antithyroid medication offers the optimum treatment when there is evidence of pre-existing renal disease. If there is no discernible deterioration of renal function once euthyroidism has been achieved medically, other more permanent treatment options (surgery, radioactive iodine) may be considered. If renal function deteriorates, the effects of the drug will dissipate within 48 hours of withdrawal.
- The decision whether to continue treatment for hyperthyroidism depends on which of the two diseases is more severe. Maintenance of a mildly hyperthyroid state may be beneficial in some cases. However, preliminary studies suggest that although there may be an initial effect of treatment on GFR, this is not a progressive problem in the long term. However, avoidance of hypothyroidism is important because it may have its own detrimental effect on GFR.

THYROID NEOPLASIA IN DOGS

Unlike thyroid tumors found in the cat, the majority of thyroid neoplasms in dogs do not secrete excessive thyroid hormone. Less than 20% of these tumors are associated with hyperthyroidism. Because these tumors can destroy normal thyroid parenchyma, hypothyroidism sometimes occurs.

▼ ***Key Point*** Most canine thyroid tumors, unlike feline thyroid tumors, are large, invasive carcinomas.

About 90% of thyroid tumors in dogs are malignant. Local invasion into the larynx; trachea; cervical muscles, vessels, and nerves; and esophagus frequently occurs. Distant metastasis, especially to the lungs, occurs in 60% to 80% of cases. The prognosis associated with most of these tumors is poor. However, early detection and surgical removal of small, non-invasive thyroid carcinomas can result in good survival rates (up to 3 years).

Clinical Signs

See Table 31-3.

Non-thyrotoxic Thyroid Tumors

Clinical signs are related to structural damage to the cervical area and metastatic disease.

- A palpable cervical mass (goiter) is often firm, attached to surrounding soft tissues, and irregular in shape.
- Respiratory distress and cough.
- Vomiting.
- Dysphagia.
- Anorexia.
- Weight loss.

Hyperfunctional Thyroid Tumors

See "Hyperthyroidism in Cats" for an explanation of the pathophysiology of similar signs.

- A palpable cervical mass (goiter) is often firm, attached to surrounding soft tissues, and irregular in shape.
- Polydipsia and polyuria are common.
- Weight loss.
- Polyphagia.
- Heat and stress intolerance.
- Nervousness and hyperexcitability.

Table 31-3. INCIDENCE OF CLINICAL SIGNS IN DOGS WITH THYROID TUMOR

Sign	Percentage of Cases
Non-toxic (Euthyroid or Hypothyroid) Thyroid Tumor	
Goiter (enlarged thyroid gland)	100
Respiratory distress/cough	30
Metastases to lung or lymph nodes	35
Vomiting	10
Dysphagia	10
Anorexia	10
Weight loss	5
Hyperfunctional (hyperthyroid) Thyroid Tumor	
Goiter	100
Polydipsia and polyuria	95
Weight loss	80
Weakness and fatigue	75
Polyphagia	70
Heat intolerance	60
Nervousness	50
Hyperdefecation/diarrhea	30
Tremor	20

- Diarrhea and increased volume of feces.
- Tremors.

▼ ***Key Point*** In dogs, most thyroid tumors that result in hyperthyroidism are malignant (carcinoma). Polydipsia and polyuria are very prominent clinical signs.

Diagnosis

Consider thyroid carcinoma in any dog with a ventral cervical mass.

- Thyroid gland biopsy is mandatory for the diagnosis of thyroid carcinoma.
- Screening laboratory tests are indicated.
- Thoracic radiography is an essential part of the diagnostic workup because pulmonary metastasis occurs commonly.
- Serum thyroid hormone concentrations are indicated when clinical signs suggest hyperthyroidism or hypothyroidism.
- Thyroid imaging (thyroid scan) can be useful in determining the size and location of neoplastic thyroid tissue.

Treatment

The prognosis for a dog with thyroid carcinoma depends on the developmental stage, size, and palpable characteristics of the tumor. Small, movable tumors that have not metastasized can often be cured by surgical excision. Dogs with bilateral tumors are more likely to have metastasis than those with unilateral tumors. External beam radiation therapy is effective in controlling many tumors that are not surgically resectable. For dogs with very invasive or metastatic tumors, the prognosis is usually poor and treatment is rarely curative regardless of the modality.

Surgery

See under "Thyroidectomy."

- Thyroidectomy can be a difficult procedure.
- Complete excision of a thyroid carcinoma is uncommon unless the tumor is small and not locally invasive (moveable on palpation).

Chemotherapy

- Doxorubicin 30 mg/m^2 body surface area (for a conversion table, see Chapter 26), IV, every 3 weeks for five treatments.
- A potentially limiting long-term side effect of doxorubicin is congestive cardiomyopathy.
- Combination treatment with doxorubicin and cyclophosphamide has been used with varying degrees of success and with less cardiac toxicity.

External Beam (Cobalt) Irradiation

- Useful therapy for thyroid carcinoma.
- Consider a combination of surgical debulking followed by external irradiation in those cases in which most of the tumor was resected.
- External beam irradiation is effective in controlling unresectable thyroid carcinomas, with median survival times exceeding 2 years.

Radioactive Iodine

- Administration of large doses of ^{131}I (10–100 mCi) can temporarily control hyperfunctional thyroid carcinoma and can lead to palliation of clinical signs of hyperthyroidism. However, this treatment will most likely fail to control metastatic growth.
- Radioiodine does not work well in dogs with nontoxic thyroid tumors that have a low degree of radioiodine uptake.

THYROIDECTOMY

Thyroidectomy in dogs and cats is usually performed to treat neoplasia of the gland. Biopsy is occasionally performed but not as commonly as the complete removal of one or both lobes. A thorough understanding of thyroid anatomy and physiology is necessary before performing surgery.

Anatomy

Thyroid

- The thyroid gland consists of two lobes located just caudal to the larynx.
- The normal gland is a pale tan color and approximately 1 to 1.5 cm in length.
- Blood supply is via the cranial thyroid artery (branch of the common carotid artery) (Fig. 31-1).

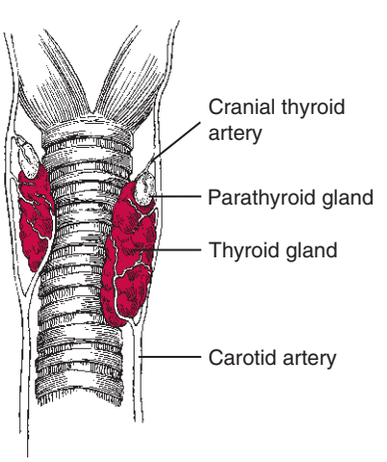

Figure 31-1. Gross appearance of bilateral thyroid tumors in a cat.

- The caudal thyroid artery is usually absent in cats. Venous drainage is via cranial and caudal thyroid veins.
- The thyroid gland has a distinct but thin capsule.

Parathyroid

- Two parathyroid glands are associated with each thyroid lobe: one intracapsular (internal) and one extracapsular (external). The extracapsular parathyroid gland is usually located at the cranial pole of the thyroid.
- The parathyroid gland is usually off-white and can be confused with fat; the gland is usually 2 to 5 mm in length.
- Blood supply to the parathyroid glands is also from the cranial thyroid artery.
- Only one functional parathyroid gland is required for normocalcemia.

Thyroidectomy in the Cat

Preoperative Considerations

- Hyperthyroidism is a multisystemic disease that can be associated with anesthetic and surgical complications.
- In addition to establishing euthyroidism with antithyroid drugs (see earlier in this chapter), correct dehydration preoperatively if necessary.
- Obtain thoracic radiographs to evaluate the heart's size and the presence of any pulmonary problems or mediastinal masses.
- If available, review the thyroid radionuclide scan to determine the extent of the disease (e.g., Is the tumor unilateral or bilateral? Are ectopic tumors present?).
- See Chapter 2 for anesthetic drug dosages and other specifics.
- Premedicate with acepromazine. Avoid anticholinergics such as atropine and glycopyrrolate.
- Induce with propofol IV.
- Maintain anesthesia with isoflurane and oxygen via a cuffed endotracheal tube.
- Closely monitor the electrocardiogram for arrhythmias.
- Have propranolol (Inderal, Wyeth-Ayerst) ready in the event that premature ventricular contractions develop. Dilute to make a solution of 0.1 mg/ml and give 0.01 mg IV slowly (over 3–5 minutes).

Surgical Procedure

Objectives

1. Remove all abnormal thyroid tissue.
2. Maintain meticulous hemostasis.
3. Preserve at least one of the parathyroid glands.
4. Avoid injury to the recurrent laryngeal nerves.

Equipment

- Standard surgical pack
- Bipolar cautery
- Tenotomy scissors
- Gelpi retractors
- Sterile cotton-tipped applicators
- Gelfoam

Technique

1. Place the cat in dorsal recumbency with the front legs tied caudally and the neck slightly hyperextended over a rolled towel.
2. Prepare the ventral cervical region from caudal mandibles to manubrium for aseptic surgery.
3. Incise the skin on the ventral cervical midline from larynx to manubrium.
4. Separate the paired sternohyoideus and sternothyroideus muscles and retract the muscles with self-retaining retractors (Gelpi).
5. Carefully examine both thyroid lobes. Remove the affected lobes. If doubt exists as to involvement of a lobe, remove it because microscopic adenomatous hyperplasia may be present.
6. Attempt to identify the parathyroid glands.
7. Ligate the caudal thyroid vein and grasp the caudal aspect of the capsule.
8. Several techniques can be used to dissect the thyroid lobes (Figs. 31-2 and 31-3), but the modified extracapsular technique is preferred.
   a. This technique offers the best chance of removing all the abnormal thyroid tissue. Use the extracapsular technique if the parathyroid glands are visible and can be easily separated from the thyroid (see Fig. 31-3). If a parathyroid gland is accidentally removed, place it in a small incision in one of the sternohyoideus muscles. Maintain meticulous hemostasis with judicious use of bipolar cautery and small pieces of Gelfoam.
   b. Use the intracapsular technique if the parathyroid glands are not visible (see Fig. 31-2). When implementing the intracapsular technique, be sure to remove all remnants of thyroid tissue that may remain attached to the capsule. The intracapsular technique is easy to perform but is associated with a high rate of postoperative recurrence of hyperthyroidism.
9. Routinely close the sternohyoideus muscle, subcutaneous tissue, and skin (see subsequent discussion of thyroidectomy in dogs).

Postoperative Care and Complications

- Monitor for hypothermia, hemorrhage at the incision site, and hypocalcemia.
- Hypoparathyroidism.
  - Rare with careful surgical technique (5% incidence of hypocalcemic tetany).

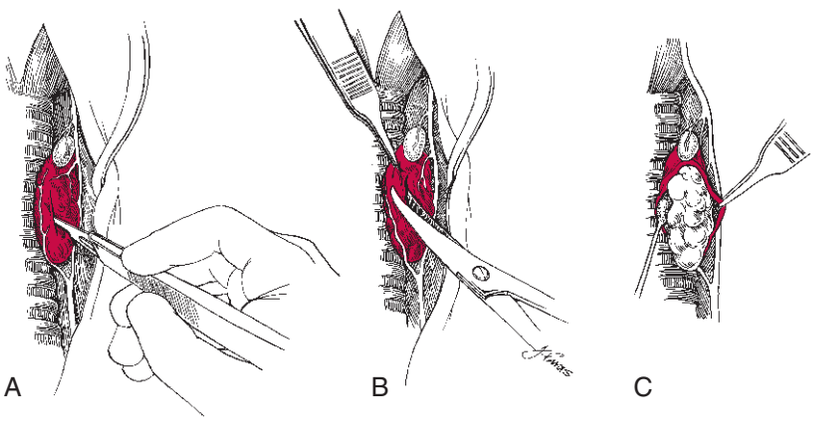

Figure 31-2. Intracapsular dissection for removal of a thyroid tumor in a cat. Make a nick incision *(A)* in a relatively avascular area of the thyroid capsule and extend the incision with scissors *(B)*. Bluntly remove the gland from the capsule using a sterile cotton-tipped applicator *(C)*. Ligate or cauterize blood vessels as necessary.

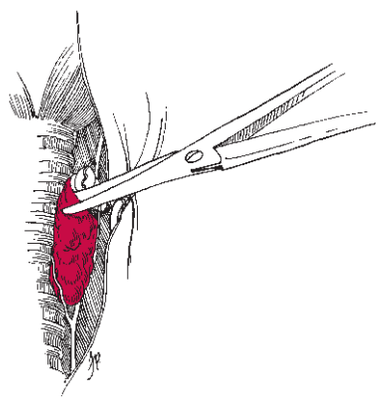

Figure 31-3. Extracapsular dissection for removal of a thyroid lobe in a cat. Incise the thyroid capsule immediately adjacent to the parathyroid gland. Carefully cauterize capsular blood vessels if necessary. Bluntly separate the thyroid gland from the parathyroid gland using a sterile cotton-tipped applicator. After ligating or cauterizing blood vessels as necessary, remove the thyroid gland and its capsule.

  - Check serum calcium concentrations for 48 hours postoperatively or longer if the concentration is dropping.
  - Monitor for tetany if calcium concentration is dropping.
  - Treatment of hypoparathyroidism is described in Chapter 32.
- Thyroid hormone replacement (see "Hypothyroidism in Cats").
- Relapse of hyperthyroidism is rare (10% incidence, 2–3 years postoperatively) but does occur, probably because of the incomplete removal of adenomatous tissue. Treat by administering radioactive iodine or by surgical removal of remaining thyroid tissue. The incidence of hypoparathyroidism tends to be higher than with the first surgery.

Thyroidectomy in the Dog

Preoperative Considerations

- Accurate preoperative diagnosis is important. Carefully palpate the tumor. Small, movable tumors are usually amenable to surgical resection. Surgical resection of encapsulated, movable thyroid tumors was found in one study to result is median survival of 20 months. Fine-needle aspirate or tissue biopsy of the thyroid tumor helps establish the type of tumor. However, recognize that bleeding associated with these procedures can obscure the surgical field and make the procedure more difficult.

▼ ***Key Point*** Biopsy of thyroid tumors in the dog can result in significant hemorrhage. Observe the patient closely after biopsy.

- Cervical radiographs or computed tomography may be helpful to determine tracheal displacement or tumor calcification. Ultrasound examination may be helpful to identify the involved thyroid lobes and evaluate for local tissue invasion. Thoracic radiographs are mandatory to rule out pulmonary metastasis or another cardiopulmonary disorder.

Surgical Procedure

Objectives

1. Completely remove or debulk the thyroid mass.
2. Preserve at least one parathyroid gland.
3. Minimize blood loss.
4. Preserve recurrent laryngeal nerves. Avoid injury to the trachea and esophagus.

Equipment

- Standard general surgical pack and sutures
- Gelpi or Weitlaner retractors
- Army-Navy retractors
- Penrose drains or closed suction drains (e.g., Jackson-Pratt)

Technique

1. Patient preparation and surgical approach are the same as those described for the cat.
2. Dissection

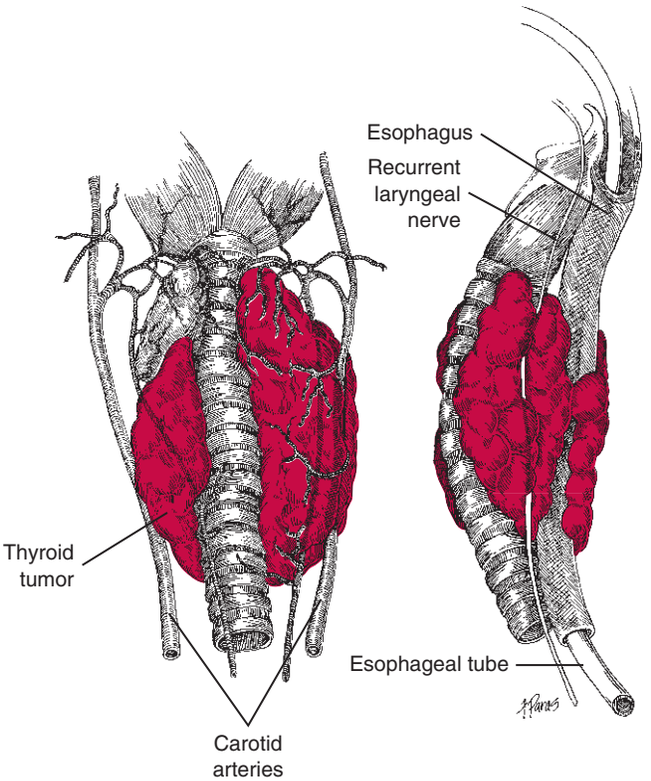

Figure 31-4. Gross appearance of an invasive thyroid carcinoma in a dog.

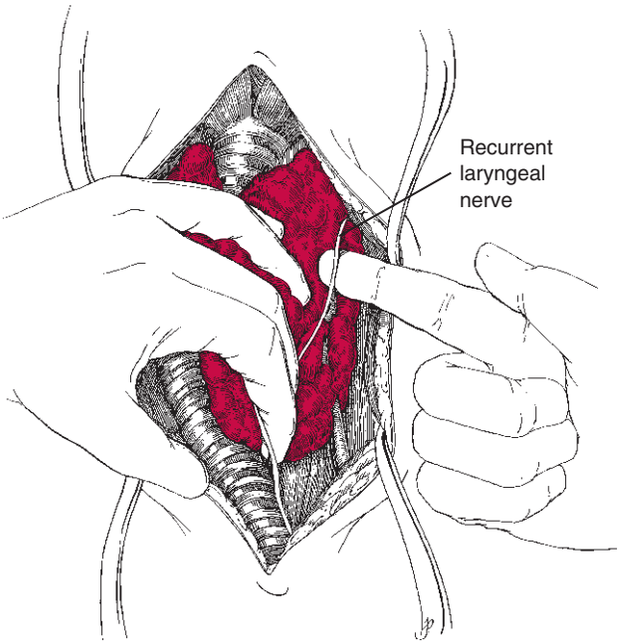

Figure 31-5. Remove canine thyroid tumors with a combination of blunt and sharp dissection. Finger dissection of the tumor and surrounding structures may be necessary for large invasive tumors. Be careful when handling the recurrent laryngeal nerve to avoid the possibility of postoperative laryngeal paralysis.

a. These tumors are very vascular, and dissection is difficult.
b. Avoid injury to the esophagus, carotid artery, jugular vein, vagosympathetic trunk, and recurrent laryngeal nerve (Fig. 31-4).
c. A stomach tube or small endotracheal tube in the esophagus helps identify this structure.
d. Ligate or cauterize the extensive vascular network and carefully dissect out the tumor (Fig. 31-5). Begin dissection at the caudal aspect of the tumor and gradually work cranially.
e. Identify and preserve the parathyroid glands if bilateral thyroidectomy is performed. With large malignant tumors, this may be impossible.
f. If complete removal is impossible, debulk the mass, leaving the portion closest to the larynx intact to preserve the parathyroid glands. Bleeding from the remaining thyroid tissue may be difficult to control.

3. Closure
a. Place Penrose drains or a closed suction drain if significant dead space results from tumor removal. Have the drains exit through separate stab incisions.
b. Close the muscle routinely with simple continuous, absorbable suture; the subcutaneous tissue with simple continuous, absorbable suture; and the skin with simple interrupted, non-absorbable suture.

Postoperative Care and Complications

Short-Term

- Closely monitor for hemorrhage or seroma formation.
- Check serum calcium concentrations at least 2 to 4 days postoperatively if a bilateral thyroidectomy was performed. Monitor the calcium concentrations longer if decreasing. Treat hypoparathyroidism if necessary, according to the guidelines in Chapter 32.
- Check serum T_3 and T_4 levels if bilateral thyroidectomy is performed. Treat hypothyroidism if present (see previous discussion of hypothyroidism).

Long-Term

- Reevaluate the dog frequently (every 3 months) for recurrence of the primary tumor and metastasis.
- Consider postoperative chemotherapy or radiotherapy if the tumor was malignant (see previous discussion on treatment of thyroid tumors and Chapter 26 on chemotherapy).

Chapter 32

Diseases of the Parathyroid Gland and Calcium Metabolism

Patricia A. Schenck / Dennis J. Chew

NORMAL CALCIUM METABOLISM

Calcium is required for many intracellular and extracellular functions, as well as for skeletal support. Ionized calcium is required for enzymatic reactions, membrane transport and stability, blood coagulation, nerve conduction, neuromuscular transmission, muscle contraction, vascular smooth muscle tone, hormone secretion, bone formation and resorption, control of hepatic glycogen metabolism, and cell growth and division. Normal homeostatic control mechanisms usually maintain serum ionized calcium concentration within a narrow range.

Distribution of Calcium

Calcium in plasma or serum exists in three fractions: ionized (free calcium), complexed, and protein bound.

▼ ***Key Point*** Ionized calcium is the biologically active fraction of serum total calcium.

- ***Ionized calcium:*** This is the biologically active fraction of calcium and accounts for approximately 55% of the total serum calcium concentration in dogs.
- ***Complexed calcium:*** Complexed calcium accounts for approximately 10% of the total serum calcium concentration in dogs but may be elevated in chronic renal failure (CRF). Complexed calcium may be bound to anions such as lactate, phosphate, bicarbonate, sulfate, citrate, and oxalate.
- ***Protein-bound calcium:*** Protein-bound calcium accounts for approximately 35% of the total serum calcium concentration. Albumin is the primary protein bound to calcium. Protein binding is affected by changes in pH, with increased binding as pH increases and decreased binding as pH decreases.

Regulation of Calcium

Regulation of serum calcium concentration is complex and requires the integrated actions of parathyroid hormone (PTH), vitamin D metabolites, and calcitonin. The intestine, kidney, and bone are the major target organs affected by calcium regulatory hormones. The skeleton provides a major supply of calcium and phosphorus when intestinal absorption and renal reabsorption are inadequate to maintain normal serum calcium concentration.

Parathyroid Hormone

PTH is synthesized and secreted by chief cells of the parathyroid gland in response to a decrease in ionized calcium concentration. The most important biologic effects of PTH are as follows:

- Increase the blood calcium concentration
- Increase tubular reabsorption of calcium, resulting in decreased loss of calcium in the urine
- Increase bone resorption and numbers of osteoclasts on bone surfaces
- Accelerate the formation of 1,25-dihydroxyvitamin D_3 (calcitriol) by the kidney

▼ ***Key Point*** The net effects of PTH are to increase serum ionized calcium and to decrease serum phosphorus concentrations.

Calcitonin

Calcitonin is synthesized by C cells in the thyroid gland and is secreted in response to hypercalcemia and to a calcium-rich meal. The effects of calcitonin on normal calcium homeostasis are considered minor. The major target site for calcitonin is bone, where it inhibits resorption of calcium and phosphorus.

Vitamin D Metabolites

The cholecalciferol (vitamin D_3 of animal origin) metabolites 25-hydroxyvitamin D_3 (calcidiol) and 1,25-dihydroxyvitamin D_3 (calcitriol) are the most important vitamin D metabolites. These metabolites may also be derived from ergocalciferol (vitamin D_2 of plant origin), and are equally bioactive. Dogs and cats inefficiently photosynthesize vitamin D in their skin and consequently are dependent on vitamin D in their diet. Hydroxylation of vitamin D occurs in the liver to produce 25-hydroxyvitamin D. This 25-hydroxyvitamin

D is further hydroxylated in the proximal tubule of the kidney to form calcitriol.

Calcitriol

Calcitriol is the only active metabolite of vitamin D. Calcitriol increases serum calcium and phosphorus concentrations and acts on the intestine, kidney, and bone.

- ***Bone:*** Calcitriol stimulates osteoclastic calcium mobilization and resorption of bone.
- ***Intestine:*** Calcitriol increases calcium, phosphorus, and magnesium absorption.
- ***Kidney:*** Calcitriol increases renal tubular resorption of calcium and phosphorus.

▼ ***Key Point*** The net effect of calcitriol is to increase both serum ionized calcium and serum phosphorus concentrations.

DIAGNOSTIC TESTS OF CALCIUM METABOLISM

Measurement of total calcium, ionized calcium, and hormones of calcium metabolism aid in the diagnosis of calcium disorders (see Tables 32-1 and 32-2).

Total Serum Calcium

Total serum calcium is part of most routine serum profile evaluations. However, ionized calcium concentration does not parallel total calcium concentration, and thus ionized calcium concentration must be measured for an accurate assessment of calcium status. Total calcium is usually measured using a colorimetric method and may be spuriously elevated if hyperlipemia or hemolysis is present.

Adjusted Total Calcium Values

Formulas to adjust serum total calcium to albumin or total protein concentration have been published for dogs. Due to a high level of diagnostic discordance between adjusted total calcium and ionized calcium concentrations, the use of these formulas is discouraged.

Ionized Calcium Concentration

- Ion-selective methods are available in some laboratories. Special handling of serum or heparinized plasma is necessary to prevent lowering of ionized calcium due to pH increases. Serum samples appear to be stable for 72 hours at 4°C if handled anaerobically. Some laboratories have developed species-specific pH adjustment formulas to allow measurement of aerobically handled samples.
- A handheld analyzer is also available for cage-side analyses. Heparinized whole blood is used for measurement; for best results, a standard quantity of dry heparin and blood should be utilized for each assay.

1,25(OH)$_2$, 1,25-dihydroxyvitamin D$_3$; 25(OH)-D, 25-hydroxyvitamin D$_3$; alb, albumin; Corr tCa, corrected total calcium; iCa, ionized calcium; N, normat; Pi, phosphorus; PTG, parathyroid glands; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related protein; tCa, total calcium; US, ultrasound.

Parathyroid Hormone

The PTH molecule is composed of three portions: amino-terminus, mid-molecule, and carboxy-terminus. The amino-terminus is the biologically active portion of the molecule. An intact PTH assay (a two-site assay) provides accurate determination of PTH concentration. PTH fragments are excreted by the kidneys. In animals with renal failure, concentration of inactive fragments may increase. Only an intact PTH assay should be used in patients with renal disease or failure. Serum or separated plasma samples can be assayed but should be kept refrigerated or frozen prior to assay.

Parathyroid Hormone-Related Protein

The parathyroid hormone-related protein (PTHrP) is a hormone secreted by some malignant neoplasms in animals with hypercalcemia. This hormone can bind to PTH receptors in the kidneys and bone and result in humoral hypercalcemia of malignancy (HHM). Separated plasma samples can be assayed but should be kept refrigerated or frozen prior to assay.

Vitamin D Metabolites

- 25-hydroxyvitamin D$_3$ (calcidiol)
  - Metabolites of vitamin D$_3$ are chemically identical in all species. Calcidiol concentration is a good indicator of vitamin D$_3$ ingestion and can be used to diagnose hypovitaminosis or hypervitaminosis D. Serum or separated plasma can be assayed, but samples should be protected from degradation due to exposure to light.
- 1,25-dihydroxyvitamin D$_3$ (calcitriol)
  - Calcitriol is the most active vitamin D metabolite, and it circulates in low concentrations. Assays have been developed for calcitriol but are not readily available due to cost.

HYPERCALCEMIA

Defining Criteria

- Serum total calcium concentration
  - Dogs: >12.0 mg/dl (3.0 mmol/L)
  - Cats: >11.0 mg/dl (2.75 mmol/L)
- Serum ionized calcium concentration
  - Dogs: >5.8 mg/dl (1.45 mmol/L)
  - Cats: >5.6 mg/dl (1.40 mmol/L)
- Young dogs may have a mild hypercalcemia (usually <13.0 mg/dl total serum calcium concentration) related to skeletal growth.
- Hyperlipemia and/or hemolysis of the sample may result in spurious elevations of calcium.

▼ ***Key Point*** Severe clinical signs are associated with a serum total calcium concentration >18 mg/dl.

Etiology

Hypercalcemia may be parathyroid-dependent (primary hyperparathyroidism) or parathyroid-independent (normal functioning of the parathyroid gland).

- In parathyroid-independent hypercalcemia, elevated ionized calcium concentration causes suppression of PTH production. On analysis, ionized calcium concentration is elevated, and PTH concentration is in the lower part of or below the reference range. PTHrP concentration may be elevated if there is a tumor producing PTHrP. Concentration of 25-hydroxyvitamin D$_3$ may be elevated in cases of vitamin D toxicity.
- Parathyroid-dependent hypercalcemia (primary hyperparathyroidism) is characterized by elevated ionized calcium concentration without the appropri-

ate suppression of PTH production due to a PTH-secreting tumor of the parathyroid gland.

See Table 32-3 for a list of hypercalcemia-related conditions.

Clinical Signs

Clinical signs in hypercalcemia depend on the magnitude of the calcium elevation, how quickly the hypercalcemia developed, and the duration of the hypercalcemia. Serum total calcium concentrations of <15 mg/dl (<3.75 mmol/L) may not be associated with systemic signs; however, serum total calcium concentrations of >18 mg/dl (>4.5 mmol/L) are often associated with severe life-threatening signs. Soft tissue mineralization may occur with prolonged hypercalcemia when the product of total calcium (mg/dl) times serum phosphorus (mg/dl) equals 70 or greater.

- Polydipsia and polyuria are the most common signs of hypercalcemia in dogs due to direct stimulation of the thirst center and a decreased ability of the kidneys to concentrate urine.
- Anorexia, vomiting, and constipation can result from decreased excitability of gastrointestinal smooth muscle.
- Generalized weakness may develop from decreased muscle excitability.
- Depression, muscle twitching, and seizures can occur as neurologic manifestations.
- Cardiac arrhythmias can develop from direct effects on the myocardium or secondary to cardiac mineralization.

▼ ***Key Point*** Polydipsia and polyuria are the most common clinical signs of hypercalcemia.

Table 32-3. CONDITIONS ASSOCIATED WITH HYPERCALCEMIA

Nonpathologic Conditions
Hyperlipemia
Non-fasted serum samples
Young growing dogs
Laboratory error or improper handling of sample

Transient Conditions
Hemoconcentration
Hyperproteinemia

Pathologic Conditions
Parathyroid-dependent hypercalcemia
  Primary hyperparathyroidism
Parathyroid-independent hypercalcemia
  Malignancy-associated hypercalcemia
    Lymphoma
    Adenocarcinoma of the apocrine glands of the anal sac
    Multiple myeloma
    Metastatic bone tumors
    Miscellaneous tumors (lymphocytic leukemia, mammary carcinoma, fibrosarcoma, pancreatic adenocarcinoma, testicular interstitial cell tumor, lung carcinoma, squamous cell carcinoma, thyroid adenocarcinoma, osteosarcoma)
Hypoadrenocorticism
Renal failure
Hypervitaminosis D
  Cholecalciferol (rodenticide) toxicity
  Dovonex ingestion
  Iatrogenic due to dietary supplementation
  Houseplants (*Cestrum diurnum, Solanum malacoxylon, Trisetum flavescens*)
  Granulomatous disease (blastomycosis, schistosomiasis)
Grape toxicity
Bone lesions (sepsis, disuse osteoporosis)
Severe hypothermia
Idiopathic hypercalcemia in cats

Diagnosis

Abnormalities depend on the underlying cause, severity, and duration of hypercalcemia (see later under "Conditions Associated with Hypercalcemia").

History and Physical Examination

- A complete history and thorough physical examination are essential for diagnosing the cause of hypercalcemia. Obtain dietary history to assess the possibility of over-supplementation or under-supplementation with vitamin D.

Laboratory Tests

- Perform a complete blood count (CBC) and serum chemistry profile, and consider tests such as serum ionized calcium, PTH, 25-hydroxyvitamin D, and PTHrP concentrations. Collect samples for diagnostic testing prior to treatment.

Radiography and Ultrasound

- Soft tissue mineralization of the kidneys, heart, lungs stomach, and other tissues may be detected.
- Abdominal masses, mediastinal masses, pulmonary lesions suggestive of metastasis, or lymph node enlargement especially in the tracheobronchial region may be visualized.

Electrocardiography

- Prolongation of the PR interval, shortening of the QT interval, and cardiac arrhythmias (ventricular fibrillation) may develop with severe hypercalcemia.

Principles of Treating Hypercalcemia

▼ ***Key Point*** The definitive treatment for hypercalcemia is to remove the underlying cause.

Unfortunately, the etiology may not be apparent, and supportive measures must be taken to decrease the serum calcium concentration (see Table 32-4 for specific drugs and dosage recommendations). Supportive measures may include the following.

Table 32-4. TREATMENT OF HYPERCALCEMIA

Treatment	Dose	Indications	Comments
Volume Expansion			
SQ saline (0.9%)	75–100 ml/kg/day	Mild hypercalcemia	Contraindicated if peripheral edema is present
IV saline (0.9%)	100–125 ml/kg/day	Moderate to severe hypercalcemia	Contraindicated in congestive heart failure and hypertension
Diuretics			
Furosemide	2–4 mg/kg q8–12h IV, SC, PO	Moderate to severe hypercalcemia	Volume expansion is necessary prior to use of this drug
Glucocorticoids			
Prednisone Dexamethasone	1–2.2 mg/kg q12h PO, SC, IV 0.1–0.22 mg/kg q12h IV, SC	Moderate to severe hypercalcemia	Use of these drugs prior to identification of etiology may make definitive diagnosis difficult
Inhibition of Bone Resorption			
Calcitonin	4–6 IU/kg q8–12h SC	Hypervitaminosis D toxicity	Response may be short lived; vomiting may occur
Bisphosphonates			
Etidronate (EHDP)	5–15 mg/kg daily to q12h	Moderate to severe hypercalcemia	Expensive; use in dogs limited
Clodronate	20–25 mg/kg in 4-hr IV infusion		Approved in Europe; availability in U.S. limited
Pamidronate	1.3 to 2.0 mg/kg in 150-ml 0.9% saline in 2-hr IV infusion; can repeat in 1–3 wks		

EHDP, ethane-1-hydroxy-1,1-diphosphonate.

Volume Expansion

Volume expansion with IV 0.9% NaCl solution decreases hemoconcentration and encourages renal calcium loss by improving glomerular filtration rate and sodium excretion, resulting in less calcium resorption.

Loop Diuretics

- Diuretics such as furosemide increase calcium excretion; however, high doses may be needed. Diuretic use in a dehydrated patient is contraindicated because volume contraction and further hemoconcentration may worsen the hypercalcemia.
- Thiazide diuretics, which decrease calcium excretion by the kidneys, are contraindicated.

Sodium Bicarbonate

Sodium bicarbonate given as an IV bolus or as a continuous infusion has been shown to decrease serum total and ionized calcium concentration. Although the magnitude of calcium reduction is mild, alkalosis favors the binding of ionized calcium to protein, resulting in a decrease in ionized calcium. Sodium bicarbonate therapy is more beneficial when combined with other treatments and is reserved for life-threatening situations.

Glucocorticoids

- Glucocorticoids decrease bone resorption of calcium, decrease intestinal calcium absorption, and increase renal calcium excretion. These effects are nonspecific and lead to a mild decrease in the magnitude of hypercalcemia.
- Glucocorticoids often cause a substantial decrease in serum calcium concentration when hypercalcemia is secondary to lymphoma, myeloma, hypervitaminosis D, or hypoadrenocorticism.

▼ ***Key Point*** The use of glucocorticoids prior to determination of the etiology of hypercalcemia may make definitive diagnosis difficult, especially for lymphoma and myeloma.

Calcitonin

Calcitonin can be useful during treatment of cholecalciferol toxicity. For calcitonin to decrease serum calcium, multiple injections per day are required. Long-term side effects include anorexia and vomiting, and diminished effectiveness of calcitonin treatment may occur over time. Use calcitonin only when other treatments have not adequately lowered serum calcium.

Bisphosphonates (Diphosphonates)

These compounds inhibit osteoclastic bone resorption.

- Etidronate (Didronel, Norwich Eaton) has been used with some success as an oral agent for long-term control of hypercalcemia, but it is not well absorbed.
- Intermittent IV injections of pamidronate (Aredia, Novartis) are effective for the control of vitamin D toxicity, hyperparathyroidism, and malignancy-associated hypercalcemia. Clodronate is an alternative.
- Since bisphosphonates have nephrotoxic potential, use these after rehydration. Use IV fluids during and for several hours after treatment with bisphosphonates.

Mithramycin

This drug is a potent inhibitor of osteoclastic bone resorption; however, mithramycin has been associated with many serious side effects, such as thrombocytopenia, hepatic necrosis, renal necrosis, and hypocalcemia, and is no longer recommended.

Peritoneal Dialysis

Using a calcium-free dialysate, this procedure can be considered as a last resort when other methods fail to decrease serum calcium concentration.

CONDITIONS ASSOCIATED WITH HYPERCALCEMIA

For a complete list of conditions associated with hypercalcemia, see Table 32-3.

Hypercalcemia Associated with Malignancy

▼ ***Key Point*** Malignancy-associated hypercalcemia is the most common cause of persistent hypercalcemia in dogs and the third most common cause in cats.

Hypercalcemia primarily results from increased osteoclastic bone resorption and increased renal tubular resorption. Rarely, increased intestinal absorption also may play a role. Factors that may be produced by tumors and result in humoral hypercalcemia of malignancy include PTH, PTHrP, transforming growth factor, calcitriol, prostaglandin E_2, osteoclast-activating factor, and other cytokines (interleukin-1, interleukin-2, and gamma interferon).

- In dogs, lymphoma, adenocarcinoma of the apocrine glands of the anal sac, and multiple myeloma are the most common tumors associated with hypercalcemia.
- In cats, lymphoma, and squamous cell carcinoma each account for one-third of the cases of malignancy-associated hypercalcemia.

▼ ***Key Point*** A normal (or negative) concentration of PTHrP does not rule out the presence of a malignancy.

Lymphoma

- Lymphoma is the most common tumor associated with hypercalcemia in the dog. Of dogs with lymphoma, 10% to 40% have concurrent hypercalcemia, and a large number of these have mediastinal lymphoma. Although lymphadenopathy is usually detected, hypercalcemia may be the first abnormality noted.
- A thorough physical examination, together with thoracic and abdominal radiography, abdominal ultrasonography, multiple lymph node aspirates or biopsies, and multiple bone marrow aspirates or core biopsies, may be necessary to confirm a diagnosis of lymphoma.
- Treatment with corticosteroids decreases serum calcium concentration; however, their lympholytic effect makes subsequent identification of lymphoma very difficult. The return of hypercalcemia may precede clinical evidence of tumor regrowth in animals undergoing chemotherapy. Treatment of lymphoma is discussed in Chapter 27.

▼ ***Key Point*** Lymphoma is the most common tumor associated with hypercalcemia in the dog.

Apocrine Gland Adenocarcinoma of the Anal Sac

- This tumor usually occurs in older female dogs, with hypercalcemia developing in approximately 50% of cases. Humoral mechanisms are typically responsible for hypercalcemia, as PTHrP has been identified from tumor tissue in dogs. The tumor is usually malignant and has metastasized to regional lymph nodes by the time of diagnosis.
- Surgical resection is associated with reduction of serum calcium. Failure to remove all of the tumor or recurrence of the tumor usually results in the return of hypercalcemia. Despite surgical excision, radiation, and various chemotherapy protocols, the tumor usually recurs, and reported survival times range from 2 to 21 months.

Multiple Myeloma

- Multiple myeloma in dogs has been associated with hypercalcemia in 10% to 15% of cases. Humoral factors as well as direct lysis of bone may account for the increased serum calcium.
- Long-term survival has been reported following treatment of multiple myeloma with chemotherapy, but associated hypercalcemia, light-chain proteinuria, and extensive bony lesions are associated with a shorter survival time.

Hypoadrenocorticism

- Approximately 30% of dogs with hypoadrenocorticism (Addison's disease) have mild to moderate hypercalcemia (total calcium concentration <15 mg/dl). Ionized calcium concentration may be normal or slightly elevated.
- Multiple factors resulting in hypercalcemia include increased calcium citrate (complexed calcium), hemoconcentration (relative increase), increase in renal resorption of calcium, and increased binding of calcium to serum proteins.
- Hypercalcemia usually resolves quickly with therapy for hypoadrenocorticism.

Hypervitaminosis D

With hypervitaminosis D, ionized calcium concentration is elevated with suppression of PTH production. Elevation of 25-hydroxyvitamin D_3 may be observed depending on the vitamin D metabolites present.

▼ ***Key Point*** In vitamin D toxicosis, hyperphosphatemia often accompanies hypercalcemia.

Rodenticides Containing Cholecalciferol

Cholecalciferol-based rodenticides have gained popularity over anticoagulant rodenticides because, unlike anticoagulant rodenticides, there is no rodenticide resistance, and there is no secondary toxicity to species that ingest poisoned rodents. Although one manufacturer (Bell Labs) reports the median lethal dose (LD_{50}) to be 88 mg/kg of body weight, toxicity in dogs and cats has been seen with much lower doses (<10 mg/kg). The effect may last for weeks.

Clinical Manifestations

- Clinical signs are vague and related to hypercalcemia (see "Clinical Signs" under "Hypercalcemia").
- Hypercalcemia is often severe (serum total calcium of 15–20 mg/dl; ionized calcium concentration of 1.9–2.5 mmol/L) and accompanied by hyperphosphatemia at initial presentation. Concentration of 25-hydroxyvitamin D_3 is typically elevated.
- Azotemia may occur several days after ingestion secondary to renal damage from hypercalcemia.

Goals of Treatment

- Decrease cholecalciferol absorption in the gastrointestinal tract.
- Correct the fluid and electrolyte imbalances.
- Reduce hypercalcemia.
- Treat miscellaneous complications such as seizures and cardiac arrhythmias.

Treatment

- Feed a low-calcium diet (most renal diets) and restrict intake of dairy products.
- Give phosphate binders that do not contain calcium (e.g., aluminum hydroxide, Amphojel, Wyeth-Ayerst; 10–30 mg/kg q8h PO with meals), to decrease the calcium X phosphorus product.
- In severe cases of hypercalcemia, aggressive treatment with IV fluids, furosemide, prednisone, and/or calcitonin may be necessary for several weeks.
- Recent reports show that intermittent IV pamidronate is effective treatment in dogs and is superior to calcitonin as ancillary treatment for long-term effects.
- Because of the prolonged half-life of 25-hydroxyvitamin D_3, monitor serum calcium, phosphorus, and creatinine weekly for 4 to 6 weeks. If aggressive therapy is maintained for several weeks, complete recovery can be achieved, depending upon the extent of the initial renal injury.

Dovonex Ingestion

- Dovonex is a calcipotriene-containing cream used to treat human psoriasis. This cream contains 50 µg of calcipotriene per gram of cream, and the oral LD_{50} in dogs is reportedly 100 to 150 µg/kg of body weight.
- Calcipotriene has a shorter duration of action than cholecalciferol, so the duration of effect is shorter.
- Measured concentration of 25-hydroxyvitamin D_3 is usually normal since calcipotriene is not detected by this assay.

Iatrogenic Vitamin D Intoxication

- Iatrogenic vitamin D intoxication may occur following the administration of vitamin D products and dietary supplements. Use of ergocalciferol (vitamin D_2) may cause hypercalcemia because its slow onset of action and prolonged duration of action make it difficult to dose correctly.
- Treatment is directed at discontinuing the supplement or decreasing the dose of vitamin D.

Houseplant Ingestion

Houseplants such as *Cestrum diurnum* (day-blooming jessamine), *Solanum malacoxylon,* and *Trisetum flavescens* contain a substance similar to calcitriol that may cause hypercalcemia when ingested.

Granulomatous Diseases

Granulomatous disorders such as systemic fungal diseases and tuberculosis are rare causes of hypercalcemia in dogs possibly due to increased vitamin D metabolites. Serum calcium concentrations return to normal with treatment (e.g., antifungal drugs or surgical removal).

Grape Toxicity

The ingestion of a small quantity of grapes or raisins has reportedly caused hypercalcemia in a few dogs. Clinical signs occurring within hours of ingestion include vomiting, diarrhea, abdominal pain, and lethargy; clinical signs in some dogs last for up to 3 weeks. Acute intrinsic renal failure occurs, and both serum calcium and phosphorus are elevated. Aggressive therapy for up to 3 weeks is required for recovery. If oliguria or anuria is present, prognosis is poor.

Renal Failure

- Chronic renal failure is associated with an increase in serum total calcium possibly due to an increase in complexed calcium. Hypercalcemia may be present in acute renal failure during the polyuric phase of recovery. Serum ionized calcium concentration is typically normal or low, and secondary hyperparathyroidism may be present.
- As kidney function decreases, calcitriol production decreases, allowing serum ionized calcium to drop. The fall in ionized calcium concentration stimulates secretion of PTH to help maintain the ionized calcium concentration within the normal range, primarily via bone resorption. Chronic elevation of PTH characterizes secondary hyperparathyroidism and is maintained by inadequate calcitriol and ionized calcium concentrations within the parathyroid gland nucleus to inhibit genomic transcription of the DNA to mRNA for PTH synthesis.
- In rare cases, as end-stage renal failure is reached, the calcium set-point may be altered, allowing the ionized calcium concentration to be elevated. In this circumstance, PTH concentration is greatly elevated and ionized calcium concentration may show a mild to moderate elevation (tertiary hyperparathyroidism).

Idiopathic Hypercalcemia in Cats

Clinical Signs

A syndrome in a wide age range of cats has emerged, where hypercalcemia occurs without obvious explanation.

- Longhaired cats appear to be affected more frequently, but there is no sex predilection.
- Serum total and ionized calcium concentrations are increased for many months, without any clinical signs in approximately half of reported cases.
- If clinical signs are present, mild weight loss and uroliths (specifically calcium oxalate stones) are common.
- Chronic constipation and inflammatory bowel disease have also been associated with idiopathic hypercalcemia.
- Most are non-azotemic at presentation, but azotemia may develop later.

Diagnosis

The cause of idiopathic hypercalcemia is unknown.

- There is no evidence of malignancy based on radiography, abdominal ultrasonography, or bone marrow evaluation.
- Concentrations of ionized magnesium and serum 25-hydroxyvitamin D_3 are within normal limits; PTH and calcitriol concentrations are normal to low.
- It is conceivable that hypercalcemia develops only in a genetically susceptible population of cats.

Treatment

- An increase in dietary fiber may decrease serum ionized calcium concentration in some affected cats.
- Prednisolone therapy results in long-term decreases in serum calcium concentration in some cats. There is concern that this treatment could increase hypercalciuria, which could subsequently enhance genesis of urinary calculi. However, the filtered load of calcium decreases as serum ionized calcium declines, which offsets the enhanced formation of calculi.
- When dietary modification and prednisolone therapy have been unsuccessful in resolving hypercalcemia, consider bisphosphonate treatment.

Primary Hyperparathyroidism

Primary hyperparathyroidism results from excessive secretion of PTH by abnormal parathyroid glands. This disease is reported sporadically in dogs and is rare in cats. Primary hyperparathyroidism is characterized by persistent and long-standing hypercalcemia.

Etiology

- A solitary parathyroid adenoma is the most common cause of primary hyperparathyroidism.
- Parathyroid carcinomas are infrequent.
- Parathyroid hyperplasia of one or all four parathyroid glands is rare.
  - Gross enlargement of the affected parathyroid gland may not be present.
  - The diagnosis is made based on microscopic abnormalities.
  - Hereditary neonatal parathyroid hyperplasia has been reported in two German shepherd puppies.

Signalment

- Middle-aged or older animals are at risk.
  - Dogs from 5 to 13 years, mean age 10 years
  - Cats from 8 to 15 years, mean age 12.9 years
- There is no sex predilection in dogs; however, there may be an increased risk in female cats.
- Any breed of dog may be affected. Breeds with an increased risk of primary hyperparathyroidism include the keeshond, briard, American Eskimo, English setter, Siberian husky, Rhodesian ridgeback,

Norwegian elkhound, Irish setter, wirehaired fox terrier, English springer spaniel, Australian shepherd, dachshund, Lhasa apso, Shih Tzu, and golden retriever. Dogs with a decreased risk of primary hyperparathyroidism include the cocker spaniel, German shepherd, Shetland sheepdog, Labrador retriever, and miniature schnauzer.
- Several reported cats were Siamese.

Clinical Signs

- Anorexia, lethargy, and depression are the most common signs, but many animals are asymptomatic.
- Polydipsia and polyuria are usually present, and calcium oxalate urolithiasis may be noted.
- Constipation, weakness, shivering, twitching, vomiting, and stiff gait.

Diagnosis

Physical Examination

- In dogs, the physical examination is usually normal.
- In cats, 50% may have palpable cervical masses due to associated cystic changes.

Biochemistry Profile

- Hypercalcemia and normal to low serum phosphorus are the most consistent findings.
- Azotemia may be present in some patients with moderate hypercalcemia.
- If renal failure is present, the serum phosphorus may be normal or above normal.

Urinalysis

- Decreased urine specific gravity is a common finding.

Endocrine Testing

- Determination of PTH concentration is helpful in the diagnosis of primary hyperparathyroidism. An inappropriately elevated concentration of PTH with an elevated ionized calcium concentration is characteristic of primary hyperparathyroidism.
- In dogs, a mid-normal range or higher concentration of PTH is inappropriately elevated in association with hypercalcemia.
- In cats, primary hyperparathyroidism is diagnosed when PTH concentration is elevated above the reference range and ionized hypercalcemia is present.
- There appears to be no benefit to measuring PTH from left and right jugular venous samples for localization of the adenoma.

▼ ***Key Point*** Primary hyperparathyroidism is characterized by elevated serum ionized calcium with lack of appropriate suppression of PTH production.

Hematology

- The hemogram is usually unremarkable.

Radiography

- Radiographs are often normal but may reveal generalized osteopenia, increased bone resorption at the subperiosteal surfaces, and cyst-like areas in bone.
- Urinary stones may also be identified.

Ultrasonography

- Ultrasound may identify the enlarged parathyroid gland and determine whether it is internal or external to the thyroid gland. A high-resolution probe (above 10 MHz) is necessary for adequate visualization of the parathyroid glands.

Exploratory Surgery

- Consider exploratory surgery of the cervical region if no other cause of hypercalcemia can be determined.
- Negative findings may be due to ectopic PTH production (e.g., parathyroid adenoma in the cranial mediastinum or the unlikely event of a nonparathyroid tumor producing PTH).
- Always submit all excised parathyroid gland tissue for histopathology to confirm the diagnosis.

Treatment

- Treatment of primary hyperparathyroidism is typically surgical excision of the parathyroid adenoma (see "Parathyroidectomy" in this chapter). Ablation of the parathyroid gland adenoma by ethanol injections or radiothermy can be considered an alternative in selected cases.
- Hypocalcemia may occur postoperatively, especially if the serum total calcium concentration is >14 mg/dl prior to surgery. Treatment with supplemental calcium or vitamin D metabolites may be required. Hypocalcemia without clinical signs usually does not require treatment unless the total serum calcium is <6 mg/dl (<1.5 mmol/L).
- Postoperative hypocalcemia can be minimized if the patient is treated with calcitriol (7.5 ng/kg q12h) for 7 to 10 days prior to parathyroidectomy. Calcitriol acts to prime the gut for increased calcium absorption.
- If the patient is unstable, treatment with bisphosphonates (see Table 32-4) for 1 to 2 months prior to surgery may decrease the serum calcium concentration, increase the chance for renal healing, and increase the recovery of the atrophied parathyroid glands.

HYPOCALCEMIA

Hypocalcemia is defined as a serum total calcium concentration <8.5 to 9.0 mg/dl (2.12–2.25 mmol/L)

or an ionized calcium concentration <5.0 mg/dl (1.25 mmol/L) in dogs or <4.0 mg/dl (1.00 mmol/L) in cats. Normal serum total calcium may be slightly lower in older animals than in middle-aged animals.

Etiology

Causes of hypocalcemia are listed in Table 32-5. Hypoalbuminemia is the most common cause of a low serum total calcium concentration; however, it is of no clinical consequence because only the protein-bound fraction is affected. A mildly decreased serum calcium without signs of hypocalcemia can be seen in various systemic conditions such as renal failure, pancreatitis, and intestinal malabsorption. Conditions associated with symptomatic hypocalcemia are discussed.

Clinical Signs

The severity of clinical signs may not always be commensurate with the degree of hypocalcemia. Concurrent acid-base disorders, other electrolyte imbalances, and ionized calcium concentration play a role in the development of clinical signs that are often episodic.

- Tremors, twitching, tetany, muscle spasms, facial rubbing, and gait changes (stiffness and ataxia) result from increased neuromuscular excitability. Occasionally, generalized seizure activity is seen.
- Behavior changes (restlessness, aggression, panting, hypersensitivity to stimuli, and disorientation) are frequent.
- Bradycardia, hyperthermia, polyuria, polydipsia, and vomiting are sometimes seen.

Table 32-5. CONDITIONS ASSOCIATED WITH HYPOCALCEMIA

Causes of Severe Symptomatic Hypocalcemia
Puerperal tetany/eclampsia
Hypoparathyroidism
Spontaneous (lymphocytic parathyroiditis)
Iatrogenic secondary to bilateral thyroidectomy
Postoperative secondary to removal of parathyroid adenoma/carcinoma
Phosphate enemas (acute hyperphosphatemia causes reciprocal calcium decrease)
Causes of Mild Asymptomatic Hypocalcemia
Hypoalbuminemia (most frequent cause of hypocalcemia)
Primary renal disease
Chronic renal failure
Acute renal failure (e.g., urethral obstruction, ethylene glycol toxicity)
Pancreatitis
Intestinal malabsorption syndromes
Chelating agents that bind calcium (EDTA, citrates, oxalates, phosphates)
Rhabdomyolysis due to soft tissue trauma
Nutritional secondary hyperparathyroidism
Dilutional with infusion of calcium-free fluids
Laboratory error/artifact
Idiopathic (unexplained)

EDTA, ethylenediaminetetraacetic acid.

Diagnostic Evaluation

History and Physical Examination

- A complete history (including dietary history) and a thorough physical examination can aid in the diagnosis of the underlying cause of the hypocalcemia.

Routine Laboratory Tests

- Evaluation of CBC and serum chemistry profile may aid in the diagnosis of hypocalcemia. Both serum total calcium and ionized calcium concentrations may be decreased; however, in patients with renal failure or hypoproteinemia, ionized calcium may not parallel changes in total calcium. Measurement of serum ionized magnesium concentration may reveal a decreased concentration. Changes in serum phosphorus may support a specific diagnosis.

Endocrine Testing

- Measurement of PTH concentration is helpful in diagnosing hypoparathyroidism. Determination of serum 25-hydroxyvitamin D_3 concentration may also be of benefit to exclude other causes.

Electrocardiography

- Hypocalcemia may cause prolongation of QT interval and ventricular premature contractions on an electrocardiogram (ECG).

Principles of Treating Hypocalcemia

The definitive treatment for hypocalcemia is to eliminate the underlying cause. Specific treatment options for hypocalcemia are listed in Table 32-6.

Parenteral Calcium

Parenteral calcium may be necessary in patients with active tetany, hyperthermia, and seizures.

- Calcium gluconate and calcium chloride usually are given by slow IV administration.
- Signs of toxicity from injection of excess calcium too quickly include bradycardia and shortening of the QT interval.
- Calcium can also be diluted in saline and given as a continuous IV drip to maintain normal serum calcium concentrations.
- Calcium gluconate (even if diluted with saline) should *not* be given subcutaneously due to the occurrence of dermal necrosis and severe granulomatous inflammation.

Table 32-6. TREATMENT OF HYPOCALCEMIA

Drug	Preparation	Calcium Content	Dose	Comment	
Parenteral Calcium*					
Calcium gluconate	10% solution	9.3 mg of Ca/ml	a. Slow IV to effect (0.5–1.5 ml/kg IV)	Stop if bradycardia or shortened QT interval occurs	
			b. 5–15 mg/kg/hr IV	Infusion to maintain normal calcium SQ calcium salts are not recommended; they can cause severe skin necrosis/mineralization	
Calcium chloride	10% solution	27.2 mg of Ca/ml	5–15 mg/kg/hr IV	Only given IV as extremely caustic perivascularly	
***Oral Calcium**†*					
Calcium carbonate	Many sizes	40% tablet	25–50 mg/kg/day	Most common calcium supplement	
Calcium lactate	325-, 650-mg tabs	13% tablet	25–50 mg/kg/day		
Calcium chloride	Powder	27.2%	25–50 mg/kg/day	May cause gastric irritation	
Calcium gluconate	Many sizes	10%	25–50 mg/kg/day		
Vitamin D				***Time for Maximal Effect to Occur:***	***Time for Toxicity Effect to Resolve:***
Vitamin D_2 (ergocalciferol)			Initial: 4000–6000 U/kg/day Maintenance: 1000–2000 U/kg once daily to once weekly	5–21 days	1–18 wks
Dihydrotachysterol			Initial: 20–30 ng/kg/day Maintenance: 10–20 ng/kg q24–48h	1–7 days	1–3 wks
$1,25\text{-}(OH)_2D_3$ (calcitriol)			Initial: 20–30 ng/kg/day for 3–4 days Maintenance: 5–15 ng/kg/day	1–4 days	2–14 days

*Do not mix calcium solution with bicarbonate-containing fluids as precipitation may occur.
†Calculate dose based on elemental calcium content.

Oral Calcium

- Oral calcium supplementation may be beneficial. The daily requirements are 1 to 4 g for dogs and 0.5 to 1.0 g for cats.
- Base the dose of calcium on the amount of elemental calcium in the product.

Vitamin D Metabolites

Vitamin D supplementation increases calcium absorption in the small intestine.

- Calcitriol is the vitamin D compound of choice for chronic maintenance treatment of symptomatic hypocalcemia.
- Several forms of vitamin D are available, and the response and duration of action of these drugs depend on the form used (see Table 32-6).
- Iatrogenic hypercalcemia is a common complication of treatment with cholecalciferol, ergocalciferol, and dihydrotachysterol. Treatment with calcitriol is rarely associated with hypercalcemia.

▼ ***Key Point*** Calcitriol is the vitamin D compound of choice for chronic maintenance treatment of symptomatic hypocalcemia.

Magnesium

- If serum magnesium concentration is decreased, supplemental oral magnesium may be beneficial. Magnesium deficiency may reduce the ability of the parathyroid glands to produce PTH, preventing correction of hypocalcemia. Magnesium deficiency also impairs PTH receptor interactions at peripheral tissues.

CONDITIONS ASSOCIATED WITH HYPOCALCEMIA

Puerperal Tetany (Eclampsia)

Puerperal tetany or eclampsia occurs in lactating bitches and queens as a result of calcium loss into milk and/or poor dietary calcium intake. In non-lactating animals, this condition may be associated with high calcium supplementation resulting in suppression of PTH secretion and increasing calcitonin secretion. These changes decrease the osteoclast pool and the availability of bone calcium.

Clinical Signs

- Small-breed bitches with large litters are most often affected; puerperal tetany is rare in large-breed dogs or larger cats.
- Onset of signs is acute, occurring most often 2 to 4 weeks postpartum when milk production is at its peak. Clinical signs may also occur in the immediate postpartum period during the initial milk letdown.
- Tetany, tremors, twitching, and seizures are common.
- Hyperthermia may occur in severe cases.
- Panting and restlessness may be early signs.

Diagnosis

Diagnosis is made based on history, clinical signs, hypocalcemia (total serum calcium concentration usually <7 mg/dl), and response to treatment.

Treatment

- Immediately give an IV infusion of calcium (slow IV administration to effect, then 5–15 mg/kg/hr of elemental calcium; see Table 32-6).
- Supplement oral calcium (25–50 mg/kg/day of elemental calcium) for the remainder of lactation.
- Supplement vitamin D if serum calcium concentration remains low.
- If tetany recurs during the same lactation, wean the litter from the bitch.

Hypoparathyroidism

The marked hypocalcemia seen in hypoparathyroidism results from a deficiency in PTH production. Hypoparathyroidism in dogs and cats may be spontaneous or iatrogenic.

Etiology

Spontaneous Hypoparathyroidism

Spontaneous hypoparathyroidism occurs uncommonly in dogs and cats. Lymphocytic parathyroiditis and atrophy are the most common causes and presumably are autoimmune. Agenesis occurs very rarely.

Iatrogenic Hypoparathyroidism

Iatrogenic hypoparathyroidism may occur after bilateral thyroidectomy or parathyroidectomy for parathyroid adenoma or carcinoma and hyperplasia due to atrophy of the remaining glands. Normal function of the atrophic glands usually returns in 4 to 6 weeks.

Signalment

- In dogs, the mean age is 6 years, although a wide age range (6 weeks to 12 years) has been reported. In cats, young to middle-aged patients are reported.
- In dogs, more females are affected; however, in cats, more males appear to be affected.
- Primary hypoparathyroidism may occur in any breed, but breeds at increased risk include the standard schnauzer, miniature schnauzer, Scottish terrier, dachshund, and West Highland white terrier. Breeds at decreased risk for development of primary hypoparathyroidism include the Labrador retriever, German shepherd, and the Shih Tzu.

Clinical Signs

- Signs are usually episodic and most often include the following:
  - Nervousness, tremors, and twitching
  - Rigid limb extension, stiff gait, and muscle spasms
- Other signs include the following:
  - Ataxia, panting, and episodic weakness
  - Facial rubbing, biting at the feet, and aggression
  - Polydipsia and polyuria
  - Vomiting and diarrhea
  - Weight loss, anorexia, depression, and listlessness

Physical Examination

- Neuromuscular findings include extensor rigidity, muscle fasciculations, and seizures.
- Cardiac findings include tachycardia, paroxysmal tachyarrhythmias, and weak pulses.
- Ocular findings include small punctate to linear cataracts (reported in a few dogs and cats).

Diagnosis

Biochemistry Profile

- Serum total calcium concentration is usually <6.0 mg/dl (<1.5 mmol/L). Ionized calcium concentration is usually <4.0 mg/dl (<1.0 mmol/L) in dogs and <3.6 mg/dl (<0.9 mmol/L) in cats.
- Hyperphosphatemia is usually present.

Electrocardiography

- Electrocardiogram findings include prolongation of QT and ST segments, deep wide T waves, and tachyarrhythmias.

Endocrine Testing

- Concentrations of PTH are low compared with normal values. Relative PTH concentrations may appear to be within the normal reference range but are inappropriately low in the presence of hypocalcemia.

Biopsy

- Parathyroid biopsy confirms lymphocytic parathyroiditis, but biopsy is not usually necessary.

Treatment of Idiopathic Hypoparathyroidism

- The goal is to restore serum calcium concentration to the low end of the normal range. Avoid

further elevation of serum calcium levels to prevent calcium-induced renal damage from the resulting hypercalciuria.
- If hypocalcemic tetany or seizures are present, immediately administer calcium IV.
- For maintenance of normocalcemia, supplement oral calcium and vitamin D compounds (see Table 32-6). If serum magnesium concentration is also low, magnesium supplementation may be required for adequate maintenance of ionized calcium concentration.
- Hypercalcemia is a common complication of vitamin D therapy, and onset may be delayed and duration may be prolonged depending on the type of vitamin D supplementation used. When starting vitamin D therapy, monitor serum calcium concentrations weekly at first then monthly when serum calcium has stabilized at the desired level. If hypercalcemia does occur as a complication of treatment, manage as discussed previously under "Hypercalcemia." Discontinue calcium supplementation and use vitamin D alone at a lower dosage for maintenance or switch to a more manageable vitamin D metabolite such as calcitriol.

Treatment for Iatrogenic Hypoparathyroidism

- Supplement calcium and vitamin D compounds postoperatively (see Table 32-6). If serum calcium concentrations remain normal, discontinue calcium supplementation and then gradually decrease and finally discontinue vitamin D supplementation. Evaluate serum calcium concentrations weekly for 1 month. If hypocalcemia returns, reinstitute vitamin D and calcium supplementation. Occasionally, permanent supplementation is necessary.

PARATHYROIDECTOMY

Parathyroidectomy is the treatment of choice for primary hyperparathyroidism caused by benign functional adenomas of the parathyroid gland in dogs. Functional adenocarcinomas are very rare. Parathyroidectomy is an infrequent procedure because primary hyperparathyroidism is uncommon in dogs and extremely rare in cats.

Familiarity with normal thyroid and parathyroid anatomy is essential before surgery.

Preoperative Considerations

- Always submit all excised parathyroid gland tissue for histopathology to confirm the diagnosis.
- Ectopic parathyroid gland adenomas are uncommon but may be present in the cranial mediastinum or near the base of the heart.
- If the animal is hypercalcemic, attempt preoperatively to decrease serum calcium levels (see Table 32-3) to reduce risks of anesthesia and surgery if possible.
- To reduce the possibility of postoperative hypercalcemia, treat with calcitriol (see Table 32-6) for 1 to 2 weeks prior to parathyroidectomy.

Surgical Procedure

Objectives

- Explore the thyroid and parathyroid region.
- Remove the parathyroid adenoma.
- Maintain meticulous hemostasis.

Equipment

- Standard general surgical pack and suture
- Self-retaining retractors (e.g., Gelpi)
- Magnifying loop (optional)

Technique

1. Place the dog in dorsal recumbency with the forelimbs tied caudally and the neck hyperextended with a rolled towel.
2. Prepare the ventral cervical region from caudal mandible to manubrium for aseptic surgery.
3. Incise the skin on the ventral midline from larynx to manubrium.
4. Separate the paired sternohyoideus and sternothyroideus muscles.
5. Exploration.
   a. Identify all four parathyroid glands if possible. The non-adenomatous glands are often atrophied and difficult to identify.
   b. Parathyroid adenomas are firm, whitish, solid structures 4 to 20 mm in diameter. They are sometimes more hyperemic than the normal parathyroids.
   c. If an enlarged parathyroid gland is cystic, it is probably not a neoplasm but an incidental congenital cyst.
   d. If a readily identifiable mass is not found in the thyroid area, explore the accessible region along the trachea to the base of the neck and cranial mediastinum.
   e. Avoid injury to the carotid sheath structures and recurrent laryngeal nerves.
6. Dissection of the mass.
   a. Perform complete excision of the mass, using appropriate blunt and sharp dissection. Remove the associated thyroid lobe if necessary to achieve complete resection of the tumor (see Chapter 31).
   b. Carefully examine the surgical field for evidence of residual hemorrhage prior to closure.
7. Routinely close the muscle (simple continuous absorbable suture), subcutaneous tissue (simple continuous absorbable suture), and skin (simple interrupted non-absorbable monofilament suture).

Postoperative Care and Complications

- Monitor for hypothermia, hemorrhage at the incision site, and hypocalcemia.
- Postoperative hypocalcemia.
  - Return of serum calcium concentrations to normal or subnormal values indicates successful parathyroidectomy.

▼ ***Key Point*** Most dogs exhibit hypocalcemia within 48 hours of tumor removal. Suspect severe hypocalcemia in those patients with long-standing hypercalcemia and those in which hypercalcemia preoperatively was not severe.

  - Check serum calcium concentrations 1 and 2 days postoperatively. Frequent evaluation of calcium concentration is indicated if a hypocalcemic trend is noted.
  - Monitor for muscle tremors, excitement, and tetany if calcium concentrations are decreasing.
  - Treat hypocalcemia according to guidelines in the "Hypocalcemia" section of this chapter.
  - Hypocalcemia without clinical signs usually does not require treatment unless the total serum calcium is <6 mg/dl.
- Use weekly evaluation of serum calcium concentrations as the basis for modifying therapy with vitamin D compounds and calcium.
  - Gradually decrease dosages to maintain low-normal serum calcium levels until the atrophied parathyroid glands begin to function normally.
- Hypercalcemia may result from replacement therapy and should be avoided if possible.

Prognosis

The prognosis is good if the tumor is found and excised. Preexisting hypercalcemia-mediated renal dysfunction may be irreversible.

Chapter

33 Diseases of the Adrenal Gland

Peter P. Kintzer / Mark E. Peterson

HYPOADRENOCORTICISM IN DOGS AND CATS

Hypoadrenocorticism is an endocrinopathy characterized by a deficiency of glucocorticoid and/or mineralocorticoid secretion from the adrenal cortex. Spontaneous hypoadrenocorticism is uncommon in dogs and is rare in cats.

Etiology

Primary Adrenocortical Insufficiency

Primary adrenocortical insufficiency (Addison disease) is the result of atrophy or destruction of all layers of the adrenal cortex, usually resulting in glucocorticoid and mineralocorticoid deficiency. Potential causes include the following:

- Idiopathic (probably immune mediated).
- Iatrogenic, which can result from mitotane therapy of hyperadrenocorticism in dogs. Mineralocorticoid concentrations remain normal in most dogs, and the glucocorticoid deficiency is usually transient (weeks to months). However, permanent iatrogenic Addison disease can occur.
- Granulomatous (fungal) adrenalitis, neoplasia, hemorrhage (very rare).

Secondary Hypoadrenocorticism

Secondary hypoadrenocorticism is due to deficient pituitary adrenocorticotropic hormone (ACTH) secretion resulting in inadequate glucocorticoid production, while mineralocorticoid secretion is preserved. Potential causes include the following:

- Abrupt withdrawal of long-term and/or high-dose glucocorticoid administration
- Megestrol acetate (Ovaban, Schering Plough) therapy in cats
- Lesions of the hypothalamus or pituitary gland (e.g., tumors)
- Idiopathic ACTH deficiency (rare)

Signalment

- *Age:* Most dogs and cats are young to middle-aged, but can range in age from 6 months to over 10 years.
- *Breed:* In dogs, any breed can be affected, but Great Danes, Portuguese water dogs, rottweilers, standard poodles, West Highland white terriers, and Wheaton terriers appear to be at an increased risk of developing naturally occurring primary hypoadrenocorticism. No breed predilection has been reported in cats.
- *Sex:* Female dogs are at an increased risk of developing naturally occurring primary hypoadrenocorticism (71% females in one study). No sex predilection has been reported in cats.

Clinical Signs

No historical or clinical finding or set of clinical signs is pathognomonic for hypoadrenocorticism, and most clinical signs occur frequently in various other more common disorders. The severity and duration of clinical signs vary greatly among patients. A high index of suspicion is needed to recognize some cases of hypoadrenocorticism.

Acute Hypoadrenocorticism

- History consistent with chronic hypoadrenocorticism preceding the acute addisonian crisis
- Weakness and depression progressing to collapse
- Slow capillary refill time, weak pulses progressing to hypovolemic shock
- Bradycardia and hypothermia
- Cardiac arrhythmias (secondary to electrolyte abnormalities, acidosis, azotemia, and poor perfusion)

Chronic Hypoadrenocorticism

- Anorexia, vomiting, and diarrhea.
- Muscle weakness, lethargy, and depression.
- Weight loss, dehydration, shaking, polydipsia, polyuria, melena, abdominal pain, and hair loss may be present.
- Waxing and waning course.

- Previous response of clinical signs to administration of fluids and/or glucocorticoids.
- Exacerbation of clinical signs associated with "stress."

Diagnosis

History and Clinical Signs

A high index of suspicion is necessary because both history and clinical signs are nonspecific and seen with many other more common disorders such as the following:

- Gastrointestinal disorders
- Primary renal failure
- Other causes of acute collapse or episodic weakness (cardiovascular disease, neuromuscular disease, and metabolic disorders)

Hemogram

- Absolute eosinophilia and lymphocytosis are present in some cases.
- High hematocrit and total plasma protein may occur secondary to dehydration.
- Mild anemia is present in some cases.

Serum Biochemical and Electrolyte Abnormalities

▼ ***Key Point*** Hyperkalemia and hyponatremia are seen in the vast majority of animals with primary hypoadrenocorticism, but do not rely on these abnormalities for definitive diagnosis as they can also be seen in other more common diseases.

- *Hyperkalemia* and a Na^+/K^+ ratio of less than 27 is present in 95% of cases of primary hypoadrenocorticism.
  - Occasionally, primary hypoadrenocorticism may be associated with normal serum electrolyte concentrations (atypical primary hypoadrenocorticism). Repeated determinations may be necessary to demonstrate the typical electrolyte abnormalities in some animals with primary hypoadrenocorticism.
  - Iatrogenic hypoadrenocorticism caused by mitotane or ketoconazole therapy is usually associated with normal serum electrolyte concentrations.
  - Secondary hypoadrenocorticism is usually associated with normal serum electrolyte concentrations, but hyponatremia can occur.
- *Azotemia* is common (>80%) in primary hypoadrenocorticism and may also occur in secondary hypoadrenocorticism.
- *Hypercalcemia* is seen in 30% of affected dogs and cats, possibly due to decreased renal calcium excretion.
- *Hypoglycemia* (rare) may occur secondary to decreased gluconeogenesis and glycogenolysis.
- *Metabolic acidosis* is not uncommon, especially in an addisonian crisis.

Urine-Specific Gravity

Urine-specific gravity is below 1.030 in over half of cases despite prerenal azotemia. This decreased urine-concentrating ability is probably due to medullary washout secondary to renal sodium wasting and decreased medullary blood flow.

Electrocardiographic Abnormalities

Electrocardiographic (ECG) changes are primarily attributable to hyperkalemia. Although electrocardiography can be of value in estimating the degree of hyperkalemia, these ECG abnormalities may correlate poorly with serum potassium concentrations because of the effects that other serum electrolyte abnormalities, metabolic acidosis, and impaired tissue perfusion have on the cardiac conduction system.

- Widening and flattening of P waves; increased duration of the PR interval
- Increased T wave amplitude
- Decreased amplitude and prolongation of QRS complexes
- Bradycardia
- Sinoatrial standstill (absence of P waves)
- Ventricular premature contractions, atrial fibrillation, and heart block

Radiographic Findings

- Microcardia, microhepatica, and hypoperfusion of lungs (as manifestations of hypovolemia)
- Megaesophagus (rare)

Adrenocorticotropic Hormone Stimulation Test

Definitive diagnosis of hypoadrenocorticism requires demonstration of inadequate adrenal reserve by use of the ACTH stimulation test. This test measures the relative "thickness" of the adrenal cortex.

Intravenous Procedure

- In dogs and cats, obtain a plasma or serum sample for cortisol determination before and 1 hour after IV injection of 5 µg/kg of the synthetic ACTH, cosyntropin (Cortrosyn, Amstar). Once reconstituted, the solution appears to be stable for at least 4 weeks if refrigerated. Alternatively, the remaining solution can be aliquoted and frozen. This method is recommended. Availability and backorder issues, however, may preclude use of this product.

Intramuscular Procedures

- Alternatively, in dogs, obtain a plasma or serum sample for cortisol analysis before and 2 hours after IM injection of 2.2 U/kg of ACTH gel. Acthar Gel (80 U/ml, Questcor Pharmaceuticals) is available but is very expensive. ACTH gel (usually 40 U/ml) is

available from various compounding pharmacies. The bioavailability and reproducibility of these various formulations have *not* been stringently evaluated. Therefore, it may be prudent to assess the activity of each new vial by performing an ACTH stimulation test on a normal dog.
- In cats, obtain a plasma or serum sample for cortisol determination before and 1 and 2 hours after IM injection of 2.2 U/kg of ACTH gel.

Interpretation

- Dogs and cats with hypoadrenocorticism show a blunted or absent cortisol response to ACTH administration.
- *Primary hypoadrenocorticism:* Basal and post-ACTH cortisol concentrations are usually <1 µg/dl (30 nmol/L).
- *Secondary hypoadrenocorticism:* The serum cortisol response to exogenous ACTH is blunted; however, post-ACTH concentrations of cortisol may be as high as 3.0 µg/dl (85 nmol/L) in some cases.
- False elevations of cortisol concentrations may occur after administration of prednisone, prednisolone, cortisone, or fludrocortisone because these cross-react on the cortisol radioimmunoassay. Discontinue these drugs 24 to 48 hours prior to the test.
- Dexamethasone and desoxycorticosterone pivalate (DOCP) do not interfere with the cortisol assay (see "Treatment"); however, dexamethasone is a potent steroid and suppresses the pituitary-adrenal axis.

Plasma Concentration of ACTH

Plasma concentration of ACTH is high (>500 pg/ml) in dogs and cats with primary hypoadrenocorticism and very low or undetectable with secondary hypoadrenocorticism. This assay is available at several diagnostic laboratories. Contact the appropriate laboratory for collection, shipping, and handling instructions (e.g., see www.ahdl.msu.edu for the Diagnostic Laboratory of Michigan State University).

Treatment

▼ ***Key Point*** Collect proper blood and urine samples and perform necessary diagnostic testing before instituting therapy.

The ACTH stimulation test (preferably using synthetic ACTH administered IV) can be performed simultaneously with initial therapy if dexamethasone is used for glucocorticoid replacement because it does not interfere with the cortisol assay. ACTH stimulation testing using ACTH gel should not be performed on dehydrated, hypovolemic, or hypotensive patients, since impaired absorption of the gel may result in erroneous results. Alternatively, testing can be performed after initial stabilization. If prednisone, prednisolone, or hydrocortisone is being administered, these are discontinued and the glucocorticoid supplementation is changed to dexamethasone for at least 24 hours before the ACTH stimulation test is done.

Acute Hypoadrenocorticism

This is a medical emergency requiring immediate intervention.

- Correct hypotension and hypovolemia.
- Improve vascular integrity.
- Provide an immediate source of rapid-acting glucocorticoid.
- Correct electrolyte imbalance and acidosis.
- Following stabilization of the acute addisonian crisis, institute long-term mineralocorticoid and glucocorticoid replacement therapy as described for treatment of chronic hypoadrenocorticism.

Hypovolemia and Hyponatremia

- Infuse 0.9% NaCl solution at a dosage of 60 to 80 ml/kg/hr IV over the first 1 to 2 hours, then gradually reduce the rate to the maintenance requirement, depending on patient response. Monitor urine output. Administer a colloid if necessary to address the hypovolemia and hypotension (uncommon).
- Administer dexamethasone sodium phosphate, 2 to 4 mg/kg IV, or prednisolone sodium succinate, 15 to 20 mg/kg IV. Repeat in 2 to 6 hours as needed. Glucocorticoid supplementation is gradually tapered to a maintenance dose of prednisone (0.2 mg/kg/day) over the following 3 to 5 days as the patient's condition improves.

Hyperkalemia

- Hyperkalemia associated with hypoadrenocorticism can often be successfully treated with parenteral fluid therapy (0.9% NaCl solution) only.
- For severe hyperkalemia causing life-threatening bradyarrhythmias and sinoatrial standstill, more aggressive therapy is indicated. Administer short-acting insulin (e.g., regular insulin) and dextrose IV (first choice), sodium bicarbonate, or calcium salts.
- A rapid-acting parenteral mineralocorticoid formulation is no longer available. However, begin oral supplementation with fludrocortisone (Florinef, Squibb) immediately if the animal is not vomiting.

Acidosis

- Correct mild to moderate acidosis with parenteral fluid therapy (0.9% NaCl solution).
- Treat severe acidosis (pH < 7.1) with serum bicarbonate. Give 25% of the calculated bicarbonate deficit over the first 6 to 8 hours of therapy if the serum bicarbonate concentration is <12 mEq/L. It is unusual for additional bicarbonate administration to be needed.

- Correction of acidosis also drives extracellular potassium into cells, thereby reducing hyperkalemia.

Other Supportive Care as Needed

- Correct hypothermia.
- Treat symptomatic hypoglycemia with a slow IV bolus of 1.5 ml/kg of 50% dextrose and 2.5% to 5% dextrose added to the IV fluids if needed.

Chronic Hypoadrenocorticism

Animals with chronic disease generally do not require aggressive therapy; however, parenteral fluid therapy and parenteral glucocorticoid supplementation may initially be indicated in some cases. Dogs and cats with primary hypoadrenocorticism require lifelong glucocorticoid and mineralocorticoid replacement therapy and sometimes the addition of salt to the diet. Animals with documented secondary hypoadrenocorticism require glucocorticoid replacement only.

Hypovolemia

- Give 0.9% NaCl solution, 60 to 80 ml/kg/day IV, for initial correction of hypovolemia.
- Decrease fluid volume over 48 to 96 hours based on return of clinical and laboratory parameters to normal.

Mineralocorticoid Supplementation

Use one of the following treatment protocols:

- DOCP (Percorten-V, Novartis)
  - DOCP is a long-acting injectable mineralocorticoid; give it initially at 2.2 mg/kg IM or SQ, every 4 weeks. A dosage interval of 3 to 4 weeks is effective in most cases.
  - Percorten-V is approved by the Food and Drug Administration (FDA) for treatment of primary hypoadrenocorticism in dogs.
  - Monitor serum electrolytes, blood urea nitrogen (BUN), and creatinine every 1 to 2 weeks until stabilized in the normal range to ensure an appropriate dose and duration of action; reevaluate every 3 to 6 months during long-term therapy.
  - Less than 10% of dogs require a dose greater than 2.2 mg/kg. Dose less than 2.2 mg/kg may be sufficient in some cases. If financial constraints are present, gradually reduce to the lowest effective dose while monitoring serum electrolyte concentrations.
  - Side effects are rare.
- Fludrocortisone acetate (Florinef, Squibb)
  - Give an initial dosage of 0.01 to 0.02 mg/kg/day PO.
  - Monitor serum electrolytes, BUN, and creatinine every 1 to 2 weeks until stabilized in the normal range, then reevaluate every 3 to 4 months.
  - Adjust dose by 0.05 to 0.1 mg/day based on serum electrolyte concentrations.
  - Average dose to control the disease is 0.02 to 0.03 mg/kg/day; very few animals can be controlled on less than 0.01 mg/kg/day.
  - Side effects include polyuria, polydipsia, polyphagia, and weight gain.
  - Development of side effects, relative resistance to the drug, or financial considerations may necessitate a change to DOCP.

Glucocorticoid Supplementation

Many patients require glucocorticoid supplementation in addition to mineralocorticoid therapy to prevent signs of glucocorticoid deficiency or to control persistent mild azotemia. Use one of the following:

- Prednisone or prednisolone, 0.2 mg/kg/day PO.
- Cortisone acetate, 1 mg/kg/day PO.
- Give 2- to 10-fold higher glucocorticoid doses for brief periods of stress, surgery, or illness.

Sodium Chloride Therapy

- NaCl, 1 to 5 g daily, may be beneficial in some patients to help normalize serum sodium concentration.
- NaCl supplementation may have a sparing effect on the required fludrocortisone dose needed occasionally in dogs.

HYPERADRENOCORTICISM IN DOGS

Spontaneous hyperadrenocorticism (Cushing's syndrome) is a collection of clinical and biochemical abnormalities caused by chronic overproduction of cortisol by the adrenal cortices.

Etiology

Hyperadrenocorticism can be pituitary dependent, secondary to cortisol-secreting adrenocortical neoplasia, or iatrogenic.

Pituitary-Dependent Hyperadrenocorticism

This is the most common cause of naturally occurring hyperadrenocorticism in dogs, accounting for 85% to 90% of cases. The excessive secretion of ACTH from pituitary corticotroph hyperplasia, microadenoma, macroadenoma, or (very rarely) adenocarcinoma results in bilateral adrenocortical hyperplasia.

Cortisol-Secreting Adrenocortical Tumors

These tumors are responsible for approximately 10% to 15% of dogs with spontaneous Cushing's syndrome. About half of adrenocortical tumors are benign and half are malignant.

Iatrogenic Hyperadrenocorticism

Excessive or prolonged administration of corticosteroids can cause iatrogenic hyperadrenocorticism.

- Clinical signs and physical examination findings are similar to those seen in the natural disease.
- Endogenous ACTH production is suppressed, resulting in atrophy of the adrenal cortices.

Signalment

- *Age:* Spontaneous hyperadrenocorticism is primarily a disease of middle-aged to older dogs but can be seen in dogs ranging from 6 months to 20 years of age.
- *Breed:* All breeds can be affected. Poodles, dachshunds, Boston terriers, and boxers appear to be at greater risk of developing pituitary-dependent hyperadrenocorticism. Adrenal tumors are more common in larger dogs (>20 kg).
- *Sex:* No sex predilection is seen in dogs with pituitary-dependent hyperadrenocorticism. In contrast, two-thirds of dogs with adrenal tumors are female.

Clinical Signs

▼ ***Key Point*** Dogs with hyperadrenocorticism usually develop clinical signs that reflect dysfunction of many organ systems, although in some dogs only one or a few clinical signs may predominate.

General Appearance

- Pendulous, distended, or "pot-bellied" abdomen
- Haircoat changes reflecting hair loss
- Muscle atrophy and weakness

Integument

- Hair loss ranging from a thinning of the coat to bilaterally symmetric alopecia
- Thin hypotonic skin susceptible to bruising
- Hyperpigmentation
- Seborrheic changes
- Secondary pyoderma and *Malassezia* dermatitis

Urinary and Reproductive Systems

- Polyuria and polydipsia are seen in up to 90% of dogs with hyperadrenocorticism. Glucocorticoids decrease the renal tubular reabsorption of water by increasing the glomerular filtration rate and renal blood flow and by inhibiting the action of antidiuretic hormone (ADH) at the tubular level.
- Urinary tract infection can occur secondary to the immunosuppressive effects of cortisol excess. The typical signs of pollakiuria, hematuria, and stranguria may be minimal in some dogs as a result of the anti-inflammatory action of cortisol.
- Glomerulopathy and associated proteinuria may occur.
- Testicular atrophy and female infertility (anestrus) can occur secondary to low concentrations of pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) caused by negative feedback from high circulating cortisol concentrations.

Respiratory System

- Excessive panting is quite common and is attributed to decreased pulmonary compliance, respiratory muscle weakness, pulmonary hypertension, or the direct effects of cortisol on the respiratory center.
- Pulmonary thromboembolic disease, a rare complication of hyperadrenocorticism, can cause moderate to severe respiratory distress and sometimes is fatal.

Endocrine System

- Some dogs with hyperadrenocorticism develop diabetes mellitus and the associated clinical signs of polyuria, polydipsia, weight loss, and polyphagia.
- The hallmark of steroid-induced diabetes is the development of insulin resistance, defined clinically as persistent hyperglycemia despite insulin doses of >2.5 U/kg per injection.
- Cortisol antagonizes the actions of insulin by interfering with its action at the cellular level (receptor and postreceptor effects).
- Hypertension may occur.

Central Nervous System and Neuromuscular System

- Lethargy is the most common central nervous system (CNS) disturbance. Lethargy may be associated with high concentrations of ACTH or the effects of excessive cortisol on cerebral enzymes and on neurotransmitter synthesis.
- CNS signs of circling, seizures, behavior change, and depression to obtundation may be caused by the local compressive effects of a large, expanding pituitary tumor.
- Muscle weakness is quite common and results from muscle wasting secondary to the catabolic effects of glucocorticoid excess.

Gastrointestinal System

- Polyphagia is common.
- Hepatomegaly is often detected.
- Pancreatitis secondary to excess cortisol levels is occasionally seen.

Diagnosis

History

Common owner complaints include polyuria and polydipsia, polyphagia, hair loss, weight gain, lethargy, and weakness. Determine recent corticosteroid administration (including eye, ear, and topical preparations).

Physical Examination

Perform a careful examination to determine the clinical signs listed on the previous page.

▼ ***Key Point*** The most important diagnostic procedures for hyperadrenocorticism are a careful and complete history and physical examination.

Routine Laboratory Testing

- The hemogram may reveal a stress leukogram and mild erythrocytosis.
- Up to 80% of dogs with hyperadrenocorticism have high serum alkaline phosphatase activity, composed primarily of the steroid-induced isoenzyme.
- Elevated serum cholesterol concentration is common.
- Increased serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) concentrations are common.
- Mild hyperglycemia is common. Overt diabetes mellitus (glucose >250 mg/dl) occurs in up to 10% of dogs with untreated hyperadrenocorticism.
- Urinalysis often reveals a low specific gravity (<1.020).
- Proteinuria is occasionally seen. A urine protein-to-creatinine ratio >3.0 is usually due to glomerular disease or urinary tract infection.

Radiography

- Hepatomegaly is common.
- Approximately one-third of adrenal tumors are mineralized and, therefore, detectable on abdominal radiographs.
- Mineralization of bronchial walls is an occasional incidental finding.
- Pulmonary metastasis is rarely detected in some dogs with adrenal carcinoma.

Ultrasonography

Ultrasonography is more sensitive than radiography for imaging the adrenal glands and is a recommended part of the workup of all dogs with hyperadrenocorticism. This is a very user-dependent technique.

- Bilateral adrenomegaly is found in most dogs with pituitary-dependent hyperadrenocorticism. The maximal adrenal diameter (thickness) is considered the best indicator of adrenal size (reference value for healthy dogs <7.4 mm); however, this lacks sensitivity and specificity as a definitive test because of overlap in adrenal size among healthy dogs, dogs with non-adrenal disease, and dogs with pituitary-dependent hyperadrenocorticism.
- An adrenal mass is usually readily identified in dogs with adrenal neoplasia. The contralateral adrenal is atrophied and unlikely to be found. Bilateral adrenal tumors are very rare.
- In dogs with adrenal neoplasia, evaluate the liver for metastasis and the caudal vena cava for tumor thrombus.

Computed Tomography and Magnetic Resonance Imaging

- Pituitary tumors >1 cm in diameter (macroadenomas or macroadenocarcinomas) are relatively easy to define with these imaging techniques.
- Pituitary microadenomas may be identified if they are ideally positioned or approach 1 cm in diameter. magnetic resonance imaging (MRI) is more sensitive than computed tomography (CT) for imaging pituitary microadenomas.
- CT and MRI are the most accurate and reliable methods for imaging the adrenal glands, followed by ultrasonography and then radiography. With CT or MRI, the location of the adrenal tumor and evidence of metastasis can be identified in most dogs.

Pituitary-Adrenal Function Tests

Basal Serum Cortisol Concentration

Basal serum (or plasma) cortisol concentrations cannot be used to diagnose hyperadrenocorticism because of significant overlap among dogs with hyperadrenocorticism, dogs with non-adrenal illness, and normal dogs.

Adrenocorticotropic Hormone Stimulation Test

This is an adrenal function test that measures the relative "thickness" of the adrenal cortex. Therefore, the ACTH stimulation test is the best test to differentiate spontaneous from iatrogenic hyperadrenocorticism.

- *Intravenous procedure*
  - Obtain a serum sample for cortisol determination before and 1 hour after IV injection of 5 µg/kg of the synthetic ACTH, cosyntropin (Cortrosyn, Amstar). Once reconstituted, the solution appears to be stable for at least 4 weeks if refrigerated. Alternatively, the remaining solution can be aliquoted and frozen. This method is recommended. Availability and backorder issues, however, may preclude use of this product.
- *Intramuscular procedure*
  - Obtain a serum sample for cortisol analysis before and 2 hours after IM injection of 2.2 U/kg ACTH gel. Acthar Gel (80 U/ml, Questcor Pharmaceuticals) is available but is very expensive. ACTH gel (usually 40 U/ml) is available from various compounding pharmacies. The bioavailability and reproducibility of these various formulations has not been stringently evaluated. Therefore, it may be prudent to assess the activity of each new vial by performing an ACTH stimulation test on a normal dog.

- *Interpretation*
  - Of the dogs with pituitary-dependent hyperadrenocorticism, 75% to 90% demonstrate an exaggerated cortisol response to exogenous ACTH. A post-ACTH cortisol concentration of more than 20 µg/dl (550 nmol/L) is consistent with hyperadrenocorticism.
  - Approximately 50% of dogs with adrenocortical tumors show an exaggerated cortisol response, whereas the remainder have a normal response. Some dogs with adrenal carcinoma have extremely high post-ACTH cortisol concentrations (>50 µg/dl or >1500 nmol/L).
  - Dogs with iatrogenic hyperadrenocorticism have a "blunted" or no response to ACTH administration.

Low-Dose Dexamethasone Suppression Test

This test is also useful for confirming the diagnosis of hyperadrenocorticism. The overall sensitivity of this test is 90% to 95%. In most dogs, this test does not differentiate pituitary-dependent hyperadrenocorticism from cortisol-secreting adrenal neoplasia.

- *Procedure*
  - Collect plasma or serum samples for cortisol determination before and 4 and 8 hours after IV or IM administration of 0.015 mg/kg dexamethasone (Azium, Schering Plough).
- *Interpretation*
  - In normal dogs, serum cortisol concentrations are suppressed below 1 µg/dl (30 nmol/L) by 4 hours after administration of dexamethasone and remain suppressed at 8 hours. In contrast, cortisol concentrations in most dogs with hyperadrenocorticism remain above 1 µg/dl (30 nmol/L) during the 8-hour test period. Some laboratories use a 1.5 µg/dl cutoff for the diagnosis of hyperadrenocorticism and consider the 1.0- to 1.5-µg/dl range a "gray zone."
  - The use of percentage of suppression to diagnose hyperadrenocorticism can be misleading in some cases. We prefer the use of a cutoff value.
  - Approximately 25% of dogs with pituitary-dependent hyperadrenocorticism show a pattern of "escape" from suppression; serum cortisol concentrations fall below 1 µg/dl (30 nmol/L) by 4 hours after administration of dexamethasone and rise above 1 µg/dl (30 nmol/L) by the eighth hour of the test. This pattern is diagnostic for pituitary-dependent hyperadrenocorticism.
  - About 5% of dogs with hyperadrenocorticism will have a normal test result. The test should be repeated in 3 to 6 months if clinical signs of hyperadrenocorticism persist.

Urine Cortisol-to-Creatinine Ratio

This is a convenient screening test for hyperadrenocorticism. A normal value virtually excludes a diagnosis of hyperadrenocorticism. A positive result must be confirmed with an ACTH stimulation test or a low-dose dexamethasone suppression test.

- *Procedure*
  - Submit a single-morning urine sample to the laboratory for measurement of urine cortisol and urine creatinine concentrations. The sample should be collected at home by the owner rather than in the hospital.
- *Interpretation*
  - When urine cortisol is expressed as nmol/L and creatinine is expressed as mmol/L, a ratio >15 is consistent with hyperadrenocorticism in most laboratories.

▼ ***Key Point*** All pituitary-adrenal function tests used to diagnose hyperadrenocorticism commonly show false-positive results in dogs with non-adrenal disease. Whenever possible, pituitary-adrenal function testing should be postponed until the non-adrenal disease has been resolved.

Endogenous Plasma Adrenocorticotropic Hormone Concentration

This test reliably distinguishes pituitary-dependent hyperadrenocorticism from adrenocortical tumors.

- *Procedure*
  - Collect blood in an ethylenediaminetetraacetic acid (EDTA) tube, centrifuge immediately, and remove the plasma. The addition of aprotinin to EDTA tubes allows routine handling of ACTH samples and shipment using cold packs (instead of dry ice). This assay is available at several diagnostic laboratories. Contact the appropriate laboratory for collection, shipping, and handling instructions (e.g., see www.ahdl.msu.edu for the Diagnostic Laboratory of Michigan State University).
- *Interpretation*
  - Dogs with pituitary-dependent hyperadrenocorticism have a normal to high ACTH concentration (>40 pg/ml).
  - Dogs with adrenal tumors have low or undetectable plasma concentration of ACTH (<20 pg/ml).

High-Dose Dexamethasone Suppression Test

This test is used to differentiate dogs with pituitary-dependent hyperadrenocorticism from those with adrenocortical neoplasia. The test is easily performed in practice.

- *Procedure*
  - Collect a serum or plasma sample for cortisol determination before and 4 and 8 hours after IV or IM injection of 0.1 to 1.0 mg/kg of dexamethasone.
  - In dogs with pituitary-dependent hyperadrenocorticism, the degree of cortisol suppression tends to

be greater after administration of the 1.0 mg/kg dose.

- *Interpretation*
  - Dogs with adrenal tumors do not show feedback suppression of cortisol after administration of a high dose of dexamethasone, with serum cortisol concentrations remaining >1.5 µg/dl (>40 nmol/L) during the testing period. Suppression of serum cortisol concentration to <1.5 µg/dl excludes an adrenal tumor.
  - In dogs with pituitary-dependent hyperadrenocorticism, approximately 80% demonstrate suppression of cortisol (<1.5 µg/dl or <40 nmol/L) after administration of a high dose of dexamethasone.
  - The remaining 20% of dogs with pituitary-dependent hyperadrenocorticism fail to demonstrate adequate cortisol suppression (i.e., all cortisol values remain >1.5 µg/dl or >40 nmol/L). Additional testing is necessary to distinguish these dogs from those with an adrenal tumor. Many dogs with non-suppressible pituitary-dependent hyperadrenocorticism have large pituitary tumors.
  - The use of percentage of suppression to differentiate between pituitary- and adrenal-dependent hyperadrenocorticism can be misleading in some cases. We prefer the use of a cutoff value.

Treatment of Pituitary-Dependent Hyperadrenocorticism

Mitotane Therapy

Mitotane (o,p′-DDD; Lysodren, Bristol-Myers Squibb) is the drug most frequently used in the treatment of hyperadrenocorticism in dogs. Mitotane causes selective necrosis of the zona fasciculata and zone reticularis of the adrenal cortex. The administration protocol for mitotane involves an initial induction phase that uses a daily dosage for induction of remission (loading dosage), followed by a maintenance phase that uses a dosage given once or twice weekly (maintenance dosage).

Induction Phase

- The *initial loading dosage* of mitotane is 30 to 50 mg/kg/day, given once daily or divided q12h PO, for 7 to 10 days. Mitotane absorption is enhanced by food (especially fat) and, therefore, should be given with a meal.
- *Concurrent glucocorticoid supplementation* with oral prednisone or prednisolone (0.15–0.25 mg/kg/day, up to a maximum daily dose of 5 mg/day/dog) can be used to mitigate the adverse effects associated with serum cortisol concentrations falling rapidly into the normal or subnormal range during this initial treatment. The major disadvantage of providing glucocorticoid is that it may not be possible to know if overdosage has occurred, since clinical signs of glucocorticoid deficiency may not develop.
- Common side effects during the induction phase of therapy (the loading period) include lethargy, vomiting, anorexia, weakness, and diarrhea. If adverse effects occur during initial therapy, discontinue mitotane and give glucocorticoids until the dog can be evaluated. Monitor the dog's appetite closely during the induction period, and if decreased appetite develops, discontinue mitotane and evaluate by an ACTH stimulation test.
- Monitor therapy with the ACTH stimulation test. Perform this test at the end of the 10-day induction phase or sooner if adverse effects develop.

▼ ***Key Point*** The goal of therapy is to achieve subclinical hypoadrenocorticism, whereby both basal and post-ACTH cortisol concentrations are within the normal basal (or resting) cortisol range (1 to 5 µg/dl or 30 to 150 nmol/L for most laboratories).

- If basal and post-ACTH concentrations fall below the normal basal range (<1 µg/dl or <30 nmol/L), temporarily suspend mitotane administration and supplement glucocorticoids as needed until circulating cortisol concentrations normalize. Cortisol concentrations generally return to the normal range within 2 to 4 weeks but occasionally take several weeks to months.
- If basal or post-ACTH cortisol concentrations are above the normal resting range, continue daily mitotane treatment and repeat ACTH stimulation tests at 5- to 10-day intervals until serum cortisol concentrations fall within the normal resting range.

Maintenance Phase

- When desired cortisol concentrations are documented by ACTH stimulation testing, continue mitotane at a *maintenance dosage* of 40 to 50 mg/kg weekly in two to three divided doses. Lifelong maintenance therapy is needed to maintain remission of the disease.
- If adverse side effects occur during maintenance therapy, discontinue mitotane and supplement glucocorticoids until the dog can be evaluated by serum electrolyte determinations and an ACTH stimulation test. In most dogs with iatrogenic hypoadrenocorticism (but normal serum electrolytes), maintenance mitotane can be resumed 2 to 6 weeks later, when serum cortisol concentrations have returned into the normal resting range. About 20% to 25% of dogs experience side effects, usually mild, at some point during induction or maintenance mitotane therapy.
- Up to 5% of dogs develop iatrogenic hypoadrenocorticism with associated hyponatremia and hyperkalemia. These dogs generally require lifelong supplementation with mineralocorticoids, that is, fludrocortisone acetate or DOCP (see "Hypoadrenocorticism in Dogs and Cats").

- Nearly 50% of dogs with hyperadrenocorticism have a relapse of disease within the first 12 months of maintenance therapy. These cases require reinduction with daily doses of mitotane for 7 to 10 days, followed by a higher maintenance dosage (weekly dosage usually increased 50%).
- To ensure continued control and prevent serious relapse during mitotane treatment, repeat ACTH stimulation testing after 3 and 6 months of maintenance treatment and every 6 months thereafter. Relapse of hyperadrenocorticism can thereby usually be detected before recurrence of clinical signs is evident.

Trilostane Therapy

Trilostane is a synthetic steroid analogue. It competitively inhibits the 3-beta hydroxysteroid dehydrogenase enzyme; thereby blocking cortisol, aldosterone, and sex hormone production. Trilostane is available in the United Kingdom (Vetoryl, Arnolds Veterinary Products). Until an approved product is available in the United States, the manufacturer recommends contacting the FDA for permission to import a 90-day supply for a given patient.

Trilostane is effective in controlling the clinical signs in most dogs with pituitary-dependent hyperadrenocorticism. Reported efficacy is less than or equal to that of mitotane.

Initial Dose

- Give 2 to 12 mg/kg PO with food (the mean starting dose is approximately 6 mg/kg/day).
- Do not use trilostane in animals with renal failure or primary liver disease, lactating animals, or those intended for breeding.

Follow-up Treatment and Monitoring

- Evaluate response to treatment based on resolution of clinical signs of hyperadrenocorticism and results of ACTH stimulation tests.
- Examine the patient and perform an ACTH stimulation test at 10 days, 1 month, 3 months, and every 3 to 6 months thereafter. Evaluate complete blood counts and serum chemistry profiles on a regular basis.
- Perform ACTH stimulation testing 4 to 6 hours after trilostane is administered.
- Increase or decrease the trilostane dosage to achieve pre-ACTH and post-ACTH cortisol concentrations between 1 and 5 µg/dl. During the first 6 months of therapy, at least 50% of dogs can be expected to require a change of dosage (usually an increase).
- Some dogs may need twice-daily administration of trilostane to adequately control clinical signs.
- If the post-ACTH serum cortisol concentration is below 1 µg/dl, discontinue trilostane for 48 to 72 hours and then start again at a lower dose. Perform an ACTH stimulation test in 7 to 10 days.
- If signs of hypoadrenocorticism occur, discontinue trilostane until the dog can be evaluated and ACTH stimulation testing and a chemistry profile (including electrolytes) can be performed. Administer glucocorticoid if necessary.

Adverse Effects

- Trilostane is usually well tolerated. Mild, self-limited adverse effects including lethargy, vomiting, and diarrhea were reported in 63% of dogs in one study.
- Side effects required withdrawal of trilostane in approximately 3% to 4% of dogs.
- Acute death was reported in two dogs a few days after starting trilostane therapy. Other anecdotal reports of acute death have been noted. The exact relationship of trilostane to these deaths is not completely clear at this time.
- One report describes bilateral adrenal necrosis seen on histopathology in two dogs on trilostane.
- Acute hypoadrenocorticism has been reported in two dogs. One of these cases died despite discontinuation of trilostane and appropriate medical intervention.
- Occasional instances of prolonged (up to several months) adrenocortical suppression can be seen in dogs receiving trilostane. It is not clear how an enzyme inhibitor can cause prolonged adrenocortical suppression or acute hypoadrenocorticism.
- Hyperkalemia and/or hyponatremia can be seen in a significant number of dogs at variable times after starting trilostane. These changes are not typically associated with clinical signs of hypoadrenocorticism or altered aldosterone levels.

Ketoconazole Therapy

Ketoconazole (Nizoral, Janssen) reversibly inhibits adrenal steroidogenesis through enzymatic blockade. The major problems of ketoconazole compared with mitotane include its high cost, the necessity for lifelong twice-daily administration, and reported lack of efficacy in some cases (up to 50% in some reports).

- The initial dosage of ketoconazole is 10 mg/kg q12h PO.
- Assess adrenal reserve with an ACTH stimulation test after 7 to 10 days of therapy. The goal of therapy is to achieve subclinical hypoadrenocorticism, whereby both basal and post-ACTH cortisol concentrations are within the normal basal cortisol range (1–5 µg/dl or 25 to 150 nmol/L for most laboratories).
- The dosage of ketoconazole can be increased (up to 20 mg/kg q12h) if necessary.
- Once adequate control is achieved, lifelong twice-daily therapy is required to maintain remission of the hyperadrenocorticism.

- Adverse effects include anorexia, vomiting, diarrhea, lethargy, and idiosyncratic hepatopathy.

L-Deprenyl Therapy

L-deprenyl (selegiline HCl; Anipryl, Pfizer) is a selective, monoamine oxidase type B inhibitor that decreases pituitary ACTH secretion by increasing dopaminergic tone to the hypothalamic-pituitary axis, with a resultant fall in serum cortisol concentrations. Drawbacks of L-deprenyl therapy include low reported efficacy rates, the need for lifelong daily administration, and the expense of the medication.

- Initiate L-deprenyl therapy at a dosage of 1 mg/kg PO daily. If an inadequate response is seen after 2 months of therapy, increase the dosage to 2 mg/kg/day. Should this dose also prove ineffective, use alternative therapy. If effective, continue daily therapy for the remainder of the dog's life.
- The drug is indicated for the treatment of uncomplicated cases of pituitary-dependent hyperadrenocorticism. L-deprenyl is not recommended for treatment in dogs with concurrent diabetes mellitus, pancreatitis, heart failure, renal disease, or other severe illness, and it is not effective for the treatment of cortisol-secreting adrenocortical neoplasia.
- The manufacturer's multicenter trial reported that 75% to 80% of dogs had a good response to therapy as assessed by resolution of clinical signs and monthly low-dose dexamethasone suppression testing. Independent studies have reported efficacy rates of 20% or less.
- The current label recommendation is to evaluate the efficacy of L-deprenyl therapy based solely on resolution of clinical signs of hyperadrenocorticism. It seems prudent, however, to monitor low-dose dexamethasone suppression tests every 4 to 6 weeks to evaluate for normalization (or improvement) of the pituitary-adrenal axis in dogs receiving the drug. The ACTH stimulation test is not indicated for assessing the response to treatment with L-deprenyl.
- Adverse effects such as anorexia, lethargy, vomiting, and diarrhea are uncommon (<5% of dogs) and usually mild.
- Do not administer L-deprenyl concurrently with other monoamine oxidase inhibitors, opioids, or tricyclic antidepressants (e.g., fluoxetine), as significant adverse drug interactions have been reported in humans.

Radiation Therapy for Pituitary-Dependent Hyperadrenocorticism

Radiation therapy may be useful in dogs with hyperadrenocorticism caused by a pituitary macroadenoma or macrocarcinoma.

- Deliver the total dose of radiation in fractions over a period of 4 to 6 weeks. Complications appear to be minimal in most cases.
- The primary prognostic factor is the severity of neurologic signs. Dogs with a pituitary macroadenoma and severe neurologic signs have a grave prognosis.
- The disadvantages of radiation therapy include its high cost, limited availability, and the need for multiple anesthetic episodes.
- Plasma ACTH and serum cortisol concentrations may take weeks to months to normalize. In the interim, medical management of the hyperadrenocorticism may be necessary.

▼ ***Key Point*** Advances in diagnostic imaging (CT and MRI) have enabled the antemortem diagnosis of pituitary macroadenomas. Treatment of pituitary tumors may be attempted with radiotherapy, especially if a diagnosis of macroadenoma can be made before the onset of profound neurologic signs.

Surgical Management of Pituitary-Dependent Hyperadrenocorticism

Hypophysectomy has recently been described in a large series of dogs and has been shown to be a viable and effective treatment for pituitary-dependent hyperadrenocorticism.

- At this writing, the procedure has limited availability in the United States.
- Preoperative advanced imaging studies (preferably MRI) are needed.
- The experience of the surgeon and the provision of intensive 24-hour postoperative care are of vital importance for the success of this procedure.

Adrenocortical Tumors

Surgical Management

See the section on "Adrenalectomy."

Mitotane Therapy

- Mitotane is an effective and relatively safe treatment alternative for most dogs with adrenal tumors. Mitotane therapy has been successful for over 24 months in some dogs with adrenocortical adenomas and carcinomas. In general, higher dosages of mitotane are required than for treatment of dogs with pituitary-dependent hyperadrenocorticism. Only 15% to 20% of dogs with adrenal tumors respond to the standard treatment protocol used in dogs with pituitary-dependent hyperadrenocorticism.

▼ ***Key Point*** In dogs with adrenal tumors, mitotane is used as a true chemotherapeutic agent with the goal of destroying all functional, neoplastic adrenocortical tissue. Therefore, both the serum

basal and the post-ACTH cortisol concentrations should be low to undetectable (<1 µg/dl or <30 nmol/L). The induction of overt hypoadrenocorticism may improve the long-term prognosis, but mitotane toxicity (from the high doses of mitotane needed) prevents this approach in many dogs.

Indications for Mitotane Therapy of Adrenal Tumors

- Gross metastatic disease evident prior to surgery
- Unresectable or incompletely resectable tumor
- Residual disease after adrenalectomy as detected by ACTH stimulation testing
- Unacceptable anesthetic or surgical risks to the patient
- Refusal of surgery by the client

Procedure

- Initiate mitotane therapy at dosage of 50 to 75 mg/kg/day and repeat ACTH stimulation testing every 10 to 14 days to evaluate adrenal reserve. Administer a glucocorticoid (e.g., prednisone or prednisolone, 0.2 mg/kg/day PO) throughout the period of mitotane administration to help prevent adverse effects secondary to hypoadrenocorticism.
- Continue daily mitotane at this dosage or increase it (based on ACTH stimulation test results) until desired cortisol levels are reached or drug intolerance develops. Dogs with adrenal tumors often require a cumulative mitotane induction dose up to 10 times higher than dogs with pituitary-dependent hyperadrenocorticism (due to a longer period of daily mitotane administration).
- Once serum cortisol concentrations are undetectable to low, start maintenance therapy at 75 to 100 mg/kg weekly in divided doses. Continue daily glucocorticoid supplementation. Perform an ACTH stimulation test in 1 month to ensure continued suppression of serum cortisol concentrations.
- Dogs with adrenal tumors typically require higher maintenance dosages of mitotane than dogs with pituitary-dependent hyperadrenocorticism; about 25% need a maintenance dosage >150 mg/kg weekly. Relapses are not uncommon.
- Although not correlated with tumor response in all dogs, cortisol determinations are a practical and relatively reliable means of monitoring therapy. They should be performed 1 month after any change in mitotane dosage and every 3 to 6 months during long-term therapy. Periodic ultrasonographic evaluation is also useful for evaluating tumor response.

Adverse Effects

- Common side effects include anorexia, weakness, vomiting, diarrhea, and lethargy and are seen in up to 60% of cases. Adverse effects may be due to development of hypoadrenocorticism, but in approximately 50% of dogs the side effects appear to result from direct drug toxicity. If adverse reactions occur, stop the drug and evaluate the dog as soon as possible to exclude glucocorticoid and mineralocorticoid deficiency. If direct drug toxicity is occurring, start mitotane again later at a 25% to 50% lower dosage. Reinstitution of the higher maintenance dosage can be attempted later but usually results in recurrence of adverse effects. Complete glucocorticoid and mineralocorticoid deficiency (Addison disease) has been reported in a few cases.

Patient Monitoring

- Mitotane overdosage and underdosage can complicate therapy; long-term monitoring is therefore necessary. Instruct owners to observe for recurrence of symptoms, especially polyuria and polydipsia. Perform an ACTH stimulation test every 3 to 6 months to assess adrenal reserve and to guide mitotane dosage adjustments.

Trilostane Therapy

Trilostane has been used to treat a small number of dogs with adrenal-dependent hyperadrenocorticism with good response in most cases.

- Being an enzyme inhibitor, trilostane provides control of serum cortisol levels but should not affect the underlying neoplastic process. However, there are a few reports of acute hypoadrenocorticism as well as bilateral adrenal necrosis in dogs with pituitary-dependent hyperadrenocorticism receiving trilostane.
- Trilostane is not cytotoxic. Therefore mitotane may be preferable for treatment of malignant adrenocortical tumors.
- Trilostane may be useful for the preoperative control of serum cortisol concentrations and clinical signs in dogs undergoing adrenalectomy.

Prognosis

The prognosis for hyperadrenocorticism is always guarded because of the many complications associated with the disease. Dogs that succumb to such complications usually do so within the first 3 to 6 months after diagnosis. Dogs that survive this period typically die of other geriatric disorders unrelated to hyperadrenocorticism. The average life span after diagnosis is 2 years. Complications include the following:

- Thromboembolism
- Infection
- Hypertension
- Congestive heart failure
- Recurrence of clinical signs

- Progression of CNS signs (expanding pituitary tumor)
- Glomerulopathy
- Pancreatitis

ATYPICAL HYPERADRENOCORTICISM IN DOGS

These dogs have the typical historical, physical examination and routine laboratory findings associated with hyperadrenocorticism but have normal cortisol values after ACTH stimulation and low-dose dexamethasone suppression testing. The adrenal steroid indicator in serum for this disease is 17-hydroxyprogesterone rather than cortisol. Atypical hyperadrenocorticism can be due to pituitary-dependent disease or adrenal tumor.

Diagnosis

Adrenocorticotropic Hormone Stimulation Test

This is an adrenal function test that measures the relative "thickness" of the adrenal cortex.

Intravenous Procedure

- Obtain a serum sample for 17-hydroxyprogesterone determination before and 1 hour after IV injection of 5 µg/kg of the synthetic ACTH, cosyntropin (Cortrosyn, Amstar). Once reconstituted, the solution appears to be stable for at least 4 weeks if refrigerated. Alternatively, the remaining solution can be aliquoted and frozen. This method is recommended. Availability and backorder issues, however, may preclude use of this product.

Intramuscular Procedure

- Obtain a serum sample for 17-hydroxyprogesterone analysis before and 2 hours after IM injection of 2.2 U/kg ACTH gel. Acthar Gel (80 U/ml, Questcor Pharmaceuticals) is available but is very expensive. ACTH gel (usually 40 U/ml) is available from various compounding pharmacies. The bioavailability and reproducibility of these various formulations has not been stringently evaluated. Therefore, it may be prudent to assess the activity of each new vial by performing an ACTH stimulation test on a normal dog.

17-Hydroxyprogesterone Assay

- This adrenal function assay is available at the University of Tennessee's College of Veterinary Medicine Endocrine Diagnostic Lab at www.vet.utk.edu/diagnostic/endocrinology.

Interpretation

- A post-ACTH 17-hydroxyprogesterone concentration >6.5 nmol/L is consistent with atypical hyperadrenocorticism. Dogs with non-adrenal illness can have elevated 17-hydroxyprogesterone levels after ACTH stimulation.

Imaging Studies

- As in cases of "typical" hyperadrenocorticism, radiography, ultrasound, CT, and/or MRI may be helpful in evaluating dogs with atypical hyperadrenocorticism and in differentiating pituitary-dependent from adrenal-dependent cases.

Treatment

- Dogs with pituitary-dependent atypical hyperadrenocorticism can be treated with mitotane or trilostane (see the corresponding sections above). Hypophysectomy is a viable treatment option if available.
- When using mitotane, pre-ACTH and post-ACTH 17-hydroxyprogesterone levels can be used to monitor therapy. Because of the shorter turnaround time, we typically use pre-ACTH and post-ACTH cortisol levels to monitor mitotane therapy. The treatment protocol and desired cortisol levels during therapy are similar to those for dogs with "typical" hyperadrenocorticism (see the previous sections).
- If trilostane is used, 17-hydroxyprogesterone levels cannot usually be used to monitor therapy. Serum concentrations of 17-hydroxyprogesterone appear to be greatly elevated, likely a result of crossreactivity with the assay by 17-hydroxypregnenolone, which is increased by trilostane inhibition of the 3-beta hydroxysteroid enzyme.
- Atypical hyperadrenocorticism caused by an adrenal tumor can be managed with surgical adrenalectomy, mitotane, or trilostane as in cases of "typical" hyperadrenocorticism (see other sections).

HYPERADRENOCORTICISM IN CATS

Etiology

Hyperadrenocorticism in cats can be due to pituitary-dependent disease, adrenocortical neoplasia, or iatrogenic disease. Hyperadrenocorticism is uncommon in cats.

- *Pituitary-dependent hyperadrenocorticism* is the most common cause of the naturally occurring disorder in cats, accounting for 80% of the cases.
- *Cortisol-secreting adrenocortical neoplasia* is present in approximately 20% of cats with spontaneous hyperadrenocorticism. About one-third of adrenal tumors in cats are malignant.
- *Iatrogenic hyperadrenocorticism* can occur in cats, despite the relative resistance of cats to the effects of glucocorticoids when compared with dogs.

Signalment

- *Age:* Spontaneous hyperadrenocorticism is a disease of middle-aged to older cats (range from 5 to 16 years).
- *Breed:* No breed predilection.
- *Sex:* Sixty percent of reported cases have been female.

Clinical Signs

General Appearance

- Pendulous, distended, or "pot-bellied" abdomen
- Bilaterally symmetric alopecia with dull, dry, haircoat and scaling (seborrhea sicca)
- Thin skin
- Muscle atrophy

Endocrine and Urinary System

- *Polyuria, polydipsia,* and *polyphagia.* In contrast to dogs with hyperadrenocorticism, polyuria and polydipsia in affected cats appear to be secondary to concurrent diabetes mellitus in the vast majority of cases.
- Glucose intolerance and insulin resistance are common.

▼ ***Key Point*** The majority of cats (almost 80%) with hyperadrenocorticism have concurrent diabetes mellitus.

Diagnosis

History

Common reported signs include polyuria and polydipsia, pot-bellied appearance, thin skin, bilateral alopecia, lethargy, and weakness. Determine if exogenous glucocorticoids have recently been given.

Physical Examination

Many of the clinical signs listed above may be noted. Other findings may include hepatomegaly, obesity or weight loss, and fragile tearing skin.

Routine Laboratory Testing

- Hyperglycemia and glycosuria are seen in up to 90% of cats.
- Hypercholesterolemia and elevated serum ALT activity are common.
- Leukocytosis, eosinopenia, and lymphopenia may be noted.

▼ ***Key Point*** In contrast to the disease in dogs, elevated serum alkaline phosphatase is *not* a consistent finding in cats with hyperadrenocorticism.

Pituitary-Adrenal Function Tests

Adrenocorticotropic Hormone Stimulation Test

This is a valuable screening test for hyperadrenocorticism in cats.

- *Procedure*
  - Collect a plasma or serum sample before and 60 minutes after IV administration of 5 µg/kg of the synthetic ACTH, cosyntropin (Cortrosyn, Amstar). Once reconstituted, the solution appears to be stable for at least 4 weeks if refrigerated. Alternatively, the remaining solution can be aliquoted and frozen. This method is recommended. Availability and backorder issues, however, may preclude use of this product.
  - Collect a plasma or serum sample for cortisol analysis before and at 60 and 120 minutes after IM injection of 2.2 U/kg ACTH gel. The maximal rise in cortisol concentration occurs at 2 hours in 60% of normal cats, whereas the remaining cats peak at 1 hour after ACTH injection. Acthar Gel (80 U/ml, Questcor Pharmaceuticals) is available but is very expensive. ACTH gel (usually 40 U/ml) is available from various compounding pharmacies. The bioavailability and reproducibility of these various formulations has not been stringently evaluated. Therefore, it may be prudent to assess the activity of each new vial by performing an ACTH stimulation test on a normal cat.
- *Interpretation*
  - Approximately 66% of cats with naturally occurring hyperadrenocorticism show a high-normal or exaggerated cortisol response to exogenous ACTH.
  - Cats with iatrogenic hyperadrenocorticism show a "blunted" or no response to ACTH.
  - The ACTH stimulation test does not differentiate pituitary-dependent hyperadrenocorticism from a functional adrenal tumor.

Low-Dose Dexamethasone Suppression Test

- Suppression of serum cortisol concentration (<1.5 µg/dl or <40 nmol/L) 8 hours after administration of a low dose of dexamethasone (0.01–0.015 mg/kg IV) excludes a diagnosis of hyperadrenocorticism.
- However, cats with non-adrenal illness (e.g., diabetes mellitus) frequently demonstrate inadequate suppression, as do cats with hyperadrenocorticism. Because of these frequent false-positive results (low specificity), this test is not recommended as the sole diagnostic test for hyperadrenocorticism in cats.

High-Dose Dexamethasone Suppression Test

- *Procedure*
  - Collect plasma or serum samples for cortisol analysis before and at 4 and 8 hours after IV administration of 0.1 mg/kg dexamethasone.

- *Interpretation*
  - This test is useful in distinguishing normal cats or cats with non-adrenal disease from cats with hyperadrenocorticism.
  - In contrast to most dogs with pituitary-dependent hyperadrenocorticism, 75% of cats with pituitary-dependent disease fail to show adequate cortisol suppression after high-dose dexamethasone suppression testing.
  - All cats with adrenal-dependent hyperadrenocorticism fail to show adequate cortisol suppression after high-dose dexamethasone suppression testing.
  - Therefore, this test cannot readily distinguish pituitary-dependent hyperadrenocorticism and adrenal tumor in cats.
  - Due to the potential for false-negative results in cats with pituitary-dependent hyperadrenocorticism, do not exclude the diagnosis on the basis of a single normal result, especially if clinical signs or imaging studies support the diagnosis.

▼ ***Key Point*** The low-dose dexamethasone suppression test has not been well standardized in the cat. The high-dose dexamethasone test (0.1 mg/kg IV) appears to be the preferred method of screening for hyperadrenocorticism in cats at this time.

Urine Cortisol-to-Creatinine Ratio

- This may be a useful screening test for hyperadrenocorticism in cats. A normal result makes a diagnosis of hyperadrenocorticism very unlikely.
- As in dogs, a positive test must be interpreted cautiously due to the low specificity of the test, and the diagnosis should be confirmed with an ACTH stimulation or a dexamethasone suppression test.

Plasma Adrenocorticotropic Hormone Concentration

- Endogenous plasma ACTH concentration can be used to distinguish pituitary-dependent hyperadrenocorticism from adrenocortical tumors in cats. Cats with pituitary-dependent hyperadrenocorticism have a normal to high ACTH concentration (>40 pg/ml).
- Cats with cortisol-secreting adrenal tumors have a low plasma concentration of ACTH (<20 pg/ml).
- The feline ACTH assay is available at the Diagnostic Laboratory of Michigan State University, www.ahdl.msu.edu.

Diagnostic Imaging

- *Radiography* has limited value in determining the etiology of hyperadrenocorticism in cats unless an obvious adrenal mass is apparent.
- *Ultrasonography* can be a sensitive means for evaluating the adrenal glands of cats with hyperadrenocorticism. A bilateral adrenal enlargement is seen in most cats with pituitary-dependent hyperadrenocorticism, and a unilateral adrenal mass is seen in almost all cats with adrenal neoplasia.
- *CT and MRI* scans can be useful and sensitive for determining the cause of hyperadrenocorticism; however, they require anesthesia and have limited availability.

Treatment

Medical Treatment

- *Mitotane* (Lysodren, Bristol-Myers Squibb) has been safely administered to cats with hyperadrenocorticism at dosages comparable to those given dogs. However, it has not been effective in controlling the disorder in most reported cases, and some cats tolerate the drug poorly.
- *Ketoconazole* does not reliably decrease serum cortisol concentrations in cats with hyperadrenocorticism. Two of four cats with pituitary-dependent hyperadrenocorticism given 10 to 20 mg/kg daily showed some improvement, whereas two cats with adrenal neoplasia failed to show significant improvement.
- *Metyrapone,* an enzyme inhibitor that blocks adrenal synthesis of glucocorticoids, has been used with mixed results in treating cats with hyperadrenocorticism at dosages ranging from 200 to 500 mg daily. Some cats showed clinical improvement without significant side effects.
- *Trilostane* is another enzyme inhibitor that blocks adrenal synthesis of glucocorticoids. Preliminary reports indicate that trilostane is efficacious in some cats with hyperadrenocorticism.
- *L-deprenyl,* as used for the treatment of dogs with pituitary-dependent hyperadrenocorticism, is not yet established as an effective treatment for cats with hyperadrenocorticism.

Surgical Treatment

- In cats with adrenal tumors, perform unilateral adrenalectomy as the treatment of choice (see under "Adrenalectomy").
- Bilateral adrenalectomy remains, at this writing, a viable and probably the most successful treatment for pituitary-dependent hyperadrenocorticism in cats. Bilateral adrenalectomy requires an experienced surgical team, intensive postoperative care, and lifelong glucocorticoid and mineralocorticoid replacement therapy. Postoperative complications are common, with approximately one-third of cats dying within 1 month of surgery. The 6-month survival rate after bilateral adrenalectomy is approximately 44%.
- Hypophysectomy has recently been reported in a few cats.

Radiation Therapy

Pituitary irradiation has been partially successful in a few cats with pituitary-dependent hyperadrenocorticism. It is the treatment of choice in cats with large pituitary tumors. Concurrent medical management may be necessary for a few to several months. Drawbacks include the high cost, limited availability, and need for multiple anesthetic episodes.

▼ ***Key Point*** Adrenalectomy appears to be the most successful means of treating hyperadrenocorticism in cats. To date, medical therapy has not been consistently successful.

PHEOCHROMOCYTOMA

Etiology

Pheochromocytoma is a rare catecholamine-producing neuroectodermal tumor derived from chromaffin cells of the adrenal medulla. About half of reported pheochromocytomas in dogs have been malignant. Reported metastatic sites include lungs, liver, bone, kidney, and lymph nodes. Concurrent pheochromocytoma and adrenocortical neoplasia has been reported.

Signalment

- Pheochromocytoma generally occurs in older dogs.
- There is no breed or sex predilection.

Clinical Signs

▼ ***Key Point*** Most pheochromocytomas are not detected antemortem and are incidental findings at necropsy because of vague, episodic clinical signs.

- Clinical signs develop either as a result of the space-occupying nature of the adrenal tumor and its metastasis or as a result of excessive secretion of catecholamines with resultant systemic hypertension and other manifestations.
- Weakness, lethargy, anorexia, vomiting, weight loss, polyuria, polydipsia, restlessness, and excessive panting are the most frequent signs, but these occur in less than 50% of affected dogs.
- Other less common signs may include diarrhea, cough, dyspnea, hind leg edema, abdominal distention, acute blindness, epistaxis, anxiety, shaking, ataxia, seizures, cyanosis, pacing, and adipsia.
- Duration of signs varies from days to years.
- An abdominal mass can be palpated in about 10% of dogs with pheochromocytoma.
- Routine laboratory findings are usually not helpful.
- ECG abnormalities may include sinus tachycardia, arrhythmias, and evidence of cardiac chamber enlargement.

Diagnosis

History, Physical Examination, and Routine Laboratory Testing

- History and clinical findings are typically vague and nonspecific (e.g., lethargy and tachypnea).

Radiography and Other Imaging

- Abdominal radiographs reveal a cranial abdominal mass in the region of the adrenal gland in up to one-third of dogs with pheochromocytoma. Ten percent of tumors show evidence of mineralization.
- Specialized imaging techniques such as ultrasonography, CT, and MRI are more sensitive than radiography and are very useful for detecting and staging pheochromocytomas.
- Echocardiography may demonstrate left ventricular hypertrophy.

Arterial Blood Pressure

Up to 50% of dogs with pheochromocytoma are hypertensive. Catecholamine secretion, and therefore hypertension, tends to be episodic.

Biochemical and Pharmacologic Tests

Measurement of urinary and resting plasma catecholamine concentrations, the clonidine suppression test, and the phentolamine test can be used to demonstrate excessive production of catecholamines (epinephrine and norepinephrine) or their metabolites. Unfortunately, the limited availability, technical difficulty, and expense of these tests severely limit routine use of these in veterinary medicine.

▼ ***Key Point*** The antemortem diagnosis of pheochromocytoma in dogs usually depends on surgical exploration and biopsy.

Treatment

- Adrenalectomy is the treatment of choice for pheochromocytoma (see following discussion under “Adrenalectomy”).
- Medical therapy is indicated preoperatively (to control hypertension and to help prevent cardiac arrhythmias before and during surgery), as well as for long-term treatment of patients with inoperable and incompletely resected tumors.
- Treat severe hypertension with phenoxybenzamine (0.2–1.5 mg/kg q12h PO) or prazosin (0.5–2.0 mg/kg q12h PO).
- Administer beta blockers such as propranolol or atenolol if necessary to control tachycardia or arrhythmias, but do not use these without concurrent alpha blockade.

- Chemotherapy and radiation therapy have been employed in humans with pheochromocytoma, but the efficacy of these modalities has not been established in dogs or cats.

ADRENALECTOMY

Adrenalectomy usually is performed for treatment of adrenal tumors and hyperadrenocorticism in the dog and cat. Unilateral adrenalectomy is done primarily for removal of adrenal neoplasia (adenoma, adenocarcinoma, or pheochromocytoma). Bilateral adrenalectomy is less commonly used for bilateral adrenocortical hyperplasia. The anatomy and surgical and medical management for adrenalectomy is the same in the dog and cat. Adrenalectomy is performed infrequently in cats owing to the low incidence of hyperadrenocorticism and adrenal neoplasia.

Surgical Anatomy of the Adrenal Gland

- The adrenal glands are paired, flattened, bilobed glands located retroperitoneally and craniomedial to the kidneys (Fig. 33-1).
- The right adrenal gland lies near the level of the last thoracic to the first lumbar vertebrae.
- The capsule of the right adrenal gland may be contiguous with the tunica externa of the caudal vena cava.
- The left adrenal gland is slightly caudal to the right and is separated from the caudal vena cava by a layer of fat.

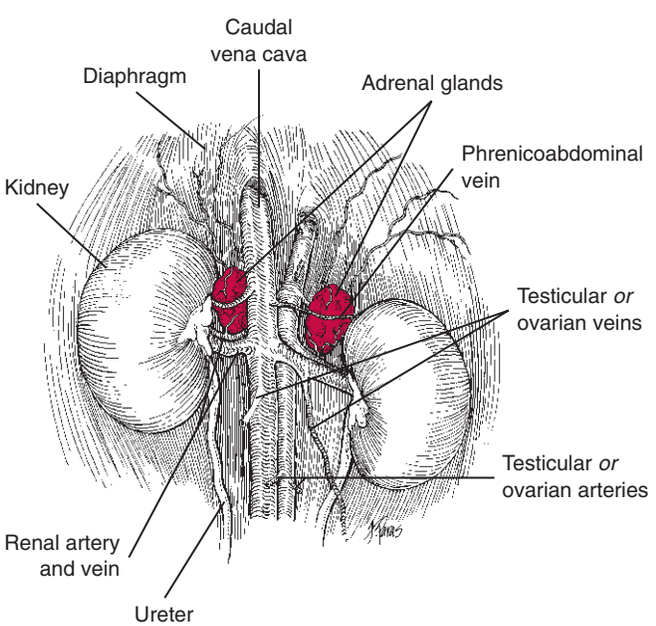

Figure 33-1. Anatomy of the adrenal glands from the ventral midline abdominal approach.

- Adrenal size is breed dependent. In dogs, the average size is 22 mm long, 10 mm wide, and 4 mm thick.
- The adrenal glands are well vascularized by branches of the renal, accessory renal, phrenic, cranial abdominal, phrenicoabdominal, and lumbar arteries.
- Venous drainage is through the left and right adrenal and the phrenicoabdominal veins.
- The phrenicoabdominal artery crosses the dorsal surface of the adrenal glands; the phrenicoabdominal vein courses across the ventral surface. These paired vessels are the largest supplying the adrenal glands.

Preoperative Considerations

- Obtain a minimum database consisting of complete blood count, serum chemistry profile, and thoracic radiographs.
- Abdominal radiographs may help localize a unilateral adrenal mass, especially if the tumor is mineralized.
- Ultrasonography and CT scan are also very helpful in identifying a mass and determining if invasion of the vena cava has occurred.
- Correct any fluid and electrolyte abnormalities.
- Treat arrhythmias and hypertension that may accompany pheochromocytoma (see the next section).
- Surgical removal of large adrenal tumors can be technically challenging, and postoperative intensive care may be necessary. Consider referral to a surgical specialist.

Anesthesia and Perioperative Care

For Hyperadrenocorticism

- Induce and maintain anesthesia following standard procedures.
- Sevoflurane and isoflurane are preferred over halothane, as there is less sensitization of the myocardium to catecholamines.
- Administer a broad-spectrum bactericidal antibiotic by IV bolus 30 minutes before surgery. Administer isotonic fluids an appropriate rate during and after surgery.
- Supplement corticosteroids in the form of dexamethasone (0.1–0.2 mg/kg IV) immediately before the onset of surgery, at the completion of the surgical procedure, and then every 6 to 8 hours during the immediate postoperative period (24–48 hours).

For Pheochromocytoma

- Avoid premedication with atropine because of the potential for severe tachycardia.

▼ ***Key Point*** Dogs with pheochromocytoma produce high circulating concentrations of the catecholamines epinephrine and norepinephrine, which may cause severe hypertension or profound cardiac arrhythmias.

- Induce anesthesia with propofol (3–5 mg/kg) or oxymorphone (0.1–0.3 mg/kg IV) and glycopyrrolate.
- Sevoflurane is the inhalant agent of choice for dogs with pheochromocytoma.
- Administer isoflurane (rather than halothane) if sevoflurane is not available.
- Administer fluids and antibiotics as for hyperadrenocorticism.
- Closely monitor the blood pressure and electrocardiogram.
- To manage ventricular arrhythmias, give either lidocaine (1 mg/kg IV) or propranolol (0.1–0.3 mg/kg IV).
- Treat hypertensive episodes with phentolamine (alpha blocker) (0.02–0.1 mg/kg IV), repeated as needed.
- Manage hypotension with vigorous IV fluid administration.

Surgical Procedure

Objectives

- Handle tissue gently, especially tumor tissue.

▼ ***Key Point*** Surgical handling of a pheochromocytoma may precipitate catecholamine release and hypertension. Profound hypotension may rapidly occur following tumor removal.

- Use meticulous hemostasis to minimize blood loss.
- Avoid trauma to the caudal vena cava.
- Close the linea alba with a non-absorbable suture material.

▼ ***Key Point*** Animals with hyperadrenocorticism are prone to delayed healing and incisional infection because of cortisol inhibition of fibroblast proliferation and collagen synthesis.

Equipment

- Standard general surgical pack and suture
- Balfour retractors
- Malleable retractors
- Bipolar cautery
- Sterile cotton-tipped applicator sticks
- Hemostatic clips
- Gelfoam

Technique

1. Make a ventral midline abdominal incision, extending from the xiphoid to about 2 cm caudal to the umbilicus. This may be combined with a paracostal incision if necessary (Fig. 33-2).
   a. Alternatively, use a retroperitoneal approach (Fig. 33-3). This provides good exposure of the ipsilateral gland but must be performed bilaterally if bilateral adrenalectomy is required.

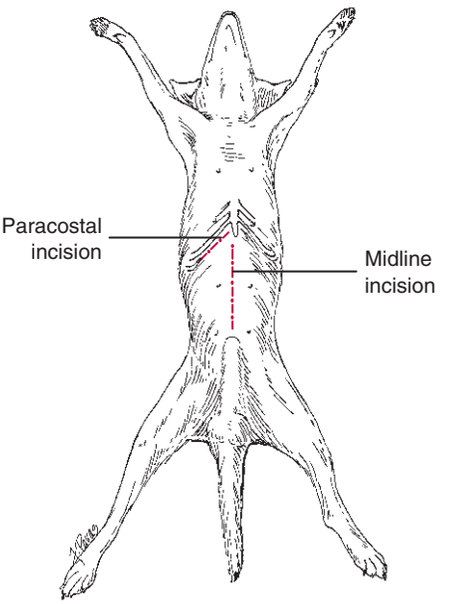

Figure 33-2. Incision for the ventral midline approach may be extended paracostally for better exposure of the adrenal gland.

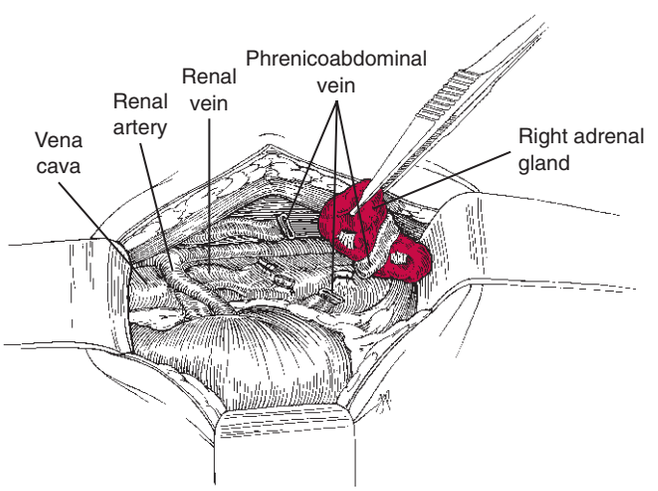

Figure 33-3. Surgical anatomy of the right adrenal gland and its associated vascular structures as viewed from the retroperitoneal approach.

2. Expose the affected gland(s) and isolate with moistened laparotomy sponges.
3. Perform gentle dissection with cotton-tipped applicator sticks, especially when separating the gland from the vena cava.
4. Ligate the phrenicoabdominal artery and vein and any other vascular structures serving the adrenal gland. Hemostatic vascular clips are very helpful for this.

▼ ***Key Point*** Identify and preserve the renal artery and vein, which may lie close to the adrenal glands.

5. Completely resect all abnormal tissue, including the adrenal capsule, and the tumor thrombus in the vena cava if possible.
6. Prior to closure, carefully check the surgical field for hemorrhage. Use Gelfoam to control minor bleeding from the site.
7. Inspect the abdominal viscera, especially the liver, for metastatic disease, and biopsy any suspicious lesions.
8. Perform a routine, three-layer abdominal closure using non-absorbable suture material (e.g., polypropylene) to close the linea alba.

Postoperative Care

Unilateral Adrenalectomy for Adrenocortical Tumor

- Supplement glucocorticoids starting at 24 to 48 hours after surgery with prednisone (0.5 mg/kg q12h PO for 3 days, then taper the dosage over 10–14 days to 0.2 mg/kg q24h PO) until the contralateral adrenal gland is functioning normally.
- Perform an ACTH stimulation test on the first postoperative day and at 2- to 4-week intervals following surgery until the adrenal reserve normalizes.
- The remaining adrenal gland usually functions normally within 2 months following surgery.

Unilateral Adrenalectomy for Pheochromocytoma

Function of the contralateral gland is not suppressed; therefore, there is no need for postoperative glucocorticoid or mineralocorticoid supplementation.

Bilateral Adrenalectomy

- Supplement glucocorticoids (prednisone, 0.2 mg/kg q24h PO).
- Supplement mineralocorticoid (fludrocortisone acetate or DOCP) as described in the preceding section on hypoadrenocorticism.
- Check serum electrolytes periodically to adjust the dosages of mineralocorticoid replacement therapy.

Complications

Complications may include the following:

- Hemorrhage
- Cardiac arrest and/or arrhythmias
- Fluid and electrolyte abnormalities
- Pulmonary artery thrombosis
- Pancreatitis
- Acute renal failure
- Pneumonia
- Adrenal insufficiency

Prognosis

Unilateral Adrenocortical Tumor

- Good if the tumor is benign
- Fair if the tumor is malignant but completely resected
- Extremely poor for invasive adenocarcinoma

Unilateral Pheochromocytoma

- Excellent prognosis for a benign tumor.
- About 50% of pheochromocytomas are malignant and metastatic at the time of surgery, indicating a grave prognosis.

Bilateral Adrenal Hyperplasia

- Fair to good prognosis; however, medical therapy is preferred over surgery for this lesion in dogs.
- Metastatic disease is not a problem; however, regulating the iatrogenic hypoadrenocorticism created by bilateral adrenalectomy may be difficult.

Chapter 34

Diabetes Mellitus

Deborah S. Greco

ETIOLOGY

Type 1 Diabetes Mellitus

- Insulin-dependent diabetes mellitus (IDDM), also referred to as type 1 diabetes, is a diabetic state in which endogenous insulin secretion is never sufficient to prevent ketone production.
- Insulin secretion may be reduced or absent, and the diabetic state is readily corrected by exogenous insulin.

Type 2 Diabetes Mellitus

- Non–insulin-dependent diabetes mellitus (NIDDM), also referred to as type 2 diabetes, is a diabetic state in which insulin secretion is usually sufficient to prevent ketosis but not enough to prevent hyperglycemia.
- Insulin secretion may be high, low, or normal but is insufficient to overcome insulin resistance in peripheral tissues.
- The metabolic hallmarks of type 2 diabetes are impaired insulin secretion, increased hepatic glucose output, and insulin resistance (Fig. 34-1).
- In cats and in humans with type 2 diabetes, insulin secretion secondary to a glucose load is impaired. The early phase of insulin secretion is delayed or absent, and the second phase of insulin secretion is delayed but exaggerated.
- Amyloid deposition in the pancreatic islets may be the cause of impaired insulin secretion in cats.
- Obesity is a risk factor in type 2 diabetes because it causes insulin resistance.

▼ ***Key Point*** Most dogs suffer from type 1 diabetes, or IDDM. Most cats probably suffer from type 2 diabetes (NIDDM); however, by the time a diagnosis of diabetes is confirmed in many cats with NIDDM, they have become insulin dependent.

Type 3 Diabetes Mellitus

- Type 3, or secondary, diabetes mellitus is the result of another primary disease or drug therapy that produces insulin resistance (e.g., hyperadrenocorticism, hyperthyroidism, acromegaly, or progestational drugs) or destroys pancreatic tissue (pancreatitis). Secondary diabetes is common in both dogs (pancreatitis) and cats (drugs, endocrinopathies, pancreatitis).

PATHOPHYSIOLOGY

Uncomplicated Diabetes Mellitus

- In animals with uncomplicated diabetes mellitus, hyperglycemia results from impaired glucose utilization, increased gluconeogenesis, and increased hepatic glycogenolysis.
- Decreased peripheral utilization of glucose leads to hyperglycemia followed by osmotic diuresis. This causes the classic clinical signs of polyuria with compensatory polydipsia and progressive dehydration.
- Impaired glucose utilization by the hypothalamic satiety center combined with loss of calories in the form of glycosuria results in polyphagia and weight loss, respectively.
- Insulin is anabolic; therefore, insulin deficiency leads to protein catabolism and contributes to weight loss and muscle atrophy.
- As a consequence of protein catabolism, amino acids are used by the liver to promote gluconeogenesis and contribute to hyperglycemia.
- With insulin deficiency, the hormone-sensitive lipase system, which is normally suppressed by insulin, becomes activated. The unrestrained lipolytic activity of hormone-sensitive lipase contributes to weight loss in a previously obese or overweight animal.

Complicated (Ketoacidotic) Diabetes Mellitus

▼ ***Key Point*** Diabetic ketoacidosis (DKA) is the culmination of IDDM that results in unrestrained ketone body formation in the liver, metabolic acidosis, severe dehydration, shock, and possibly death.

- With time, uncomplicated diabetes mellitus may progress to complicated or ketoacidotic diabetes. In these animals, insulin deficiency causes abnormal lipid metabolism in the liver such that non-esterified

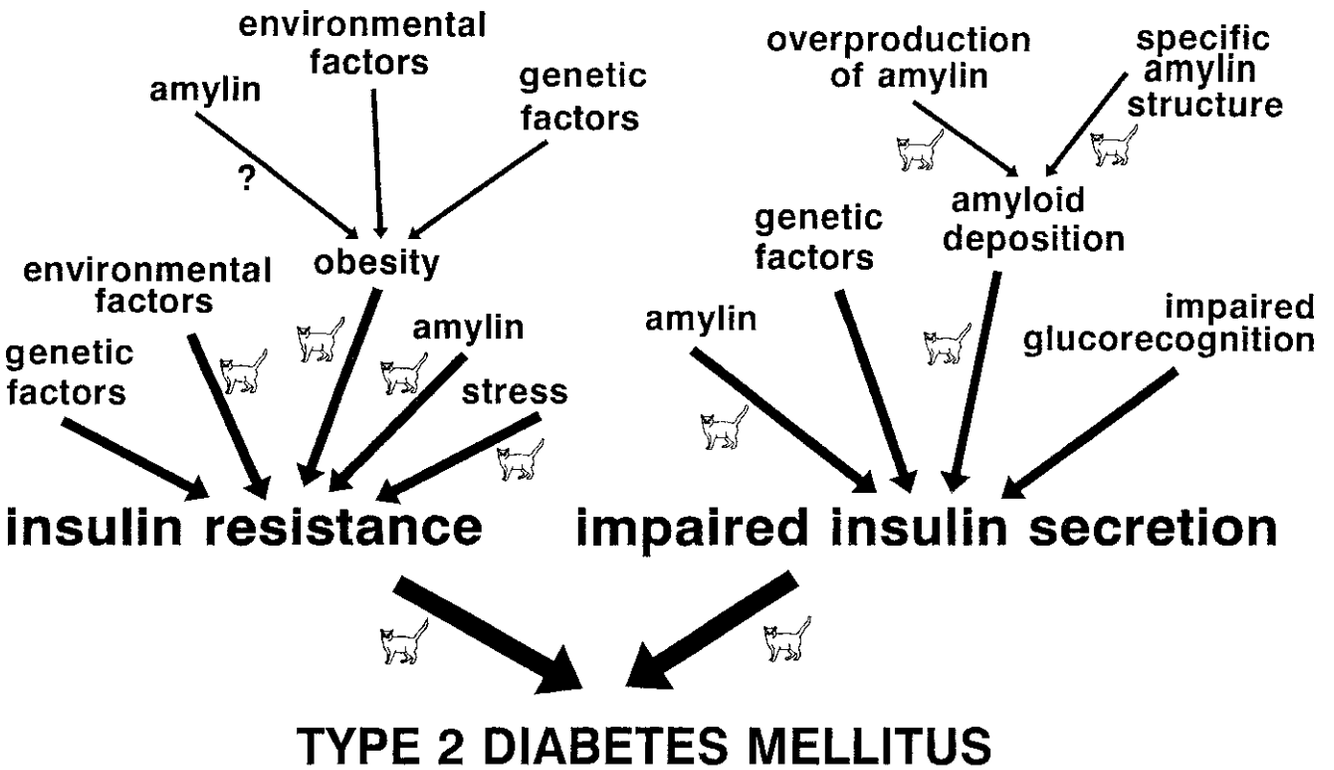

Figure 34-1. Summary of the pathophysiologic factors contributing to hyperglycemia in non–insulin-dependent (type 2) diabetes mellitus. (From Lutz TA, Rand JS: Pathogenesis of feline diabetes mellitus. Vet Clin North Am Small Anim Pract 25:544, 1995; with permission.)

fatty acids are converted to acetyl coenzyme A (acetyl-CoA) rather than being incorporated into triglycerides.

- Acetyl-CoA accumulates in the liver and is converted into acetoacetyl-CoA and then ultimately to acetoacetic acid. Finally, the liver starts to generate ketones including acetoacetic acid, beta-hydroxybutyrate, and acetone.
- As insulin deficiency culminates in DKA, accumulation of ketones and lactic acid in the blood and loss of electrolytes and water in the urine results in profound dehydration, hypovolemia, metabolic acidosis, and shock.
  - Ketonuria and osmotic diuresis caused by glycosuria result in sodium and potassium loss in the urine and exacerbation of hypovolemia and dehydration.
  - Nausea, anorexia, and vomiting, caused by stimulation of the chemoreceptor trigger zone via ketonemia and hyperglycemia, contribute to the dehydration caused by osmotic diuresis.
  - Dehydration and shock lead to prerenal azotemia and a decline in the glomerular filtration rate. This declining rate leads to further accumulation of glucose and ketones in the blood.
- Stress hormones such as cortisol and epinephrine contribute to the hyperglycemia in a vicious cycle.
- Eventually, severe dehydration may result in hyperviscosity, thromboembolism, severe metabolic acidosis, renal failure, and finally death.

CLINICAL SIGNS

Uncomplicated Diabetes Mellitus

- Most diabetic animals have the classic clinical signs of polyuria and polydipsia.
- Weight loss is more common in dogs than in cats.
- Acute onset of blindness caused by bilateral cataract formation is a common presenting complaint of diabetes mellitus in dogs.
- Cats may present with chronic complications of diabetes, such as diabetic neuropathy leading to gait abnormalities, plantigrade stance, difficulty jumping, and inappropriate elimination. Chronic gastrointestinal signs such as vomiting, diarrhea, and anorexia may also result from concurrent pancreatitis or from autonomic neuropathy.

Complicated (Ketoacidotic) Diabetes Mellitus

- Depression, vomiting, anorexia, and weakness are the most common clinical signs of ketoacidosis in dogs and cats.
- Animals with DKA often present in shock.
- Physical examination findings may include depression, tachypnea, dehydration, weakness, vomiting, and occasionally, a strong acetone odor on the breath.
- Cats may present recumbent or comatose, which may be a manifestation of severe ketoacidosis or mixed ketotic hyperosmolar syndrome.
- Approximately one-third of diabetic cats with ketosis exhibit icterus at presentation. Icterus may be a result of associated hemolysis, hepatic lipidosis, or acute pancreatitis.

DIAGNOSIS

Base the diagnosis of diabetes mellitus on typical clinical signs and evidence of fasting hyperglycemia and glycosuria.

Clinicopathologic Findings in Uncomplicated Diabetes Mellitus

- Fasting hyperglycemia
- Hypercholesterolemia
- High serum activity of liver enzymes (alkaline phosphatase, alanine aminotransferase)
- Glycosuria

Clinicopathologic Findings in Diabetic Ketoacidosis

Findings in DKA may include all of the above findings plus the following:

- Azotemia
- Hyponatremia
- Hyperkalemia
- Ketonemia and ketonuria

Diagnostic Pitfalls

- With regard to fasting hyperglycemia, many cats are susceptible to "stress-induced" hyperglycemia in which the serum glucose concentrations may approach 300 to 400 mg/dl.
- Renal glycosuria may be found in animals with renal tubular disease and occasionally with stress-induced hyperglycemia.
- It may be difficult to differentiate early type 2 diabetes in cats from stress-induced hyperglycemia, because cats with early NIDDM are often asymptomatic.

Glycosylated Proteins

Glycosylated proteins, such as glycosylated hemoglobin and fructosamine, may aid in the diagnosis of early type 2 diabetes in cats.

Glycosylated Hemoglobin

- Glycosylated hemoglobin is formed by an irreversible, non-enzymatic binding of glucose to hemoglobin. As plasma glucose concentrations increase, hemoglobin glycosylation increases proportionately.

Fructosamine

- Serum fructosamine is formed by glycosylation of serum protein such as albumin. The concentration of fructosamine in serum is directly related to blood glucose concentration.
- Serum fructosamine measurement may be beneficial in differentiating early or subclinical diabetes mellitus in the cat from stress-induced hyperglycemia.

TREATMENT OF DIABETIC KETOACIDOSIS

Treatment of DKA, as outlined in Table 34-1, includes the following steps in order of importance:

1. Fluid therapy using 0.9% saline initially, followed by 2.5% or 5% dextrose as serum glucose declines
2. Insulin therapy (low-dose IM or IV)
3. Electrolyte supplementation (potassium, phosphorus, magnesium)
4. Treatment of metabolic acidosis

Fluid Therapy

- Use 0.9% NaCl supplemented with potassium as the fluid therapy of choice when insulin therapy is initiated (see Table 34-1).
- Administer fluid therapy using a large central venous catheter, as animals in DKA are severely dehydrated and require rapid fluid administration; central venous pressure may also be monitored via a jugular catheter to avoid overhydration.
- Base the fluid administration rate on the severity of dehydration, maintenance requirements, continuing losses (vomiting and diarrhea), and the presence of concurrent disease (e.g., congestive heart failure; see Chapter 5).

Insulin Therapy

Initiate insulin therapy as soon as possible using either IV insulin or low-dose IM methods. Administer IV insulin via a separate peripheral catheter using the guidelines in Table 34-1.

- The species of origin of regular insulin (beef, pork, or human) does not affect response; however, the type of insulin given is very important. Use only

Table 34-1. STEPWISE TREATMENT OF DIABETIC KETOACIDOSIS

Step One: Fluids

a. Place an IV catheter, preferably central venous.
b. Fluid rate: Estimate dehydration deficit (%) × body weight (kg) × 1000 ml = no. of ml to rehydrate.
Estimate maintenance needs: 2 ml/kg/hr × no. of hr required to rehydrate (in 24 hr).
Estimate losses (vomiting, diarrhea).
Dehydration deficit + maintenance + losses = no. of ml of fluid/24 hr = hourly fluid rate
c. Fluid composition

Blood Glucose (mg/dl)	Fluids	Rate	Route	Monitor	Frequency
>250	0.9% saline	Up to 45 (cat) and 90 (dog) ml/kg/hr to rehydrate	IV	PCV, TS, Na, K, osmolality	q4h
200–250	0.45% saline plus 2.5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	PCV, TS, Na, K, osmolality	q4h
150–200	0.45% saline plus 2.5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	CVP, urine output	q2h
100–150	0.45% saline plus 2.5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	CVP, urine output	q2h
<100	0.45% saline plus 5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	CVP, urine output	q2h

Step Two: Insulin

Intravenous (regular only), mixed in 250 ml of 0.9% NaCl; discard 50 ml through IV tubing.

Blood Glucose (mg/dl)	Rate	Route	Dose (u/kg)	Monitor	Frequency
Intravenous (Regular Only)					
>250	10 ml/hr	IV	1.1 (cats), 2.2 (dogs)	Blood glucose	q1–2h
200–250	7 ml/hr	IV	1.1 (cats), 2.2 (dogs)	Blood glucose	q1–2h
150–200	5 ml/hr	IV	1.1 (cats), 2.2 (dogs)	Blood glucose	q1h
100–150	5 ml/hr	IV	1.1 (cats), 2.2 (dogs)	Blood glucose	q1h
<100	Stop IV, begin insulin q4h	SC	0.1	Blood glucose	q4h
Intramuscular (Regular Only)					
>250	Initial dose	IM	0.2	Blood glucose	Hourly
	q1h	IM	0.1	Blood glucose	Hourly
<250	q4–6h	IM	0.1	Blood glucose	q4–6h
	q6–8h	SC	0.1–0.4	Blood glucose	q6–8h

Step Three: Electrolytes

Concentration	Amount (mEq/L) Added to 1 L of Fluids	Maximum Rate (ml/kg/hr)
Potassium (mEq/L)		
3.6–5.0	20	26
2.6–3.5	40	12
2.1–2.5	60	9
<2.0	80	7
Phosphorus (mg/dl)		
1–2	0.03 mmol phosphate/kg/hr	Monitor serum phosphorus q6h
<1.0	0.1 mmol phosphate/kg/hr	Monitor serum phosphorus q6h
Magnesium (mg/dl)		
<1.2	0.75–1 mEq/kg/day constant rate infusion; use MgCl or $MgSO_4$	Use 5% dextrose: magnesium is incompatible with calcium-containing and $NaHCO_3$ solutions

Step Four: Acid-Base Balance

pH	Bicarbonate Concentration	Dose of Bicarbonate (ml)	Rate
<7.1	<12 mEq/L	IV = 0.1 × body weight (kg) × (4 − HCO_3 [mEq/L])	Over 2 hr

CVP, central venous pressure; IM, intramuscular; IV, intravenous; PCV, packed cell volume; SC, subcutaneous; TS, total solids.
From Greco DS: Endocrine pancreatic emergencies. Comp Cont Educ Pract 19:23, 1997; with permission.

regular insulin because it has a rapid onset and short duration of action and it can be given IV. Never give Lente, Ultralente, or NPH insulin IV.
- Dilute regular insulin at a dosage of 2.2 U/kg in dogs or 1.1 U/kg in cats in 250 ml of saline.
- Allow approximately 50 ml of fluid and insulin mixture to flow through the IV drip set and discard it, because insulin binds to the plastic tubing.
- With IV insulin administration, blood glucose decreases to below 250 mg/dl by approximately 10 hours in dogs and after about 16 hours in cats.
- Once euglycemia has been achieved, maintain the animal on SC regular insulin (0.1–0.4 U/kg q4–6h SC) until it starts to eat and/or the ketosis has resolved.
- For the transition from hospital to home maintenance insulin therapy, use a low dose (1–2 U) of regular insulin combined with intermediate- or long-acting maintenance insulin at the recommended dosages (see "Treatment of Uncomplicated Diabetes").

Electrolyte Supplementation

Potassium

- Supplement potassium as soon as insulin therapy is initiated (see Table 34-1).
- Although serum potassium may be normal or elevated in ketoacidosis, the animal actually suffers from total body depletion of potassium. Correction of the metabolic acidosis tends to drive potassium intracellularly in exchange for hydrogen ions. Insulin facilitates this exchange, and the net effect is a dramatic decrease in serum potassium, which must be attenuated with appropriate potassium supplementation in fluids.

Magnesium

- Refractory hypokalemia may be complicated by hypomagnesemia. Supplementation of magnesium along with potassium as outlined in Table 34-1 may be indicated in cats or dogs with hypokalemia that are unresponsive to potassium chloride supplementation in fluids.

Phosphorus

- Serum and tissue phosphorus may also be depleted during a ketoacidotic crisis; thus, supplement one-third of the potassium dose as potassium phosphate (see Table 34-1), particularly in small dogs and cats that are most susceptible to hemolysis caused by hypophosphatemia.
- Use caution, as oversupplementation of phosphorus can result in metastatic calcification and hypocalcemia.

▼ ***Key Point*** In cats suffering from ketoacidosis, hemolysis may be caused by hypophosphatemia and/or Heinz body anemia.

Bicarbonate Therapy

- Bicarbonate therapy may be necessary in some patients with blood pH <7.1 or if serum HCO_3 is less than 12 mEq/L.
- Bicarbonate dosages are given in Table 34-1. Use caution, because metabolic alkalosis may be difficult to reverse.

TREATMENT OF UNCOMPLICATED DIABETES

Insulin Therapy

Insulin Source (Species of Origin)

- *Human recombinant insulin* is the most available insulin preparation on the market and is perfectly acceptable as insulin therapy for all dogs and most cats.
- *Porcine insulin* is identical to canine insulin in its amino acid structure, and human insulin is very similar to canine insulin.
- *Beef insulin* is most similar to cat insulin, differing by only one amino acid in the A chain.

Insulin Preparations (Duration of Action)

Insulin preparations may be short-acting (regular insulin), intermediate-acting (Lente, NPH), or long-acting (Ultralente, protamine zinc insulin [PZI]).

NPH and Protamine Zinc Insulin

- NPH insulin and PZI are made by adding protamine in increasing concentrations to retard insulin absorption.
- PZI was discontinued as a human preparation in 1991 but is available as a veterinary preparation (PZI VET, IDEXX Pharmaceuticals).

Semilente, Lente, and Ultralente

- Lente preparations control absorption by regulating the size of the insulin crystals.
- Semilente is composed of small zinc-insulin crystals, and Ultralente is composed of large zinc-insulin crystals that are more slowly absorbed.
- Lente insulin is a mixture of 30% prompt zinc-insulin suspension (Semilente) and 70% extended zinc-insulin (Ultralente).
- Lente insulin, because of the small zinc-insulin crystal component, may be used to attenuate postprandial hyperglycemia.

Synthetic Insulins

- Lispro insulin
- Glargine insulin

Insulin Concentration

- Insulin is commercially available in 40, 100, and 500 units per milliliter concentrations, which are designated U-40, U-100, and U-500, respectively. One unit of insulin is approximately equivalent to 36 µg. PZI is manufactured in U-40 concentration only.
- Regardless of the concentration of insulin used for therapy, it is absolutely essential that owners purchase the appropriate syringe for the concentration of insulin. U-100 insulin syringes are manufactured in low-dose (0.3 ml, 0.5 ml) and 1-ml capacities; U-40 syringes are available only in 1-ml capacity.
- In cats and small dogs (<10 kg), use low-dose (0.3 or 0.5 ml) syringes. These syringes are designed to accurately draw up a small dosage of U-100 insulin without the need for dilution.
- All insulin syringes are packaged with a 27-, 29-, or 31-gauge injection needle.

Insulin Dosage (Table 34-2)

- Intermediate-acting insulin tends to be more bioavailable and, therefore, more potent. For this reason, dose intermediate-acting insulin (NPH, Lente) at the lower end of the range.
- In dogs, if intermediate-acting insulin is administered twice daily, use an initial dosage of 0.4 to 0.5 U/kg q12h SC (see Table 34-2).
- In cats, use an initial insulin dosage range of 0.2 to 0.5 U/kg for intermediate-acting insulin (NPH, Lente). NPH twice daily is preferred in cats over Lente insulin.
- PZI is available as a beef-pork product. Ultralente is available only as human recombinant insulin. Use an initial dosage range of 0.5 to 0.7 U/kg once or twice daily for long-acting insulin such as PZI or Ultralente.

Frequency of Insulin Administration (see Table 34-2)

- To mimic the physiologic release of insulin, ideally insulin should be given with each meal. Feed the animal and inject the insulin at the same time. Table 34-3 lists the fiber and caloric content of various pet foods.
- If the animal does not eat, reduce the insulin dosage (usually by one-half) or skip the insulin entirely and determine the cause of the anorexia.

Adjusting Insulin Dose

- In dogs, make adjustments to insulin dosage in increments of 0.5 to 3 U/dog (depending on the size of the dog).
- In cats, make adjustments to insulin dosage in increments of 0.5 to 1 U/cat.
- Once adequate insulin therapy has been established, reassess diabetic control every 3 to 6 months as described in the following section.

Monitoring Insulin Therapy

Home Monitoring

- Instruct the client to monitor the insulin effect and overall control of hyperglycemia by noting changes in appetite, attitude, body condition, poly-

Table 34-2. INITIAL INSULIN REGIMENS FOR DIABETIC DOGS AND CATS

Insulin Type	Initial Dose	Frequency of Dosing	Feeding Schedule	Insulin Adjustment	Frequency of Adjustment
Dogs					
Lente Humulin-L (Lilly), Novolin-L (Novo Nordisk)	0.5 U/kg	q12h	q12h	0.5–3 U/dog	q5–7d
NPH Humulin-N (Lilly), Novolin-N (Novo Nordisk)	0.5 U/kg	q12h	q12h	0.5–3 U/dog	q5–7d
Ultralente Humulin-U (Lilly)	0.7 U/kg	q24h	$^2/_3$ morning; $^1/_3$ evening	1–4 U/dog	q5–7d
Cats					
NPH NPH (Novo Nordisk)	0.2–0.5 U/kg	q12h	Throughout day	0.5 U/cat	q5–7d
Lente Humulin-L (Lilly), Novolin-L (Novo Nordisk)	0.2–0.5 U/kg	q12h	Throughout day	0.5–1 U/cat	q5–7d
Ultralente Humulin-U (Lilly)	1–3 U/cat	q12–24h	Throughout day	0.5 U/cat	q5–7d
Protamine zinc insulin Protamine analine zinc (Anthony)	1–3 U/cat	q24h	Throughout day	0.5 U/cat	q5–7d

dipsia, polyuria, and urine glucose and ketone concentrations.

- Initially monitor urine glucose and ketones daily (morning). Urine glucose should decrease to trace or 1+ with appropriate therapy. Decrease urine monitoring to once weekly or biweekly in well-regulated diabetic animals.
- Consistently high urine glucose readings coupled with uncontrolled clinical signs, such as polyuria or polydipsia, indicate that the insulin dose may be inadequate.
- Consistently negative readings on urine glucose may indicate that insulin dosages are either adequate or excessive.
- In dogs, collect urine with a long-handled cup holding device (males) or a flat pie tin (females). Collect cat urine by placing a small amount of litter in the pan, by placing plastic wrap over litter, or by using a non-absorbent litter substitute (e.g., aquarium gravel).

Blood Glucose Curves

Evaluate insulin therapy once weekly for the first month and as needed thereafter by serial blood glucose curves (blood glucose, 100–250 mg/dl), assessment of body weight, and resolution of clinical signs.

Procedure for Blood Glucose Curve

1. Collect initial blood sample.
2. Feed usual amount and type of food.
3. Feed and give insulin at the usual time.
4. Watch the owner administer the insulin.
5. Assess the owner's injection technique.
6. Collect serial blood samples at 2-hour intervals for 12 hours.

Ideal Blood Glucose Curve

The ideal blood glucose curve is characterized by three features (Fig. 34-2): the glucose nadir, the timing of the nadir, and the glucose differential.

- The ideal blood glucose curve has a glucose nadir (lowest blood glucose concentration on the curve) between 100 and 120 mg/dl.
- The time of the glucose nadir indicates peak insulin action. The nadir should occur approximately halfway through the dosing interval. For example, if insulin is being given every 12 hours, the nadir should occur 5 to 6 hours after the dose.
- The glucose differential is the difference between the glucose nadir and the blood glucose concentration prior to the next insulin dose.
  - Aim for a glucose differential of <100 mg/dl in dogs without cataracts and <150 mg/dl in dogs with cataracts.
  - Cats generally have a higher glucose differential; however, aim for <200 to 250 mg/dl.
- The duration of insulin action is related to both the time of the glucose nadir and the absolute concentration of the glucose nadir. Insulin duration cannot be determined unless the target glucose nadir concentration (80–120 mg/dl) has been achieved. If the glucose nadir occurs approximately halfway through the dosing interval, the duration of action of insulin should be adequate.

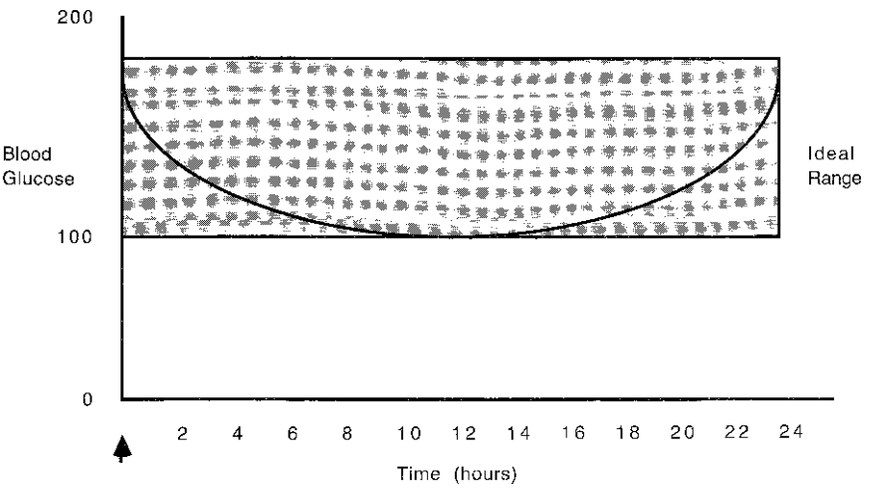

Figure 34-2. Ideal blood glucose curve for an animal on once-daily insulin therapy (*arrow* indicates insulin injection). (From Miller E: Long-term monitoring of the diabetic dog and cat: Clinical signs, serial blood glucose determinations, urine glucose, and glycated blood proteins. Vet Clin North Am Small Anim Pract 25:573, 1995; with permission.)

Problems Identified on the Blood Glucose Curve

It is rare to obtain a perfect glucose curve. Several possible outcomes of blood glucose monitoring are illustrated in Figure 34-3. Generally, blood glucose curve problems can be differentiated by the characteristics of the curve and the insulin dosage (per dosing interval).

- If the patient is receiving >2.2 U/kg of insulin per dose, evaluate for causes of insulin resistance or antagonism, such as hyperthyroidism, hyperadrenocorticism, acromegaly, estrus, drug therapy, and infections. The approach to insulin resistance is outlined in Tables 34-4 for cats and 34-5 for dogs.
- If the animal is receiving <2.2 U/kg of insulin per dose, the blood glucose curve may indicate one of the following (see Fig. 34-3):
  - Insufficient dosage of insulin. Corrective action—Increase the insulin dose.
  - Short duration of action of insulin. Corrective action—Change to a longer-acting insulin or twice-daily insulin regimen.

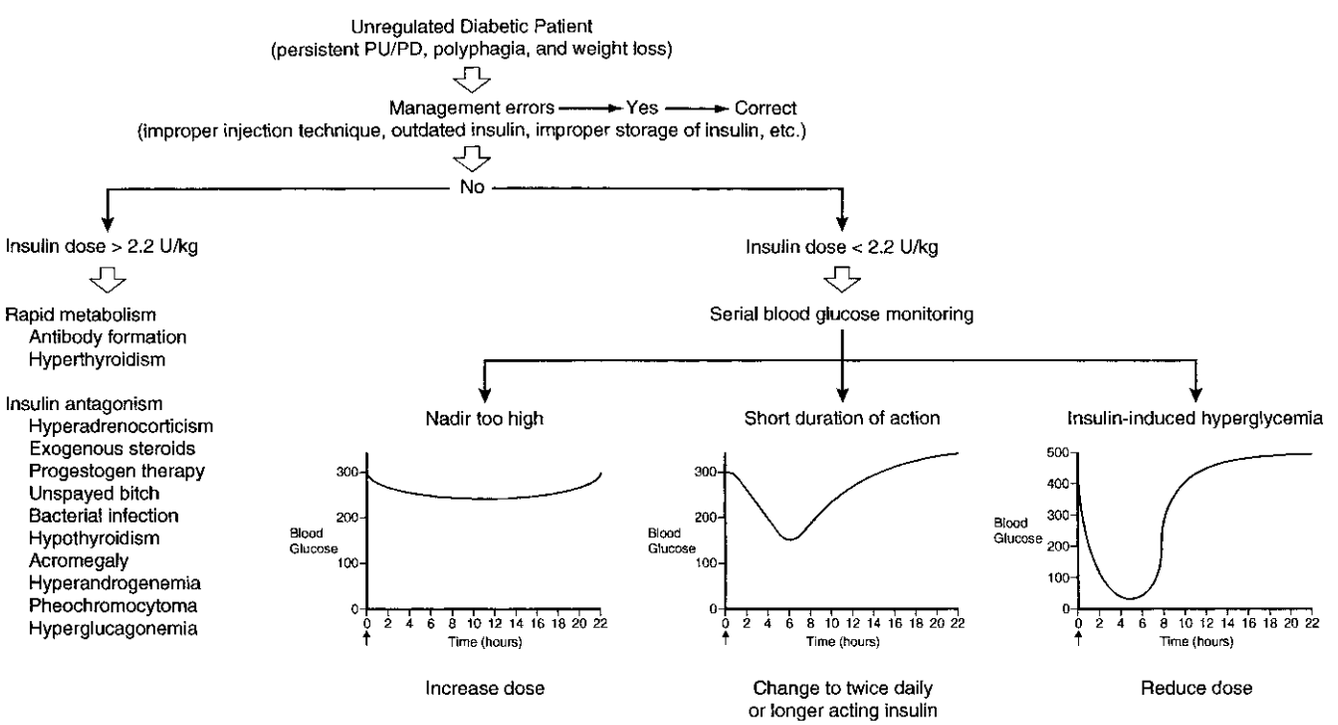

Figure 34-3. Algorithm for the unregulated diabetic dog or cat. (From Miller E: Long-term monitoring of the diabetic dog and cat: Clinical signs, serial blood glucose determinations, urine glucose, and glycated blood proteins. Vet Clin North Am Small Anim Pract 25:582, 1995; with permission.)

Table 34-4. STEPS FOR THE DIAGNOSIS AND TREATMENT OF INSULIN RESISTANCE IN CATS

Steps	Causes of Insulin Resistance	Procedure or Test	Treatment
Step 1	Glucocorticoids or megestrol acetate administration	History	Discontinue use of drugs
Step 2	Obesity	Physical examination, weight	Diet change (low calorie, high fiber)
Step 3	Poor absorption of subcutaneous insulin (long-acting preparation)	Evaluate response to change in insulin type; evaluate serum glucose response to regular insulin administered IV or IM	Change from long-acting insulin to insulin with shorter duration of action; use insulin mixtures (e.g., NPH/regular)
Step 4	Infection, ketoacidosis, or concurrent disease	CBC; serum chemistry profile; urinalysis; urine culture; radiographs; abdominal ultrasound	Appropriate antibiotics; correct ketoacidosis or underlying illness
Step 5	Hyperthyroidism	Serum T_4 concentration	Antithyroid drugs; thyroidectomy; radioiodine
Step 6	Cushing syndrome	Review clinical signs and physical examination; ACTH stimulation and dexamethasone suppression tests; CT scan	Adrenalectomy, pituitary (cobalt) radiation therapy
Step 7	Acromegaly	Review clinical signs and physical examination; CT scan; measure serum insulin-like growth factor concentration	Pituitary (cobalt) radiation therapy
Step 8	Insulin antibodies	Measure serum insulin concentration 24 hr after last insulin injection; insulin antibody titers (not widely available)	Switch to human insulin (or beef insulin, if available)
Step 9	Clinically undefined insulin resistance	All of the above procedures and tests	Raise insulin dose; change to insulin with shorter duration of action; mix NPH/regular insulin

ACTH, adrenocorticotropic hormone; CBC, complete blood count; CT, computed tomography; IM, intramuscularly; IV, intravenously; T_4, thyroxine.
From Peterson ME: Diagnosis and management of insulin resistance in dogs and cats with diabetes mellitus. Vet Clin North Am Small Anim Pract 25:705, 1995.

Table 34-5. STEPS FOR THE DIAGNOSIS AND TREATMENT OF INSULIN RESISTANCE IN DOGS

Steps	Causes of Insulin Resistance	Procedure or Test	Treatment
Step 1	Glucocorticoids or megestrol acetate administration	History	Discontinue use of drugs
Step 2	Diestrus/acromegaly	History (intact female; last estrus); serum progesterone concentration	Ovariohysterectomy
Step 3	Obesity	Physical examination, weight	Diet change (low calorie, high fiber)
Step 4	Poor absorption of subcutaneous insulin (long-acting preparation)	Evaluate response to change in insulin type; evaluate serum glucose response to regular insulin administered IV or IM	Change to insulin with shorter duration of action; use insulin mixtures (NPH/regular)
Step 5	Infection, ketoacidosis, or concurrent disease	CBC; serum chemistry profile; urinalysis; urine culture, radiographs; abdominal ultrasound	Appropriate antibiotics; correct ketoacidosis or underlying illness
Step 6	Cushing syndrome	Review clinical signs and physical examination; ACTH stimulation and dexamethasone suppression tests; CT scan	Mitotane; pituitary (cobalt) radiation therapy; unilateral adrenalectomy for adrenal tumor
Step 7	Hyperlipidemia	Review signalment (Schnauzer); measure serum cholesterol and triglycerides	Low-fat diet; lipid drugs
Step 8	Hypothyroidism	Serum T_4 free T_4, and cTSH concentrations	Thyroid hormone (L-thyroxine) replacement therapy
Step 9	Insulin antibodies	Measure serum insulin concentration 24 hr after last insulin injection; insulin antibody titers (not widely available)	Switch to human or pork insulin
Step 10	Clinically undefined insulin resistance	All of the above procedures and tests	Raise insulin dose; change to insulin with shorter duration of action; mix NPH/regular insulin

ACTH, adrenocorticotropic hormone; CBC, complete blood count; CT, computed tomography; cTSH, canine thyroid-stimulating hormone; IM, intramuscularly; IV, intravenously; T_4, thyroxine; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone.
From Peterson ME: Diagnosis and management of insulin resistance in dogs and cats with diabetes mellitus. Vet Clin North Am Small Anim Pract 25:706, 1995.

  - Insulin-induced hypoglycemic hyperglycemia (Somogyi effect). Corrective action—Reduce insulin dose by 25%.
  - Insulin overlap. Corrective action—Change to a shorter-duration insulin.
  - Prolonged insulin action. Corrective action—Change to an insulin mixture of 30% regular and 70% NPH.
- Causes of hyperglycemia and hypoglycemia in diabetic dogs and cats are listed in Table 34-6.

Fructosamine and Glycosylated Hemoglobin

Monitor long-term insulin therapy by serum fructosamine or glycosylated hemoglobin concentrations. These glycosylated blood proteins are indicative of mean glucose concentrations in serum over an extended period of time.

- Glycosylated blood proteins are particularly useful for monitoring diabetic cats that may be stressed by hospitalization and venipunctures for serial blood glucose curves.
- As plasma glucose concentrations increase, hemoglobin glycosylation increases proportionately. Similarly, serum fructosamine is formed by glycosylation of serum protein such as albumin; thus, serum concentration of fructosamine is also directly related to blood glucose concentration.
- Because of the shorter life span of albumin compared with hemoglobin, fructosamine concentrations reflect more recent (1–3 weeks) changes in serum glucose concentrations.
- In general, fructosamine and glycosylated hemoglobin concentrations that lie within reference range limits indicate good to excellent diabetic control, whereas slightly increased levels indicate fair to good control and very high levels indicate poor glycemic control. Relative changes in serum concentrations may be more helpful than absolute values in some cases.

Table 34-6. CAUSES OF HYPERGLYCEMIA AND HYPOGLYCEMIA IN DIABETIC DOGS AND CATS

Causes of Hyperglycemia in Diabetic Cats and Dogs
Insufficient insulin dosage
Insufficient duration of insulin action
Outdated, inactive insulin
Owner administration problems
Overfeeding
Stress
Insulin resistance caused by Cushing syndrome, infections, drugs, thyroid, disease, pancreatitis, acromegaly
Causes of Hypoglycemia in Diabetic Cats and Dogs
Insulin overdose
Concentrated insulin (old)
Overlap of insulin action
Transient diabetes
Somogyi effect
Anorexia caused by oral disease, ketosis
Maldigestion caused by exocrine pancreatic insufficiency, bacterial overgrowth
Malabsorption caused by inflammatory bowel diseases, lymphangiectasia, lymphoma, and so forth

Hypoglycemia

- Clinical signs of hypoglycemia in diabetic animals are associated with epinephrine excess, which is released to counter the hypoglycemia. Nervousness, anxiety, vocalization, muscle tremors, ataxia, and pupillary dilatation should alert the owner to the possibility of hypoglycemia. Have the owner offer food to the animal then bring it in for reevaluation.
- Late in the course of hypoglycemic shock the animal may become recumbent or comatose, or the animal may have a seizure.
- If access to a vein is not readily available or if the owner is administering therapy, 50% dextrose solution, Karo syrup, or pancake syrup may be applied to the mucous membranes of the mouth using a large syringe. Caution the owner to pour the syrup on the gums from a reasonable distance from the animal's teeth to prevent accidental injury from biting. Have the owner transport the animal to a veterinarian as soon as possible.
- In a veterinary facility, treat hypoglycemia by slow IV bolus of 50% dextrose (0.5 g/kg diluted 1:4) followed by continuous infusion of 5% dextrose until the animal can be fed.
- Many animals that experience insulin overdose suffer cerebral edema and temporary blindness or behavior changes; often these signs are temporary and resolve after several weeks or months.

▼ ***Key Point*** Endogenous glucose stores may have been depleted by the insulin overdose and it may take several days for hyperglycemia to recur. In these cases, discontinue insulin therapy until hyperglycemia recurs.

Diet

The goals of dietary therapy in diabetes mellitus for both cats and dogs are to provide sufficient calories to maintain ideal body weight and correct obesity or emaciation, to minimize postprandial hyperglycemia, and to facilitate ideal absorption of glucose by timing meals to coincide with insulin administration. However, the approach to feeding will vary between dogs and cats. Cats require low-carbohydrate, high-protein foods to promote reversal of glucose toxicity in type 2 diabetes, whereas dogs require low-fat, high-fiber foods to prevent ketosis in type 1 diabetes.

- Maintain caloric intake at 60 to 70 kcal/kg/day for smaller dogs and cats, and 50 to 60 kcal/kg/day for larger dogs.

- Reduce the body weight of obese animals gradually over a period of 2 to 4 months by feeding 60% to 70% of the calculated caloric requirements for ideal body weight.
- Feed underweight animals a high caloric-density food based on caloric intake for optimum body weight. Once ideal body weight is reached, switch the animal to a high-fiber diet. Table 34-3 lists the fiber and caloric content of various pet foods.

▼ ***Key Point*** In dogs, increased dietary fiber improves glycemic control by slowing glucose absorption from the intestinal tract, reducing postprandial hyperglycemia, and controlling obesity.

TREATMENT OF TYPE 2 (NON–INSULIN-DEPENDENT) DIABETES

▼ ***Key Point*** Treatment of type 2 diabetes is aimed at decreasing hepatic glucose output and glucose absorption from the intestine, increasing peripheral insulin sensitivity, and increasing insulin secretion from the pancreas.

Diet

The goals of dietary therapy in diabetes mellitus will vary between dogs and cats. Cats require low-carbohydrate, high-protein foods to promote reversal of glucose toxicity in type 2 diabetes, whereas dogs require low-fat, high-fiber foods to prevent ketosis in type 1 diabetes.

- Maintain caloric intake at 60 to 70 kcal/kg/day for cats.
- Reduce the body weight of obese animals gradually over a period of 2 to 4 months by feeding 60% to 70% of the calculated caloric requirements for ideal body weight.
- Feed underweight animals a high caloric-density food based on caloric intake for optimum body weight.

▼ ***Key Point*** A low-carbohydrate, high-protein diet, which is similar to a cat's natural diet (mice), may ameliorate some of the abnormalities associated with diabetes mellitus in the cat. Comparison of canned high-fiber versus low-carbohydrate diets showed that cats fed low-carbohydrate diets were 2 to 3 times more likely to discontinue insulin injections. Most dry cat food formulations contain excessive carbohydrates; therefore, canned cat foods should be used for initial treatment of diabetic cats. Caution should be used when initially changing from dry to canned foods as insulin requirements may decrease dramatically; a reduction in insulin dosage may be required.

Exercise

- Keep the exercise level constant in a diabetic animal. Instruct the owner to walk the dog daily and avoid intermittent episodes of strenuous exercise, such as racing or hiking.
- Increasing exercise in an obese diabetic animal reduces insulin resistance and improves glycemic control.

Oral Hypoglycemic Drugs

Overview

- Human diabetics can be divided into three therapeutic categories according to beta cell function:
  1. Those who require exogenous insulin to control hyperglycemia
  2. Those who require only dietary therapy because of sufficient pancreatic islet cell function and insulin sensitivity to maintain relatively normal glucose levels
  3. Those who have sufficient pancreatic islet cell function and insulin sensitivity to respond to oral hypoglycemic drugs
- In cats, differentiation among these categories is almost impossible before treatment; therefore, use the *response* to oral hypoglycemic agents as a guide to whether the cat can be managed with oral hypoglycemic agents.
- Oral hypoglycemic agents include the following categories (Table 34-7):
  - Sulfonylureas (e.g., glipizide, glyburide, and glimepiride)
  - Biguanides (e.g., metformin)
  - Thiazolidinediones (e.g., troglitazone)
  - Alpha-glucosidase inhibitors (e.g., acarbose)
  - Transition metals (e.g., chromium and vanadium)
- Most oral hypoglycemic agents work by increasing insulin secretion, decreasing insulin resistance, decreasing glucose absorption, decreasing hepatic glucose production, or a combination of these (Fig. 34-4).

▼ ***Key Point*** Indications for oral hypoglycemic therapy in diabetic cats include normal or increased body weight, lack of ketones, probable type 2 diabetes with no underlying disease (pancreatitis, pancreatic tumor), and the owner's willingness to administer oral medication rather than an injection.

Sulfonylureas (e.g., Glipizide)

- The mechanism of action of the sulfonylureas is to increase insulin secretion and improve insulin resistance; however, these agents also cause an increase in hepatic gluconeogenesis. This leads to delayed hyperinsulinemia, weight gain, and atherosclerosis in humans treated with sulfonylureas.

Table 34-7. ORAL HYPOGLYCEMIC DRUGS USED IN THE TREATMENT OF TYPE 2 DIABETES (NIDDM) IN HUMANS AND CATS

Drug (Trade Name)	Dose	Frequency	Side Effects	Mechanism of Action
Glipizide (Glucotrol, Pfizer)	2.5–5 mg/cat	q8–12h, PO	Hepatotoxicity, hypoglycemia, vomiting	Increases insulin secretion and sensitivity
Glimepiride (Amaryl, Hoechst-Marion Roussel)	1–4 mg (humans); 1 mg/cat	q24h (humans); q24h (cat)	Same as above but lower incidence	Same as above
Metformin (Glucophage, Bristol-Myers Squibb)	500–700 mg (humans); unknown (cat)	q12h (humans); unknown (cat)	Anorexia, vomiting	Inhibits hepatic glucose production
Precose (Acarbose, Bayer)	50 mg (humans); 12.5–25 mg (cat)	q8–12h with meals	Flatulence, soft stool	Alpha-glucosidase inhibitor, impairs glucose absorption from gut
Troglitazone (Rezulin, Parke-Davis)	200–400 mg (humans); unknown (cat)	q24h	Mild decreases in WBC, platelet, and Hb counts	Increases insulin receptor sensitivity
Chromium	200 µg/cat	q24h	Unknown	Increases insulin receptor sensitivity
Vanadium	200–400 µg/cat	q24h in food or water	Anorexia, vomiting	Increases insulin receptor sensitivity

Hb, hemoglobin; WBC, white blood cell count.

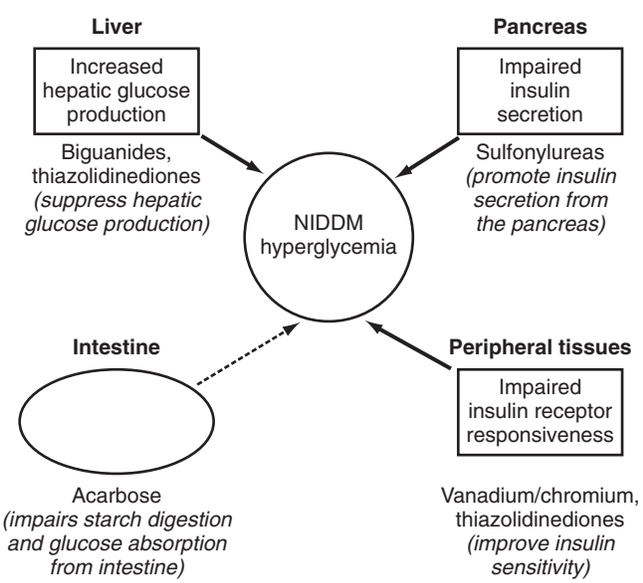

Figure 34-4. Mechanisms of action of oral hypoglycemic agents in the treatment of non–insulin-dependent (type 2) diabetes mellitus.

- Glipizide (Glucotrol, Roerig), a sulfonylurea drug, has been used successfully to treat type 2 diabetes in cats at a dosage of 2.5 to 5 mg q12h PO with food (low-carbohydrate diet). An outline for monitoring and managing cats undergoing glipizide therapy is shown in Figure 34-5.
- Side effects of sulfonylureas include severe hypoglycemia (rare in cats), cholestatic hepatitis, and vomiting. Gastrointestinal side effects, which occur in about 15% of cats treated with glipizide, resolve when the drug is administered with food.

Biguanides (e.g., Metformin)

- Metformin belongs to the biguanide group of oral hypoglycemic agents, which work by *inhibiting* hepatic glucose release and by improving peripheral insulin sensitivity.
- One advantage of the biguanides is that they do not promote insulin release; therefore, there is little potential for the development of hypoglycemia when metformin is used as a sole agent.
- Side effects of the biguanides include lactic acidosis and gastrointestinal signs such as nausea and diarrhea.
- Studies have shown that metformin is not a viable option in the cat.

Alpha-Glucosidase Inhibitors (e.g., Acarbose)

- Acarbose, an alpha-glucosidase inhibitor, impairs glucose absorption from the intestine by decreasing fiber digestion and hence glucose production from food sources.
- Acarbose is used as initial therapy in obese prediabetic patients suffering from insulin resistance or as adjunct therapy with sulfonylureas or insulin to enhance the hypoglycemic effect in patients with overt diabetes mellitus.
- One advantage of acarbose is that it is not absorbed systemically and may be used in conjunction with other oral hypoglycemics.
- Side effects of acarbose include flatulence, loose stool, and overt diarrhea at high dosages.
- Acarbose is not indicated in patients of low or normal body weight because of the negative effects on nutrition.

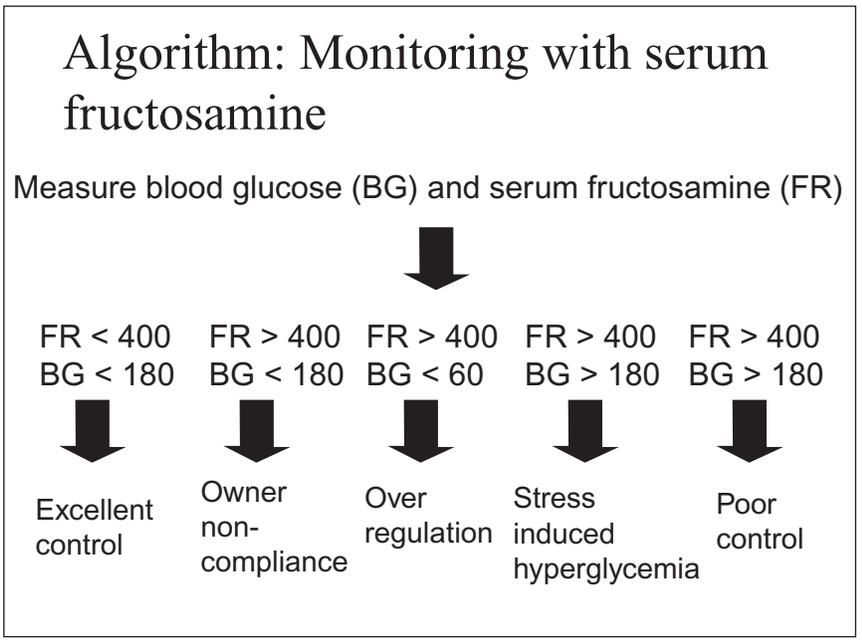

Figure 34-5. Algorithm for monitoring with serum fructosamine.

Thiazolidinediones (e.g., Troglitazone)

- The thiazolidinedione compounds facilitate insulin-dependent glucose disposal and inhibition of hepatic glucose output via attenuation of gluconeogenesis and activation of glycolysis. In addition, the thiazolidinediones have been shown to have beneficial effects on lipid disturbances in type 2 diabetes.
- Thiazolidinedione compounds have been used early in the course of type 2 diabetes to prevent development of overt diabetes.
- Initial studies using troglitazone for the treatment of feline type 2 diabetes are ongoing.

Transition Metals: Vanadium and Chromium

- Vanadium and chromium are transition elements that have been shown to have extensive insulin-like properties. Oral vanadium and chromium cause a marked and sustained improvement in glucose homeostasis in type 2 diabetes by exerting an insulin-like effect on peripheral tissues; furthermore, vanadium prevents the exhaustion of insulin stores in the pancreas. Unlike insulin, vanadium does not lower blood glucose concentrations in normal animals.
- Low doses of oral vanadium decrease blood glucose and serum fructosamine concentrations and alleviate the signs of diabetes (polydipsia, polyuria) in cats with *early* type 2 diabetes mellitus.
- Side effects of oral vanadium include anorexia and vomiting.

Insulin and Oral Hypoglycemics

- Changes from insulin to oral hypoglycemic agents or vice versa may be necessary in some diabetic cats. If a cat is particularly sensitive to insulin or exhibits transient diabetes because of reversal of "glucose toxicity," consider a change to an oral hypoglycemic.
- If a cat is being managed with oral hypoglycemic agents and ketosis develops, switch the cat to insulin therapy.
- Agents that impair glucose absorption from the intestine (acarbose) or increase insulin sensitivity (vanadium, metformin, troglitazone) may be combined with insulin to improve glucose control.
- In the case of "brittle diabetics" in which small incremental changes in the insulin dose may precipitate hypoglycemia, the addition of a drug that enhances the action of insulin may lead to a reduction in the insulin dose required to attain euglycemia.
- In humans, acarbose, chromium, vanadium, and metformin are commonly used in conjunction with insulin or with other oral hypoglycemics (sulfonylureas) that cause insulin release.
- Use caution when combining an oral hypoglycemic agent with insulin, as hypoglycemic reactions may occur.

Monitoring Oral Hypoglycemic Therapy

- It appears that methods of assessing *long-term* glycemic control are better indicators of response to therapy with oral hypoglycemics than are spot glucose determinations or blood glucose curves. Monitor resolution of clinical signs and serum fructosamine concentrations in cats undergoing oral hypoglycemic therapy.
- For clinical signs, body weight should increase or remain stable and polydipsia and polyuria should resolve with effective oral hypoglycemic therapy.

- Normal fructosamine concentrations are consistent with moderate to good long-term control of hyperglycemia. Relative improvement of serum fructosamine may be more important than absolute fructosamine values.

PREVENTION

- In humans, and presumably in cats, obesity management may be helpful in preventing development of type 2 diabetes mellitus.
- In dogs and cats, prevention of secondary forms of diabetes is possible by limiting the use of diabetogenic drugs such as glucocorticoids, progestational compounds, and somatotropin.
- Similarly, prevention and treatment of underlying disease is the mainstay of prevention of secondary diabetes resulting from hyperthyroidism, hyperadrenocorticism, or acromegaly.

Chapter 35

Pancreatic Beta Cell Neoplasia

Nyssa J. Reine / Jennifer Bonczynski

Tumors of the beta cells of the pancreatic islets are functional tumors that secrete excessive amounts of insulin independent of normal regulatory mechanisms. Hyperinsulinism causes hypoglycemia and corresponding clinical signs. Consider beta cell neoplasia in the differential diagnosis of hypoglycemia in middle-aged and older dogs.

ETIOLOGY

- Insulin-secreting tumors are almost always malignant.
- Metastatic sites include the lymphatics and lymph nodes (duodenal, mesenteric, hepatic, splenic), liver, mesentery, and omentum.
- The hyperinsulinemia caused by beta cell tumors interferes with glucose homeostasis by decreasing the rate of glucose release from the liver and by increasing the uptake of glucose by insulin-sensitive tissues.
- The net effect is hypoglycemia and secretion of the counter-regulatory hormones (most notably glucagons, epinephrine, cortisol and growth hormone).
- The brain is dependent on a constant supply of glucose for energy and has very limited storage capacity. Hypoglycemia results in decreased delivery of glucose to the brain (neuroglycopenia).

CLINICAL SIGNS

- The most common clinical signs of insulinoma are weakness, ataxia, collapse, seizures, muscle fasciculations, polyphagia, and weight gain (Table 35-1).
- Dogs have clinical signs for a duration of 1 to 6 months before presentation to the veterinarian.
- Clinical signs tend to be episodic and often develop during fasting, exercise, excitement, and eating.
- The severity of clinical signs depends on the glucose nadir and the rate of development and duration of hypoglycemia. Patients with chronic hypoglycemia seem to tolerate lower blood sugars without neurologic signs.

DIAGNOSIS

▼ ***Key Point*** The diagnosis of an insulin-secreting beta cell tumor requires initial confirmation of hypoglycemia and then documentation of simultaneous, inappropriately high insulin secretion.

Signalment

Signalment is not always useful in differentiating insulinoma from other common causes of hypoglycemia (Table 35-2).

- Insulin-secreting tumors typically occur in the middle-aged or older dog, with an age range of 6 to 14 years.
- There is no apparent sex or breed predilection, although the Labrador retriever, German shepherd, Irish setter, golden retriever, collie, fox terrier, and standard poodle are commonly affected in our hospital.
- Islet cell neoplasia is rare in cats.

Physical Examination

The physical examination of dogs with insulin-secreting tumors is surprisingly unremarkable.

- Weight gain is evident in some dogs and is probably a result of the potent anabolic effects of insulin.
- Peripheral neuropathies have been reported in dogs with insulin-secreting tumors and may be manifested as proprioception deficits, depressed reflexes, and muscle atrophy.

Laboratory Studies

- The only consistent abnormality found on the hemogram, biochemical panel, and urinalysis is hypoglycemia.
- Hypoalbuminemia, hypophosphatemia, hypokalemia, and an increase in alkaline phosphatase and alanine aminotransferase have been reported, but these findings are considered nonspecific and not helpful in achieving a definitive diagnosis.
- A correlation has not been found between liver enzyme elevations and metastasis of the pancreatic tumor to the liver.

Table 35-1. CLINICAL SIGNS ASSOCIATED WITH BETA CELL NEOPLASIA IN THE DOG

Seizures	Muscle fasciculations
Weakness	Bizarre behavior
Collapse	Lethargy
Ataxia	Weight gain
Posterior paresis	Polyphagia

Table 35-2. DIFFERENTIAL DIAGNOSIS FOR HYPOGLYCEMIA

Beta cell neoplasia
Non-pancreatic neoplasia
Hepatocellular carcinoma, hepatoma
Leiomyosarcoma, leiomyoma
Hemangiosarcoma
Hepatopathy
Vascular shunts
Chronic fibrosis, cirrhosis
Hepatic necrosis
Sepsis
Hypoadrenocorticism
Toy-breed puppy
Chronic renal failure
Glycogen storage disorder
Polycythemia
Starvation
Artifact

- A normal physical examination and lack of abnormalities other than hypoglycemia on hemogram, serum biochemical panel, and urinalysis strongly suggest beta cell neoplasia as the cause of the hypoglycemia. It is important to systematically eliminate other causes before pursuing a diagnosis of insulinoma (see Table 35-2).

Blood Glucose Assay

- Up to 98% of dogs with insulinoma reportedly present with hypoglycemia.
- Dogs with insulin-secreting tumors occasionally may have a normal blood glucose concentration on random testing. Such a finding does not eliminate intermittent hypoglycemia as a cause of episodic weakness or seizure activity.
- If hypoglycemia is not present on initial examination, fast the patient to induce hypoglycemia. Measure blood glucose hourly. Closely observe the patient for worsening of signs (i.e., seizures or collapse).
- Typically, point-of-care glucose monitors are adequate for glucose assessment. If such equipment is not available, separate serum from red blood cells immediately to minimize effects of red blood cell metabolism.
- A fast of 8 hours or less is usually successful in demonstrating hypoglycemia in most dogs with insulin-secreting tumors.
- Concurrent assessment of serum fructosamine level may provide supportive evidence of insulinoma. Patients with insulinoma should have a low serum fructosamine in the presence of normoglycemia. This has recently been reported in a dog with insulinoma without measurable hypoglycemia.

Ultrasonography

Abdominal ultrasonography can be used to identify the tumor in the region of the pancreas and to assess for potential metastatic lesions in the liver and surrounding structures; however, negative findings do not rule out an insulin-secreting tumor or the presence of metastasis.

- Pancreatic masses are reportedly identified in 27% to 93% of dogs.
- In one study, only 42% of the metastatic lesions found with ultrasonography were confirmed at surgery.

Insulin Secretion Measurement

Confirmation of an insulin-secreting neoplasm requires documentation of inappropriate insulin secretion during hypoglycemia. Measuring serum insulin concentration when the blood glucose is <60 mg/dl (<40 mg/dl using glucose reagent strips) usually establishes the diagnosis. A 4- to 8-hour fast may be required to obtain this level of hypoglycemia, but when the blood glucose concentration falls below 60 mg/dl, the simultaneous blood insulin concentration is interpreted as follows:

- Blood insulin is above normal (>120 pmol/L): An insulin-secreting neoplasm is likely.
- Blood insulin is in the high-normal range (60–120 pmol/L): An insulin-secreting tumor is possible.
- Blood insulin is in the low-normal range (30–60 pmol/L): An insulin-secreting tumor has not been confirmed.
  - Blood insulin in the low-normal range with hypoglycemia can be associated with non-islet cell tumors as well as insulin-secreting tumors. This is an indication for further diagnostics, including repeating the blood glucose and insulin determinations.
- Blood insulin is in the below-normal range (<30 pmol/L): Insulinopenia has been documented, and an insulin-secreting tumor has been ruled out.

MEDICAL TREATMENT FOR ACUTE HYPOGLYCEMIC CRISIS

The acute onset of clinical signs of hypoglycemia (see Table 35-1) typically occurs in the dog in the home environment or immediately postoperatively in the dog with an inoperable tumor or metastases. Therapy depends on the severity of clinical signs and the location of the dog or cat (i.e., home or hospital).

- In the hospital, administer 50% dextrose solution (1 ml/kg) slowly IV until clinical signs are controlled.
- If the dog is home, instruct the owner to rub a sugar-containing solution (e.g., Karo syrup) on the buccal mucosa until clinical signs are controlled.
- Dogs and cats with hypoglycemia should respond to the administration of glucose in 30 to 120 seconds.

▼ ***Key Point*** Avoid overstimulation of the tumor when administering dextrose IV. Overzealous administration of dextrose can stimulate the tumor to release excessive amounts of insulin into the circulation and cause severe rebound hypoglycemia. A vicious cycle that is difficult to break may ultimately result in persistent seizures and eventually death.

- The goal of therapy is to control the clinical signs, not correct hypoglycemia, through the judicious administration of dextrose.
- Administer small amounts of dextrose slowly rather than large boluses rapidly to minimize stimulation of the tumor.
- IV dextrose supplementation should be replaced by frequent feedings as soon as possible.
- Constant rate infusion of glucagon has been used to successfully manage acute hyperinsulinemic-hypoglycemic crisis in a dog with insulinoma.

Seizures

Occasionally, seizures will persist despite normalization of blood glucose concentration. This may indicate the presence of cerebral edema or rarely the presence of a permanent cerebral lesion (i.e., necrosis). If intractable seizures due to hypoglycemia develop, take the following actions:

- Discontinue bolus injections of dextrose.
- Begin continuous IV infusion of 2.5% to 5.0% dextrose solution that is $1\frac{1}{2}$ to 2 times the maintenance rate (90–120 ml/kg/day).
- Consider mannitol (0.5 g/kg IV) if signs of cerebral edema are present (i.e., anisocoria).
- Consider the addition of rapid acting glucocorticoids (i.e., dexamethasone sodium phosphate).
- Administer the somatostatin analog SMS 201-995 (octreotide; Sandostatin, Sandoz), 10 to 40 mg q8–12h SC, to decrease insulin secretion by the tumor.
- Anti-convulsants may be needed if seizures persist (i.e., phenobarbital; see Chapter 127).

SURGICAL TREATMENT

Surgical Anatomy

The pancreas consists of the right lobe, left lobe, and the body.

Right Lobe

The right lobe is located in the mesoduodenum adjacent to the descending duodenum. The proximal portion of the right lobe is intimately associated with the duodenum (Fig. 35-1). The proximal half of the

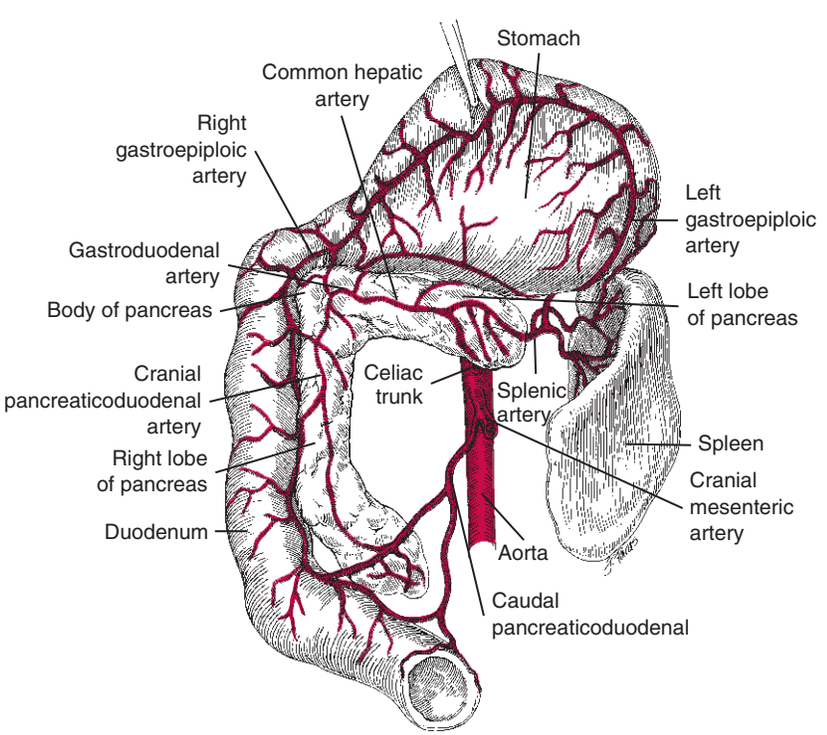

Figure 35-1. Anatomy and blood supply of the right and left lobes of the pancreas.

right limb is supplied by the cranial pancreaticoduodenal artery, which is the terminal branch of the hepatic artery. The distal half of the right limb is supplied by the caudal pancreaticoduodenal artery, which is a branch of the cranial mesenteric artery. Damage to the pancreaticoduodenal vessels may result in avascular necrosis of the duodenum.

Left Lobe

The left lobe is located caudodorsal to the stomach in the deep leaf of the greater omentum. It is exposed by reflecting the greater omentum, spleen, and stomach cranially and retracting the transverse colon caudally. This lobe of the pancreas is mainly supplied by branches of the splenic artery.

Body of the Pancreas

The body of the pancreas is located at the cranial duodenal flexure and is close to the pylorus and common bile duct. Branches of the hepatic artery (gastroduodenal) supply the body of the pancreas. The portal vein crosses the dorsal portion of the body.

Lymphatics

Lymphatics from the pancreas drain into the duodenal, hepatic, splenic, and mesenteric lymph nodes.

Pancreatic Ducts

Excretory ducts of the pancreas exit the pancreatic parenchyma in the area of the body to enter the duodenum. There are usually two, which intercommunicate within the gland. There are several variations in the anatomy of the pancreatic ducts.

- In the dog, the pancreatic duct usually enters the duodenum adjacent to the common bile duct at the major duodenal papilla approximately 5 cm distal to the pylorus. The accessory pancreatic duct, which is the larger pancreatic duct, enters the duodenum at the minor duodenal papilla approximately 8 cm distal to the pylorus (Fig. 35-2).
- In the cat, the pancreatic duct is the main excretory duct; the accessory duct often is absent.

Preoperative Considerations

- The goal of fluid therapy prior to and during surgery is to maintain systemic blood pressure and pancreatic perfusion, thereby minimizing the development of pancreatitis.
- Although correction of hypoglycemia is not usually feasible, maintain blood glucose above 40 mg/dl or so that no clinical signs are apparent.
- To minimize hypoglycemia during the preoperative period, feed the animal frequent small meals and, if necessary, give prednisone, 0.25 to 0.5 mg/kg q12h PO.

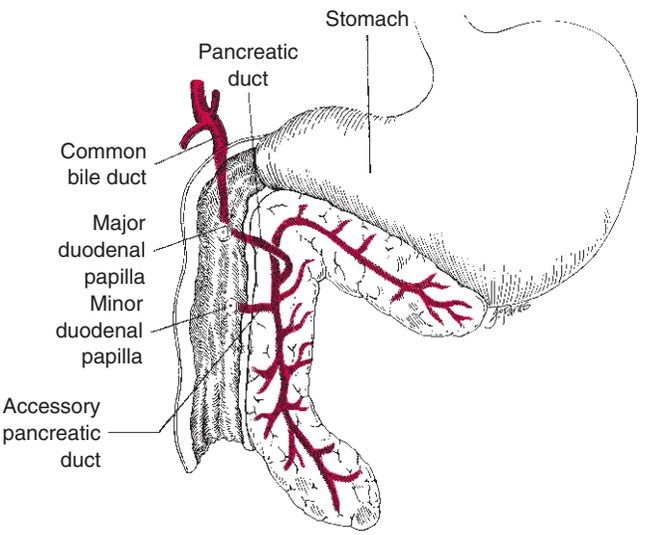

Figure 35-2. Anatomy of the pancreatic ducts in relationship to the duodenum.

▼ ***Key Point*** On the *day of surgery,* administer a balanced electrolyte solution containing 2.5% to 5% dextrose IV that is 1½ to 2 times the daily maintenance requirements. *Intraoperatively,* administer this same solution at a rate of 8 to 16 ml/kg/hr .

Surgical Procedure

Objectives

- Confirm a neoplasm.
- Carefully examine the entire pancreas. Islet cell tumors occur with approximately equal frequency in all areas of the pancreas. Although single lesions are most common, multiple lesions in non-adjacent areas of the pancreas have been reported in about 15% of cases. Diffuse involvement of the pancreas without a discrete mass also has been reported.
- Define the clinical stage of the tumor.

▼ ***Key Point*** A study suggests that abdominal ultrasound findings do not correlate well with surgical findings. Abdominal ultrasound may falsely identify metastatic disease.

- Remove the primary pancreatic tumor and any metastatic lesions (see the following section). Although this may not be a cure, it usually reduces clinical signs and may facilitate medical management.

Equipment

- Standard abdominal surgery instrument pack and suture
- Hemoclips—Various sizes
- Gelfoam
- Malleable retractors

Technique (Using Visual Examination and Palpation)

1. Approach the abdomen via a ventral midline incision from the xiphoid to the pubis.
2. Examine the entire pancreas visually and by careful palpation.
   a. Islet cell tumors are usually firmer than the surrounding tissue.
   b. Islet cell tumors may be small and sandwiched between pancreatic lobules so that they are not readily visible.

Technique (Using Methylene Blue Intravenous Infusion)

The following technique to facilitate tumor identification utilizes IV infusion of methylene blue. It should be considered only if a mass cannot be identified at surgery.

1. Surgically expose the pancreas as described previously.
2. Administer methylene blue as an IV infusion in normal isotonic saline solution to a total dose of 3 mg/kg of body weight. Begin the infusion 30 minutes before the pancreas is exposed.
3. Methylene blue is concentrated by the endocrine pancreas and intensely stains hyperfunctional areas.
   a. Normal pancreatic endocrine tissue is stained a dusky slate blue.
   b. Hyperfunctional tissue is stained more intensely (often a reddish blue).
4. Potential complications include hemolytic anemia and acute renal failure postoperatively.

Technique (Using Intraoperative Ultrasound)

The following technique is commonly used in human patients with 90% diagnostic accuracy. It is not yet widely used in veterinary medicine but offers a safer alternative to methylene blue IV infusion.

1. Use a 7.5- or 10-MHz probe in a sterile sleeve.
2. Apply a thin layer of saline to the tissues to improve contact.
3. Scan for primary tumors in the pancreas and metastasis in the liver.
4. Direct intraoperative ultrasonography decreases the effect of gas in the surrounding gastrointestinal (GI) tract, which allows better identification of the masses.

Technique (Removal of Neoplastic Tissue)

1. Handle the pancreas and masses gently to avoid pancreatitis and potential insulin release.
2. Check the blood glucose frequently during surgery.
3. Remove abnormal pancreatic masses by partial pancreatectomy or by local excision. Make a wide excision if possible.
4. Remove tumors located in the left lobe or the distal portion of the right lobe by partial pancreatectomy (Fig. 35-3).
   a. Isolate the affected pancreas with moistened abdominal sponges.
   b. Divide the mesentery surrounding the affected lobe and ligate and divide the appropriate vessels (see Fig. 35-3*A*).
   c. Incise the mesentery covering both surfaces of the pancreas at the level of transection of the lobe.
   d. Remove the lobe at least 1 to 2 cm proximal to the tumor.

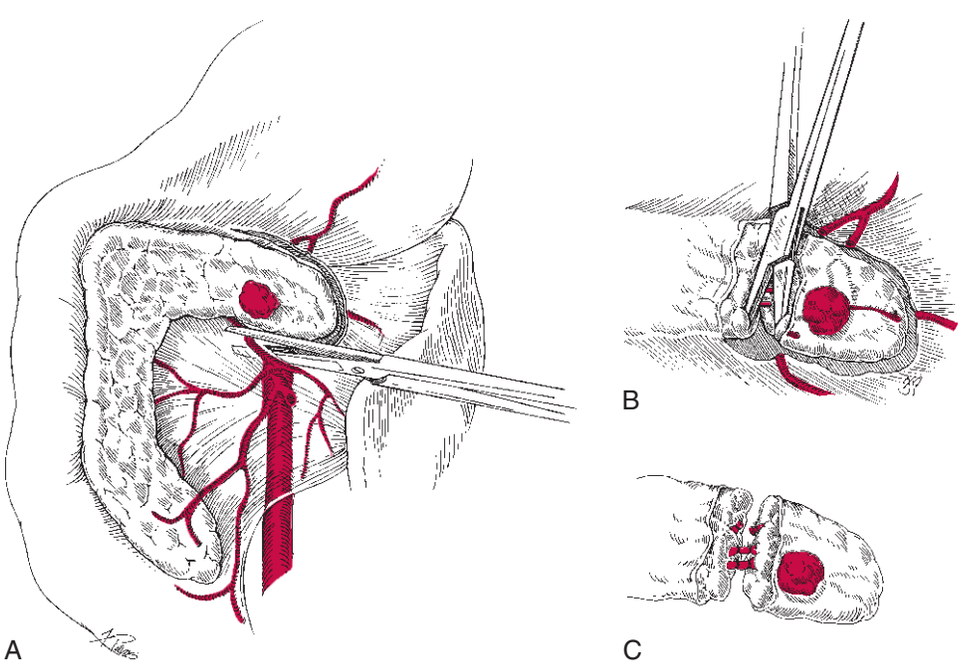

Figure 35-3. Schematic of partial pancreatectomy procedure. See text for details.

e. Bluntly separate the lobules using a mosquito hemostat, dissecting alternately from each side of the gland (see Fig. 35-3*B*).
f. Isolate the main duct, ligate with a monofilament absorbable synthetic suture material, and transect it (see Fig. 35-3*C*).
g. Alternatively, simply ligate the pancreatic tissue in guillotine style to occlude the vessels and ducts (3-0 or 4-0 polydioxanone suture).

5. When the tumor is located in the proximal portion of the right lobe or the body, local excision of the tumor, including at least 1- to 2-cm margins of normal-appearing pancreatic tissue, is the preferred technique because of the vascular and ductal anatomy of the area.
   a. Gently separate the pancreatic lobules by blunt dissection with a mosquito hemostat. Cauterize small vessels and ligate and divide larger vessels.
   b. Preserve the pancreaticoduodenal vessels supplying the duodenum. Avoid damaging the pancreatic ducts and the common bile duct.
6. Explore the entire abdomen for evidence of metastatic disease. The most common sites of metastasis are the liver and regional lymph nodes (duodenal, hepatic, splenic, greater mesenteric).

▼ ***Key Point*** Metastatic disease is common; approximately 30% to 50% of cases have identifiable metastasis to the liver or regional lymph nodes at the time of surgery.

   a. Resect all enlarged lymph nodes and suspicious hepatic lesions if possible and submit them for histopathologic examination.
   b. A recent study (Tobin et al., 1999) showed a poor correlation between gross inspection during surgery and histopathologic examination of biopsy specimens for potential metastatic lesions. Only 57% of the lesions biopsied as metastatic disease were confirmed metastatic beta cell neoplasia by histopathologic examination.
   c. Biopsy lesions that cannot be completely excised.

▼ ***Key Point*** Many dogs with metastases of islet cell neoplasms can be managed medically for longer than a year.

7. Close the abdomen routinely.

Postoperative Care and Complications

Postoperative Care

- Give nothing by mouth for 48 hours.
- Administer a balanced electrolyte solution IV containing 5% dextrose that is 1½ to 2 times the daily maintenance requirements (90–120 ml/kg/day). Maintain adequate blood pressure and perfusion to prevent pancreatitis.
- Monitor blood glucose concentration at least twice daily.
- Discontinue the dextrose infusion if hyperglycemia (>150 mg/dl) develops.
- If vomiting does not occur, offer small amounts of water after 48 hours and then small amounts of a bland, easily digestible diet.
- If the dog tolerates a bland diet well, resume the normal diet in 5 to 7 days.

Complications

- Hyperglycemia may occur following surgery due to inadequate insulin secretion by atrophied non-neoplastic beta cells. This often resolves within a few days.
- If hyperglycemia and glycosuria persist for several days following surgery, initiate insulin therapy (see Chapter 34).
- Diabetes mellitus is usually transient and resolves within a few weeks to several months.
- Periodically, discontinue insulin therapy on a trial basis to determine if endogenous insulin production is resuming.
- If hypoglycemia does not resolve postoperatively or if it recurs following resection of an islet cell tumor, assume metastatic disease to be present and institute medical therapy for chronic hypoglycemia, as described in the following section.
- Other potential postoperative complications include pancreatitis (see Chapter 73 for treatment), duodenal necrosis (from vascular compromise), ventricular arrhythmias, and central nervous system dysfunction secondary to prolonged hypoglycemia.

MEDICAL TREATMENT FOR CHRONIC HYPOGLYCEMIA

Institute palliative medical management for chronic hypoglycemia in preparation for exploratory laparotomy, for patients with persistent postoperative hypoglycemia, when exploratory surgery is refused by the owner or when an inoperable tumor or metastases result in recurrence of clinical signs.

Goals of Chronic Palliative Therapy

- To reduce the frequency and severity of clinical signs. This is typically achieved initially via dietary therapy. If dietary therapy is inadequate, other medical therapies are added.
- To prevent an acute hypoglycemic crisis through dietary management and nonspecific anti-hormonal therapy.

Diet and Exercise Recommendations

- Feed frequent small meals to provide a constant source of calories, which may prevent or reduce the number of hypoglycemic episodes.

- Use a diet that is high in proteins, fats, and complex carbohydrates—similar to those recommended for patients with diabetes mellitus. These are recommended to minimize postprandial hyperglycemia.
- If commercial pet food is used, recommend a combination of canned and dry food, fed three to six small meals daily.
- Avoid simple sugars (including soft moist foods) except as needed to treat signs of hypoglycemia.
- Limit exercise to short walks on a leash.

Anti-Hormonal Therapy

Anti-hormonal therapy minimizes hypoglycemia through the following:

- Increasing absorption of glucose from the intestinal tract
- Increasing hepatic gluconeogenesis and glycogenolysis
- Inhibiting the synthesis, secretion, or peripheral cellular actions of insulin

Glucocorticoid Therapy

Mechanisms

Glucocorticoids antagonize the actions of insulin at the cellular level, stimulate hepatic glycogenolysis, and provide the necessary substrates for hepatic gluconeogenesis.

Goal of Therapy

Initiate glucocorticoids when dietary manipulations are no longer effective in preventing signs of hypoglycemia.

Dosage

- Administer prednisone at an initial dosage of 0.5 mg/kg/day given in divided doses.
- Increase the dosage as needed to control clinical signs of hypoglycemia up to a maximal daily dose of 4 to 6 mg/kg.
- Signs of iatrogenic hypercortisolism ultimately limit the amount of prednisone that can be administered.

Diazoxide Therapy

Mechanism

Diazoxide (Proglycem, Schering-Plough) is a benzothiadiazide diuretic that inhibits insulin secretion, stimulates hepatic gluconeogenesis and glycogenolysis, and inhibits tissue use of glucose. The net effect is hyperglycemia.

Goal of Therapy

The goal of diazoxide therapy is to establish a dosage in which hypoglycemia and its clinical signs are reduced or absent while avoiding hyperglycemia (>180 mg/dl) and its associated clinical signs.

Dosage

- Administer diazoxide at an initial dosage of 10 mg/kg q12h PO.
- Gradually increase the dose as needed to control signs of hypoglycemia, but do not exceed 60 mg/kg/day.

Side Effects

- The most common adverse reactions to diazoxide are anorexia and vomiting. Minimize these by administering diazoxide with a meal or temporarily decreasing the dosage.
- Other potential complications include diarrhea, tachycardia, bone marrow suppression, aplastic anemia, thrombocytopenia, diabetes mellitus, sodium and fluid retention, and cataracts.

Somatostatin Analog (SMS 201-995) Therapy

Mechanism

SMS 201-995 (octreotide; Sandostatin, Sandoz) is an analog of somatostatin that inhibits the secretion of insulin by normal and neoplastic beta cells.

- The responsiveness of insulin-secreting tumors to the suppressive effects of SMS 201-995 is variable, being dependent on membrane receptors for somatostatin on the tumor cells.

Dosage

- The dosage is 10 to 20 µg q8–12h SC. The dose is increased as needed to control hypoglycemia.

Side Effects

- Adverse reactions have not been seen at these dosages. Patients may become refractory to the medication.

CHEMOTHERAPY FOR INSULINOMA

Streptozotocin

Mechanism

Streptozotocin is a nitrosourea alkylating agent that is cytotoxic to pancreatic beta cells. It has been shown to be efficacious in some dogs with insulinoma. It provides a treatment option for patients with unresectable disease or recurrence after surgery.

Goal of Therapy

Decrease insulin secretion by the tumor cells.

Dosage

- The current recommended dose is 500 mg/m^2 (see Chapter 26 for body weight to surface area conversion table). Follow saline diuresis protocol very closely (Table 35-3).

Table 35-3. PROTOCOL FOR STREPTOZOTOCIN ADMINISTRATION FOR INSULINOMA

1. Administer 0.9% NaCl at a constant-rate infusion of 18.3 ml/kg/hr for 3 hours *prior to* administration of chemotherapy.
2. Administer streptozotocin (500 mg/m^2) diluted in the appropriate volume of 0.9% NaCl at a rate of 18.3 ml/kg/hr for 2 hours.
3. Administer 0.9% NaCl at a constant-rate infusion of 18.3 ml/kg/hr for 2 hours after completion of streptozotocin infusion.
4. Administer butorphanol at a dose of 0.4 mg/kg IM after or during streptozotocin infusion.

- Five treatments are given at 3-week intervals unless severe side effects, progression of disease, or hyperglycemia occur.

Side Effects

- Acute renal failure is reported following bolus administration of streptozotocin. The saline administration protocol reduces the risk of nephrotoxicity and enables administration of repeated doses.
- Other potential complications include bone marrow suppression (usually mild), vomiting (can be severe), anorexia, diarrhea, increased alanine aminotransferase, transient hypoglycemia, and type I diabetes mellitus.

PROGNOSIS

- Survival time is influenced by treatment protocols (i.e., surgical versus medical management) and the stage of disease on initial presentation. The stages are as follows:
  Stage 1: Pancreatic nodule only
  Stage 2: Regional lymph node metastasis
  Stage 3: Distant metastasis (usually liver)
- A multi-university study (Caywood et al., 1988) involving a total of 73 dogs with insulin-secreting neoplasia found the following:
  - Younger dogs and dogs with distant metastasis or higher insulin levels resulted in a significantly shorter survival time.
  - Fifty percent of dogs with stage 1 disease at the time of surgery were free of hypoglycemia 14 months after surgery.
  - Less than 20% of dogs with stage 2 or 3 disease were disease-free at 14 months.
  - Eighty percent of dogs with a solitary mass were dead at 24 months from the time of diagnosis.
  - Approximately 50% of dogs with metastasis to the liver (the most common site) were dead by 6 months, and all were dead by 18 months from the time of diagnosis.
- A more recent study (Tobin et al., 1999) documented a significantly longer median survival time in dogs treated with partial pancreatectomy versus those treated with medical therapy alone (381 days versus 74 days, respectively).
  - There was no correlation to survival or significant difference between the two groups in signalment, duration of clinical signs, radiographic findings, abdominal ultrasound findings, severity of hypoglycemia, insulin level, or prevalence of metastasis at the time of diagnosis.
  - The authors attributed the unexpectedly lower survival in non-surgical dogs to an increase in likelihood to euthanize dogs in people who choose not to pursue surgery. Regardless, this paper certainly supports the role of surgery in the treatment of insulinoma.
- Recurrence of tumor and clinical signs is likely. There are reports of successful resolution of clinical signs with surgical re-exploration to decrease tumor burden.

Chapter 36

Diseases of the Hypothalamus and Pituitary

John F. Randolph / Rhett Nichols / Mark E. Peterson

NORMAL ANATOMY AND PHYSIOLOGY

The *pituitary* gland (hypophysis) consists of the neurohypophysis surrounded by the adenohypophysis.

Neurohypophysis

The neurohypophysis, also called the *pars nervosa* and *infundibulum* (Fig. 36-1), extends ventrally from the hypothalamus.

- It is composed of nerve tracts terminating from nuclei within the hypothalamus.
- Antidiuretic hormone (ADH, vasopressin) and oxytocin, produced by the supraoptic and paraventricular hypothalamic nuclei, travel down the axons to be stored in and secreted from the neurohypophysis.

Adenohypophysis

The adenohypophysis is an embryonic outgrowth of the pharynx connected to the hypothalamus by a vascular network that allows humoral control of adenohypophyseal secretions by the hypothalamus.

- In response to the neurotransmitters, specialized neurosecretory cells within the hypothalamus release factors that control production and secretion of hormones from the adenohypophysis (Table 36-1).
- Hormones produced by target endocrine organs in response to specific adenohypophyseal hormones exert negative feedback (or feedback inhibition) on further elaboration of the hypothalamohypophyseal hormones.
  - Because growth hormone (GH), prolactin, and melanocyte-stimulating hormone do not have target endocrine organs to participate in negative feedback controls, releasing and inhibiting factors from the hypothalamus control production of these hormones (see Table 36-1).
- The adenohypophysis is subdivided into the pars distalis, pars tuberalis, and pars intermedia (see Fig. 36-1).
- The pars intermedia, unlike the pars distalis, does not have an extensive blood supply contiguous with the hypothalamus. The cells of the pars intermedia appear to release their hormones in response to dopaminergic and serotonergic innervation.

Adenohypophyseal Cells

These are classified by staining properties of their secretory granules.

- Immunohistochemical staining identifies the specific hormone content of the cells.
- Hematoxylin and eosin staining identifies adenohypophyseal cells as follows:
  - Acidophils: Somatotrophs and lactotrophs
  - Basophils: Gonadotrophs, corticotrophs, and thyrotrophs
  - Chromophobes (cells that do not stain selectively): Degranulated, undifferentiated, or actively synthesizing cells (some investigators consider chromophobes to include corticotrophs)

Alternative Nomenclature

Alternatively, the pituitary gland is composed of the anterior lobe and posterior lobe, with the two lobes separated by the hypophyseal cleft (the residual lumen of Rathke's pouch) (see Fig. 36-1). The terms *anterior* and *posterior*, although anatomically correct for the human pituitary, are not accurate when used to describe the lobes of the feline or canine pituitary gland.

- Anterior lobe: Pars tuberalis (glandular pituitary stalk) and pars distalis
- Posterior lobe: Pars nervosa and pars intermedia

DISEASES OF PITUITARY HORMONE EXCESS

Growth Hormone-Secreting Pituitary Neoplasia: Acromegaly

Excess production of GH causes overgrowth of bone, connective tissue, and viscera. If GH oversecretion

Table 36-1. ADENOHYPOPHYSEAL HORMONES AND THEIR REGULATORY HYPOTHALAMIC HORMONES

Adenohypophyseal Hormone	Hypothalamic Hormone
Thyroid-stimulating hormone (TSH)	Thyrotropin-releasing hormone (TRH)
Adrenocorticotropic hormone (ACTH)	Corticotropin-releasing hormone (CRH)
Growth hormone (GH, somatotropin)	GH-releasing hormone (GHRH, somatocrinin)
	GH release-inhibiting hormone (somatostatin)
Follicle-stimulating hormone (FSH)	Gonadotropin-releasing hormone (GnRH)
Luteinizing hormone (LH)	Gonadotropin-releasing hormone (GnRH)
Prolactin (lactotropic hormone [LTH])	Prolactin-releasing factor
	Prolactin inhibitor (dopamine)
Melanocyte-stimulating hormone (MSH)	MSH-releasing hormone (MSH-RH)
	MSH release-inhibiting hormone (MSH-RIH)

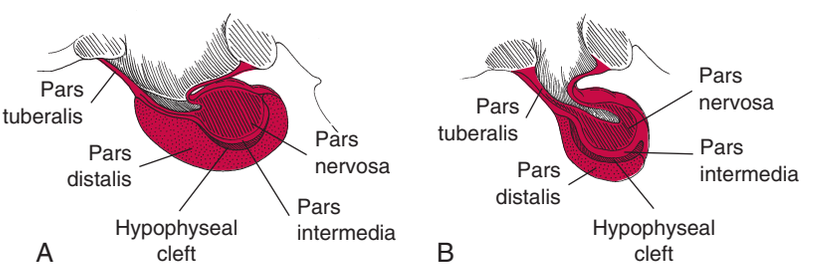

Figure 36-1. Schematic diagram of a mid-sagittal section through the pituitary gland of a normal dog *(A)* and cat *(B)*. (Modified from Dellmann HD: Veterinary Histology: An Outline Text-Atlas. Philadelphia: Lea & Febiger, 1971.)

(hypersomatotropism) occurs after closure of the epiphyses, acromegaly develops. In acromegaly, only the membranous bones (e.g., nose, mandible, and portions of the vertebrae) increase in length, because the long bones cannot grow longitudinally once the epiphyses close.

GH exerts both direct and indirect effects on the body. The indirect actions of GH, mediated by insulin-like growth factor I (IGF-I), are anabolic and include increased protein synthesis and soft tissue and skeletal growth. In contrast, the direct effects of GH are predominantly catabolic (e.g., lipolysis and restricted cellular glucose transport).

Etiology

- *In cats:* The major cause of acromegaly is a GH-secreting tumor of the pituitary gland.
- *In dogs:* Endogenous (diestrus) or exogenous progestogens may cause acromegaly by inducing GH production from the hyperplastic ductular epithelium of the mammary glands.

▼ ***Key Point*** Acromegaly in dogs is caused by progestogens. Feline acromegaly develops from a GH-secreting pituitary tumor.

Clinical Signs

Signalment

- Age: Middle to old age
- Breed: No breed predilection
- Sex: Most acromegalic cats are male, whereas acromegalic dogs are female

General Appearance

▼ ***Key Point*** The clinical features of acromegaly develop so insidiously that they are frequently overlooked.

- Large paws
- Soft tissue swelling of the head and neck with prominent skin folds
- Prognathism due to mandibular enlargement
- Widened interdental spaces
- Macroglossia
- Increase in body size and weight; weight loss in some cases
- Pot-bellied appearance
- Long, thick, or coarse haircoat
- Rapid growth of toenails

Respiratory System

- *In cats:* Dyspnea as a result of pulmonary edema or pleural effusion from GH-induced cardiac failure.
- *In dogs:* Excessive panting, exercise intolerance, and inspiratory stridor develop because oropharyngeal soft tissue proliferation compresses the upper airway.

Cardiovascular System

In cats, cardiac involvement includes the following:

- Systolic murmur
- Cardiomegaly
- Congestive heart failure (43%) characterized by pulmonary edema, pleural effusion, or ascites

Endocrine System

▼ ***Key Point*** Some dogs and most cats with acromegaly have insulin-resistant diabetes mellitus.

- Diabetes mellitus and its accompanying clinical signs of polyuria, polydipsia, and polyphagia develop because GH restricts cellular glucose transport. Insulin resistance results and large dosages of insulin (>2.2 U/kg/day) are frequently needed to control the hyperglycemia.
- In acromegalic cats, the growth-promoting effects of GH lead to enlargement of endocrine glands (thyroid, parathyroid, adrenal), but the function of these glands remains normal.
- In contrast, dogs in which acromegaly is caused by chronic administration of progestogens have subnormal basal cortisol concentrations. The glucocorticoid-like activity of these progestogens probably suppresses adrenocorticotropic hormone (ACTH) secretion and causes secondary hypoadrenocorticism.

Skeletal System

- Spondylosis deformans.
- Hyperostosis of the skull.
- Mandibular enlargement (prognathism).
- Arthropathy: Excess GH causes proliferation of cartilage and soft tissue, resulting in widening of the joint space. Some cats develop degenerative arthropathy with time. Acromegalic dogs seem less likely to develop joint problems.

Nervous System

- Growth of the pituitary tumor in feline acromegaly may impinge on brain tissue, causing circling, seizures, or behavioral changes.

Urinary System

- GH excess causes renal hypertrophy and increased glomerular filtration rate and renal plasma flow.
- Renal failure develops in about 50% of acromegalic cats. The kidneys of these cats have mesangial thickening of the glomeruli that may result from the glomerulosclerosis associated with unregulated diabetes mellitus and GH-mediated glomerular hyperfiltration.

Reproductive System

- Dogs with progesterone-induced acromegaly may develop pyometra, mucometra, and mammary gland nodules.

Diagnosis

Basis for a Presumptive Diagnosis of Feline Acromegaly

- Clinical and laboratory features characteristic of acromegaly
- CT or MRI documentation of a pituitary mass
- Normal results on thyroid and adrenal testing

Basis for a Presumptive Diagnosis of Canine Acromegaly

- Characteristic clinical and laboratory findings
- Exposure to a progestogen source and improvement in clinical signs following removal of that progestogen source
- No evidence of spontaneous hyperadrenocorticism on adrenal testing

▼ ***Key Point*** Suspect acromegaly in female dogs receiving progestogens and in intact female dogs that develop diabetes mellitus or laryngeal stridor due to soft tissue overgrowth. Suspect acromegaly in cats with insulin-resistant diabetes mellitus.

Physical Examination

Look for the clinical signs listed previously. To confirm enlargement of the head and paws, redundant skin folds, and prognathism, compare the animal's appearance with earlier photographs of the animal, if possible.

Routine Laboratory Tests

- Severe hyperglycemia and glycosuria are found in most cats and some dogs with acromegaly. Despite the poorly regulated diabetic state of most acromegalic cats and the enhancement of ketogenesis by GH, ketosis rarely develops.
- Less frequently, increases in cholesterol, alanine aminotransferase (ALT), and serum alkaline phosphatase (ALP) may be caused by the diabetic state. However, in many acromegalic dogs without diabetes, ALP activity is increased.
- Mild to moderate hyperproteinemia occurs in 50% of acromegalic cats, but the serum protein electrophoretic pattern is normal.
- Hyperphosphatemia may develop secondary to increased renal tubular reabsorption of phosphorus promoted by GH.
- There may be a stress leukogram, anemia (in dogs, the cause is uncertain), or mild erythrocytosis (in cats, due to GH-stimulated erythropoiesis).
- Acromegalic cats that develop renal failure have persistent proteinuria (100–300 mg/dl) with dilute urine specific gravity (USG) (1.015–1.025).

Radiography

Examine for the following:

- Visceral enlargement (cardiomegaly, hepatomegaly, renomegaly)
- Soft tissue proliferation (oropharyngeal region, head, limbs)
- Bony changes (spondylosis, hyperostosis of the calvarium, periarticular periosteal reaction)
- Left ventricular and septal hypertrophy in acromegalic cats with cardiomegaly (by echocardiogram)

Other Diagnostic Imaging

Magnetic resonance imaging (MRI) and computed tomography (CT) may be helpful in identifying a possible pituitary tumor (see Chapter 4 for an overview of CT and MRI).

Growth Hormone Determination

Increased circulating GH concentrations confirm a diagnosis of acromegaly. However, GH concentrations may be normal in some acromegalic patients and may be increased in a variety of other diseases.

- Increased GH concentration in the presence of profound hyperglycemia supports a diagnosis of acromegaly because hyperglycemia would normally be expected to suppress GH secretion.
- Alternatively, an integrated 24-hour GH concentration determined by frequent sampling throughout the day may be more indicative of GH hypersecretion than solitary determinations.
- Validated GH radioimmunoassays are not widely available for the dog or cat. Utrecht University in the Netherlands measures canine and feline GH concentrations in plasma. However, until such assays are routinely obtainable, diagnose acromegaly presumptively (see "Diagnosis" on page 400).

Insulin-Like Growth Factor

Determination of IGF-I gives an indirect indication of GH concentration. Increased IGF-I concentrations develop in acromegalic dogs and, seemingly, in acromegalic cats; however, increased IGF-I concentrations may also be found in diabetic cats without evidence of acromegaly. A validated assay is available at the Endocrine Diagnostic Laboratory of Michigan State University (telephone: 517-353-0621, website: www.ahdl.msu.edu).

Treatment of Progesterone-Induced Acromegaly

Treat progesterone-induced acromegaly by ovariohysterectomy or discontinuation of progestogen drugs. The soft tissue overgrowth and respiratory stridor resolve; however, the skeletal changes persist. The insulin requirement for GH-induced diabetes mellitus also declines, but the reversibility of the diabetes depends on the insulin reserve of the pancreatic beta islet cells.

Treatment of Growth Hormone-Secreting Pituitary Tumors

Manage these tumors by surgery, radiation, or drug therapy.

Surgery

- Because surgical excision of the tumor probably necessitates a hypophysectomy, expect deficiencies of pituitary hormones postoperatively.
- Before surgery, precisely localize the pituitary tumor by CT or MRI because neoplastic extension into the hypothalamus precludes surgery.
- Trans-sphenoidal cryotherapy of a pituitary tumor in an acromegalic cat has been performed.

Radiation

The results of *cobalt irradiation* of pituitary tumors (total dose of 4800 cGy divided equally in 12 treatments during 4 weeks) in acromegalic cats have been variable. In one report involving two cats, no effect was seen on tumor size or GH concentration in one cat; in the other cat, the tumor reduced in size with subsequent reduction in GH concentration. These changes developed within 2 months of radiation treatment but lasted only 6 months before relapse. In another report, two of three acromegalic cats treated by irradiation had long-term remission (16 and 28 months).

Pharmacologic Management

This includes dopamine agonists and long-acting somatostatin analogues.

- Dopamine agonists: Bromocriptine lowers GH concentrations in many acromegalic humans, but its effect on GH concentrations in acromegalic cats is unknown. Selegiline (Anipryl, Deprenyl Animal Health) at oral dosages of 0.75 and 1.5 mg/kg/day failed to reduce the insulin requirements or improve the clinical signs in one acromegalic cat.
- Long-acting somatostatin analogues: Analogues such as SMS 201-995 (octreotide) inhibit GH secretion in most humans with acromegaly. However, subcutaneous dosages of octreotide, ranging from 10 to 200 µg/day, did not reduce GH concentrations in four acromegalic cats.

Management of Concurrent Growth Hormone-Induced Conditions

Provide symptomatic treatment of GH-related disorders in the initial management of acromegalic dogs and the long-term care of acromegalic cats.

- Congestive heart failure in some acromegalic cats initially responds to furosemide treatment (see Chapter 147 for more details on treatment of congestive heart failure).

- Inspiratory stridor in acromegalic dogs partially responds to cage rest, cooling, and oxygen therapy.
- The diabetes mellitus of feline acromegaly generally is refractory and requires insulin (neutral protamine Hagedorn [NPH], Lente, protamine zinc insulin, or Ultralente) twice daily. In some cats, combinations of short-acting insulin (regular insulin) with NPH insulin may help control hyperglycemia (see Chapter 34 for more details on management of diabetes mellitus).

Prevention

- No preventive measures currently are known to avoid the development of GH-secreting pituitary tumors in cats.
- Prevent acromegaly in dogs by ovariohysterectomy of non-breeding females and judicious use of progestogen drugs.

ACTH-Secreting Pituitary Hyperplasia or Neoplasia: Cushing Disease

Hyperplasia or neoplasia of the pituitary corticotrophs with resultant oversecretion of ACTH is the major cause of hyperadrenocorticism (Cushing disease) in the dog and cat. Excess ACTH may originate from the corticotrophs in either the pars distalis or the pars intermedia. Clinical signs, diagnostic testing, and treatment of Cushing disease are discussed in Chapter 33.

DISEASES OF PITUITARY HORMONE DEFICIENCY

Hypopituitary Dwarfism: Growth Hormone Deficiency

Etiology

- In German shepherds, hypopituitary dwarfism is associated with cystic distention of the craniopharyngeal duct (Rathke's pouch).
- It is not known whether expansion of the pituitary cyst destroys adjacent adenohypophyseal tissue or whether a primary defect in differentiation and secretory capability of the adenohypophyseal cells creates the cyst.
- Weimaraners develop GH deficiency in association with thymic abnormalities.

Clinical Signs

Signalment

- Age: Young animals are affected. Discrepancies in growth compared with littermates are apparent from 6 to 8 weeks of age.
- Breed: This is an autosomal recessive trait in the German shepherd and Carelian bear dog.
- Sex: There is no sex predilection.

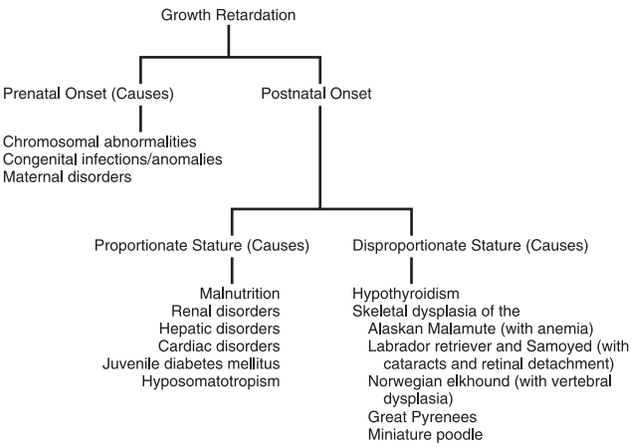

Figure 36-2. Classification of growth retardation by onset of growth problems and stature of dog.

General Appearance

- Growth retardation is characterized by proportionately stunted short stature. Affected German shepherds usually fail to exceed 13.5 kg in body weight or 47.5 cm in shoulder height by 1 year of age.
- The hair is soft and woolly, with retention of secondary (lanugo) hairs and lack of primary (guard) hairs. Progressive, bilaterally symmetrical truncal alopecia develops with age.
- Dental eruption may be delayed.

Concurrent Deficiencies of Other Pituitary Hormones

- Thyroid-stimulating hormone deficiency (secondary hypothyroidism) (see Chapter 31)
- ACTH deficiency (secondary hypoadrenocorticism) (see Chapter 33)
- Follicle-stimulating hormone or luteinizing hormone deficiency (secondary hypogonadism)

Diagnosis

Differentiate hypopituitary dwarfism from other causes of growth retardation (Fig. 36-2).

History

Identify breed predisposition and postnatal onset of growth problems (see Fig. 36-2).

Physical Examination

- The puppy is proportionately stunted.
- The haircoat initially remains as the animal matures, but truncal alopecia eventually develops.
- Additional clinical features characteristic of hypothyroidism, hypoadrenocorticism, or hypogonadism depend on the extent of hypophyseal involvement.

Routine Laboratory Tests

Hematologic, serum biochemical, and urinalysis results usually are normal for immature dogs. Hypophosphatemia may result from lack of GH-mediated renal tubular reabsorption of phosphorus.

Radiographic Abnormalities

- Delayed closure of the epiphyses
- Delayed dental eruption
- Delayed or incomplete calcification of the os penis

Growth Hormone Determination

- Basal GH concentrations do not differentiate normal dogs from dogs with GH deficiency.
- GH stimulation tests classically have been used to evaluate pituitary GH secretory capability.
  - Measure circulating GH concentrations in fasted dogs before and 5, 15, 30, 45, 60, and 90 minutes after intravenous administration of one of the following:
  - 0.1 or 0.3 mg of xylazine/kg (Gemini, Butler)
  - 3 or 10 µg of clonidine/kg (Catapres, Boehringer Ingelheim)
  - 1 µg of human GH-releasing hormone (hGHRH)/kg (Geref, Serono Laboratories)

Interpretation

- In normal dogs, circulating GH concentration increases within 30 minutes of xylazine, clonidine, or GHRH administration and then declines by 60 to 90 minutes.
- In dogs with hypopituitary dwarfism, no substantial increase in GH concentration develops after pharmacologic stimulation.
- In some children with GH neurosecretory dysfunction, GH response to pharmacologic stimulation is normal; nevertheless, spontaneous physiologic pulsatile GH secretion is decreased, as determined by 24-hour blood sample monitoring. A similar disorder may account for the delayed growth reported in a litter of German shepherds.

Insulin-Like Growth Factor I Measurement

Currently, validated GH radioimmunoassays are not routinely available for the dog except at Utrecht University, the Netherlands. However, measurement of serum IGF-I, produced in response to GH, gives an indirect indication of GH concentration. Importantly, IGF-I concentrations positively correlate with body size in various breeds of dogs. This assay is available at the Endocrine Diagnostic Laboratory of Michigan State University (www.ahdl.msu.edu).

- In GH-deficient German shepherds with pituitary dwarfism, IGF-I concentrations are subnormal.
- IGF-I concentrations in related but clinically unaffected dogs that are presumably heterozygous for the dwarf trait are intermediate between the IGF-I concentrations found in normal German shepherds and those obtained in dwarf German shepherds.

Other Endocrine Tests

Investigate for secondary hypothyroidism associated with hypopituitary dwarfism (see Chapter 31) and for secondary hypoadrenocorticism associated with hypopituitary dwarfism (see Chapter 33).

Skin Biopsy

- In canine GH deficiency, nonspecific histologic skin changes (atrophy of hair follicles, epidermis, and sebaceous glands) are similar to those seen in other canine endocrinopathies; however, a decreased number of elastin fibers are present in the dermis.

Treatment

Growth Hormone Replacement Therapy

- Current guidelines recommend bovine or porcine GH preparations subcutaneously at 0.1 IU/kg 3 times weekly for 4 to 6 weeks. Historically, GH replacement for the dog has been difficult to obtain and expensive. With the development of biosynthetic bovine GH (Posilac, Monsanto), an inexpensive source of GH seemed readily available. Unfortunately, this product, designed for use in cattle, cannot be formulated for the dog's smaller dose requirement and is not approved for use in dogs.
- Biosynthetic human GH appears to induce antibody formation in dogs that interferes with its effectiveness, and similar immunogenicity problems may be associated with bovine GH administration to dogs. Porcine GH, similar immunologically to canine GH, is available through Dr. A. F. Parlow, Pituitary Hormones and Antisera Center, Harbor-UCLA Medical Center, Torrance, California.
- No increase in size occurs if dogs are treated after epiphyseal closure.
- Because GH is diabetogenic, monitor blood glucose concentrations during treatment.
- Treatment of canine GH deficiency with progestogens to induce GH production by the ductular epithelium of the mammary glands has been reported.

Thyroid Hormone or Glucocorticoid Replacement Therapy

Initiate therapy if concurrent hypothyroidism or hypoadrenocorticism exists (see Chapters 31 and 33).

Prevention

Because hypopituitary dwarfism is inherited in an autosomal recessive manner in German shepherd and Care-

lian bear dogs, genetic counseling may help eliminate this disease. Identify possible heterozygotes by IGF-I assay, and eliminate these carrier animals from breeding programs.

Central Diabetes Insipidus: Antidiuretic Hormone Deficiency

Diabetes insipidus (DI) is a disorder of water metabolism characterized by polyuria and polydipsia. It is caused by defective secretion or synthesis of ADH (central DI) or the inability of the renal tubule to respond to this hormone (primary nephrogenic DI).

Deficiency of ADH or renal insensitivity to ADH can be partial or complete.

Etiology

Central DI (also called neurogenic DI) is an uncommon condition that results from disorders that disrupt the ADH-producing hypothalamic neurohypophyseal neurons.

- Idiopathic
- Central nervous system (CNS) trauma
- CNS neoplasia
- CNS inflammation
- Congenital anomalies

Clinical Signs

Signalment

- Age is variable, depending on the cause.
  - Idiopathic and trauma-induced DI has no specific age predilection.
  - Animals with suspected congenital DI are <1 year of age.
  - Animals with DI caused by CNS neoplasia are usually middle-aged to older.
- Breed: No predilection
- Sex: No predisposition

Polyuria and Polydipsia

- ADH acts on the distal tubules and collecting ducts of the kidneys to allow increased water reabsorption.
- Lack of ADH or interference with the ability of ADH to bind to its receptors results in water diuresis.
- This primary polyuria results in volume contraction and subsequent compensatory polydipsia.

Diagnosis

The diagnosis of DI requires its differentiation from other more common causes of polyuria and polydipsia, such as renal insufficiency, diabetes mellitus, hypercalcemia, pyometra, feline hyperthyroidism, and canine hyperadrenocorticism.

History

Profound polyuria and polydipsia (>100 ml/kg/day; normal is approximately 40–70 ml/kg/day) are found.

Physical Examination

Findings are usually normal with the following exceptions:

- Weight loss (if the animal is preoccupied with drinking).
- Dehydration (if water is withheld).
- Neurologic signs (e.g., disorientation, seizures, and blindness) may develop in animals with pituitary or hypothalamic neoplasia or trauma.

Routine Laboratory Tests

- Hematologic and serum biochemical results are usually normal or consistent with mild dehydration (mild increases in packed cell volume and serum concentrations of total protein and sodium).

▼ ***Key Point*** Urine dipstick and sediment evaluations are normal, but USG is typically in the range of 1.000 to 1.007.

- Animals with partial deficiencies in ADH may produce more concentrated urine (USG 1.008–1.020).
- Urine culture is negative.

Radiography

Findings usually are normal.

Other Diagnostic Imaging

MRI and CT can aid in identifying a pituitary or hypothalamic lesion.

Water Deprivation Test

This test is designed to determine whether endogenous ADH is released in response to dehydration and whether the kidneys can respond to ADH. Minimal increases in plasma osmolality should stimulate the release of ADH.

▼ ***Key Point*** Water deprivation tests are contraindicated in animals that are already dehydrated (since the stimulus for ADH release already exists) or in the presence of other laboratory abnormalities such as azotemia or hypercalcemia.

Because water deprivation causes dehydration, this test is potentially dangerous and can result in acute renal failure, neurologic complications, and death. For this reason, perform comprehensive diagnostic testing,

Table 36-2. PROCEDURE FOR WATER DEPRIVATION TEST

- Quantitate daily unrestricted water consumption.
- Measure urine specific gravity (USG) and weigh the animal.
- Gradually restrict water intake over 3 to 5 days to 100 ml/kg/day. Monitor body weight and USG daily. Use the criteria below as end points.
- To continue the test, empty the urinary bladder and measure USG (and urine osmolality if possible).
- Withhold all food and water.
- Every 2 hours, reweigh the animal, empty the urinary bladder, and measure USG (and urine osmolality if possible). Use the criteria below as end points.
- *Stop the test when any of the following occur:*
  - The animal loses 5% of its body weight.
  - The animal is clinically dehydrated or ill.
  - USG ≥ 1.030.

including complete blood count, serum biochemical profile with electrolyte determinations, complete urinalysis, urine culture, and imaging of body cavities, to rule out disorders that may decompensate following dehydration (e.g., pyometra, pyelonephritis, renal insufficiency, and hypercalcemia). Tests of renal function (e.g., iohexol or 99m technetium-diethylenetriaminepentaacetic acid clearance), adrenal function (e.g., low-dose dexamethasone test, ACTH stimulation test, or urine cortisol-to-creatinine ratio), and thyroid function (total thyroxine determination in cats) also may be indicated before initiating water deprivation.

Procedure

- See Table 36-2. Initial gradual reduction in water intake in patients with renal medullary washout (which often accompanies polyuric disorders) allows them to reestablish the medullary concentration gradient.

Interpretation

- When deprived of water, normal animals can concentrate the USG to 1.075 in cats and 1.045 in dogs. Nevertheless, a USG of 1.030 is generally considered an adequate response to water deprivation. Failure to concentrate to this degree in the absence of renal disease or other laboratory abnormalities indicates that the animal has central or nephrogenic DI (Fig. 36-3).

Antidiuretic Hormone Response Test

If the animal fails to concentrate urine adequately following water deprivation, perform an ADH response test. The test evaluates the ability of the renal tubule to respond to exogenous ADH and concentrate urine in the face of dehydration.

Procedure

- Immediately following the water deprivation test, administer aqueous vasopressin (Pitressin, Parke-Davis) at 0.5 U/kg (maximum dose is 5 units) IM.
- Withhold all water and food during the test.
- Empty the urinary bladder and measure USG (and osmolality if possible) at 30, 60, 90, and 120 minutes after vasopressin injection.
- The animal may drink after the test is completed.

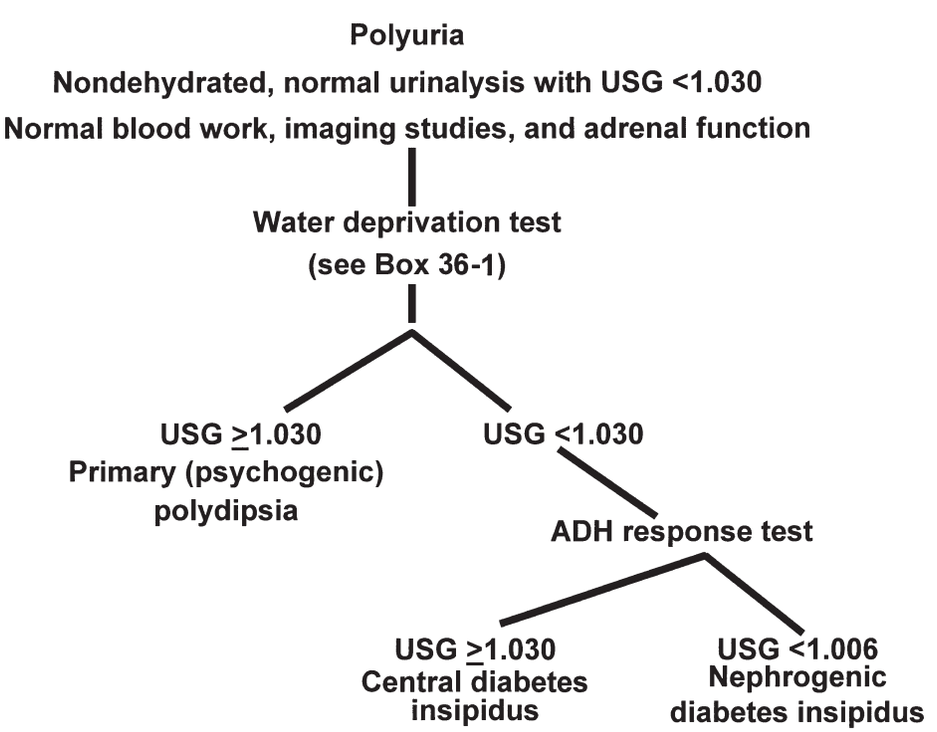

Figure 36-3. Algorithm for evaluation of an animal with polyuria and polydipsia. ADH, antidiuretic hormone; USG, urine specific gravity.

Alternative Procedure

- Immediately following the water deprivation test, administer the synthetic analogue of ADH, desmopressin acetate (DDAVP, Rhone-Poulenc Rorer) at a dose of 10 to 20 µg IV. Although desmopressin is commercially available as a parenteral preparation for IV injection (4 µg/ml), this formulation is more expensive than the intranasal preparation of desmopressin (100 µg/ml). The intranasal DDAVP has been given to animals by injection; but, because this preparation is not sterile, it should be passed through a bacteriostatic filter.
- Offer small amounts of water hourly (2.5–3.0 ml/kg) during the test.
- Measure USG (and osmolality if possible) every 2 hours for 6 to 10 hours after desmopressin injection. The maximum response to IV desmopressin usually occurs in 4 to 8 hours, but in some animals it takes longer than 10 hours to see a maximal response.

Interpretation

Failure to concentrate urine with water deprivation followed by a rise in USG ≥ 1.030 after ADH administration is supportive of central DI; urine that remains hyposthenuric after the ADH response test is suggestive of primary nephrogenic DI (see Fig. 36-3). However, USG values between 1.006 and 1.030 may be difficult to interpret without also evaluating the change in USG and urine osmolality.

Antidiuretic Hormone Determination

Measurement of endogenous ADH levels after water deprivation may aid in differentiating central DI (ADH levels subnormal) from primary nephrogenic DI (ADH levels within or above the normal range). Unfortunately, validated canine and feline ADH assays are not routinely available.

Therapeutic Antidiuretic Hormone Trial

As an alternative to the water deprivation test and the ADH response test following water deprivation, perform a closely monitored therapeutic trial with desmopressin acetate.

▼ ***Key Point*** Prior to performing a therapeutic ADH trial, rule out all common causes of polyuria and polydipsia, thus limiting the differential diagnosis to central DI, primary nephrogenic DI, and primary (psychogenic) polydipsia.

- Procedure: Administer the intranasal preparation of DDAVP in the conjunctival sac (1–4 drops q12h) for 3 to 5 days while monitoring daily water intake.
- Interpretation: A dramatic reduction in water intake (greater than 50%) during the treatment period would strongly suggest a diagnosis of central DI. When polyuria is due to other causes, the decrease is seldom more than 30%. Beware of water intoxication if ADH treatment reduces polyuria yet excessive water intake persists in animals with primary (psychogenic) polydipsia.

Treatment

Antidiuretic Hormone Replacement Therapy

- Desmopressin acetate is the drug of choice for the treatment of central DI in dogs and cats.
- Repositol ADH (vasopressin tannate in oil), once the only long-acting ADH preparation available, is no longer manufactured.
- DDAVP is available as an aqueous solution (100 µg/ml) intended for intranasal use and as oral tablets (0.1 mg and 0.2 mg).
- The intranasal form of DDAVP is also effective when applied topically in the conjunctival sac (1–4 drops q12–24h) or injected subcutaneously (2–5 µg q12–24h after sterilization by passing through a bacteriostatic filter). The oral form of DDAVP (a 0.1-mg DDAVP tablet is equivalent to approximately 1 large drop [5 µg] of intranasal DDAVP) is given initially at 0.1 mg once to twice daily.
- Adjust the daily dose to control polyuria and polydipsia.
- The major disadvantage of this treatment is expense.

Non-hormonal Therapy

- Thiazide diuretics may reduce the polyuria of DI but are never as effective as ADH replacement. Thiazide diuretics reduce total body sodium by an initial natriuresis, resulting in decreased extracellular fluid volume and reduced glomerular filtration rate. These changes cause increased fluid reabsorption in the proximal renal tubule and reduce urine output.
  - Administer chlorothiazide (Diuril; Merck, Sharp, & Dohme) at a dosage of 20 to 40 mg/kg q12h PO.
  - Restrict salt intake to potentiate the drug's effectiveness.
  - Because hypokalemia may develop with thiazide diuretic therapy, monitor serum electrolyte concentrations during treatment.
- Chlorpropamide (Diabinese, Pfizer) is an oral hypoglycemic agent that potentiates the action of ADH on the renal distal tubules and collecting ducts. Because chlorpropamide requires some ADH to be effective, it reduces the polyuria in animals with partial ADH deficiency only.
  - Administer chlorpropamide at a dosage of 10 to 40 mg/kg/day.
  - Monitor blood glucose concentrations during treatment.

Secondary (Pituitary) or Tertiary (Hypothalamic) Hypoadrenocorticism

This is caused by ACTH or corticotropin-releasing hormone deficiency. See Chapter 33.

Secondary (Pituitary) or Tertiary (Hypothalamic) Hypothyroidism

This is caused by thyroid-stimulating hormone or thyrotropin-releasing hormone deficiency. See Chapter 31.

MISCELLANEOUS DISORDERS

Adipsia and Hypodipsia

Adipsia and hypodipsia are defined as absent and reduced thirst, respectively. Normally with water loss, mild increases in plasma osmolality stimulate osmoreceptors in the hypothalamus to increase water consumption and ADH secretion. However, even with maximal ADH secretion, hyperosmolality (specifically hypernatremia) escalates unless the thirst mechanism is intact. With adipsia or hypodipsia, hypernatremia develops with resultant dehydrating effects on the cells of the CNS. It is usually unclear whether the defect in thirst in affected animals is due to an increased osmoreceptor threshold (reset setpoint) or to structural lesions in the thirst center of the hypothalamus.

Etiology

- Idiopathic
- Hypothalamic dysplasia or congenital anomalies
- Hypothalamic degeneration
- Hypothalamic inflammation, neoplasia, or trauma

Clinical Signs

- Signalment
  - Age: Young (usually <1 year) in idiopathic and congenital forms of the disorder
  - Sex: Female predisposition in the miniature schnauzer
  - Breed: Miniature schnauzer
- Depression, stupor, or coma
- Personality change
- Disorientation
- Anorexia
- Weakness or lethargy
- Irritability or seizures

Because hypothalamic conditions associated with adipsia or hypodipsia may cause neurologic signs independent of the sodium concentration, the relative contribution of hypernatremia to the CNS signs can be assessed once a normal sodium concentration is restored.

Diagnosis

History

Adipsia or hypodipsia has occurred despite free access to water, and the clinical signs listed previously are present.

Physical Examination

There is evidence of dehydration and signs of altered mentation.

Routine Laboratory Tests

Hematologic, serum biochemical, and urinalysis results are consistent with dehydration:

- Hypernatremia (profound)
- Hyperosmolality (profound)
- Hyperchloremia
- Azotemia (mild)
- Hyperalbuminemia (mild)
- Hypersthenuria

Radiography

Findings usually are normal.

Other Diagnostic Imaging

MRI and CT may identify a hypothalamic lesion.

Treatment

The brain attempts to adapt to the hyperosmolar state by increasing its cellular osmolality with sodium, potassium, amino acids, and unidentified solutes (idiogenic osmoles). If plasma hyperosmolality is corrected too rapidly, the brain cells continue to be hyperosmolar relative to the plasma, and cerebral edema may develop.

▼ ***Key Point*** Rapid correction of the chronic hyperosmolar state in adipsia or hypodipsia may lead to cerebral edema.

Initial Therapy

- If the animal is dehydrated, reestablish tissue perfusion with isotonic saline or Ringer's solution before using sodium-restricted fluids. The osmolality of these solutions is still less than the patient's serum osmolality, so some reduction in serum sodium concentration and osmolality may occur.
- For initial management of the hydrated animal in order to correct hypernatremia without lowering serum osmolality too rapidly, administer a sodium-restricted isotonic fluid IV (D5W or 0.45% NaCl with 2.5% dextrose) only to correct the animal's water deficit. Preferably, if the animal is cooperative, administer oral fluids to correct the water deficit.

- Calculate the animal's water deficit based on the serum sodium concentration or osmolality and a normal total body weight of water of 60%:

$$\text{Water deficit (liters)} \cong 0.6 \times \text{Body weight (kg)} \times \left(1 - \frac{\text{Normal sodium (mEq/L)}}{\text{Patient sodium (mEq/L)}}\right)$$

- Replace the water deficit to lower serum sodium concentration ≤ 0.5 mEq/L/hr. Generally, this rule translates to replacing the calculated water deficit during a period of 3 days.

- Add maintenance fluid requirement (60 ml/kg/day) with isotonic polyionic solution to the daily infusion.
- Monitor serum electrolytes frequently and adjust fluid type and rate as needed to ensure that serum sodium concentration is not lowered too rapidly.

Maintenance Therapy

For chronic management once the animal is eating, mix maintenance daily water intake (50–60 ml/kg/day) with food.

Skin Cytology and Biopsy

Sonya V. Bettenay

The use of a variety of cytologic diagnostic tools and skin biopsy may greatly facilitate the treatment and ultimate outcome for the dermatologic patient. Interpretation of the results is as important as the correct collection of the sample.

Skin cytology is a tool that can be used on almost every patient presenting with an inflammatory dermatitis or otitis externa. It often provides therapeutically relevant information, particularly regarding the selection of antimicrobial therapy. Individual preference and the actual clinical presentation will dictate which of the different sampling techniques is selected. The first part of this chapter elaborates on the various cytology techniques, their special indications, and their interpretation. The second part reviews skin biopsies.

There are specific indications for performing a skin biopsy that, along with interpretation tips, will be discussed. The aim is to take steps required to obtain the most diagnostic sample and to give the pathologist the best chance of reaching a diagnosis. Special reference is made to the biopsy techniques used for sampling the inner pinnae and claws.

SKIN CYTOLOGY

Skin cytology techniques range from those that sample the surface to those that sample deep inside a cutaneous nodule. To the practitioner, the importance of in-house skin cytology in the diagnosis and management of many dermatoses has become more apparent over the past decade. The use of in-house skin cytology is no longer restricted to the patient with nodules or draining tracts but has been expanded to most patients with inflammatory skin disease (and some with non-inflammatory dermatitis).

▼ ***Key Point*** Surface cytology is indicated at the initial presentation of many, if not all, dermatology patients.

One of the major reasons for the increased usage of this diagnostic method is the recognition of the prevalence and significance of staphylococcal pyoderma (see Chapter 38) and yeast dermatitis caused by *Malassezia pachydermatis* (see Chapter 41). Furthermore, the widespread availability of "user friendly" diagnostic aids such as in-house rapid cell-staining kits and good quality, price competitive microscopes has facilitated the use of these techniques by general practitioners.

Sampling Techniques

The most common sampling techniques include Scotch tape impression, adhesive glass slide impression, direct glass slide impression, skin-scrape and smear (using a spatula or scalpel blade), cotton bud (Q-tip) "sample and smear," and aspiration. In-house processing typically uses one of the rapid-stain products; these stains

are generally not used by cytologists, who prefer the traditional Wright stain because of a superior appearance of cellular morphology with these stains. Thus air-dry but do not stain samples that will be submitted to a cytologist. Obtain a smear of one cell thickness to clearly observe cellular morphology, irrespective of the stain.

Scotch Tape Impression

This is particularly advantageous for scanning the surface for yeast and/or significant numbers of bacteria (both rods and cocci). It gives poor cellular definition, although inflammatory cells can be identified. Two techniques with different staining have been described, but the collection method is identical. The use of Scotch tape that is not the "invisible" type avoids the problem of numerous small artifactual circles. In my hands, the cheapest brands of clear Scotch tape are often the best.

Technique

- Press a small (4–5 cm) piece of the tape "sticky side down" onto the skin.
- Place the Scotch tape onto a glass slide that has a drop of the "Blue" or third stain in the triple fixative stain packs (e.g., Diff-Quik). Undiluted new methylene blue is too strong a stain to easily see through and will need to be diluted before use.
- The alternative method is to process the Scotch tape as though it were a glass slide, dipping it in all of the "rapid fix" solutions in order.
- Avoid obtaining small, scrunched pieces of tape that appear to have lost some of their contents.
- Using a single piece of tape to screen a variety of sites saves time but lacks site specificity. Nevertheless, it provides a rapid technique of screening for yeast in particular. A negative result rules out *Malassezia* dermatitis quickly.
- If yeast are found, precise knowledge of the yeast-positive sites is important from a therapeutic point of view; each of the sites screened must then be resampled individually.

Adhesive Glass Slide Impression

This technique has been used for suspected *Malassezia* dermatitis cases in particular; it is probably most indicated for use in standardized tests, such as in a scientific study. The slides must be specially ordered and purchased, and they are relatively expensive. The sampling is through direct impression, and the processing is through regular cytologic staining.

Direct Glass Slide Impression

Technique

- Place the glass slide directly onto the skin surface with gentle pressure.
- This technique is most practical for areas that are moist or exudative.
- Take care to obtain a thin enough smear.
- The sample collected may need to be separated onto another slide and thinly smeared. Some anatomic sites are not well suited to this technique, such as the ventral interdigital fold and periocular area. Pressure must often be applied to have the material adhere to the slide; beware of breaking the slide with too much pressure.
- A variation of this technique may yield significantly higher numbers of organisms. The glass slide is not simply pressed downward but also pushed a little along the surface at a 45-degree angle so that the skin is smeared along the glass surface. This technique requires a little more pressure, which is directed at the leading edge of the slide. Take care that this leading edge does not cut the skin.

Surface Skin Scrape

This technique is aimed at collecting cells and organisms (bacteria and yeast) from the skin surface. It is different from the deep skin scrape and the superficial skin scrape, which use mineral oil and are used for the detection of mites (such as *Demodex* and *Sarcoptes,* respectively).

Technique

- Gently scrape a blunt, straight-edged instrument (such as a spatula or #10 scalpel blade) along the surface of the skin and collect cells and debris, even from a dry surface.
- "Scoop" these up using the same motion as buttering bread.
- Transfer the contents on the edge of the instrument to the glass slide; smear the collected material out as you would with a "squash prep" aspirate.
- Heat fix the slide before routine processing.
- This technique is excellent for evaluation of keratinocytes, bacteria, yeast, and other material on the skin surface.
- In human medicine, it is most often used to search for surface fungi such as *Pityrosporum* (yeast forms and hyphae) or dermatophytes (hyphae, rarely endothrix spores) and is first processed with potassium hydroxide (KOH) to remove the keratinocytes and leave the organisms. KOH dissolution of keratinocytes is almost never used in my practice. If it is indicated, then one of the modified formulations that does not require heating is preferred.
- If KOH dissolution *is* planned, then the KOH (modified) solution is dropped on to the slide and the cell debris is mixed through and allowed time to work. This is then smeared thin, air-dried, and stained. In both cases, staining is routine after the sample material dries.

Cotton Bud (Q-Tip) Sample and Smear

Technique

- Because the Q-tip can be inserted into a small opening, this sampling technique is most useful for external ear canals, draining tracts, or interdigital folds.
- Gently roll the collected material onto the glass slide; a thin layer of material is best for cytologic interpretation.
- Rolling with too much pressure or "rubbing" the tip to and fro may disrupt the cells, affecting interpretation (see below).
- Organisms found on the surface of the sample should correlate to those "deepest" in the exudate; consider evaluation of two smears to distinguish organisms on the surface from those that are deeper.
- In cases of otitis externa, in which there is a considerable amount of exudate within the ear canal, a third smear may even be added—taken after most of the exudate has been gently removed. Multiple organisms will often be identified in these situations, and some may be missed if only one "level" of the exudate is sampled. A recent bacterial culture study, using samples taken sequentially from the *same anatomic site* of ears with otitis externa, revealed different organisms on sequential samples.

Tzanck Preparation or Smear

As originally described, this technique is *an aspirate of the contents* of a pustule; however, it is technically difficult unless there is a large pustule and is therefore rarely performed this way. Such large pustules are typically seen on the ventral abdomen and with cases of "puppy impetigo" and pemphigus foliaceus.

Technique

- Gently insert the tip of the needle into the pustule, bevel side upward, and with a lifting motion to use the sharp edge of the bevel to cut through the "roof" or surface of the pustule.
- Transfer the contents of the pustule to a glass slide by gentle impression.
- Rupturing the roof of the pustule changes the possible interpretation and negates the possibility of a "sterile" culture. However, this modified technique is adequate to look for cytologic clues about the etiology of the pustule, which is the major reason to perform this technique.

Assessment for inflammatory cells, bacteria, and the presence or absence of acantholytic keratinocytes may help prioritize the differential diagnosis list. The presence of eosinophils should alert you to the possibility of ectoparasites, in particular scabies or fleas. Neutrophils are most commonly associated with a bacterial infection; when they are intact and the predominant cell type, scan carefully for any evidence of intracellular organisms. Conversely, and importantly, superficial pyodermas are often *not* associated with bacteria on cytologic examination. Acantholytic keratinocytes, which are referred to as "fried eggs" because of their large, rounded shape with a large, round central nucleus, may be used as supportive evidence for a diagnosis of pemphigus foliaceus; however, these rounded keratinocytes may also be seen in superficial pyodermas. Regard acantholytic keratinocytes as suggestive or supportive of a diagnosis of pemphigus foliaceus but not as sufficient evidence to confirm a diagnosis. Never institute immunosuppressive therapy on the basis of those findings alone.

"Aspiration Cytology" Sampling

This type of sampling is used predominantly for nodules. Cytologic evaluation is useful in the initial investigation because it may allow an early differentiation between neoplasia and infection.

Technique

- Firmly fix the nodule with one hand, insert the needle to the center of the nodule, and obtain cells for subsequent cytologic staining.
- The first method uses a needle without an attached syringe. Insert the needle several times at multiple angles without withdrawing it through the skin. Aim the tip of the needle at the center of the nodule. By this movement, the cells will be driven into the body of the needle. This technique is favored by oncologists because they believe there is the least chance of "seeding" tumor cells into the surrounding tissue.
- The alternative technique uses a needle with an attached syringe. Once the needle is inserted into the center of the nodule, apply negative pressure. Release this negative pressure before the needle is removed from the skin to avoid sucking the cells into the body of the syringe.

With either technique, once the needle is removed from the tissue, attach an air-filled syringe and blow the cells out onto the surface of the glass slide. Hold the needle *bevel side down* to collect as many cells as possible. Smear thinly using a blood smear technique or squash prep technique as appropriate, air-dry, and stain. The absence of cellular material using this technique is interpreted by some as indicating a densely cellular mass such as a fibrous cell tumor.

"Touch" Preparation

Use this with a surgical biopsy specimen.

Technique

- Gently touch the undersurface or base of the tissue to the glass slide.

- This technique is also useful for cytologic evaluation of crusts: Gently touch the undersurface of the crust or the exposed surface of the skin once a crust has been removed with the glass slide.
- Air-dry and stain as usual. Submit the tissue from a surgical excision for histopathology. I routinely save four additional air-dried, unstained slides. These may be used by the laboratory for adjunctive tests.
- In rare instances, organisms have been identified on the touch prep but not on histopathology.
- With some atypical neoplasms, cytology may give clues about the cell of origin, which even "special stains" may fail to differentiate on histopathology.
- Immunohistochemical staining may be possible with cytology samples that have been deep-frozen. With some select types of immunohistochemical staining, formalin-fixed tissue cannot be used because of the degeneration of antigens. In those instances, a cytology slide that has been air-dried and deep-frozen can be used immediately, eliminating the expense, discomfort, and delays created by a repeated surgical procedure. Transport these slides to the laboratory so that the formalin fumes that may emit from the tissue specimen do not contact the cells on the slide. Shipping in separate packages may be required.

Processing

As mentioned previously, there are some important principles with regard to the processing of cytology samples.

- Handle the sample gently, whether the material is rolled onto the glass slide or "squashed and pulled" between two slides as in a squash prep. The cells are friable and may rupture if handled roughly. Breakage of the cells not only affects the cytologic evaluation but also may interfere with interpretation. For example, the presence of ruptured neutrophils in a carefully handled sample may be used as an indication of neutrophil toxicity.
- Always make a duplicate slide, which remains unstained and ready for submission to a cytology laboratory should there be a need for more expert interpretation based on the in-house test results. Laboratory cytologists *do not* regard the "instant staining" methods available in general practice as adequate. This may be particularly useful for clinicians with less experience in cytology but who are trying to improve their skills in this area; compare the results reported by the laboratory cytologist with those obtained in-house.
- Process the sample carefully if cellular morphology is important, following the exact instructions for the staining technique. Examples would be impression smears from inflammatory dermatoses or aspirates from nodules. Under- or over-staining may affect the color of the contents of the cell. The Scotch tape impression smear is not suitable for those cases in which cell morphology is important.
- Heat fixing is contraindicated if cellular morphology is of interest. This procedure is most relevant for exudates with a large wax content, such as an otitis externa sample, but even in those cases cellular detail may be important to assess. Air-drying is the preferred technique; in practice, the use of a cold air–low heat hair dryer may help reduce the time required for drying.
- Although clinician preference varies, I typically view these samples using 400× microscopic magnification.

Interpretation

Surface Cytology

Regardless of the collection technique, I use surface cytology to look for organisms and perhaps for inflammatory cells. Microbes identified by the regular cytology stains can be classified by shape, size, and quantity. Perform a culture to determine the species. The subclassification of gram positive or negative is not possible using the regular cytology stains. Therefore, surface cytology screening looks for the presence of yeast, cocci, and rods; hyphae may be seen as ghosts (they do not typically take up the stain) by more experienced cytologists.

You should not be able to see significant numbers of microbes on the surface cytology of normal skin. Surface cytology sampling yields a significant amount of debris, associated with the dirt, environmental mold spores, surface lipids, and free keratin, which all sit on the outer surface of the stratum corneum. Practice on non-lesional skin of normal dogs to become familiar with normal versus abnormal surface cytology.

On the skin, the cocci will be predominantly the *Staphylococcus* species, the yeast predominantly the *Malassezia* species, and the rods generally contaminants.

- Yeast organisms are found in the more humid areas of the skin, such as the ventral neck, perianal, interdigital, and perioral areas. Geographic variation may be possible so that the "normal" number of yeast is higher in warm and humid areas. In one report, the presence of one or two organisms per high power field (HPF) was defined as within normal limits. However, in a temperate climate, this number of yeast is high, and an animal with clinical signs of infection and one or two yeast per HPF (400×) is regarded as having an active infection and will receive topical therapy. Systemic therapy is based not simply on numbers of organisms but also on severity of clinical symptoms and total area of the body affected. Systemic antifungals are expensive, and some have the potential for severe toxicity.
- Cocci may be seen attached to the surface of keratinocytes. This may be interpreted as active colonization, indicating a more pathogenic strain. More

often, cocci are seen scattered throughout the sample, often in small groups either with or between keratinocytes. This is abnormal and typically consistent with a superficial pyoderma. Intracellular cocci are regarded as a sign of increased severity of infection. Prescribe systemic antibiotics in these animals.

▼ ***Key Point*** The absence of cocci on cytology does *not* rule out the possibility of staphylococcal pyoderma.

- The presence of significant numbers of rod-shaped bacteria is not normal on the skin surface and may be interpreted as representing an abnormal surface environment, with overgrowth of a nonpathogen, or colonization. Perform culture if there are abundant rod-shaped organisms, the area of affected skin is large, or a deep pyoderma is clinically determined. Many cases with surface rod overgrowth but mild clinical signs will respond to topical shampoo therapy, often with specific therapy aimed at the underlying disease, such as hypothyroidism or severe chronic allergies. If *systemic* therapy is necessary, never select an antibiotic empirically. Perform culture and susceptibility testing in these cases because rod-shaped bacteria (e.g., *Pseudomonas* spp.) are often resistant to multiple antibiotics.

Ear Cytology

Compared with skin surface cytology (as described previously), interpretations of ear cytology vary significantly with otitis externa because the ear canal provides a unique surface environment. The narrow, long canal is associated with an increased local humidity and temperature compared with the skin surface in general. Variation with season, humidity, degree of hair growth, and anatomy (pendulous versus erect pinna types) is important. Finally, the surface of the canal is not readily visible, so observation of increased exudate or redness by the owners is not possible until it extends to the entrance of the canal and on to the pinna or surrounding skin.

- *Yeast* are a normal inhabitant of the external ear canal. Small numbers are regarded as "normal" because they may be cultured from most normal canine ears. Nevertheless, on surface cytology this number has yet to be clearly quantified. For an external ear canal with significant numbers of yeast on cytology, consider the clinical signs.

▼ ***Key Point*** If there are up to five yeast/HPF and no evidence for clinical otitis, then yeast are regarded as an overgrowth and an ear cleaner is recommended. If there is clinical evidence of inflammation, then as few as two yeast/HPF will be interpreted as supportive of a yeast otitis.

- *Bacteria* form part of the normal otic skin flora. However it is unusual to identify bacteria with surface cytology of the external ear canals; therefore, consider any notable numbers as suspicious of an infection. The presence of small, round organisms that are not well defined or large enough to be staphylococci or streptococci probably represent the *Bacteroides* species, which is a ubiquitous organism whose pathogenicity is controversial. A significant number of these organisms on surface cytology at least represents an aberrant surface population and possibly suggests overgrowth.
- Rod-shaped bacteria on surface cytology of the external ear canal suggests the need for a bacterial culture and susceptibility testing, especially if initial empiric therapy has been attempted and was not successful.
- Record the number of bacteria of each type (cocci and rods), for example, as none, few, many, or abundant or on a semiquantitative scale from 0 to 3 (0 = none, 1 = easily countable, 2 = not easy to count, 3 = impossible to count). This is useful in monitoring response to therapy at recheck visits.

Fine-Needle Aspiration

Interpretation of fine-needle aspiration (FNA) is helpful to differentiate an infectious or cystic process and may or may not identify neoplastic cells (also see Chapters 26 and 30). Performing in-house cell cytology allows the development of a prioritized differential diagnosis list. Evaluate cytologic aspirates with some specific criteria (see below). Send to an experienced cytologist those samples that require more expert interpretation.

Palpate the lesion before obtaining an aspiration sample. Determine if the nodule is within the epidermis, dermis, or subcutaneous tissue. The epidermis contains four major cell groups, which may become neoplastic. These are the squamous (epidermal) cells, melanocytes, a pluripotential follicular cell (which produces basal cell carcinoma), and cells that comprise the hair follicle and adnexae. Most inflammatory nodules are localized in the dermis. The dermis contains nerve cells and vascular and connective tissue. In addition, the dermis is often the host site for neoplastic cells derived from bone marrow. Lymphocytes, mast cells, and macrophages may form cutaneous accumulations of neoplastic cells. The subcutaneous tissue contains predominantly fat.

- From a clinical viewpoint, neoplasms arising in the subcutaneous tissue initially do not affect the hair follicles and adnexae; thus the overlying skin and hair remain normal in appearance.
- More superficially located neoplasms (such as those in the epidermis and superficial dermis) commonly affect adnexal structures, resulting in alopecia.

Palpation can also reveal whether the lesion is mineralized, painful, cystic, or cellular. Fluctuant tumors must be differentiated from an inflammatory lesion

such as an abscess. When they are not warm to the touch or painful, infection is less likely but cannot be ruled out. Cystic epidermal tumors (epidermal cysts and hair follicle tumors) are common in the dog but rare in the cat. The typical keratin-filled cavity is often palpable as a fluid-filled cystic lesion.

Inflammatory Lesions

Inflammation is present in most cases that contain a "mixed cell" population in which no one cell type predominates. Significant numbers of neutrophils are seen with an acute inflammatory process. As the relative numbers of macrophages increase, the process is considered chronic inflammation. A chronic inflammatory process, with few neutrophils and significant numbers of large, foamy macrophages, would be consistent with an inflammatory process in which there had been some tissue destruction but which may even be spontaneously resolving. Alternatively, an increased number of neutrophils, in association with macrophages, indicates the need for cultures to determine whether there is an infectious cause for this active, chronic inflammation. Cultures for bacterial or fungal organisms will not always reveal the infectious etiology of the nodule, however.

▼ ***Key Point*** The most common causes of folliculitis and furunculosis are the "big three" follicular infections, namely, *Demodex* mites, dermatophytes, or Staphylococcal pyoderma.

The latter two may be identified using a tissue culture but may be missed on an aspiration sample. Many of the cutaneous mycoses and unusual infections (e.g., protozoal infections) also require a tissue biopsy for histopathology and possibly culture.

Cutaneous Neoplasms

The most common cutaneous neoplasms (see Chapter 30) in dogs include lipomas, mast cell tumors, and sebaceous gland adenomas. Basal cell tumors are most common in cats. Do not rely on cytology alone as a diagnostic and prognostic indicator of cutaneous neoplasia. Should cytology reveal a uniform population of cells or aberrant cells that may be neoplastic, submit the sample for cytologic evaluation by a clinical pathologist and perform surgical excision for histopathologic evaluation. When cytology is inconclusive, perform either incisional or excisional biopsy (see Chapter 26).

SKIN BIOPSY

Indications (Table 37-1)

Specific indications for skin biopsy include the following:

Table 37-1. SPECIFIC INDICATIONS FOR SKIN BIOPSY

Lesion/Indication	Reason to Biopsy
Nodules	Nodules that have the potential for neoplasia or a deep-seated infection, especially if cytology does not yield a specific diagnosis
Ulcers	Severe, ulcerative, especially mucocutaneous lesions that may be potentially fatal
Expense with treatment	If the major differential diagnosis would require expensive medication or medical follow-up
Open diagnosis	To establish a diagnosis
Further investigations needed	The ability to prioritize differential diagnoses may allow a logical investigative approach, especially when in-house tests, physical exam, and history have failed to narrow the diagnostic list
Severe illness	Allows a fast diagnosis if the disease may have systemic and potentially fatal implications

- *Failure to respond to apparently appropriate presumptive therapy* may indicate that the diagnosis is incorrect or that the correct diagnosis has been made but in this particular case is resistant to the treatment. Use of the skin biopsy *to confirm* the clinical diagnosis is entirely appropriate and may save time, unnecessary "trial drug therapies," and client costs.
- *Before prescribing potentially harmful or expensive therapy, establish a specific diagnosis.* If an unusual or immune-mediated disease is a possible diagnosis, the supportive blood testing and drug costs may be considerable. Immune-suppressing drugs are potentially lethal. Do not prescribe without a specific diagnosis.
- *Biopsy for culture.* Improved antimicrobials have revolutionized the treatment of deep pyodermas and unusual infections in dogs and cats; however, resistance develops rapidly and tissue culture and sensitivity may prevent the choice of an antibiotic to which there is already resistance.
- *Biopsy unusual clinical lesions* or those that occur acutely or are particularly severe.
- *Biopsy to help prioritize a list of differential diagnoses,* especially when the clinical picture supports many possible etiologies. Although skin biopsy may not allow a definitive diagnosis, some differential diagnoses can be ruled out and a prioritization can be made of the others, enabling a therapeutic and diagnostic plan to be formulated.
- *Biopsy potentially neoplastic nodules.* Histopathology is the definitive diagnostic tool when assessing neoplasia.
- *Biopsy severe ulcerative disease,* especially involving mucocutaneous junctions.

Skin Biopsy Sampling Methods

There are two major types of biopsy technique—the punch and the wedge or ellipse. The most common sampling techniques include punch biopsy and incisional and excisional wedge or elliptical biopsies. Two less common and more site-specific techniques include "shave" biopsy and "onychobiopsy without onychectomy" claw biopsy. The biopsy for deep tissue culture has specific modifications to that sampled primarily for histopathologic evaluation.

Punch biopsy refers to the use of the biopsy punch instrument, which for veterinary purposes is used in 4-, 6-, and 8-mm diameters. Punch biopsies are fast and easy to use, and they yield a circular plug of tissue with clean, surgical, non-traumatized edges. *Wedge biopsy* refers to the elliptically shaped surgical biopsy, which takes a deeper section (or wedge) of tissue. Each method is used for specific indications, but in general the choice for smaller samples is one of personal preference.

Principles of Tissue Sampling

Regardless of the technique to be chosen, there are some basic principles when sampling skin for histopathology submission that are contrary to routine surgery. The first of these is that no skin antisepsis is practiced. This is to minimize any changes to the epidermal surface. Surgical cleaning may remove layers of stratum corneum, which contain clues through their thickness, associated pathology, or the presence of organisms. Indeed, even the use of the surgical clip is avoided because it may alter the epidermis. The second principle is that the tissue must be handled gently to avoid crushing. Tissue crush artifact alters the tissue architecture and obscures the cell type.

Punch Biopsy

When selected for non-nodular dermatoses, punch biopsy is useful to sample multiple small areas that may represent various stages of the disease process. Nodules are typically removed with an excision biopsy method. However punch biopsy is indicated when sampling nodules for several reasons:

- A large nodule is present in an area for which complete excision would be difficult, and a smaller sample from the core may provide the diagnosis without the concurrent excisional surgical treatment.
- An animal with a high anesthetic risk, an animal for which extensive surgery or adjunctive oncologic therapy will not be elected by the owners, or when a cytology aspirate from the nodule suggested an inflammatory and possibly an infectious etiology may be further reasons for using a punch biopsy on nodular disease.

In all of these cases, a punch from the center of the lesion may provide a rapid, relatively non-invasive diagnosis.

Punch biopsy is quick, relatively atraumatic, and usually employed with suspected infectious, inflammatory, and endocrine dermatoses. Disposable biopsy punches are readily available in 4-, 6-, and 8-mm diameter sizes. They can be autoclaved and reused at least once without greatly affecting their sharpness. Routinely use 8-mm punches; however, in very small dogs and cats, use 6-mm punches. Reserve 4-mm punches for biopsies of foot pads, nasal planum, or eyelids.

Punch Biopsy for Deep Tissue Culture

If cytology revealed a mixed population of cells or histiocytic cells, and therefore infection etiologies are possible, consider two options for sampling for culture:

- Insert a culture swab into the defect left by the excisional biopsy, taking care not to contaminate this with surface organisms *and remembering that for histopathology purposes the surface has not been aseptically prepared.*
- Alternatively (and preferably), section the tissue sample, once excised and using sterile blades, and place a piece of that tissue into culture transport media. If this was a punch biopsy, then section it longitudinally in half, with one half submitted for histopathology and the other half reserved for tissue culture. Make the longitudinal cut with the blade starting at the deeper tissue area and finishing at the skin surface so that surface organisms are not dragged through the tissue. Remove with a new sterile scalpel blade and make a single cut to remove the upper half of the punched out tissue. Submit this upper part for histopathology as a shave specimen.

Incisional Biopsy

Incisional sampling is used when evaluation of the lesional margin is considered important. Examples include the edge of a depigmented lesion and the edge of an ulcer. Consider incisional samples for areas in which there is a transition from one stage or age of the lesion to another. This may reveal important abnormalities. Choosing to perform an incisional biopsy may decrease the potential for laboratory error during processing (Figure 37-1).

Excisional Biopsy

Excisional sampling is useful to avoid the rupture of a large pustule or vesicle. Also use excision when a lesion involving the deeper tissues, especially the panniculus, must be sampled or when a solitary lesion, which could be cured by excision, is present. For a *solitary nodule,* perform *wide surgical* excision, because this technique provides the entire specimen for histologic examination and allows margins to be examined if the lesion is a tumor. Excise a 2- to 3-cm margin of tissue if a neoplasm

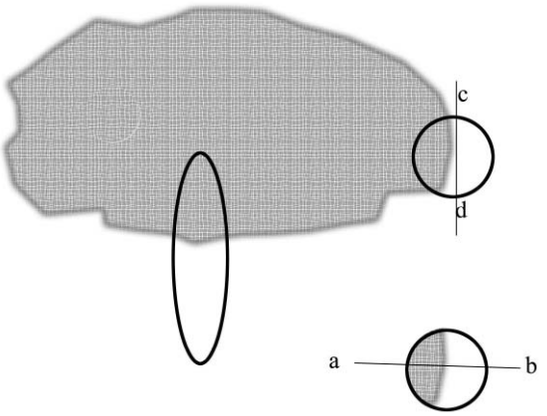

Figure 37-1. The histopathology technician will usually section the elliptical biopsy specimen along the midline of the long axis of the ellipse. Orientation of the ellipse across the junction between abnormal and normal tissues will allow the pathologist to view the skin from affected, through active (depigmenting), to non-affected areas and so gain the best possible appreciation of the stages of the disease and hence the etiology. Obtain a circular punch biopsy and section appropriately using the orientation line. Have the technician section along *line a–b*. Should a circular punch biopsy be taken, without drawing an orientation line, the technician may section the sample, providing only normal tissue to the pathologist (see *line c–d*).

is suspected. Depending on the size of the tumor, it may be necessary to section through the lesion to allow formalin to penetrate into the tissue for proper fixation. Nodules that are relatively small (less than 3 cm) may be left intact. For moderate-sized nodules (between 3 cm and 6 cm), incise the nodule once through the epidermal surface but leave the deep pannicular margin intact. Formalin can then penetrate into the incised surface of the nodule. The deep margin is left intact to prevent the subcutaneous fat and/or muscle from retracting from the incision line, which facilitates examination of the margin. For large masses (greater than 6 cm), make multiple incisions through the mass, leaving the deep pannicular tissue intact if possible.

Shave Biopsy

Use this technique when the clinical lesions are very superficial (i.e., epidermal) and when removal of deeper dermal tissue may result in unwanted scarring. In the canine it is most indicated for the inner pinna, where deeper sampling may affect the underlying cartilage. Remove the surface layers by a shallow scalpel incision that runs almost parallel to the line of the epidermis. Make the cut deep enough that it has some tissue and is not just stratum corneum, but keep it shallow enough to avoid scarring. Because the excision is superficial, there is no need to close with suture.

Onychobiopsy without Onychectomy Claw Biopsy

See Chapter 63.

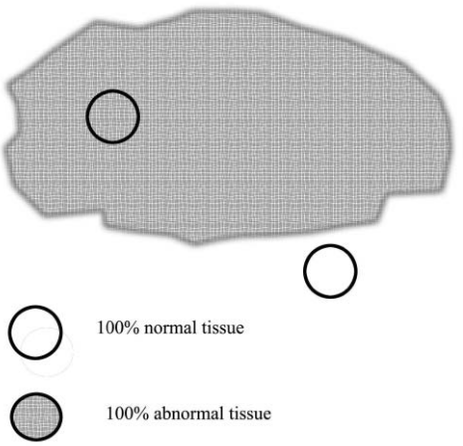

Figure 37-2. When sampling using a biopsy punch, selection of 100% lesional or 100% non-lesional skin will help avoid technical processing errors.

Site Selection

Perform a thorough dermatologic examination to select the biopsy sites. The clinical lesions present, the differential diagnosis list, and the need to provide the pathologist with the complete range of lesions dictates which and how many lesions are sampled. Also follow these guidelines:

- When a variety of different lesions are present (which is most commonly the case), multiple samples may be necessary for a full appreciation of the pathologic changes.
- Always sample pustules intact if present; take at least three if possible.
- Always use an excisional elliptical biopsy technique for *vesicles or large pustules*. These are fragile and may rupture if handled, losing their diagnostic potential.
- Where possible, *do not sample* the non-haired areas of the body in a suspected endocrinopathy. These areas normally contain fewer hair follicles and smaller sebaceous glands, which can make follicular evaluation more difficult. Preferentially, select a normally hairy site such as the shoulder.
- *Include samples of normal and abnormal tissue* when sampling with a punch biopsy (Figure 37-2) to allow comparison.
- *Biopsy depigmenting lesions* in an area of active depigmentation (i.e., a gray color rather than the final stage of depigmentation, which is white).
- *Biopsy alopecia* in the center of the worst area and in junctional and normal areas.
- *Areas of ulceration* require the adjacent intact skin to be included using a wedge biopsy section. If only the ulcerated area is sampled, the pathologist will merely describe a nonspecific ulcer.
- *Include crusts* because they may contain valuable clues about the formation (or malformation) of the skin or the presence of infectious agents.

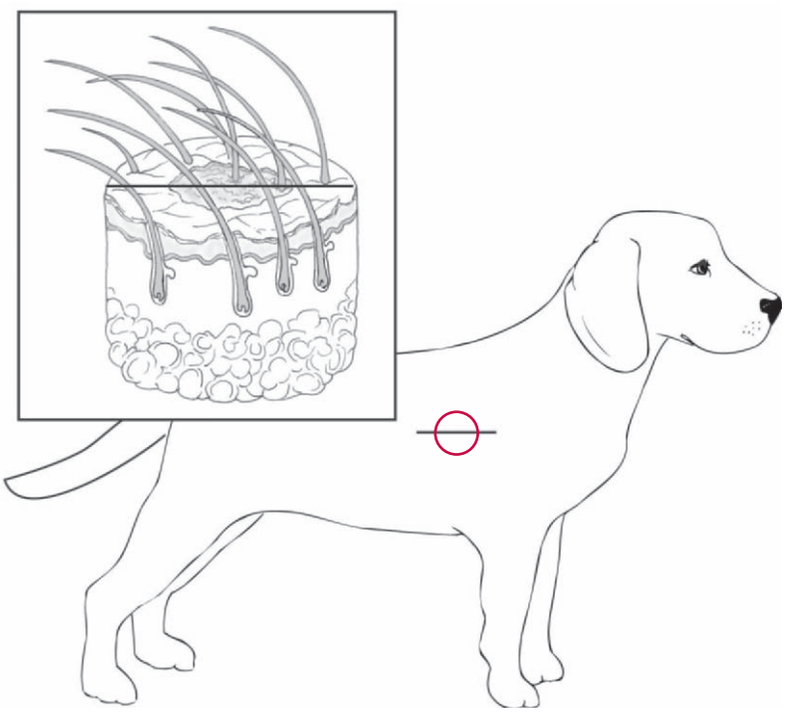

Figure 37-3. Draw a line at the biopsy site, in "permanent" marker pen, in the direction from the nose to the tail. This enables the technician to cut along a plane that runs parallel to the hair shafts, providing the pathologist with hair follicles in longitudinal section. (Borrowed, with permission, from "Practical Veterinary Dermatopathology," Bettenay & Hargis. Teton New Media.)

- *Always include normal skin in biopsies for comparison.* Skin from the ventral chest and abdomen is not regarded as "normal" because the hair follicles are smaller and less numerous and the dermis is generally thinned in this area.

Skin Biopsy Equipment

Regardless of the skin biopsy sampling method, several dedicated skin biopsy instruments can help minimize trauma to the sample, thus enabling the pathologist to obtain the best impression from the tissue. Obtain the tissue sample without placing any external forces on the tissue. These are applied when cutting the tissue and grasping it for handling or processing. I use ophthalmology instruments because they can be used with the 4-, 6-, and 8-mm punches with ease. Select thumb forceps that minimize crushing of the tissue (e.g., Addison thumb forceps). Scissors are often used to separate the tissue sample from the underlying tissue; use blunt, fine-tipped tenotomy of Metzenbaum scissors.

- When sampling tissue for deep tissue culture, use only instruments sterilized by autoclave to avoid having antiseptic residue interfere with the culture.
- For regular biopsy sampling, "cold sterilization" is adequate. Allow the instruments to drain well before use so that the liquid does not run on to and alter the surface of the skin.

Surgical Technique

1. Clip and gently remove the overlying hair. If crusts are present, it may be less traumatic to use scissors than electric clippers. Unless this will be an excision biopsy (i.e., removal of the entire lesion en masse) and therefore require aseptic preparation, a "surgical clip" is not necessary. Leaving a few millimeters of hair may help preserve some of the upper stratum corneum layers.
2. If general anesthesia is employed (as is indicated for nasal, ear pinna, or foot pad biopsies), no further preparation of the skin is necessary. If the biopsy is to be performed under manual restraint or with sedation, subcutaneously inject 0.3 to 1.0 ml of Xylocaine *without* epinephrine. If administered subcutaneously with the needle entry point outside the proposed biopsy area, there should be no disruption to the tissue in the biopsy. Mark the biopsy site with a large circle or four "framing dots" of a permanent marker pen before injection of the local anesthetic.
3. Indicate the orientation of the hair shafts to the laboratory technician with a line drawn in the direction of hair follicle growth (Figure 37-3). Hair shafts are angled caudally; they do not grow vertically from the skin. Section the piece of tissue longitudinally, parallel to the follicle, to enable the pathologist to observe the entire follicular unit in one piece, a distinct advantage for lesions characterized by alopecia and for inflammatory skin lesions. The laboratory

technician will routinely section the elliptical biopsy along the "long axis" of the sample. When the long axis does not correspond to the direction in which the hair follicles grow, the follicles may be cut in "cross section."

4. *For the punch biopsy:*
   a. Hold the punch at right angles to the surface of the skin and gently place it over the selected lesion. Hold the surrounding skin with the other hand.
   b. Apply firm continuous pressure and rotate the punch in *one direction* until a sufficient depth has been reached to free the dermis from its underlying attachment. This is evident when the skin no longer tries to "turn" with the rotation of the punch and by a gentle easing of pressure required for the turning. For thin-skinned areas such as the ventral abdomen, or with cats and small dogs, this may not be noted and some visual note of the depth is warranted.
   c. Remove the punch, lift the section of tissue, grasp *at the base* (which should be the panniculus), and sever the subcutaneous attachments using fine blunt/blunt iris scissors and iris forceps.

▼ ***Key Point*** During skin biopsy, do not grasp the dermis or epidermis with forceps because this leads to crush artifact.

Crushed tissue may be misinterpreted as scarring at best and may render the sample worthless.

5. *For wedge or elliptical biopsy:*
   a. Make an elliptical incision, taking care not to crush or tear the edges.
   b. Attempt to orient the central axis of the ellipse along several different stages of lesion development to allow the pathologist to interpret the development of the pathology.
6. Roll the tissue on gauze to gently blot the blood from its surface.
7. Place large, thin pieces of tissue panniculus side down onto a rigid piece of cardboard or a wooden tongue depressor. This prevents the tissue from curling when placed in the formalin, optimizing the interpretation by the pathologist.
8. Place the tissue and cardboard or tongue depressor into 10% formalin (tissue side down) and allow it to fix for at least 8 hours before sectioning. The volume of formalin required is approximately 10 times the volume of the sample.
9. Section nodules into 1-cm-thick pieces to allow adequate penetration of the formalin into the center of the lesion.
10. A valuable adjunctive test is to perform cytology from the impression of such a freshly excised surface of a nodule. Make multiple slides and submit some air-dried, unstained slides separately to the laboratory for storage.

Processing and Submitting

A differential diagnosis list is *essential* with dermatologic cases. This list is important for the clinician to ensure that he or she has considered the options and obtained from both pet and owner as much information as possible and as necessary before taking the biopsy, and it is important to alert the pathologist to the possible pathologic processes. If the list of clinical differentials fails to correlate with the histopathology, review the sections. If the biopsy submission form clearly states that a deep infectious process is suspected, perform special stains to rule out infectious organisms. If an immune-mediated dermatosis is suspected and convincing supportive evidence is not seen on the first section, order recuts of the biopsy sample. Many dermatoses are diagnosed using a combination of the signalment (age, breed, sex), clinical presentation (distribution, type of primary lesions if present), history (in particular previous response to therapy), and *supportive* histopathology.

Identification of each sample is important. This may be achieved by placing each sample in a separate container or inking the samples. Inking the margins may identify a particular sample (e.g., the one sample of "clinically normal skin") or help the technician with orientation (e.g., inking the haired skin surface of an onychectomy sample). Various commercial dyes are available, or simple India ink can be used. However it is most important that *the ink dries on the surface of the tissue* before it is placed in the formalin.

Chapter 38

Pyoderma

Edmund J. Rosser Jr.

Pyoderma refers to any pyogenic infection of the skin and is most commonly used in reference to bacterial skin infections. However, fungal organisms (especially yeast) have also been recognized as potentially significant opportunists in the development of surface pyoderma in the dog (see Chapter 41). Pyoderma is a common problem in clinical practice.

- Primary pyoderma refers to a skin infection that does not recur after the appropriate treatment. These infections are most likely the result of a transient and non-recurrent insult to the skin.
- Secondary pyodermas are far more common and are associated with a persistent or recurrent underlying problem that alters the skin's resistance to infection. Until the underlying problem is identified and corrected, the infection usually responds only temporarily to therapy and subsequently recurs.
- Pyodermas are caused by bacterial colonization or invasion of the skin by coagulase-positive staphylococci, usually *Staphylococcus intermedius*. In chronic, recurrent, or deep pyodermas, secondary bacterial invaders may also be present, especially *Pseudomonas* spp., *Proteus* spp., and *Escherichia coli*. When deep pyoderma occurs, anaerobic bacteria such as *Bacteroides* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., *Porphyromonas* spp., and *Clostridium* spp. may be further opportunistic pathogens. Recently, two additional staphylococci have been isolated from cases of recurrent pyodermas, namely *Staphylococcus schleiferi* subsp *schleiferi* and *Staphylococcus schleiferi* subsp *coagulans,* both of which are frequently methicillin-resistant staphylococci.

SURFACE PYODERMAS

Surface pyoderma is a bacterial colonization of the surface of the epidermis only, without invasion into the stratum corneum or hair follicles. Two types of surface pyoderma are recognized: acute moist dermatitis ("hot spot" or pyotraumatic dermatitis) and skin fold pyoderma.

Acute Moist Dermatitis (Hot Spot) (Pyotraumatic Dermatitis)

Etiology

Self-trauma to the skin, due to an underlying pruritic or painful process, can result in a focal surface pyoderma referred to as acute moist dermatitis. Underlying conditions that may be associated with the development of acute moist dermatitis are listed in Table 38-1.

Clinical Signs

- Acute moist dermatitis is usually a single alopecic lesion that is circumscribed, erythematous, thickened, and erosive. An exudative film occurs over the surface, and peripheral hairs are matted onto the lesion. The lesion develops subsequent to the dog's chewing and licking at a focal area of pruritus or pain, and it develops within a matter of hours. The lesion is usually painful.
- Thick-coated, longhaired breeds are most commonly affected.
- Lesions that appear clinically similar to an acute moist dermatitis (pyotraumatic dermatitis), but develop in the absence of a history of self-trauma, are often associated with a deeper bacterial folliculitis and/or furunculosis and are most commonly observed on the side of the face, or cheek region (also referred to as pyotraumatic folliculitis). The breeds more commonly affected by this deeper form of an acute moist dermatitis are golden retrievers, Saint Bernards, Bouviers, and Newfoundlands. In these cases, satellite popular lesions can usually be detected surrounding the area of acute moist dermatitis once the area has been clipped.

Diagnosis

▼ ***Key Point*** Diagnose acute moist dermatitis by the history of self-trauma to the skin, acute onset, rapid development of the lesion (within hours), and the typical appearance of the lesion on physical exam.

Table 38-1. CONDITIONS ASSOCIATED WITH HOT SPOTS

Disease Category	Examples
Allergic skin diseases	Flea allergy dermatitis
	Atopic dermatitis (atopy)
	Cutaneous adverse food reactions (food allergy)
	Allergic contact dermatitis
	Secondary staphylococcal hypersensitivity
Ectoparasites	Canine scabies
	Cheyletiellosis
	Demodicosis
Otitis externa	Allergic otitis externa
	Ceruminous otitis externa
Environmental causes	Irritant contact dermatitis
	Poor grooming
	Burs or plant awns in the skin or haircoat
Musculoskeletal disorders	Hip dysplasia
	Degenerative joint disease
	Arthritis and other arthropathies
Anal sac problems	Impacted anal sacs
	Anal sacculitis

From Rosser EJ, Sams A: Pruritus. In Allen DG (ed): Small Animal Medicine. Philadelphia: JB Lippincott, 1991, p 704.

- History includes questioning the owner about any pruritic skin disease, painful process, or environmental irritant that might indicate the reason for the dog's self-trauma of the area (see Table 38-1). In instances of recurrent acute moist dermatitis, identify the underlying problem to prevent any further recurrences.
- Biopsy lesions that appear clinically similar to an acute moist dermatitis, that develop in the absence of a history of self-trauma, and that respond poorly or are non-responsive to initial treatment. This is to determine if the lesion is associated with a deeper bacterial folliculitis and/or furunculosis, which requires a more aggressive treatment regimen.

Treatment

Whenever an underlying disease process can be identified, institute the specific treatment recommended for that disease as well as the treatment necessary for the hot spot. A main objective of treatment is to clip and clean the lesion to facilitate better aeration and to allow better contact and penetration of topical agents.

Topical Therapy

- First gently clip and thoroughly cleanse the area with an antiseptic shampoo, such as povidone-iodine (Betadine, Purdue Frederick) or chlorhexidine (Hexadene, Allerderm/Virbac; ChlorhexiDerm, DVM Pharmaceuticals). Because the lesion is often very painful, this step may require sedation or general anesthesia.
- Dry the lesion by applying an astringent, such as Burow's solution (Domeboro powder and water; Bayer) or hamamelis extract (DermaCool with Lidocaine, Allerderm/Virbac), and then apply a nystatin-neomycin sulfate-thiostrepton-triamcinolone acetonide cream (Panalog Cream, Fort Dodge; Animax Cream, Pharmaderm; Dermagen Cream, Butler). Repeat these treatments q12h, for 5 to 10 days.

Systemic Therapy

- Corticosteroids are indicated in the treatment of hot spots because the lesion is often painful or pruritic and because the most common underlying causes are allergic skin diseases. Begin treatment with a short-acting, injectable corticosteroid. Since prednisolone and prednisone are no longer available in non-repositol injectable forms, dexamethasone solution—2 mg/ml (Aspen) at 0.05 mg/kg IM (not to exceed 1 mg/dog)—may be given for a rapid anti-inflammatory and anti-pruritic effect. The next day administer oral prednisolone or prednisone at 0.5 mg/kg q12h for 5 to 7 days, then 0.5 mg/kg q24h for the next 5 to 7 days.
- Use systemic antibiotics in cases in which a deep folliculitis and/or furunculosis is suspected or has been confirmed after histopathologic examination of a skin biopsy (see the discussion of treatment under "Deep Pyodermas").

Prevention

- In instances of recurrent acute moist dermatitis, the underlying disease problem must be identified to prevent any further recurrence of the lesions (see Table 38-1).

Skin Fold Pyoderma

Etiology

- Deep skin folds, where the skin rubs against itself and causes irritation and maceration, can result in a surface pyoderma referred to as a skin fold pyoderma (intertrigo). These skin folds create a moist, dark, and warm environment with poor air circulation, which retains skin secretions and desquamated keratinocytes that promotes subsequent bacterial *(S. intermedius)* or yeast *(Malassezia pachydermatis)* overgrowth and inflammation.
- Pyoderma can occur in any skin fold in any breed of dog, but intertrigo is most commonly associated with the skin folds in certain breeds of dogs. Table 38-2 lists the anatomic sites of the more common skin fold pyodermas and their breed predispositions, and it includes lip fold, facial fold, vulvar fold, tail fold, body fold, and leg fold pyodermas.

Table 38-2. SKIN FOLD PYODERMAS

Anatomic Site	Breed Predisposition	Comments
Lip fold	Cocker spaniel Springer spaniel Saint Bernard Irish setter	Lower lip fold, halitosis
Facial fold	Brachycephalic types Shar-Pei	Between nose and eyes Lateral facial region
Body fold	Shar-Pei	Also any breed with pendulous mammary glands, obese patients
Vulvar fold	None	Obese females, juvenile vulva, spayed early in life
Leg fold	Chondrodystrophic types (basset hound, dachshund)	Obese patients
Tail fold	Bulldog Boston terrier Pug	"Corkscrew tails," anal odor

Clinical Signs

- Skin fold pyoderma is characterized by inflammation and mild exudation. This pyoderma is best identified by simply widening the skin fold. The area is often malodorous.
- The animal is usually rubbing, licking, or biting excessively at the area. Evidence may exist of excoriation, alopecia, and erythema around the skin fold region.

Diagnosis

▼ ***Key Point*** Skin fold pyodermas are usually diagnosed by close inspection of the skin fold and demonstration of inflammation, mild exudation, and malodor from within the fold.

- *Direct impression skin cytology:* Press a clean glass microscope slide over the exudative area, and then gently heat fix and stain with Diff-Quik (Dade Behring). Examine microscopically under oil immersion (1000×) to best identify and quantitate the presence of cocci versus rods versus yeast type of opportunistic organisms (see Chapter 37). This will aid in the selection of the most appropriate active ingredient in your topical therapy, especially in chronic, recurrent cases.

Treatment

The objectives of treatment are to cleanse and disinfect the skin fold region using agents that will dry the area and prevent recurrence of pyoderma. Topical therapy is usually adequate to control the problem.

- First gently expose and cleanse the skin fold with a benzoyl peroxide shampoo (OxyDex Shampoo, DVM Pharmaceuticals; Pyoben Shampoo, Allerderm/Virbac; Benzoyl-Plus, EVSCO Pharmaceuticals).
- Dry the area manually and apply a topical mild astringent, such as Burow's solution (Domeboro powder and water; Bayer).
- When only bacteria are found on direct impression skin cytology, follow with a twice-daily application of a benzoyl peroxide-containing gel (OxyDex Gel, DVM Pharmaceuticals; Pyoben Gel, Allerderm/Virbac) into the skin fold region for 10 to 14 days. When only yeast organisms or both bacteria and yeast organisms are found on direct impression skin cytology, follow with a twice-daily application of a miconazole- and chlorhexidine-containing preparation (Malaseb Pledgets, DVM Pharmaceuticals) into the skin fold region for 10 to 14 days.
- In cases involving a more severe inflammatory response, treat for the first 2 to 3 days with twice-daily applications of a nystatin-neomycin sulfate-thiostrepton-triamcinolone acetonide cream (Panalog Cream, Fort Dodge; Animax Cream, Pharmaderm; Dermagen Cream, Butler) into the skin fold region. Once the inflammation has subsided, institute the benzoyl peroxide or miconazole and chlorhexidine preparation.

Prevention

Topical Therapy

Because the skin folds that develop pyoderma are usually deep, owing to a given breed characteristic, this condition tends to be a low-grade, recurrent problem. Once the infection has been treated as recommended, use the benzoyl peroxide or miconazole and chlorhexidine preparation as needed to prevent recurrence. This measure may require application ranging from daily to once or twice weekly.

Corrective Surgery

When a more permanent solution to the problem is desired, or when rapid recurrence of moderate to severe skin fold pyoderma occurs, the only permanent cure is removal of the skin fold using cosmetic surgery techniques (see Chapter 54).

SUPERFICIAL PYODERMAS

- Superficial pyoderma is a bacterial invasion of the epidermis that can manifest itself in one of two ways. First, the bacteria can penetrate the stratum corneum with the subsequent formation of subcorneal pustules and is referred to as impetigo (puppy pyoderma). Second, the bacteria can invade the opening of the hair follicle causing inflammation and is referred to as folliculitis.

- Coagulase-positive staphylococci are the most common pathogens involved in a superficial pyoderma. *S. intermedius* is most frequently isolated.

Impetigo

Etiology

Impetigo is most often observed in young dogs before puberty. The condition may be more likely in the presence of contributing factors such as poor nutrition, dirty environment, and ectoparasite or endoparasite infection. However, well–cared-for individual puppies or litters of puppies may also develop this condition.

Clinical Signs

- Impetigo occurs as pustules in the inguinal and ventral abdominal regions. Occasionally, pustules are noted in the axillary region. When the pustules rupture, a yellow to brownish crust forms.
- The pustules are not oriented around hair follicles (i.e., no hair shafts protrude through the center of the pustule). Minimal erythema is noted, and the patient is usually non-pruritic.
- Impetigo may be an incidental finding during the physical examination of a recently acquired puppy.

Diagnosis

▼ ***Key Point*** Impetigo is usually diagnosed in young dogs before puberty by observing non-follicular pustules in the inguinal and ventral abdominal regions with minimal erythema and absence of pruritus.

- *History:* Ask the owner about the animal's previous and current nutrition and housing environment.
- *Physical examination:* See the related "Clinical Signs" section.
- *Cytologic examination:* Stained contents of an intact pustule most often reveal neutrophils and cocci.
- *Skin scrapings:* Examine routine skin scrapings for ectoparasites such as *Demodex canis, Sarcoptes scabiei,* and *Cheyletiella* spp.
- *Bacterial culture:* This is rarely necessary, but if performed, *S. intermedius* is usually isolated.
- *Skin biopsy:* This is rarely necessary to establish the diagnosis of impetigo. Histopathology indicates subcorneal pustules containing neutrophils and cocci.
- *Fecal flotation:* Evaluate the puppy for intestinal parasites.

Treatment

▼ ***Key Point*** Objectives include identifying contributing factors and correcting these as an adjunct to specific treatment. Improve the nutritional status and the housing environment and treat any endoparasite or ectoparasite infections.

Table 38-3. EMPIRICAL TREATMENT OF PYODERMAS CAUSED BY STAPHYLOCOCCUS INTERMEDIUS

Antibiotic	Recommended Oral Dosage
Erythromycin	11 mg/kg q8h
Cephalexin	22 mg/kg q8h or 33 mg/kg q12h
Cefadroxil	22 mg/kg q8–12h
Trimethoprim/sulfadiazine	30 mg/kg q12h
Ormetroprim/sulfadimethoxine	55 mg/kg on day 1, then 27.5 mg/kg q24h
Amoxicillin/clavulanate	14 mg/kg q12h
Clindamycin	5 mg/kg q12h or 11 mg/kg q24h

Topical Therapy

Once any predisposing factors have been eliminated, topical therapy is usually all that is required for this superficial staphylococcal infection. Bathe the dog with a benzoyl peroxide shampoo (OxyDex Shampoo, DVM Pharmaceuticals; Pyoben Shampoo, Allerderm/Virbac; Benzoyl-Plus, EVSCO Pharmaceuticals) or chlorhexidine shampoo (Hexadene, Allerderm/Virbac; ChlorhexiDerm, DVM Pharmaceuticals) 2 to 3 times weekly for 2 to 3 weeks.

Antibiotics

Systemic antibiotic therapy is rarely necessary in impetigo. However, when topical therapy fails to resolve the pyoderma, add a systemic antibiotic to the topical therapy protocol (Table 38-3).

Superficial Folliculitis

Etiology

- Superficial folliculitis induced by coagulase-positive staphylococci occurs occasionally as a primary problem. These infections are most likely the result of a transient and non-recurrent insult to the skin.
- Secondary superficial folliculitis is far more common and is associated with a persistent or recurrent underlying problem that alters the skin's resistance to infection. Until the underlying problem is identified, the infection usually responds only temporarily to therapy and subsequently recurs (see the discussion under "Recurrent Superficial and Deep Pyodermas").

Clinical Signs

- Superficial folliculitis initially appears similar to impetigo, with papules and pustules in the inguinal and ventral abdominal regions. However, pustules often extend to the axillary region and the ventrolateral thorax.

- The papules and pustules are oriented around the hair follicle (i.e., hair shafts protrude through the center of the pustule). The base of the pustule is often erythematous, and the patient is usually pruritic.
- Other lesions may include papules, crusts, and epidermal collarettes.
- When the truncal skin is affected, the haircoat often takes on a "moth-eaten" appearance.
- Rarely, multifocal areas of alopecia are seen without erythema or other lesions.

Diagnosis

▼ ***Key Point*** Superficial folliculitis is usually diagnosed by observing papules and pustules oriented around hair follicles in the inguinal, ventral abdominal, and axillary regions. The base of the pustule is erythematous and the patient is usually pruritic.

- *History:* Superficial folliculitis is often secondary to an underlying disease problem. Question the owner about the effect of antibiotic therapy alone on the disease problem. This is a very important diagnostic tool in the systematic approach to a patient with a recurrent pyoderma. See also the discussion under "Recurrent Superficial and Deep Pyodermas."
- *Physical examination:* See the related "Clinical Signs" section.
- *Cytologic examination:* The contents of an intact pustule usually reveal neutrophils and cocci.
- *Skin scrapings:* These are routinely examined for the presence of ectoparasites, such as *D. canis, S. scabiei,* and *Cheyletiella* spp.
- *Bacterial culture and susceptibility tests:* Consider these in cases of recurrent superficial folliculitis that have not responded to appropriate empirical antibiotic therapy and are designed to evaluate for resistant bacteria. Cultures usually reveal *S. intermedius.* Use the sensitivity results as a guideline for antibiotic selection.
- *Fungal culture:* Submit a sample of the hairs from follicular pustules for a fungal culture in cases that are non-responsive to appropriate anti-bacterial therapy. In some instances, a folliculitis due to a dermatophyte infection can appear clinically indistinguishable from a folliculitis caused by bacteria.
- *Skin biopsy:* Typical findings include folliculitis or perifolliculitis, with coccoid bacteria within the hair follicle. Folliculitis due to a dermatophyte infection would reveal the presence of spores or hyphae within the hair follicle. Usually, biopsy is not necessary in the diagnosis of superficial pyoderma.

Treatment

▼ ***Key Point*** Be certain that an appropriate antibiotic for staphylococci has been selected (see Table 38-3) and that the duration of therapy has been adequate. The treatment required for folliculitis is generally more vigorous than that required for impetigo. In recurrent cases, define the underlying disease process and initiate a systematic approach to the disease. See the discussion under "Recurrent Superficial and Deep Pyodermas."

Topical Therapy

Use twice-weekly bathing with a benzoyl peroxide shampoo (OxyDex Shampoo, DVM Pharmaceuticals; Pyoben Shampoo, Allerderm/Virbac; Benzoyl-Plus, EVSCO Pharmaceuticals) or a chlorhexidine shampoo (ChlorhexiDerm, DVM Pharmaceuticals; Hexadene, Virbac; SebaHex, EVSCO Pharmaceuticals) for 3 weeks.

Antibiotics

Systemic antibiotic therapy can be initially selected on an empirical basis, choosing an antibiotic effective against coagulase-positive staphylococci (see Table 38-3). Treat for a minimum of 21 consecutive days and for at least 7 days beyond apparent clinical cure.

DEEP PYODERMAS (DEEP FOLLICULITIS AND FURUNCULOSIS)

A deep pyoderma is a bacterial skin infection that extends beyond the epidermis, into the dermis, and occasionally into the subcutaneous tissues. Although there are many possible forms of deep pyoderma, this discussion is limited to the most common form, deep folliculitis and furunculosis.

- The disease begins as a superficial folliculitis then extends deeper into the hair follicle, causing a deep folliculitis.
- This inflammatory process often results in furunculosis, which is the destruction of the hair follicle wall and the release of the bacteria, hair shaft material, and follicular keratins into the surrounding dermis and occasionally the subcutaneous tissues.
- Subsequently, the bacteria can produce septicemia and/or bacteremia, and the released hair shafts and follicular keratins induce a foreign body and pyogranulomatous inflammatory reaction in the dermis.

Etiology

- Coagulase-positive staphylococci are the most common pathogens initially involved in deep pyoderma. *S. intermedius* is the most frequently isolated.
- In contrast to a superficial pyoderma, secondary invasion with other aerobic bacteria often occurs with *Pseudomonas* spp., *Proteus* spp., and *E. coli.* Anaerobic bacteria may also become opportunistic pathogens, especially *Bacteroides* spp., *Peptostreptococcus* spp.,

Fusobacterium spp., *Porphyromonas* spp., and *Clostridium* spp.
- Deep pyoderma is rarely a primary disease process and is invariably related to some other underlying problem.

Clinical Signs

- Deep folliculitis and furunculosis initially begin as superficial folliculitis. See the discussion of clinical signs under "Superficial Pyodermas," and see "Superficial Folliculitis."
- When deep folliculitis and furunculosis develop, the papules and pustules become larger and nodular on palpation. Exudation and crust formation follow. Ulcers and draining tracts may develop. Hemorrhagic bullae may also be noted.
- In addition to the inguinal, ventral abdominal, and axillary regions, the pressure and wear areas of the body can also be affected. The disease may become generalized.
- The lesions are painful and/or pruritic.
- Peripheral lymphadenopathy is a common finding. Signs of systemic illness may be present (anorexia, depression, weight loss). The patient may also be febrile, an indication of bacteremia and/or septicemia.
- A specific form of deep pyoderma can occur in German shepherds (so-called German shepherd dog pyoderma), which is often related to multiple underlying problems in the affected patient.

Diagnosis

▼ ***Key Point*** Deep folliculitis and furunculosis are usually diagnosed by observing papules and pustules that become nodular on palpation, with exudation, crust formation, ulcers, draining tracts, and hemorrhagic bullae.

History and Physical Examination

Deep folliculitis and furunculosis are invariably secondary to an underlying disease process. Question the owner about the effect of antibiotics alone on the disease, as this is a very important diagnostic tool in the systematic approach to a patient with recurrent pyoderma. See the discussion under "Recurrent Superficial and Deep Pyodermas." Physical exam findings were described earlier under "Superficial Pyodermas" and "Superficial Folliculitis."

Laboratory Tests

- *Cytologic examination:* Pustules, exudates, and draining tracts usually reveal neutrophils, macrophages, cocci, and sometimes rods.
- *Skin scrapings:* Evaluate for *D. canis* mites, a common underlying cause of deep pyoderma.
- *Bacterial culture:* Perform both aerobic and anaerobic bacterial culture and susceptibility tests in all cases of deep pyoderma. This form of pyoderma is capable of causing bacteremia and/or septicemia, resulting in a life-threatening situation. Usually, biopsy is not necessary in the diagnosis of superficial pyoderma.
- *Fungal culture:* Do this in cases of deep pyodermas that are refractory to antibiotic therapy. Fungi are another possible cause of a deep folliculitis and furunculosis. Fungal diseases to consider include sporotrichosis, blastomycosis, coccidioidomycosis, aspergillosis, histoplasmosis, and cryptococcosis.
- *Skin biopsy:* This usually reveals deep folliculitis, perifolliculitis, and furunculosis. Bacterial or fungal organisms may or may not be identified on special staining.
- *Blood culture:* Perform these cultures when bacterial sepsis is suspected in patients with a fever and evidence of systemic illness.

Treatment

▼ ***Key Point*** Be certain that an appropriate antibiotic has been selected to eliminate the organism causing the deep pyoderma. Choose the antibiotic based on the results of bacterial culture and sensitivity tests. In general, treatment is more vigorous than that for superficial folliculitis. In recurrent cases, define the underlying disease process and initiate a systematic approach. See the discussion under "Recurrent Superficial and Deep Pyodermas."

Topical Therapy

- Clip the hair around the affected areas. In cases of generalized deep pyoderma in long-coated breeds of dogs, clip the entire body.
- Initially bathe the patient twice daily (preferably in a whirlpool bath) using a povidone-iodine preparation (Betadine Whirlpool Concentrate, Purdue-Frederick) or chlorhexidine solution for the first 1 to 2 weeks of treatment. As the patient responds to treatment and the lesions have dried and begun to heal, change the treatment to once- to twice-weekly bathing with a benzoyl peroxide shampoo (OxyDex Shampoo, DVM Pharmaceuticals; Pyoben Shampoo, Allerderm/Virbac; Benzoyl-Plus, EVSCO Pharmaceuticals) for the next 4 to 8 weeks.

Systemic Antibiotics

- Always base systemic antibiotic selection on the results of a bacterial culture and sensitivity tests in cases of deep pyoderma. Use the appropriate dosage (see Table 38-3). Treat for approximately 6 to 8 consecutive weeks. Severe cases of deep pyoderma may require a longer treatment regimen. Treat for at least

2 weeks beyond the complete clinical remission of the infection.

- In instances when a *Pseudomonas* spp. is the primary isolate, a fluoroquinolone antibiotic is often most appropriate. Base the dosing of fluoroquinolones on the minimal inhibitory concentration (MIC) of the isolated organism, using the flexible labeled dosing schedule provided by the manufacturer, to obtain a serum maximum concentration (C_{max}) that is 8 to 10 times the MIC for that organism. Commonly used fluoroquinolones for these *Pseudomonas* spp. infections include marbofloxacin at a dosage from 2.75 to 5.5 mg/kg PO q24h (Zeniquin, Pfizer), and ciprofloxacin at a dosage from 10 to 22 mg/kg PO q24h (Cipro, Bayer).

RECURRENT SUPERFICIAL AND DEEP PYODERMAS

Antibiotic-responsive but recurrent pyoderma is often a very frustrating problem in clinical practice. This section stresses the need to evaluate the patient with this problem for some of the more common, underlying diseases associated with recurrent pyoderma.

Etiology

Inadequate Treatment

- Inappropriate antibiotic selection or inadequate duration of therapy can be simple reasons for the development of recurrent pyoderma. Antibiotic administration for 10 to 14 days will usually lead to improvement (maybe significant) in the lesions but will usually not lead to total resolution of the infection.
- Long-term glucocorticoid use can predispose the patient to recurrent pyoderma and cause varying degrees of iatrogenic Cushing disease. Most patients with a pyoderma are pruritic; therefore, glucocorticoids are often used as adjuncts to the antibiotic therapy. This treatment may be acceptable the first time; however, discontinue glucocorticoids once it becomes apparent that the pyoderma is a recurrent problem. By treating the pruritic patient that has a pyoderma with antibiotics only, very important information can be learned. This can help guide the clinician to the underlying disease condition. See the related section on "Diagnosis" for guidelines on the use of antibiotics and response to therapy as a diagnostic tool.

▼ ***Key Point*** The following discussion of common underlying diseases resulting in recurrent pyoderma requires that the patient has first been placed on a prolonged systemic antibiotic treatment protocol, as discussed under the related "Diagnosis" section. Therefore, the observations being made are those that are noted after the pyoderma has been symptomatically put into remission.

Allergic Skin Disease

- ***Flea allergy dermatitis:*** Patients with flea allergy dermatitis have pruritus that persists after resolution of the pyoderma and that primarily affects the caudal third of the body. Most patients initially have the problem in warmer weather only. For further discussion, see Chapter 45.
- ***Atopic dermatitis:*** Patients with atopic dermatitis have pruritus that persists after resolution of the pyoderma and that affects various combinations of the following areas of the body: face, ears, axillae, inguinal region, proximal cranial foreleg region, and feet. Most patients initially have the problem in warmer weather only. For further discussion, see Chapter 46.
- ***Cutaneous adverse food reactions (food allergy):*** Patients with food allergy have pruritus that persists after resolution of the pyoderma and that affects various combinations of the following areas of the body: face, ears, axillae, inguinal region, proximal cranial foreleg region, and feet. All patients have a non-seasonal (i.e., year-round) problem from the onset. For further discussion, see Chapter 47.

Parasitic Skin Disease

- ***Demodicosis:*** Patients with demodicosis may or may not be pruritic once the pyoderma has resolved. As previously stated, all patients with pyoderma require that several deep skin scrapings be performed, because demodicosis is a common cause of recurrent pyoderma that can be easily diagnosed. For further discussion, see Chapter 43.
- ***Scabies:*** Patients with sarcoptic mange have pruritus that persists after resolution of the pyoderma and that initially affects the ear, elbow, and hock regions. All patients have a non-seasonal (i.e., year-round) problem from the onset. For further discussion, see Chapter 44.

Keratinization Disorders

Patients with keratinization abnormalities may be pruritic once the pyoderma has resolved. The lesions that persist are suggestive of a keratinization (seborrheic) abnormality. For further discussion, see Chapter 50.

Endocrine Skin Diseases

Patients with hypothyroidism and hyperadrenocorticism (Cushing disease) are non-pruritic once the pyoderma has resolved. Evaluate the patient by history and physical examination for evidence suggestive of these metabolic diseases. For further discussion, see Chapters 31 and 33.

Staphylococcal Hypersensitivity

Patients with staphylococcal hypersensitivity exhibit a temporary resolution of both the pyoderma and the pruritus on antibiotic treatment alone. Staphylococcal hypersensitivity as a primary disease is one of the more controversial topics in veterinary dermatology. In my opinion, staphylococcal hypersensitivity invariably develops as a secondary complication. However, when no underlying cause can be established, the staphylococcal infection alone is the cause of the pruritus (i.e., a primary pruritic pyoderma). This disease is best diagnosed by exclusion of other underlying causes for a recurrent pyoderma. Therefore, systematically rule out all of the underlying diseases discussed up to this point before diagnosing primary staphylococcal hypersensitivity.

Immunodeficiency

Immunodeficiency disorders as the primary cause for a recurrent pyoderma are extremely rare. Disorders to consider are cell-mediated immunity disorders, such as T lymphocyte deficiency, and humoral immunity disorders, such as immunoglobulin A (IgA) deficiency.

Clinical Signs

See discussions of the clinical signs under "Superficial Pyodermas," "Superficial Folliculitis," and "Deep Pyodermas" elsewhere in this chapter.

Diagnosis

- First consider the procedures recommended elsewhere in this chapter for the diagnosis of superficial pyoderma, superficial folliculitis, and deep pyoderma.
- Use antibiotics as a diagnostic tool. Use antibiotics with anti-bacterial shampoo therapy without any antipruritic drugs, especially glucocorticoids. Treat in this manner for 3 weeks and then reexamine. If the patient is still pruritic, note the distribution pattern and question the owner as to whether the condition was initially a predominantly warm-weather seasonal problem or a non-seasonal problem. For common underlying pruritic skin diseases, refer to the section on etiologic and predisposing conditions.
- If the lesions *and* pruritus have both resolved on antibiotics alone, continue the antibiotic treatment for a total of 8 consecutive weeks. In some instances, this treatment results in a permanent resolution of the pyoderma. If the pyoderma recurs after stopping antibiotic therapy, evaluate the animal for underlying endocrine disease, staphylococcal hypersensitivity, and immunodeficiency disorders.
- For the specific testing procedures to diagnose the various underlying disease problems, please refer to the appropriate chapters in this book as recommended under the section on etiologic and predisposing conditions.
- Specific tests for primary immunodeficiency disorders are not readily available and are usually only offered by veterinary university laboratory services. Testing procedures to consider are the mitogen stimulation test for evaluation of lymphocyte function and the measurement of serum IgA levels as an indirect evaluation for a secretory IgA disorder.

Treatment

General Principles

- Specific treatment of identifiable underlying diseases is essential for the resolution of an antibiotic-responsive but recurrent pyoderma.
- Topical therapy is discussed under the treatment sections for "Superficial Pyodermas," "Superficial Folliculitis," and "Deep Pyodermas."
- Systemic therapy is discussed under the treatment sections for "Superficial Pyodermas," "Superficial Folliculitis," and "Deep Pyodermas."

Immunomodulators

- Immunomodulating drug therapy is indicated in cases of primary staphylococcal hypersensitivity and primary immunodeficiency disorders. Many treatment alternatives are available, but my preference is to use a staphylococcal bacterin (Staphage Lysate, Delmont Labs). See Table 38-4 for the recommended Staphage Lysate injection protocol.
- Also administer an appropriate systemic antibiotic for the first 4 to 8 weeks of treatment (until the infection has resolved).

Maintenance Antibiotics

- In instances in which an underlying disease process cannot be identified (so-called idiopathic chronic recurrent pyoderma), consider a maintenance antibiotic treatment protocol.
- Before this recommendation is offered, make the owner aware of the possible risk for resistant bacter-

Table 38-4. STAPHAGE LYSATE INJECTION PROTOCOL*

Week	Volume (ml)
1	0.25
2	0.50
3	0.75
4	1.00

*Follow this protocol with 1–2 ml every 3–21 days as needed to prevent recurrence of the pyoderma. Administer injections subcutaneously.

ial infections, either in the skin or elsewhere in the body.

- There are several protocols, but my preference is use of the antibiotic on a continuous basis at a suboptimal dose. As an example, if the initial appropriate dose of the antibiotic is 500 mg q8h, give the antibiotic at that dosage until clinical remission of the pyoderma has been reestablished. Then gradually decrease the dosage over several weeks to 500 mg q12h and finally to 250 to 500 mg q24–48h.
- Bactericidal antibiotics with a low potential for development of resistance and minimal side effects have been most effective, such as cephalexin. In cases of a relapse of the pyoderma, perform bacterial culture and sensitivity to examine for possible bacterial resistance to the antibiotic.

METHICILLIN-RESISTANT STAPHYLOCOCCAL SKIN INFECTIONS

Recently, methicillin-resistant staphylococci have been isolated from the skin of dogs with pyoderma. Typically, dogs have had recurrent skin infections and have been treated repeatedly with antibiotics. Response to empirical antibiotic therapy is poor or only partial. Bacterial culture reveals methicillin resistance (equivalent to, and reported as, oxacillin resistance). Antibiotic selection is based on susceptibility results. Be aware that regardless of the apparent in vitro susceptibility of methicillin-resistant strains of staphylococci, they should be regarded as resistant to all B-lactam and cephalosporin antibiotics.

Chapter 39

Mycobacteriosis

Andrew Hillier / Alan C. Mundell

Mycobacteria are gram-positive organisms that cause sporadic disease in human beings and in animals. All mycobacterial organisms contain a lipid-rich cell wall that inhibits host defense mechanisms and imparts a characteristic staining property in the laboratory. This staining property involves the retention of carbolfuchsin after acid and alcohol decolorization. Thus mycobacteria are classified as acid-fast staining organisms.

Recently, a new conceptual framework for classification of mycobacterial infections of dogs and cats was proposed. This classification takes into account the mammalian host, the infecting bacteria, and the environment. Consideration of mycobacterial infections within this framework provides the clinician with important information for diagnosis, treatment, and prevention. The categories of mycobacterial diseases as they relate to skin disease specifically are as follows:

1. Diseases caused by obligate mycobacterial organisms (e.g., feline leprosy syndromes)
2. Localized disease caused by saprophytic mycobacteria in immunocompetent hosts
   a. Where the infection is self-limiting and the immune response eventually eliminates the organisms (e.g., canine leproid granuloma syndrome)
   b. Where the infection remains localized but requires intervention for cure (e.g., panniculitis syndromes, caused by rapidly growing mycobacteria, and *Mycobacterium avium* complex infections)
3. Disseminated disease caused by mycobacteria in immunodeficient hosts

FELINE LEPROSY SYNDROMES

Feline leprosy is a mycobacterial disease of cats that was first recognized in Australia during the early 1960s. The condition has since been identified in New Zealand, Great Britain, France, the Netherlands, and the west coast of the United States and Canada. The disease is usually confined to cats living in coastal areas.

Feline leprosy refers to mycobacterial disease in which single or multiple skin granulomas are present. The granulomas contain large numbers of organisms that cannot be cultured using standard techniques. Until recently, all cases of feline leprosy were thought to be caused by *M. lepraemurium* and to occur in young cats. Recent studies have identified different syndromes of feline leprosy.

Feline Leprosy Caused by Mycobacterium Lepraemurium

Etiology

- Caused by *M. lepraemurium,* the rat leprosy organism. Although the rat leprosy organism had been suspected for many years, it was only in the 1980s that sophisticated culture techniques and biochemical analysis could identify *M. lepraemurium* as the etiologic agent.
- The mode of transmission is unknown, although cats are thought to become infected following bite injuries from infected rats.
- In experimental infections, the incubation period is 2 to 18 months.

Clinical Signs

- Young adult cats are affected, predominantly males living in either suburban or rural environments.
- Lesions are painless, raised, fleshy, freely movable nodules of a few millimeters up to 4 cm in diameter. They may develop rapidly, and some ulcerate when large.
- Nodules are usually multiple (but may be single), tend to initially concentrate in one body region, and may spread to adjacent areas and regional lymph nodes.
- Nodules may occur anywhere on the body, but the head and limbs are more frequently affected. Additionally, lesions may occur on the lips, oral mucosa, tongue, and nasal mucosa. The condition disseminates rarely to the spleen, bone marrow, liver, kidney, lung, or adjacent muscle. Cats with disseminated

disease usually show signs of systemic illness, which are not seen in cats with localized infection.
- Lesions tend to recur following surgical excision.

Diagnosis

- The diagnosis is achieved primarily through histologic evaluation of biopsy samples in conjunction with compatible history, physical examination, cytology, culture, and laboratory animal inoculation findings.
- The differential diagnoses for feline leprosy include atypical mycobacteriosis, tuberculosis, foreign body dermatitis, deep mycotic infections, mycetomas, dermatophyte pseudomycetomas, chronic bacterial infections, eosinophilic granuloma complex, and neoplastic diseases.

History

- History must be compatible with feline leprosy. The cat will typically be young, allowed to roam, and living in a cool, moist, coastal climate.

Cytology

- Cytology of needle aspirates or lesional impression smears reveals mixed inflammatory cells with macrophages and histiocytes containing variable numbers (often many) of acid-fast bacilli (long slender rods). In Diff-Quik–stained preparations, negative-staining organisms are seen within macrophages. Ziehl-Neelsen stain and a modified Fite's stain are the acid-fast stains most commonly used.

Culture

▼ ***Key Point*** Culture of the feline leprosy mycobacterium is difficult because the organism fails to grow on blood agar and standard mycobacterial media (Löwenstein-Jensen and Stonebrink).

- A 1% Ogawa egg yolk medium can be used to grow the organism when incubated under precise temperature and CO_2 conditions. Most commercial laboratories do not perform Ogawa egg yolk medium cultures.

Biopsy

- Biopsy specimens of lesions are fixed in 10% buffered formalin and evaluated histologically, using both hematoxylin-eosin and acid-fast stains (Ziehl-Neelsen and modified Fite's stains). (See Chapter 37 for skin biopsy technique.)
- Histologically, two forms are seen: tuberculoid and lepromatous forms. The tuberculoid form (most common in the United States and Canada) consists primarily of non-encapsulated epithelioid granulomas that are interspersed with neutrophils and surrounded by a zone of lymphocytes with low numbers of organisms. The lepromatous form is composed of sheets of large foamy macrophages that contain large numbers of acid-fast bacilli. The tuberculoid form is associated with a more competent host immune response.

Polymerase Chain Reaction

- Polymerase chain reaction (PCR) amplification of gene fragments from tissue samples provides a rapid and accurate diagnosis and identification of the causative organisms. Fresh (frozen) tissue or freeze-dried tissue is best, although PCR can also be performed on formalin-fixed, paraffin-embedded samples. (PCR for mycobacterial organisms is performed at the School of Veterinary Medicine, University of California, Davis, CA.)

Laboratory Animal Inoculation

- Laboratory animal inoculation is used primarily in research to propagate and investigate the feline leprosy organism. This procedure is of greatest value for differentiating feline leprosy from tuberculosis. Only tuberculosis-producing mycobacteria routinely kill guinea pigs within 6 to 8 weeks after inoculation.

Treatment

Treatment may not be necessary when lesions are small, unobtrusive, and likely to be self-limiting. However, this strategy is seldom effective and is recommended only for lesions that appear to be resolving spontaneously at the time of diagnosis.

▼ ***Key Point*** Surgical excision is the treatment of choice when lesions are limited in number and wide surgical margins can be obtained. However, disease recurrence is common and may require additional surgical intervention and/or medical management. Even then, adjunct antimicrobial therapy starting a few days prior to surgery is recommended.

Clofazimine is an iminophenazine dye with antimycobacterial properties that is suspended in olive oil and packaged in 50- and 100-mg capsules. Although the pharmacokinetics of clofazimine in the cat are unknown, a dosage of 10 mg/kg once daily PO (25–50 mg every 1–2 days), for 6 to 12 weeks past complete clinical resolution appears to be very effective. Wear latex gloves to prevent staining of hands. Clofazimine is not approved by the U.S. Food and Drug Administration (FDA) for animal use.

- Clofazimine may cause a reversible hepatopathy, and regular biochemical monitoring of cats is mandatory. Vomiting and inappetence are strong indications to

reduce the dose and to perform a biochemical evaluation of the patient. Photosensitivity and pitting corneal edema have also been noted in cats.
- Combination therapy is likely to achieve the best results. Clofazimine may be administered with one or more of the following drugs:
  - Rifampicin (10–15 mg/kg once daily)—Beware of hepatopathy
  - Clarithromycin (62.5 mg per cat once daily)—Less commonly associated with side effects and adverse reactions

Prevention

- This is probably best achieved by confining cats to an exclusively indoor environment. Because of the rare and sporadic nature of the disease, it is unlikely that this measure is necessary.
- Avoidance of immunosuppressive drugs while the disease is active may help prevent exacerbation.

Feline Leprosy Caused by Other Mycobacteria

Etiology

- This condition is caused by a new species, likely a fastidious, slow-growing mycobacterium that is yet to be named.
- Recently, a third form of the disease has been described in the western United States and Canada that is caused by *M. visiblis*.

Clinical Signs

- Older cats (>9 years) living in rural areas are affected.
- Generalized nodular skin lesions are typical (a few may start with localized disease). The lesions are similar in appearance to those caused by *M. lepraemurium*, but they do not ulcerate and disease progression is usually protracted over many months.
- As many as 50% of affected cats are feline immunodeficiency virus (FIV) positive.
- *M. visiblis* causes diffuse (rather than nodular) cutaneous disease with widespread dissemination to multiple internal organs. This syndrome has been termed *feline multisystemic granulomatous mycobacteriosis*.

Diagnosis

- Similar to feline leprosy caused by *M. lepraemurium* as described in the previous section.
- Very large numbers of organisms are usually detected on cytology or histopathology with acid-fast staining.
- PCR provides help with identification of the causative organism.
- Perform bloodwork (complete blood count and serum chemistry profile) and check the FIV status of the patient.

Treatment

- Treat the same as described in the previous section for feline leprosy caused by *M. lepraemurium*, although surgical excision is usually not an option due to the typically generalized nature of the disease.
- Affected cats are usually older and have compromised immune systems (e.g., FIV infection), and response to treatment may not be as good.
- Only one reported case of *M. visiblis* infection has been treated, and response to clofazimine and clindamycin resulted in a cure.

CANINE LEPROID GRANULOMA SYNDROME

Etiology

- Canine leproid granuloma syndrome (CGLS) is caused by a novel, fastidious, slow-growing mycobacteria that has yet to be named.
- This organism appears to be different from any other mycobacteria reported to affect humans or animals; thus the public health risk is believed to be minimal.
- It is believed that organisms are inoculated into tissue by biting flies, midges, or mosquitoes.

Clinical Signs

- Short-coated breeds, especially boxers and boxer crosses, are typically affected.
- Single or multiple well-circumscribed nodules that are firm and painless may be present anywhere on the body. However, the head, and especially the dorsal fold of the ear pinna (locations where dogs are bitten by flies) are most often affected.
- Nodules are 2 mm to 5 cm in diameter. Very large lesions may ulcerate and lead to local disfiguration.
- Regional lymph nodes and internal organs are *not* affected, and dogs are not systemically ill.

Diagnosis

- The distribution of lesions (ear pinna) and at-risk breeds (short-coated dogs, especially boxers) are usually strong clues.
- Cytology (fine-needle aspiration) and histopathology (see Chapter 37 for cytology and biopsy technique) usually reveals variable numbers of acid-fast, medium-length bacilli in macrophages and extracellularly.
- Organisms are fastidious and cannot be cultured.
- PCR may help identify this novel mycobacterial species.

Treatment

- Lesions are self-limiting in most cases, and resolution occurs over 1 to 3 months.
- Surgical excision of single lesions is often curative.

- In the case of chronic, non-resolving, and disfiguring lesions, combination antimicrobial therapy is effective. The following drug combinations have been used with success:
  - Rifampicin (10–15 mg/kg PO once daily) and clarithromycin (15–25 mg/kg total daily dose divided and given 2–3 times daily)
  - Rifampicin (10–15 mg/kg PO once daily) and doxycycline (5–10 mg/kg PO twice daily)

Prevention

- Prevent insects from biting dogs by keeping the dog indoors at the time of day of peak insect activity or use fly and insect repellants.

MYCOBACTERIAL PANNICULITIS

Non-tuberculous, non-lepromatous mycobacteria are classified as atypical or opportunistic. These mycobacteria have been placed by Runyon into four groups, depending on laboratory culture properties. Almost all dog and cat atypical mycobacterial skin infections belong to the rapid-growing group IV. These saprophytic, facultative pathogens are ubiquitous in nature and are typically isolated from water and moist soil. Atypical mycobacteriosis is more prevalent in cats than in dogs, with no apparent age, breed, or sex predilection.

Etiology

- *M. fortuitum, M. chelonei, M. smegmatis, M. thermoresistible,* and *M. xenopi* have produced skin lesions in dogs and cats. In the United States, *M. fortuitum* and *M. chelonae* are responsible for most atypical mycobacterial infections.
- Typically, these organisms have low virulence for mammals and, unless there is a breakdown of defense mechanisms, infections remain localized. The infected patient usually mounts a vigorous immune response that may not be sufficient to resolve the infection but usually prevents hematogenous or lymphatic spread of the infection. Widely disseminated disease is only seen in severely immunocompromised patients.
- The organisms have a preference for fat tissue.
- Skin infection follows contamination of traumatized skin, especially bite wounds and deep scratches. Cats are more commonly infected with rapidly growing mycobacteria than dogs are.

Clinical Signs

- Overweight and obese animals tend to be affected. The infection is most typically seen in cats that are allowed outdoors, where they may get into fights or sustain penetrating wounds and have concurrent exposure to mycobacterial organisms from the environment.

Cats

- The inguinal region (fat pad) is most commonly affected; the axilla, flanks and dorsum are less commonly affected. Lesions may spread to the lateral and ventral abdominal wall. Lesions resemble cat-fight abscesses initially (but without the fetid odor and turbid pus). A nodular to plaque-like lesion is visible, and the skin and subcutis become thickened and firm. Punctate ulcers and fistulas with a watery to purulent discharge appear in the affected area. If surgery is performed, wound breakdown and chronic, non-healing wounds persist. Cats may become systemically ill: depression, fever, inappetence, weight loss, pain, and hypercalcemia of granulomatous disease are occasionally noted.

Dogs

- Typically, mycobacterial panniculitis is suspected in dogs with chronic, non-healing wounds that have failed to respond to empirical treatment. Lesions consist of firm to fluctuant nodules that ulcerate, drain, and spread to affect large areas of the panniculus. A few animals may have fever, pain, and discomfort.

Diagnosis

- Perform bacterial culture and histologic evaluation of lesions. The differential diagnosis for cutaneous atypical mycobacteriosis is extensive and includes feline leprosy (in cats only), tuberculosis, foreign body dermatitis, deep mycotic infections, mycetomas, dermatophyte pseudomycetomas, chronic bacterial infections, generalized demodicosis (in dogs primarily), sterile nodular panniculitis, pansteatitis, eosinophilic granuloma complex, and neoplasia.

▼ ***Key Point*** Atypical mycobacterial organisms are difficult to isolate. In all suspected cases, perform cultures, biopsies for histopathology, and cytologic examination of lesional exudates.

History

- History must be compatible with cutaneous atypical mycobacteriosis. A history of trauma to the involved skin site weeks to months before the onset of lesions is not uncommon.

Cytology

- The cytology of lesional impression smears and smears of biopsy tissue consists of mixed inflammatory cells and, occasionally, acid-fast bacilli. (See

Chapter 37 for cytology and biopsy technique.) Cytologic evaluation frequently fails to confirm acid-fast organisms. Ziehl-Neelsen stain and modified Fite's stain are the acid-fast stains most commonly used. An exhaustive search is sometimes necessary to find organisms. Sometimes, organisms may show "beading" or appear as ghosts if they are poorly stained.

Culture

- Culture consists of growing the organism on standard mycobacterial media (Löwenstein-Jensen and Stonebrink) as well as on blood agar.
- Use sterile swab and biopsy techniques to obtain cultures. Notify the laboratory that atypical mycobacteriosis is suspected so that appropriate cultures are performed. Runyon group IV mycobacteria are called rapid growers because colonies appear within 7 days after media inoculation (often there is significant growth after 2–3 days). In contrast, most other mycobacteria are either difficult to culture or require weeks to months to grow. Species identification of the organisms is very important as this may have a significant impact on antimicrobial drug strategies. The MIC (minimum inhibitory concentration) for selected antibiotics should be determined to aid in the selection of antibiotics—this can be performed with the Etest or broth microdilution.

Biopsy

- Handle biopsy samples of lesions similar to those in feline leprosy except that special techniques, such as snap (instant) freezing the formalin-fixed tissue before staining or rapid Ziehl-Neelsen staining, may be necessary to reveal the organisms. Characteristically, fewer acid-fast bacilli are observed in atypical mycobacteriosis than in feline leprosy. Nodular pyogranulomatous dermatitis along with panniculitis is the common histologic pattern. If organisms are found, they are usually located within extracellular lipid vacuoles that are ringed by neutrophils. Besides the paucity of organisms, atypical mycobacteriosis also differs from feline leprosy by the extracellular location of the organisms.

Laboratory Animal Inoculation

- Laboratory animal inoculation is seldom performed. If cultures fail to identify the mycobacterial organism and the possibility of tuberculosis exists, perform guinea pig inoculation.

Treatment

Most reports of successful disease management are anecdotal or involve low numbers of cases. Because the condition naturally waxes and wanes with occasional prolonged periods of remission, carefully assess the success of all treatment options. Clinical remission may be more easily achieved in the dog than in the cat.

- An approach of no therapy may be taken if the disease involves a reasonably small area and the condition does not bother the animal or owner. This is rarely the case. When owners are unwilling to commit to a prolonged course of therapy, allowing the disease to naturally undergo its cycle may be a viable alternative. In time, the skin lesions may become more extensive; however, the disease rarely becomes systemic.
- Surgical excision is most successful for small, easily excised lesions. Obtain wide surgical margins. Unfortunately, surgical site dehiscence is common. Surgical excision without concurrent antimicrobial therapy is not recommended.

▼ ***Key Point*** Surgically debulking the lesions while treating the animal with a prolonged course of an appropriate antibiotic can be very helpful in providing a cure for mycobacterial panniculitis. Surgical excision may be more effective when managing canine lesions. Recent reports indicate increased success when presurgical antimicrobial therapy is administered for 2 to 3 weeks, followed by surgical debulking and then continued antimicrobial therapy until resolution.

- Medical management has been attempted using a variety of drugs. Table 39-1 provides the dosages of the most effective agents. Most of these drugs are not approved by the FDA for use in dogs or cats. In vitro

Table 39-1. SELECTED DRUGS FOR TREATMENT OF CUTANEOUS ATYPICAL MYCOBACTERIOSIS

Drug	Brand Name	Manufacturer	Dosage
Clofazimine	Lamprene	Ciba-Geigy	10 mg/kg PO q24h
Enrofloxacin	Baytril	Bayer	5–15 mg/kg PO q24h (not to be used in cats)
Marbofloxacin	Zeniquin	Pfizer	5.5 mg/kg q24h
Doxycycline	Vibramycin	Pfizer	5–10 mg/kg PO q12h
Amikacin	Amiglyde-V	Fort Dodge	5–7 mg/kg SC, IM q12h
Kanamycin	Kantrim	Fort Dodge	5–7 mg/kg SC, IM q12h
Gentamicin	Gentocin	Schering-Plough	6 mg/kg SC q24h
Clarithromycin			10–15 mg/kg q12h

sensitivity testing may be helpful when selecting a therapeutic agent. However, the clinical response is frequently less than what the sensitivity test suggests.
  - In general, administer medication for 2 to 6 months past clinical cure. If the medication is effective in achieving clinical remission but the lesions return after discontinuing the medication, prolonged or indefinite therapy may be needed.
  - Closely monitor the animal for adverse side effects. This monitoring typically requires periodic blood and urine laboratory evaluation, especially for drugs with known potential toxicities (e.g., aminoglycosides with nephrotoxicity and ototoxicity). It is beyond the scope of this chapter to discuss drug toxicities and the monitoring procedures. However, this information is available in current human and veterinary pharmacology textbooks. A thorough understanding of all drugs administered increases the safety of the therapeutic protocol.
- *M. fortuitum* and *M. chelonae* (more common in the United States) tend to be more resistant—in fact, the only oral antibiotic that has in vitro susceptibility for *M. chelonae* is clarithromycin.
- Whatever antibiotic is selected (based on in vitro susceptibilities), administer the highest possible dose. It is sometimes, best to start on a lower dose and titrate the dose up, always observing and monitoring for side effects and adverse reactions.

Prevention

- This is best achieved by decreasing the likelihood of traumatic injury to the skin and subcutaneous tissue. If animals are allowed to roam freely, confining them to a house or yard may decrease the likelihood of trauma. However, because of the rare and sporadic nature of the disease, these measures are probably unnecessary.
- Avoidance of immunosuppressive drugs may help prevent exacerbation or recurrence of atypical mycobacteriosis.

Chapter 40

Deep Fungal Infections

Amy M. Grooters

Deep "mycotic" infections are caused by a heterogeneous group of fungal and pseudofungal pathogens. Cutaneous and subcutaneous lesions may result from direct inoculation of an opportunistic fungal pathogen via trauma or may represent dermatologic manifestations of a systemic mycosis. Because the organisms that cause systemic mycoses typically exhibit unique morphologic features in tissue, the diagnosis of diseases such as blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis can often be made by histologic or cytologic identification of the pathogen in biopsy specimens or exudates (see Chapter 20). In contrast, specific identification of the less familiar opportunistic fungal pathogens that typically cause infection via wound contamination is not usually possible without culture. Despite this fact, opportunistic fungal pathogens can often be placed in a general category based on their morphologic features in tissue (such as pigmentation, hyphal diameter, and septation) and the inflammatory response that they induce. These categories include the following:

- Phaeohyphomycosis (pigmented hyphal forms)
- Hyalohyphomycosis (unpigmented hyphal forms)
- Eumycotic mycetoma (fibrosing granuloma with tissue grains containing pigmented or unpigmented fungal elements)
- Pythiosis, lagenidiosis, or zygomycosis (pyogranulomatous and eosinophilic inflammation associated with wide, infrequently septate, unpigmented hyphae)

A list of the pathogens discussed in this chapter and their categorization is found in Table 40-1.

DIAGNOSTIC APPROACH FOR DEEP MYCOSES

Dogs and cats with deep fungal infections are typically presented with dermal or subcutaneous nodules (with or without ulceration) and/or draining tracts. In addition to fungal infection, differential diagnoses for such lesions include bacterial infections (e.g., actinomycosis, nocardiosis, mycobacteriosis, and furunculosis), protozoal infections (e.g., leishmaniasis), neoplastic lesions (e.g., cutaneous lymphoma, cutaneous histiocytosis, and disseminated histiocytic sarcoma), foreign body reaction, and sterile nodular dermatoses (e.g., sterile pyogranuloma syndrome and idiopathic panniculitis). Phaeohyphomycosis and melanoma should be suspected when lesions are visibly pigmented. The presence of granules or grains in exudate is suggestive of actinomycosis, nocardiosis, actinobacillosis, and eumycotic mycetoma.

Cytology

Cytologic examination is often the quickest and least expensive tool for either making a definitive diagnosis or categorizing diseases that cause nodules and draining tracts. Fine-needle aspirates of cutaneous nodules or enlarged lymph nodes, direct smears of exudate, or impression smears of ulcerated lesions often contain infectious organisms in animals with blastomycosis, cryptococcosis, histoplasmosis, or rhinosporidiosis and in cats with sporotrichosis. In other types of deep fungal infections, organisms are variably present in cytologic specimens.

Biopsy

Lesion biopsy for histopathology and culture should be pursued when a definitive diagnosis cannot be established cytologically. When possible, obtain multiple biopsies of representative lesions (including both draining and intact nodules) and include normal tissue at the margin of the biopsy sample.

▼ ***Key Point*** Wedge biopsies are preferred to punch biopsies for the diagnosis of deep fungal infections.

In most cases, tissue biopsies should be submitted for bacterial (aerobic and anaerobic), mycobacterial, and fungal cultures and should be shipped at ambient temperature to arrive at the laboratory within 24 hours of collection. When unusual pathogens are suspected, it is helpful to contact the laboratory prior to collecting and shipping the samples. For additional information on diagnostic skin biopsy techniques, see Chapter 37.

Table 40-1. DEEP CUTANEOUS MYCOSES OF DOGS AND CATS

Disease	Causative Agents	Histologic/Cytologic Characteristics
Pythiosis	*Pythium insidiosum*	Pyogranulomatous and eosinophilic inflammation associated with broad (2–7 µ), infrequently septate hyphae
Lagenidiosis	*Lagenidium* spp.	Pyogranulomatous and eosinophilic inflammation associated with broad (4–25 µ), infrequently septate hyphae
Zygomycosis	*Basidiobolus ranarum, Conidiobolus* spp.	Pyogranulomatous and eosinophilic inflammation associated with broad (5–20 µ), infrequently septate hyphae
Sporotrichosis	*Sporothrix schenckii*	Pyogranulomatous inflammation associated with round, oval, or cigar-shaped yeast forms, 5–9 µ long, within macrophages or extracellular
Rhinosporidiosis	*Rhinosporidium seeberi*	Mixed inflammatory response associated with large (300 µ) sporangia that contain many endospores; released endospores often visible in cytologic samples
Candidiasis	*Candida albicans,* other *Candida* spp.	Suppurative inflammation associated with numerous oval yeasts 2–6 µ), pseudohyphae (chains of oval yeast cells), and true hyphae
Phaeohyphomycosis	*Alternaria, Bipolaris, Cladophialophora* (previously *Cladosporium*), *Curvularia, Exophiala, Fonsecaea, Moniliella, Phialophora, Ramichloridium,* and *Scolecobasidium,* among others	Pyogranulomatous inflammation associated with pigmented, irregularly septate hyphae or yeast-like cells that may be solitary or cluster in small groups or chains
Hyalohyphomycosis	*Acremonium, Fusarium, Geotrichum, Paecilomyces, Pseudallescheria,* and *Scedosporium,* among others	Pyogranulomatous inflammation associated with hyphal elements that have hyaline (transparent, non-pigmented) walls
Mycetoma (black grain)	*Curvularia*	Pyogranulomatous inflammation associated with pigmented tissue grains (which represent aggregates of fungal organisms)
Mycetoma (white grain)	*Pseudallescheria boydii, Acremonium*	Pyogranulomatous inflammation associated with non-pigmented tissue grains (which represent aggregates of fungal organisms)
Blastomycosis	*Blastomyces dermatiditis*	Suppurative to pyogranulomatous inflammation associated with large (8–15 µ), spherical, thick-walled, broad-based budding yeasts
Cryptococcosis	*Cryptococcus neoformans*	Granulomatous inflammation (may be minimal) associated with pleomorphic, narrow-based budding yeasts (3–7 µ) surrounded by a variably thick (1–30 µ) polysaccharide capsule
Histoplasmosis	*Histoplasma capsulatum*	Granulomatous inflammation associated with intracellular, round to oval yeast cells (2–4 µ) characterized by a basophilic center and clear halo
Coccidioidomycosis	*Coccidioides immitis*	Pyogranulomatous inflammation associated with large (20–200 µ), round, thick-walled spherules that at maturity contain many small (2–5 µ) endospores
Aspergillosis	*Aspergillus terreus, A. deflectus, A. flavipes, A. fumigatus*	Suppurative to granulomatous inflammation associated with multiple, non-pigmented, septate hyphae (3–6 µ) with parallel walls and 45-degree angle branching

Other Diagnostics

Additional diagnostic tests that may help further characterize deep fungal infections (and determine involvement of other organ systems) include a complete blood count, chemistry panel, urinalysis, and thoracic radiographs. Although serologic testing may help establish a diagnosis for some mycoses (such as cryptococcosis, blastomycosis, coccidioidomycosis, and pythiosis), in general, a diagnosis of deep fungal infection should not be based on serology results alone.

PYTHIOSIS

Pythiosis, lagenidiosis, and zygomycosis are caused by a taxonomically diverse group of pathogens but share similar clinical and histologic characteristics. Because of these similarities, they have previously been grouped under the now-obsolete term *phycomycosis.*

Etiology

Pythium insidiosum is an aquatic pathogen in the class oomycetes. *Pythium* species and other oomycetes differ from true fungi in producing motile, flagellate zoospores; having cell walls that contain cellulose and beta-glucan but not chitin; and having cell membranes that generally lack ergosterol.

- The infective stage of *P. insidiosum* is thought to be the biflagellate aquatic zoospore, which is released into warm water environments and likely causes infection by encysting in damaged skin or gastrointestinal (GI) mucosa.

- In the United States, pythiosis is most common in the Gulf Coast states but has been recognized in animals living in New Jersey, Virginia, Kentucky, Tennessee, southern Illinois, southern Indiana, Oklahoma, Missouri, and Kansas. Recently, a number of cases of GI pythiosis have been confirmed in dogs living in Arizona and northern California.
- Pythiosis occurs most often in young, large-breed, male dogs (especially outdoor working breeds such as Labrador retrievers). Affected dogs are most frequently presented to the veterinarian between October and March and often have a history of recurrent exposure to lakes or ponds.
- In cats, specific breed and sex predilections have not been observed in the few cases that have been reported to date. However, of 13 cats with cutaneous pythiosis diagnosed through my laboratory since 1999, 8 were less than 10 months old, with an age range of 4 months to 9 years.

Clinical Signs

The two forms of pythiosis are cutaneous and GI, depending on the route of infection. Both forms are rarely found concurrently in the same patient.

Cutaneous Pythiosis

Cutaneous pythiosis causes non-healing wounds and invasive masses that contain ulcerated nodules and draining tracts.

- Infected dogs often have solitary or multiple cutaneous or subcutaneous lesions involving the extremities, tail-head, ventral neck, perineum, or lateral thorax.
- In cats, lesions include subcutaneous masses in the inguinal, tail-head, or periorbital regions, draining nodular lesions or ulcerated lesions on the extremities, and nasopharyngeal lesions associated with retrobulbar masses.

Gastrointestinal Pythiosis

GI pythiosis in dogs is characterized by severe segmental thickening of the stomach, small intestine, colon, rectum, or, rarely, esophagus or pharyngeal region (see Chapter 69). The gastric outflow area, duodenum, and ileocolic junction are the most frequently affected portions of the GI tract, and it is not uncommon to find two or more segmental lesions in the same patient.

- Mesenteric lymphadenomegaly due to reactive hyperplasia is common.
- Involvement of the mesenteric root may form a single large, firm mass in the midabdomen.
- Extension of disease into mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen.
- Clinical signs associated with GI pythiosis include weight loss, vomiting, diarrhea, and/or hematochezia. Physical examination often reveals thin body condition and a palpable abdominal mass. Signs of systemic illness are usually absent unless intestinal obstruction or infarction occurs.

Diagnosis

Histopathology and Cytology

Pythiosis causes pyogranulomatous and eosinophilic inflammation associated with broad (mean, 4 μ; range, 2–7 μ), infrequently septate hyphae that are not well visualized on H&E-stained sections but are readily detected with a Gomori methenamine silver (GMS) stain. Because these same general features are associated with lagenidiosis and zygomycosis, a histologic diagnosis of pythiosis should be confirmed with culture, serology, polymerase chain reaction (PCR), or immunohistochemical staining of tissue sections with polyclonal antibodies specific for *P. insidiosum*.

- In animals with suspected cutaneous pythiosis, obtain wedge biopsies rather than punch biopsies to adequately reach infected tissues.
- Similarly, because inflammation in GI pythiosis centers on the submucosal and muscular layers rather than the mucosa and lamina propria, surgical biopsies are more likely to detect hyphae than are endoscopic biopsies. Therefore, consider pythiosis when endoscopic biopsies reveal eosinophilic or pyogranulomatous inflammation without identification of an etiologic agent.
- Cytologic examination of exudate associated with cutaneous pythiosis often reveals pyogranulomatous and eosinophilic inflammation but rarely reveals hyphae.

Culture

For best results, ship unrefrigerated tissue samples wrapped in a sterile, saline-moistened gauze sponge overnight at ambient temperature to a laboratory that has experience with the isolation of pathogenic oomycetes. Because *P. insidiosum* isolates rarely produce sexual reproductive structures in the laboratory, identification should be based on specific PCR amplification or ribosomal RNA gene sequencing whenever possible.

Serology

▼ ***Key Point*** Detection of anti–*P. insidiosum* antibodies in canine serum using either enzyme-linked immunosorbent assay (ELISA) or immunoblot techniques has high sensitivity and specificity for the diagnosis of pythiosis.

- Although these techniques have only been evaluated in a small number of cats, they appear to have high diagnostic accuracy for feline pythiosis.
- In addition to providing a means for early, non-invasive diagnosis, the ELISA is also useful for monitoring response to therapy in affected patients. Recheck *P. insidiosum* serology 2 months after surgical resection of infected tissues or every 3 months in animals receiving medical therapy for non-resectable lesions.
- Veterinarians interested in submitting diagnostic samples for serology or culture from animals with suspected pythiosis, lagenidiosis, or zygomycosis should contact Dr. Grooters at 225-578-9600.

Treatment

▼ ***Key Point*** Complete surgical resection of infected tissues provides the best opportunity for cure of pythiosis.

Surgical Resection

- Pursue aggressive surgical resection of pythiosis lesions whenever feasible. If cutaneous lesions are limited to a single distal extremity, recommend amputation.
- In animals with GI pythiosis, resect segmental lesions with a minimum of 3-cm margins if possible. The presence of non-resectable mesenteric lymphadenomegaly (which is more often due to reactive hyperplasia than infection) should not dissuade the surgeon from pursuing complete resection of a segmental bowel lesion. In this situation, biopsy enlarged lymph nodes for prognostic information.

Postoperative Medical Therapy

- Because local postoperative recurrence of pythiosis is common, administer itraconazole (10 mg/kg PO q24hr) and terbinafine (5–10 mg/kg PO q24hr) for at least 2 months after surgery (see Chapter 20 for more information on these drugs).
- To monitor for recurrence, perform ELISA serology prior to and 2 months after surgery. In animals that have had a complete surgical resection and go on to have no recurrence of disease, serum antibody levels drop significantly within 2 months of surgery.

Medical Therapy without Surgery

- Medical therapy is usually unsuccessful in animals with non-resectable pythiosis. However, clinical and serologic cures have been obtained in a small number of *P. insidiosum*–infected dogs treated with a itraconazole and terbinafine and rarely in dogs treated with amphotericin B lipid complex (2–3 mg/kg 3 times weekly to cumulative dose of 24–27 mg/kg) (see Chapter 20 for more information on these drugs).
- A vaccine derived from *P. insidiosum* antigens has been utilized with good success in the treatment of pythiosis causing cutaneous granulomas in horses and vasculitis in humans but has not been documented to have efficacy in small animals and, in my experience, is rarely associated with any clinical improvement in dogs or cats.

LAGENIDIOSIS

Until recently, *P. insidiosum* was considered the only mammalian pathogen in the class oomycetes. However, in 1999, a pathogenic oomycete in the genus *Lagenidium* was identified as a cause of severe multifocal cutaneous lesions and regional lymphadenomegaly in a dog. Since that time, more than 40 dogs with serologic, histologic, and/or culture evidence of *Lagenidium* species infection have been identified.

Etiology

The epidemiologic and clinicopathologic features of lagenidiosis are similar in many respects to those that have previously been associated with cutaneous pythiosis. Affected animals are typically young to middle-aged large-breed dogs living in the southeastern United States. Although most of these dogs have been from Florida or Louisiana, cases in Texas, Tennessee, Virginia, and Indiana have been identified as well. A number of infected dogs have had frequent exposure to lakes or ponds.

Clinical Signs

Dogs with lagenidiosis are usually presented with progressive cutaneous or subcutaneous lesions (often multifocal) involving the extremities, mammary region, perineum, or trunk. Grossly, these lesions appear as firm dermal or subcutaneous nodules or as ulcerated, thickened, edematous areas with regions of necrosis and numerous draining tracts.

Regional lymphadenopathy is often present and may occur in the absence of cutaneous disease. Inguinal and sublumbar lymph node involvement is common in dogs with hind-limb lesions.

▼ ***Key Point*** In contrast to pythiosis, the majority of dogs with lagenidiosis have been found to have lesions in distant sites, including caudal vena cava, aorta, sublumbar and inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum.

Dogs with caval lesions or sublumbar and inguinal lymph node involvement may be presented with hind-limb edema. Warn owners that sudden death may result from acute rupture of an occult great-vessel lesion, even in dogs without clinically apparent systemic disease.

Diagnosis

Biopsy and Cytology

Lagenidiosis causes pyogranulomatous and eosinophilic inflammation associated with broad, infrequently septate hyphae that may be visualized on H&E-stained sections but are more easily detected with a GMS stain. *Lagenidium* hyphae vary in size but in general are larger than *P. insidiosum* hyphae, ranging from 4 to 25 µm in diameter, with an average of 12 µm.

Cytologic examination of lymph node aspirates or exudate from draining tracts may reveal pyogranulomatous to eosinophilic inflammation with or without broad, poorly septate hyphal elements.

Serology

Immunoblot serology for the detection of anti-*Lagenidium* antibodies in canine serum can provide a presumptive diagnosis of lagenidiosis but must be interpreted in conjunction with results of serologic testing for *P. insidiosum* infection because of the potential for crossreactivity in serum from dogs with pythiosis. Do not use serology alone to make a diagnosis of lagenidiosis; instead, interpret serology in conjunction with histologic findings.

Culture

The definitive diagnosis of lagenidiosis is best made by culture of infected tissue by a laboratory experienced with the isolation of pathogenic oomycetes. Ship unrefrigerated tissue wrapped in a sterile, saline-moistened gauze sponge to arrive within 24 hours. Because of the current limitations associated with morphologic characterization of this pathogen, identify *Lagenidium* spp. based on ribosomal RNA gene sequencing or specific PCR amplification.

Treatment

In general, the prognosis for dogs with lagenidiosis is grave.

Surgical Resection

Aggressive surgical resection of infected tissues is the treatment of choice for lagenidiosis. In animals with lesions limited to a single distal extremity, recommend amputation. In those with cutaneous or subcutaneous lesions in other areas of the body, pursue aggressive resection with wide margins. Prior to attempting surgical resection of cutaneous lesions, perform radiographic imaging of the chest and abdomen and sonographic imaging of the abdomen to determine the extent of disease. Unfortunately, most *Lagenidium*-infected dogs have non-resectable disease in regional lymph nodes or distant sites by the time the diagnosis is made.

Medical Therapy

Medical therapy for lagenidiosis is typically ineffective. However, a combination of itraconazole with terbinafine (see Chapter 20), along with aggressive surgical resection, was effective in resolving *Lagenidium* spp. infection in two dogs with multifocal cutaneous lesions but no systemic lesions.

ZYGOMYCOSIS

The term *zygomycosis* refers to infections caused by fungi in the class zygomycetes, including the genera *Basidiobolus* and *Conidiobolus* in the order entomophthorales, and the genera *Rhizopus, Absidia, Mucor,* and others in the order mucorales. Infections caused by the mucorales have not been well documented in small animal patients. However, in dogs, *Basidiobolus* spp. and *Conidiobolus* spp. have been reported to cause cutaneous lesions that are grossly and histologically similar to those caused by *P. insidiosum* and *Lagenidium* spp. In addition, *Conidiobolus* spp. can infect the canine respiratory tract.

Etiology and Epidemiology

Basidiobolus ranarum, Conidiobolus coronatus, C. incongruus, and *C. lamprauges* are saprophytes that are widely distributed in nature. Cutaneous infection with *Basidiobolus ranarum* or *Conidiobolus* spp. likely occurs by percutaneous inoculation of spores via minor trauma or insect bites. Infection may also result from inhalation or ingestion of spores.

Clinical Signs

Conidiobolomycosis

Conidiobolomycosis occurs most often as a nasopharyngeal infection with or without involvement of tissues of the face, retropharyngeal region, and retrobulbar space. Infected animals may present with signs of chronic nasal cavity disease, ulcerative dermatitis of the nasal planum, or ulcerative lesions of the hard palate. *Conidiobolus* infection may also cause multifocal nodular draining subcutaneous lesions and regional lymphadenomegaly.

Basidiobolomycosis

Basidiobolomycosis is a rare cause of ulcerative draining skin lesions in dogs and has also been reported in a single case as a cause of tracheobronchitis. Disseminated *Basidiobolus* spp. infection involving the GI tract and other abdominal organs has been described in two dogs.

Diagnosis

The histologic features of zygomycosis (pyogranulomatous to eosinophilic inflammation associated with wide,

poorly septate hyphae) are similar to those associated with pythiosis and lagenidiosis. Hyphal diameter tends to be significantly larger for *Basidiobolus* spp. (mean 9 µ; range, 5–20 µ) and *Conidiobolus* spp. (mean 8 µ; range, 5–13 µ) than for *P. insidiosum*. Because serologic and immunohistochemical techniques are not currently available for the diagnosis of conidiobolomycosis and basidiobolomycosis, definitive diagnosis must be based on isolation of the pathogen from infected tissues.

Treatment

- For focal cutaneous lesions, perform aggressive surgical resection and follow with 2 to 3 months of itraconazole administered orally at a dosage from 5 to 10 mg/kg q24hr (see Chapter 20 for more information on this drug).
- For non-resectable lesions, treat with either itraconazole for 3 to 6 months or amphotericin B lipid complex (see Chapter 20). Monitor closely for signs of recurrence after discontinuation of medical therapy.
- For focal cutaneous lesions that can be completely resected, the long-term prognosis is good.
- For non-resectable lesions and those involving regional lymph nodes, the prognosis is guarded.

SPOROTRICHOSIS

Etiology

Sporotrichosis is caused by the dimorphic fungus *Sporothrix schenckii,* which exists as a yeast in tissue (37°C) but as mold in the environment and in the laboratory from 25°C to 30°C. The organism is a saprophyte typically found in organically rich soils, decaying vegetation, or other organic materials such as sphagnum moss and hay. Infection occurs by direct inoculation of the fungus into tissues, often through puncture wounds associated with thorns or splinters in dogs or through claw wounds in cats.

Although sporadic outbreaks involving significant numbers of animals have been reported, in general, sporotrichosis is uncommon in cats and rare in dogs. It is most often diagnosed in outdoor, roaming male cats and hunting dogs, presumably because of their increased risk for puncture wounds.

Clinical Signs

Sporotrichosis in dogs and cats is manifested as cutaneous, cutaneolymphatic, or disseminated disease. The cutaneous and cutaneolymphatic forms are most common and may be present concurrently. The disseminated form is extremely rare in dogs, but infected cats often have evidence of internal organ or lymphatic infection at necropsy, even when lesions clinically appeared to be limited to cutaneous and subcutaneous tissues. In addition, there is recent evidence that hematogenous dissemination of sporotrichosis may occur in as many as a third of infected cats.

Canine Sporotrichosis

Dogs with the cutaneous form of sporotrichosis are typically presented with multiple firm dermal or subcutaneous nodules on the head or trunk. These nodules may ulcerate, drain a purulent exudate, and become crusted. The cutaneolymphatic form is characterized in dogs by the formation of nodules on a distal limb, followed by proximal ascension of infection through lymphatic vessels with subsequent development of secondary nodules, draining tracts, and regional lymphadenopathy.

Feline Sporotrichosis

Infected cats may initially be presented with abscesses, cellulitis, or draining puncture wounds that resemble routine bacterial fight wound infections but fail to respond to antibiotic therapy. Cutaneous lesions are most often found on the head (especially nose and face), distal limbs, or tail-head region. They generally appear as subcutaneous nodules that ulcerate to form draining tracts and crusted nodules and may progress to form large, coalescing exudative ulcers and crusting lesions. Extensive areas of necrosis may develop, exposing underlying muscle and bone. Regional lymphadenopathy may be present.

▼ ***Key Point*** Because of the high numbers of *Sporothrix* organisms typically present in exudates from cat lesions, people handling infected cats are at risk for acquiring sporotrichosis. Always wear gloves when handling cats with ulcerative cutaneous lesions or draining nodules, and take precautions when handling cytology and culture specimens.

Diagnosis

Suspect sporotrichosis in cats with presumed fight wound abscesses that do not respond to appropriate antibacterial therapy.

Cytology

Cytologic examination of exudates will often demonstrate *S. schenckii* in lesions from infected cats but will demonstrate it only infrequently from infected dogs, in which lesions typically contain low numbers of organisms. The use of a fungal stain such as GMS or PAS (periodic acid-Schiff) may assist in identification of the organisms, which appear as round, oval, or cigar-shaped yeast forms, 5 to 9 µ long, found either within macrophages or extracellularly.

Biopsy

Histologically, sporotrichosis is characterized by nodular to diffuse pyogranulomatous inflammation. When possible, submit biopsy samples from intact nodules. Organisms are usually numerous and easily identified in lesions from cats but are difficult to find in canine lesions, often necessitating the careful examination of multiple GMS or PAS-stained sections for detection of the pathogen.

Culture

For culture of *S. schenckii,* submit exudate obtained from deep in a draining tract for culture on routine fungal media. In addition (especially for dogs), submit a surgically obtained tissue sample to be macerated prior to culture.

Treatment

- The treatment of choice for sporotrichosis in the dog and cat is itraconazole administered orally at a dosage from 5 to 10 mg/kg once daily until 30 days beyond complete resolution of detectable lesions (see Chapter 20 for more information on this drug).
- Oral administration of a supersaturated solution of potassium iodide (40 mg/kg q12hr with food for dogs and 20 mg/kg q12–24hr with food for cats) is often effective but is more likely than itraconazole to cause adverse effects (especially in cats).
- Terbinafine has been shown to be effective for the treatment of cutaneous and lymphocutaneous sporotrichosis in human patients but has not been well evaluated for this use in dogs or cats.

RHINOSPORIDIOSIS

Rhinosporidiosis is caused by *Rhinosporidium seeberi,* a member of a novel group of protists recently designated as the class mesomycetozoea. The disease occurs most commonly in India, southeast Asia, east Africa, and tropical regions of South America. It is rare in the United States, occurring sporadically in large-breed male dogs from southern states. It has not been described in cats.

Infection is likely associated with trauma to a mucosal surface followed by exposure to stagnant water. The infective form of *Rhinosporidium* is a small, round endospore that proliferates in epithelial tissue to form large (300 µ) sporangia, within which develop thousands of endospores that are released when the sporangial wall ruptures.

Clinical Signs

Infected dogs have signs of nasal cavity disease, including sneezing, unilateral nasal discharge, and epistaxis. Single or multiple red to gray polyps are present within the rostral nasal cavity and may be observed protruding from the nares. Sporangia on the surface of the polyps may be visualized as small, white spots.

Diagnosis

The identification of *Rhinosporidium* endospores is often possible during cytologic examination of exudate, nasal swabs, or impression smears of polypoid tissue. Histologic examination of a resected polyp should also provide a straightforward diagnosis through visualization of sporangia and endospores.

Treatment

Surgical resection is the treatment of choice for rhinosporidiosis, but lesions may recur. Despite sporadic reports of response to dapsone or ketoconazole, in general, rhinosporidiosis is poorly responsive to medical therapy.

CANDIDIASIS

Candida spp. are commensal yeasts that normally inhabit the oral cavity, GI tract, upper respiratory system, and genital mucosa of mammals. Cutaneous lesions associated with candidal infection are uncommon in dogs and rare in cats. When present, they represent either local proliferation of the organism or manifestation of disseminated disease.

Potential risk factors for the development of candidiasis include prolonged antibiotic therapy; immunosuppression due to persistent chemotherapy-induced neutropenia, long-term glucocorticoid therapy, hyperadrenocorticism, or diabetes mellitus; and damage to normal cutaneous or mucosal barriers, such as surgical wounds or indwelling vascular or urinary catheters.

Clinical Signs

Localized candidiasis causes non-healing, erythematous, oozing lesions involving mucous membranes, mucocutaneous junctions, and persistently moist regions of skin, such as skin folds, interdigital areas, and nail beds. Lesions on mucous membranes are typically moist ulcers that are surrounded by a hyperemic margin and may be covered by a whitish plaque. Skin lesions may initially appear as pustular lesions that progress to exudative or crusting ulcerated plaques.

Diagnosis

Cytologic and histologic examination of lesions shows suppurative inflammation associated with numerous 2- to 6-µ, oval yeasts, pseudohyphae (chains of oval yeast cells), and true hyphae. *Candida* species can be isolated on routine fungal media, and their identification based on morphologic and metabolic features is fairly straightforward. However, positive culture results are only sig-

nificant in conjunction with histologic demonstration of tissue invasion.

Treatment

Treatment of localized candidiasis consists of removing risk factors (if possible), clipping and drying affected areas of skin, and performing topical antifungal therapy (nystatin, miconazole, or clotrimazole).

PHAEOHYPHOMYCOSIS

Etiology

The term *phaeohyphomycosis* refers to cutaneous, subcutaneous, cerebral, or disseminated infections caused by dematiaceous (pigmented) filamentous fungi that contain melanin in their cell walls. Infection is thought to be the result of traumatic implantation of fungal elements, which leads to chronic granulomatous inflammation.

Fungal genera that have been identified as agents of phaeohyphomycosis in veterinary patients include *Alternaria, Bipolaris, Cladophialophora* (previously *Xylohypha* or *Cladosporium*), *Curvularia, Exophiala, Fonsecaea, Moniliella, Phialophora, Ramichloridium,* and *Scolecobasidium,* among others.

Clinical Signs

▼ ***Key Point*** Cutaneous or nasal lesions in cats are the most common clinical presentations for phaeohyphomycosis in small animals.

Patients are presented with ulcerated cutaneous nodules, upper respiratory signs, and/or a visible nasal mass. Infected tissues may appear grossly pigmented.

Diagnosis

In H&E-stained tissue sections, fungi that cause phaeohyphomycosis appear as dark-walled, irregularly septate hyphae or as yeast-like cells, solitary or in small groups or chains. The presence of melanin in the walls of lightly pigmented hyphae can be confirmed by the examination of unstained sections or the use of a Masson-Fontana stain for melanin.

Treatment

Because response of phaeohyphomycosis to medical therapy is variable, aggressive surgical removal of the lesion is the treatment of choice. Clinical response to either itraconazole or amphotericin B has been reported in cats with cutaneous phaeohyphomycosis, but relapse is common following either surgical or medical therapy.

HYALOHYPHOMYCOSIS

Etiology

The term *hyalohyphomycosis* refers to infections caused by non-pigmented fungi, or those that in tissue form hyphal elements that have hyaline (clear or transparent) walls. By convention, this term is not applied to infections caused by hyaline fungi in the genera *Aspergillus* or *Penicillium* or in the class zygomycetes. Genera that have been described as causing hyalohyphomycosis in veterinary patients include *Acremonium, Fusarium, Geotrichum, Paecilomyces, Pseudallescheria,* and *Scedosporium,* among others. In general, hyalohyphomycosis is less frequently encountered in small animal patients than is phaeohyphomycosis.

Clinical Signs

Infected animals present with lesions ranging from local disease confined to the skin, nasal mucosa, or cornea to disseminated disease in the lungs, bone marrow, lymph nodes, central nervous system, kidneys, liver, spleen, and bones.

Treatment

Surgical removal of the lesion (if feasible) is the treatment of choice for localized hyalohyphomycosis, but warn owners that recurrence or dissemination is likely and recommend postoperative medical therapy with itraconazole or amphotericin B (see Chapter 20).

MYCETOMA

Etiology and Clinical Signs

The term *mycetoma* refers to localized, mass-like, mycotic or actinomycotic infections of the skin, subcutaneous tissue, muscle, or bone that are characterized by the presence of colonies or aggregates of organisms that form "grains" in tissue. Actinomycotic mycetomas are caused by bacteria such as *Actinomyces* spp. and *Nocardia* spp., whereas eumycotic mycetomas are caused by fungi. Lesions result from traumatic implantation of soil organisms into tissue, resulting in chronic pyogranulomatous inflammation and abscessation.

The grains or granules associated with eumycotic mycetomas are characteristically pigmented (black-grain mycetoma, caused by dematiaceous fungi) or hyaline (white-grain mycetoma, caused by non-dematiaceous fungi), depending on the type of fungal pathogen involved.

Black-grain mycetomas are most often caused by *Curvularia* spp., and typically result in the development of chronic non-healing wounds and cutaneous nodules on the extremities. Lesions often develop weeks to months after a traumatic incident in the same area.

Draining sinus tracts are often present, and black grains may be observed in the exudate. Extension of disease through muscle or fascial planes into underlying bone may occur.

White-grain mycetomas, usually caused by *Pseudallescheria boydii* or *Acremonium* spp., are most often manifested as body wall and/or intra-abdominal granulomas that develop subsequent to contamination following surgical wound dehiscence. Affected dogs may be presented with a draining mass on the body wall or may develop clinical signs of peritonitis.

Treatment

The treatment of choice for eumycotic mycetoma is aggressive surgical excision of infected tissues, including amputation if clinically indicated. Response to medical therapy is routinely poor. Dissemination of eumycotic mycetoma beyond local tissues is rare.

DERMATOLOGIC LESIONS IN SYSTEMIC MYCOSES

Refer to Chapter 20 for information regarding the etiology, systemic manifestations, diagnosis, and treatment of systemic mycoses.

Blastomycosis

Because direct inoculation of *Blastomyces* organisms into the skin is rare (and only well documented in situations such as necropsy or laboratory accidents), cutaneous lesions in animals with blastomycosis should be considered signs of disseminated disease, even when obvious pulmonary lesions are absent.

Clinical Signs

Cutaneous lesions are present in 20% to 40% of infected dogs and, although they can be present on any part of the body, are most often found on the face, nasal planum, and nail beds. Skin lesions are often proliferative and ulcerated, draining a serosanguineous or purulent exudate. However, discreet subcutaneous abscesses may also occur.

Cutaneous lesions appear to be common in cats with blastomycosis, and localized cutaneous infection may occur more often in this species.

Diagnosis

The diagnosis of blastomycosis is most often made by identification of the organism on cytologic examination of draining exudates or tissue aspirates or on histologic examination. In more than half of infected dogs, organisms can be identified in cytologic specimens obtained from either cutaneous lesions or enlarged lymph nodes.

Cryptococcosis

Cutaneous lesions are common in cats with cryptococcosis and have been described in nearly half of reported cases. Dermal lesions (which are often multifocal) include small, firm papules or nodules that may enlarge and ulcerate, producing a serous or mucoid exudate. The head (especially around the nares) is a common location for dermal lesions, and a firm, subcutaneous swelling over the bridge of the nose is often present.

In dogs with cryptococcosis, cutaneous lesions are usually characterized by ulcerations involving the nose, oral cavity, palate, tongue, lips, or nail beds or by dermal masses involving the face.

Histoplasmosis

Cutaneous lesions are uncommon in animals with histoplasmosis. Those that have been described include dermal and subcutaneous nodules, ulcerated lesions, and fistulous tracts.

Coccidioidomycosis

In dogs with coccidioidomycosis, cutaneous lesions are often found over sites of infected bone and include ulcerated nodules, draining tracts, and subcutaneous abscesses. Infected cats develop similar lesions, but underlying bone involvement is less common.

Primary cutaneous coccidioidomycosis secondary to direct inoculation is rare but has been described, and is usually associated with regional lymphadenopathy.

Aspergillosis

Dermatologic lesions caused by aspergillosis (including cutaneous nodules, abscesses, and draining tracts) have been associated with disseminated disease in dogs (usually German shepherds). Mucocutaneous lesions (including ulceration and crusting of the external nares) may be associated with nasal aspergillosis in dogs.

Chapter

41 Malassezia Dermatitis

Daniel O. Morris

Malassezia dermatitis (MD) is a superficial fungal (yeast) infection occurring on and within the stratum corneum of the epidermis of many mammalian species. There are several different species of *Malassezia* yeast recognized, and various animals may serve as the natural hosts for specific species of the yeast. For example, most domestic carnivores harbor *Malassezia pachydermatis* as part of their natural cutaneous microflora, while human beings primarily harbor *Malassezia furfur.* As commensal organisms, *Malassezia* yeast colonize the skin in very low numbers. Overt infection is defined by increased numbers of the yeast on the skin surface in conjunction with inflammation. In dogs with atopic dermatitis (AD), *M. pachydermatis* may be recognized by the immune system as an allergen, in which case a highly inflammatory and pruritic response can be mounted to relatively low numbers of yeast organisms, blurring the line between "colonization" and "infection." The role of *M. pachydermatis* in feline dermatitis is less well defined, although it is a known commensal of feline skin as well.

ETIOLOGY

The genus *Malassezia* is now described to consist of nine species: *M. furfur, M. sympodialis, M. globosa, M. obtusa, M. restricta, M. sloofiae, M. equi, M. japonica,* and *M. pachydermatis. Malassezia* yeasts are characterized by a thick, multilayered cell wall and the production of blastoconidia by budding. With *M. pachydermatis,* the budding process imparts the appearance of unshelled peanuts when examined microscopically.

In dogs and cats, *Malassezia* yeast colonize the skin during the immediate perinatal period. Although *M. pachydermatis* is the species most commonly isolated from normal and inflamed skin of dogs and cats, other species are occasionally identified. *M. globosa,* which has a more spherical shape with tiny budding "heads," is sometimes associated with feline ceruminous otitis, but rarely so in dogs. *M. furfur,* which is a commensal of human skin, has been isolated from normal and inflamed canine skin, although its role in true "infection" is unknown; dogs may serve as mechanical carriers only. Other species isolated from normal canine and feline skin include *M. sympodialis* and *M. obtusa.*

PATHOGENESIS

In dogs, cats, and human beings, *Malassezia* yeast contribute to the pathogenesis of several disease states, including seborrheic dermatitis, AD, endocrine or metabolic diseases, paraneoplastic diseases, and disorders of cornification.

Canine Malassezia Dermatitis

M. pachydermatis colonizes sparsely haired areas and moist areas of the skin and mucosa of normal dogs in higher numbers than in more densely haired and dry areas.

- In a diseased state, alterations of the skin's surface microclimate contribute to increased susceptibility to yeast infection. Primary diseases that cause increased moisture, altered surface lipids, and/or disruption of stratum corneum barrier function encourage secondary overgrowth of the organism.
- Pruritic inflammatory diseases (allergic and parasitic) cause microclimate changes due to scratching (disruption of barrier function), licking (added moisture), and increased production of sebum.
- Endocrinopathies (especially hyperadrenocorticism) directly cause alterations in sebum characteristics and stratum corneum function.
- Metabolic diseases that result in parakeratotic hyperkeratosis (such as zinc-responsive dermatosis, generic dog food dermatosis, and hepatocutaneous syndrome or superficial necrolytic dermatitis) also appear to be risk factors.
- Secondary MD is also associated with primary (idiopathic) seborrhea of dogs, especially in basset hounds, cocker spaniels, dachshunds, and West Highland white terriers. Several other skin disorders can also be associated with MD (Table 41-1).
- A correlation between the onset of MD (or otitis) and the recent use of antibiotics has been documented. However, the opposite has also been noted where MD

Table 41-1. COMMON DIFFERENTIAL DIAGNOSES FOR SKIN DISORDERS THAT MAY BE ASSOCIATED WITH SECONDARY MALASSEZIA DERMATITIS

Reaction Pattern	DDx for Primary Causes	Species
Localized, regional, or generalized pruritus	Allergic diseases (atopy, adverse food reaction, flea bite allergy, contact allergy)	D & C
	Parasitism scabies, cheyletiellosis	D & C
	Demodex gatoi	C
	Infectious diseases (bacterial pyoderma, dermatophytosis)	D & C
Seborrhea oleosa	Most causes of pruritus (as above)	D & C
	Endocrinopathies	D & C
	Iatrogenic hyperglucocorticoidism	D & C
	Idiopathic (primary) seborrhea	D
	Vitamin A–responsive dermatosis	D
Seborrhea sicca	Same as for seborrhea oleosa	
	Sebaceous adenitis	D
Hyperkeratosis or crusting (face, foot pads, pressure points)	Zinc-responsive dermatosis, generic dog food dermatosis, superficial necrolytic dermatitis	D
(facial only)	Idiopathic facial dermatosis of the Persian	C
(regional *or* generalized)	Pemphigus foliaceus	D & C
	Thymoma-associated dermatosis	C
Acquired symmetrical alopecia	Causes of pruritus (as above)	C > D
	Endocrinopathies (including iatrogenic)	D > C
	Paraneoplastic alopecia	C
Facial acne	Bacterial folliculitis, demodicosis, dermatophytosis, adverse food reaction	C
Otitis externa +/− otitis media	Conformational/anatomic (hirsute canals, congenital infantile stenosis, etc.)	D
	Microclimate changes (heat and humidity retention)	D > C
	Allergic diseases	D & C
	Parasitic diseases (ear mites, demodicosis)	D & C
	Endocrinopathies	D > C
	Erosive diseases (drug eruption, pemphigus)	D & C
	Space-occupying masses	D & C
	Immunosuppression (including iatrogenic)	D & C
	Contact irritants	D & C

C, cat; D, dog; DDx, differential diagnosis.

resolved following treatment of concurrent staphylococcal pyoderma with antibiotics alone.

- Similarly, glucocorticoids have also been suggested to be a risk factor for development of MD; but again, some cases will spontaneously resolve with steroid therapy of an underlying inflammatory disease and without specific antifungal therapy.

▼ ***Key Point*** The most common primary disease association with canine MD is AD.

The role of *M. pachydermatis* in AD has been well described clinically and immunologically. The inflamed skin and ear canals of dogs with AD often harbor increased numbers of yeast (compared with the skin of normal dogs), and specific antifungal therapy will ameliorate a large portion of the pruritus experienced by many of these dogs.

- Dogs have been shown to mount an immunoglobulin E (IgE)-mediated (immediate) hypersensitivity response to allergens produced by the yeast in a manner similar to other environmental allergens (such as pollens, dust mites, animal danders, and molds).

▼ ***Key Point*** *Malassezia* overgrowth can provoke an overwhelming pruritic response in atopic dogs, which can occur acutely and be misconstrued as increased exposure to aeroallergens. Resolution of the yeast infection can reduce the pruritic threshold of an atopic dog by 75% to 100% in some cases, depending on concurrent exposure to other allergens. Therefore, undiagnosed MD is one of the most common reasons for perceived failure in the management of atopic dogs.

Canine Malassezia Otitis

- *M. pachydermatis* is commonly associated with otitis externa. As with the skin, there appears to be an increased incidence of *Malassezia* overgrowth in the ear canals of dogs with allergic and seborrheic otitis, endocrinopathies, and iatrogenic immunosuppression.
- It is also commonly seen in general practice occurring in otherwise normal dogs, but after swimming or bathing (i.e., water trapping or "swimmer's ear").
- The ear canals, which express a higher temperature and humidity than the surface skin, are a very favor-

able environment for yeast growth, and the lipid-rich cerumen is also supportive.
- I have noted a higher incidence of primary *Malassezia* otitis and pododermatitis (in otherwise normal dogs) living in a humid coastal climate than in dogs living in more arid and temperate climates.

Canine Malassezia Mucositis

While rare, it has been reported that *M. pachydermatis* can promote oral pathology (stomatitis, pharyngitis, tonsillitis).

Feline Malassezia Dermatitis and Otitis

- While a definitive (immunologic) relationship between *Malassezia* yeast and AD has not been described in cats, it does appear to be associated with pruritic or inflammatory dermatoses such as AD, adverse food reaction, and ectoparasitism.
- Cats with increased numbers of *Malassezia* spp. in the external canals often exhibit a highly pruritic ceruminous otitis.
- In addition to primary pruritic diseases, feline MD appears to occur in conjunction with paraneoplastic skin diseases; in a review of 550 feline skin biopsies, *Malassezia* spp. were most commonly associated with feline paraneoplastic alopecia and thymoma-associated dermatosis or erythema multiforme. All cats with histology consistent with these underlying systemic diseases died within 8 weeks of skin biopsy sampling.

CLINICAL SIGNS

Canine Malassezia Dermatitis

- Although MD is usually intensely pruritic, the only primary lesion produced is *erythema*.
- *Secondary lesions* including excoriations, seborrheic plaques, lichenification, maceration, and intertrigo are common and cannot be reliably distinguished from staphylococcal pyoderma without cytologic examination.
- In rare cases, *M. pachydermatis* can cause a *folliculitis* that mimics staphylococcal folliculitis, dermatophytosis, and demodicosis.
- The *clinical appearance* of the skin in cases of MD is highly variable. It may either be dry and flaky (seborrhea sicca) or tacky and greasy (seborrhea oleosa).
- The *distribution pattern* of canine MD is variable but most commonly affects some combination of the face (especially periocular and perioral skin), feet (interdigital spaces and claw folds), intertriginous areas (axillae, groin or inguinum, facial folds, and vulvar and mammary folds), and perineum.
- Generalized cases of MD may occur in chronic cases of allergic dermatitis.
- *Malassezia* pododermatitis may occur with or without more widespread MD. The feet are the most common single body area affected in allergic dogs. Patients with interdigital *Malassezia* pododermatitis will be presented for the complaint of paw licking or chewing.
- *Paronychia* (inflammation of the claw beds) may also occur as the sole presenting sign of MD and often causes claw biting (also see Chapter 63). Physical examination will usually reveal a reddish-brown staining of the proximal claw or a waxy exudate in the claw fold, with inflammation of the surrounding soft tissue.
- MD can occur in any breed (or mixed breeds) but West Highland white terriers, English setters, Shih Tzus, basset hounds, and American cocker spaniels are at increased risk. This increased risk may in turn reflect the propensity for these breeds to develop allergic dermatitis as a predisposing factor.
- In any dog with a known endocrine or metabolic disease, rule out MD (by surface cytology) if pruritus, cutaneous inflammation, or non-inflammatory seborrhea are present.
- Cases of non-pruritic MD are rare, and most will be associated with hyperadrenocorticism, hepatocutaneous syndrome, zinc-responsive dermatosis, or iatrogenic immunosuppression from cancer chemotherapy.

▼ ***Key Point*** The most common presenting complaint associated with non-pruritic MD is seborrhea oleosa accompanied by a foul odor.

Canine Malassezia Otitis

- *M. pachydermatis* plays an important role in cases of ceruminous otitis externa, in which it is often highly inflammatory (see Chapter 59). However it is a normal inhabitant of 15% to 49% of healthy canine ear canals, depending upon the study reported.
- *M. furfur* and *M. obtusa* have also been isolated from dogs with otitis externa.
- As with the skin, there is no reliable smell or characteristic of otic exudate that routinely indicates an infection is associated with yeast rather than bacteria (contrary to anecdotal claims), so cytologic evaluation is essential (see "Diagnosis").
- Otitis media may also occur in which *Malassezia* is the sole infectious organism isolated (see Chapter 61). These cases result from extension of the infection through a ruptured tympanum, which may sometimes heal and therefore seal the infection within the bulla. Undiagnosed otitis media is a common underlying cause of chronic or relapsing otitis externa and must be identified and treated in order for permanent resolution of the case to occur.

Feline Malassezia Dermatitis and Otitis

- Feline MD is rare compared with canine MD.
- It may be associated with any primary pruritic disease and often causes a diffuse erythematous, scaly to waxy dermatitis. However, not all cases of MD in cats are pruritic.

- MD seems to be especially pruritic when associated with facial dermatitis and/or otitis externa in cats. Facial pruritus is one of the most common and frustrating problems encountered in feline dermatology, and the list of primary etiologies that can incite it is extensive.
- Markedly pruritic ceruminous otitis may be associated with *Malassezia* spp.
- As in dogs, *Malassezia* paronychia may be associated with waxy exudates in the claw beds and rust-colored staining of the proximal claws. The Cornish and Devon Rex breeds appear to be predisposed.
- *Malassezia* spp. may also be associated with some cases of *feline facial acne* (affecting any combination of the chin, neck, and perioral and periocular regions). Many cases are non-pruritic.
- Cats with thymoma-associated dermatosis (regional dorsal to generalized exfoliative dermatitis), may have MD that may not be pruritic.
- Cats with pancreatic or hepatobiliary carcinomas may develop a paraneoplastic alopecia of the ventrum and legs (skin has a glistening sheen). Secondary *Malassezia* overgrowth may provoke pruritus in this otherwise non-pruritic disease, but even non-pruritic cats should be screened cytologically.

ZOONOSIS

It has recently been documented in a human neonatal intensive care unit (ICU) that the zoophilic species *M. pachydermatis* can cause a similar life-threatening fungemia in humans. The source of a yeast infection was shown to be a pet dog owned by a nurse who worked in the ICU. This observation suggested that *M. pachydermatis* could represent an emerging infectious zoonotic pathogen. An epidemiologic survey conducted by my clinical research group has shown that *M. pachydermatis* can be isolated very commonly from the hands of dog owners, regardless of whether the dogs have MD or healthy skin. However, the public health significance appears to be extremely minor, considering the commonality of mechanical carriage by dog owners and the paucity of fungemia cases reported in the human literature.

DIAGNOSIS

▼ ***Key Point*** *Malassezia* organisms can be identified on animal skin by cytology, culture, histopathology, and polymerase chain reaction (PCR).

Cytology

Methods for collection include dry skin scrapings, adhesive tape stripping, cotton-tipped swabs, and direct impression smears with glass slides (also see Chapter 37).

For Dry Skin

- Scrapings and adhesive tape stripping (or direct skin impression with adhesive-coated slides) work best. With scrapings, it may be necessary to mix the material with saline and heat fix until dry (in order to adhere the material to the slide).

For Greasy Skin

- Direct impression smears allow quantification of yeast per microscopic field (as does tape stripping and adhesive-coated slides).
- Cotton-tipped swabs are useful for interdigital spaces if they are tacky, as it can be difficult to impress slides directly—especially in small-breed dogs. Adhesive tape also works nicely in tight spaces.
- For diagnosis of *Malassezia* paronychia, use the broken end of a cotton-tipped swab's wooden handle or a metal spatula to scrape the claw fold and press or roll exudate firmly onto a glass slide.
- For examination of ear exudate in dogs with ceruminous or exudative otitis externa, roll exudate in a thin layer on glass slides with a cotton-tipped swab. It is often useful to sample the skin of the concave pinna separately from the ear canal if pinnal dermatitis is present.

Preparing Samples for Microscopic Examination

- When material is applied to a glass slide, use a modified Wright's stain (such as Diff-Quik). Heat fixing of the slide prior to staining is performed by many dermatologists, but a study has shown it to be generally unnecessary.
- Examine under an oil immersion (1000×) or high-power dry (400×) field for oval or peanut-shaped (budding) yeast. Use oil immersion for more reliable identification of bacteria and yeast cells.
- When adhesive tape is used, it may be dipped in the stain, rinsed, and dried with a warm air dryer. Apply the tape to a glass slide while it is still warm and sticky for best adhesion. Some clinicians prefer wet mounts: A drop of new methylene blue stain is placed on a glass slide, and the tape strip is laid on top.

Interpretation of Cytologic Results: How Many Is Too Many?

- For skin, 1 yeast per oil immersion field (oif) is a general guideline used by many dermatologists, although the only controlled study published has suggested 1 yeast per 27 oif may be sufficient to correlate with pathologic effect.
- Normal dogs may routinely exhibit up to 5 organisms per high-dry (400×) field (roughly <2 per oif), while cats may harbor up to 12 organisms per high-dry field (roughly <5 per oif).

▼ ***Key Point*** These numbers are guidelines only. Since dogs may mount a hypersensitivity response to *M. pachydermatis,* it is possible that some indi-

viduals will suffer a pathologic effect from what would otherwise be considered a "normal" population of yeast colonizing the skin or ear canals.

Culture

Culture for *Malassezia* organisms is generally unnecessary and rarely performed.

Histopathology

This should *not* be necessary to make the diagnosis of MD if routine cytology is performed. While *Malassezia* spp. are often found on biopsies submitted for evaluation of pruritic dermatitis, histopathology cannot be relied upon to make the diagnosis of MD; loss of stratum corneum during tissue processing may yield a false-negative result.

Polymerase Chain Reaction

This technique is capable of identifying the *Malassezia* species with an extremely high degree of accuracy but is primarily used for research purposes or to monitor for point sources in epizootic outbreaks.

TREATMENT

Chose therapy based upon the distribution of the infection, the general health status of the patient, and the expectations of the pet owner in regards to time and effort commitment (relevant to topical therapy) and side effects (most relevant to systemic therapy). Diagnose and eliminate (or control) underlying diseases to prevent of recurrence. Since *M. pachydermatis* is part of the normal cutaneous microflora, complete elimination of the organism is likely to be impossible.

Systemic Therapy (Table 41-2)

▼ ***Key Point*** Unless there is a specific contraindication to using an oral antifungal drug, treat most cases of generalized and regional MD (e.g., pododermatitis) systemically. Otitis media also requires systemic therapy to reliably achieve therapeutic drug levels within the tympanic cavity. Oral ketoconazole, itraconazole, or fluconazole is most commonly recommended. Griseofulvin is ineffective against *Malassezia* spp.

Ketoconazole

- *Ketoconazole* (Nizoral, Janssen, and generics) is an imidazole antifungal with proven efficacy for canine MD. It undergoes extensive metabolism by the liver, and its use in patients with hepatic disease is contraindicated. It is also a known teratogen in dogs. Adverse effects include gastrointestinal upset (anorexia, vomiting, diarrhea), thrombocytopenia (rare), and hepatotoxicity, although none of these side effects are at all common. Hepatotoxicity is a moderate risk in cats, however, and its use in feline MD is not recommended. In aged or debilitated dogs, evaluate hepatic enzymes prior to use of ketoconazole. I do not routinely perform screening tests in young or healthy dogs. For long-term or repeated use, monitor hepatic function on a case-by-case basis as dictated by clinical signs (some dermatologists recommend monthly monitoring). Always administer this drug along with food for maximum absorption.

Itraconazole

- *Itraconazole* (Sporanox, Ortho Biotech) and *fluconazole* (Diflucan, Roerig) are triazole antifungals with less risk for hepatotoxicity than ketoconazole. Itraconazole is metabolized by the liver, while fluconazole is excreted via the kidneys. Due to cost, fluconazole is rarely chosen as a first-line treatment. Itraconazole is the treatment of choice in cats unless preexisting hepatopathy is known, in which case fluconazole should be used. Always administer itraconazole with food; feeding does not influence the absorption of fluconazole.

Table 41-2. SYSTEMIC DRUGS FOR TREATMENT OF MALASSEZIA DERMATITIS AND OTITIS MEDIA

Drug	Supplied As	Dose, Frequency, Duration	Species
Ketoconazole	200-mg tablets	5–10 mg/kg q24h × 21–28 days, or	D
		low dose regimen: 5 mg/kg q24h × 10 days, then eod × 10	D
		Pulse dose regimen for *prophylaxis:* 5–10 mg/kg for 2 consecutive days/wk	D
Itraconazole	100-mg capsules	5 mg/kg q24h × 21–28 days, or	D & C
		5 mg/kg for 2 days/wk × 3 weeks	D
	10-mg/ml of elixir	2.25–5 mg/kg q24h × 21–28 days (pulse dose not reported)	D & C
Fluconazole	50-, 100-, 150-, 200-mg tablets and oral powder for a 10-mg/ml suspension	2.5–5 mg/kg q24h × 21–28 days	D & C
Terbinafine	200-mg tablets	30 mg/kg q24h × 21–28 days	D
		30–40 mg/kg q24h × 21–28 days	C

Terbinafine

- *Terbinafine* (Lamisil, Novartis) is an allylamine antifungal with a high margin of safety for use in mammals. It is a less proven drug for MD, but based upon its ability to reduce *Malassezia* colonization on healthy basset hounds, it is likely to be effective.

Lufenuron

- *Lufenuron* (Program, Novartis Animal Health) is a benzoylphenylurea drug that disrupts chitin synthesis in the cell wall of insects and perhaps some fungi. There is no evidence at this time to suggest that this drug is effective in the treatment of MD.

Topical Therapy

▼ ***Key Point*** Topical antifungals are most useful for treatment of localized infections or as adjunctive therapy along with oral drugs. Topical antifungals are also quite valuable in the prophylaxis of chronic or relapsing MD.

- For regional or generalized disease, shampoos containing miconazole, ketoconazole, chlorhexidine, or selenium sulfide are available and have met with variable success depending upon client compliance, frequency and technique of application, and severity of disease. Conditioners containing miconazole and chlorhexidine are also available, as is lime sulfur dip. Enilconazole is available as a rinse in some countries, but not in the United States.
- For frequently relapsing cases, shampoo therapy (once to twice weekly, 10 minutes minimum contact time) may be adequate for prophylaxis.
- *Malassezia* pododermatitis and paronychia may be treated with topical therapy alone in a limited number of cases, but such therapy can be labor intensive for the client and poorly received by the patient. Success with shampooing or soaking the feet in miconazole, ketoconazole, or chlorhexidine products (minimum of 10 minutes contact time) and use of miconazole and/or chlorhexidine spray or wipes on a daily basis has been reported anecdotally. For *Malassezia* paronychia, gentle scrubbing of the claw folds with a toothbrush using miconazole shampoo has been described but is labor intensive.
- Use miconazole, clotrimazole, or ketoconazole sprays, lotions, wipes, or creams for "spot" therapy.
- Use ointments and lotions containing nystatin, thiabendazole, miconazole, or clotrimazole for otitis externa. Some products also contain glucocorticoids and antibacterials.

Immunotherapy

A commercial *M. pachydermatis* extract (Greer Laboratories, Lenoir, NC) is now available for intradermal testing and use in immunotherapy vaccines. A multicenter study is under way to determine its utility as an immunotherapeutic extract.

Dermatophytosis

Karin Muth Beale

Dermatophytosis is an infection of keratinized tissues usually caused by dermatophytes of the genera *Microsporum, Trichophyton,* and *Epidermophyton*. These organisms are keratinophilic and invade and live within the keratinized hair, nail, or skin. The majority of infections in dogs and cats are caused by three species of dermatophytes: *Microsporum canis, Microsporum gypseum*, and *Trichophyton mentagrophytes*. Other fungi are uncommon causes of dermatophytosis in pets. Dermatophytes are classified into groups based on their natural habitat as geophilic, zoophilic, or anthropophilic. Geophilic dermatophytes naturally inhabit the soil, zoophilic species are adapted to animals, and humans are the hosts for anthropophilic species. As a general rule, geophilic and anthropophilic dermatophytes tend to produce many more inflammatory lesions in animals than do the more host-adapted species.

ETIOLOGY

Microsporum Gypseum

M. gypseum is a geophilic dermatophyte that normally inhabits the soil and decomposes keratinaceous debris. However, this organism is the second most common cause of dermatophytosis in dogs in the United States, and it occasionally infects cats. *M. gypseum* is most commonly isolated from animals that spend much time outdoors. Because the organism is not specifically adapted to living on animals, it tends to incite inflammation. Lesions are commonly seen in areas with significant soil contact, such as the feet and muzzle.

Microsporum Canis

This zoophilic dermatophyte is responsible for the majority of the clinical cases of dermatophytosis in dogs. *M. canis* is the cause of approximately 98% of the cases of feline dermatophytosis. It was previously thought that cats served as the reservoir for *M. canis;* however, studies show that it is rarely isolated from healthy pet cats. The isolation of *M. canis* from a dog or cat is a significant finding, and the condition requires treatment.

Trichophyton Mentagrophytes

This zoophilic dermatophyte is the third most common cause of dermatophytosis in dogs and less commonly affects cats. *T. mentagrophytes* is the most common cause of dermatophytosis in rodents and rabbits. Pet rodents or rabbits should be considered possible reservoirs of infection. Wild rodents are commonly infected, and the infections may be clinically inapparent. Cats that hunt may be pre-disposed to acquiring this dermatophyte infection, as are dogs that dig and root in soil.

Anthropophilic Dermatophytes

Anthropophilic dermatophytes such as *Microsporum audouinii* rarely affect pets but can cause intensely inflamed lesions in animals. Zoophilic species of dermatophytes other than *M. canis* and *T. mentagrophytes,* such as *Trichophyton equinum, Trichophyton verrucosum,* and *Microsporum nanum,* may cause dermatophytosis in dogs or cats; however, such animals usually are in contact with livestock that are natural reservoirs or hosts for those organisms.

CLINICAL SIGNS

Canine Dermatophytosis

- Canine dermatophytosis is characterized by alopecia and scaling. Usually there are focal to multifocal, circumscribed, affected patches of skin.
- Hair loss, broken hairs, scaling, pustules, papules, exudation, crusting, and hyperpigmentation may be seen.
- Pruritus is variable.
- The classic lesion is a circular area of alopecia and scaling with central healing; however, the lesions may be irregular in appearance.
- Several factors influence the severity of the lesions. Young and immunocompromised animals tend to develop more extensive lesions that take longer to resolve than do those of healthy adult animals. This is because the ability to mount an effective inflam-

matory response is necessary to eliminate the infection. In addition, the pathogenicity and the species of dermatophyte affect the degree of inflammatory response.

Kerion

A kerion is a round, raised, well-circumscribed, erythematous, alopecic, nodular lesion that results when follicular rupture, furunculosis, and pyogranulomatous inflammation occur with a dermatophyte infection. The lesions have a spongy feel on palpation and will sometimes exude purulent to hemorrhagic material that may result in crust formation.

- Kerions are most commonly seen on the limbs and face of dogs. They are usually solitary and mimic histiocytomas.
- The etiology usually is *M. gypseum*.
- These lesions may be secondarily infected with *Staphylococcus intermedius*.

Generalized Dermatophytosis

Generalized dermatophytosis is uncommon in the dog.

- Characteristic findings are widespread alopecia and seborrhea with or without pruritus.
- Other lesions, similar to those of focal dermatophytosis, may also be present.
- Generalized dermatophytosis in adult dogs is often associated with immunosuppression or systemic disease.

Feline Dermatophytosis

▼ ***Key Point*** Feline dermatophytosis can occur in many different clinical forms. Consider dermatophytosis in the differential diagnosis of most feline dermatoses. Feline dermatophytosis is the most common infectious skin disease in cats.

▼ ***Key Point*** Cats of any age may be infected, but younger, older, and long-haired cats seem to be affected more frequently. Systemic disease may increase susceptibility to infection. Cats with feline immunodeficiency virus (FIV) have an increased risk of dermatophytosis.

Classic Ringworm

Ringworm lesions may be present in cats; however, the circular lesions of alopecia and scaling with central healing are less common in cats than in dogs. Crusting, scaling, and hair loss are most commonly seen. Cats may have what appears to be a localized infection when in reality the infection is generalized. This is especially true of long-haired cats.

Subclinical Infection

Adult cats may have subclinical dermatophyte infections. These cats may have minimal (e.g., a minor degree of scaling or a few broken hairs) or no apparent clinical lesions. These cats serve as an important reservoir in the spread of dermatophytosis, and culture is necessary to identify affected cats.

Miliary Dermatitis

In cats, dermatophytosis may occur as a *miliary dermatitis* that may or may not be pruritic (see Chapter 53).

Symmetrical Alopecia

Symmetrical alopecia may be caused by dermatophytosis in cats. Excessive grooming as a result of pruritus, combined with follicular inflammation, can lead to excessive hair loss in some cats.

Pseudomycetoma

- Pseudomycetoma (Majocchi granuloma) is a form of granulomatous dermatitis in the cat caused by a dermatophyte, usually *M. canis*.
- This type of lesion is almost exclusively seen in Persian cats.
- In this lesion the fungus is sequestered in the dermis but does not proliferate; a nodular, ulcerating dermatitis is the result.
- Affected cats usually have generalized dermatophytosis.

Onychomycosis

- This dermatophyte infection of the nails is seen in both dogs and cats (also see Chapter 63).
- The lesions usually are caused by *T. mentagrophytes* in dogs and *M. canis* in cats.
- The nails are dry, cracked, brittle, and frequently deformed.
- Onychomycosis very rarely affects all four feet.
- Usually there is a concurrent infection with inflammation of the nail fold, and the pads may be affected as well.

DIAGNOSIS

▼ ***Key Point*** False-positive diagnosis of dermatophytosis in animals with circular lesions of alopecia is common. Follicular infections with *Demodex* and *Staphylococcus* organisms produce similar lesions.

- Do *not* diagnose dermatophytosis solely on the basis of clinical signs. Because of the numerous clinical conditions in dogs and cats that can mimic dermatophytosis, perform specific diagnostic procedures to obtain a definitive diagnosis.

Differential Diagnoses

Canine Dermatophytosis

- In the dog, the most common cause of circular alopecia is staphylococcal folliculitis (see Chapter 38), followed by localized demodicosis (see Chapter 43).
- Follicular infections with different organisms share common reaction patterns of papules, pustules, alopecia, scaling, and crusting.
- Use diagnostic tests such as skin scrapings, surface cytology, bacterial cultures, and skin biopsies to rule out some of the more common causes of focal alopecia in dogs.
- Consider dermatophytosis in the differential diagnosis of a generalized scaling, crusting, alopecic dermatosis. A number of different conditions can cause a generalized dermatitis similar to that seen in generalized dermatophytosis in the dog (Table 42-1).
- The differential diagnosis for kerions and pseudomycetomas includes the various causes of nodular dermatitides, such as cutaneous neoplasms, staphylococcal furunculosis, and acral lick dermatitis (see Table 42-1).

Table 42-1. DIFFERENTIAL DIAGNOSIS FOR DERMATOPHYTOSIS IN DOGS

Focal to Multifocal Dermatophytosis
Demodicosis
Staphylococcal folliculitis
Abrasions
Pemphigus foliaceus/erythematosus
Zinc-responsive dermatosis
Generalized Dermatophytosis
Demodicosis
Staphylococcal folliculitis
Dermatophilosis
Pemphigus foliaceus
Cheyletiellosis
Sebaceous adenitis
Primary cornification defects
Secondary cornification abnormalities (allergic dermatoses, endocrinopathies, nutritional deficiencies, etc.)
Epidermotropic lymphoma
Kerions
Histiocytoma, mast cell tumor, other neoplasms
Staphylococcal furunculosis
Demodicosis and furunculosis
Acral lick dermatitis
Foreign bodies
Subcutaneous mycoses
Actinomycotic infections
Mycobacterial infections
Onychomycosis/Nail Fold Dermatophytosis
Staphylococcal onychitis
Demodicosis
Zinc-responsive dermatosis
Pemphigus vulgaris/foliaceus
Symmetric lupoid onychodystrophy

Feline Dermatophytosis

The list of disorders to be considered in the differential diagnosis of feline dermatophytosis is extensive and includes all causes of miliary dermatitis and symmetrical alopecia (see Chapters 52 and 53).

History

An accurate history can provide useful information regarding the possible source of infection.

- Obtain an accurate drug history. Consider the possibility of exposure to dermatophytes from other infected animals, cattery/grooming/boarding facilities, or the environment of the animal (outdoor exposure in the case of geophilic dermatophytes, the introduction of a new kitten or cat, etc.).
- Determine whether the animal has had any abnormalities suggestive of underlying systemic disease, particularly in older animals.

Physical Examination

- Look for signs suggestive of dermatophytosis. Wood's light examination, microscopic examination of glowing hairs, and cultures are recommended in the following patients:
  - Dogs with lesions characteristic of dermatophytosis
  - Dogs with generalized lesions of alopecia and scaling
  - Cats with clinical signs of dermatophytosis (hair loss, scaling, broken, frayed hairs, pruritus)
  - Cats with systemic disease or viral infections that have concurrent skin disease
  - Any cat whose owner develops lesions suggestive of dermatophytosis
  - Recently adopted or purchased cats with skin disease
- Thoroughly examine adult animals with widespread lesions, especially dogs, for signs indicative of underlying systemic disease such as hyperadrenocorticism.

Wood's Light Examination

- Use the Wood's light to screen for dermatophytosis. The light emitted may cause fluorescence of hairs infected with *M. canis*. Electric lamps are preferred over battery-operated lamps due to superior light intensity.
- Be wary of false-positive results. Scale, ointments, creams, and bacterial folliculitis may all fluoresce under the light; however, they do not give the typical apple-green fluorescence of the hair shaft seen with *M. canis* infection.
- Hairs may remain fluorescent after an *M. canis* infection has resolved. Therefore, positive fluorescence alone should not be used to confirm active infection or monitor therapy.

▼ ***Key Point*** Hairs infected with *M. gypseum* and *T. mentagrophytes* do not fluoresce an apple-green color under Wood's light, and less than 50% of *M. canis*–infected hairs fluoresce. Use the Wood's light only as a screening tool, not as a confirmatory diagnostic test.

Direct Microscopic Examination of Hair

Direct microscopic examination can provide a diagnosis of dermatophytosis within minutes if affected hairs are properly examined.

- Selection of the sample to be examined is critical.
  - Pluck hair from areas of active inflammation.
  - Broken or frayed hairs are ideal.
  - If there was fluorescence with Wood's light examination, select those individual hairs that fluoresced.
- Place the hairs to be examined on a glass slide.
  - Clear the sample to facilitate observation of spores and hyphae (Table 42-2).
  - When the specimen has been cleared, scan the slide using low magnification (10×) for abnormal hairs. Look for hairs that are frayed, swollen, and pale.
  - When you have located the hair, examine it at a higher magnification (20–40×).
- The presence of ectothrix spores surrounding the hair and of hyphae within the hair shaft is diagnostic for dermatophytosis. Ectothrix spores appear as round to oval, greenish, translucent beads (Fig. 42-1).

This technique requires some practice. A negative direct microscopic examination does *not* rule out dermatophytosis.

Table 42-2. CLEARING AGENTS USED FOR MICROSCOPIC EXAMINATION OF SPECIMENS OF HAIR

Agent	Instructions
10–20% KOH	Place several drops on the slide, apply a coverslip, and allow the slide to clear for 30 min before examining.
10–20% KOH	Follow the same procedure as above, but gently heat the slide for 15 sec, allow it to cool, and then examine it.
2 parts KOH, 1 part DMSO	Place several drops on the slide, apply a coverslip, and allow it to clear for 5 min before examining.
Chlorphenolac (50 g chloral hydrate, 25 ml liquid phenol, and 25 ml liquid lactic acid)	Place several drops on the slide, apply a coverslip, and examine immediately.

DMSO, dimethyl sulfoxide; KOH, potassium hydroxide.

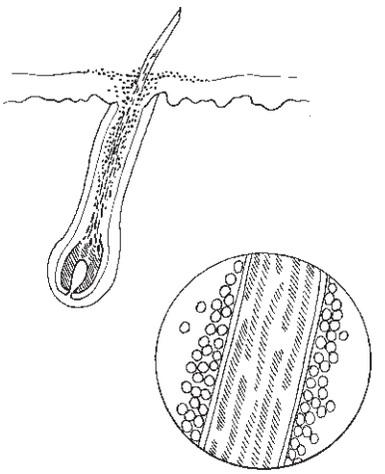

Figure 42-1. Arthrospores can be identified outside infected hair shafts (ectothrix) in animals. Fungal hyphae may be seen within infected hair shafts *(inset)*.

▼ ***Key Point*** Avoid false-positive diagnoses based on direct examination. Dermatophytes do not produce macroconidia in the tissue. Nonpathogenic fungal conidia and plant pollen are frequently mistaken for dermatophytes; these structures are darkly pigmented, whereas dermatophytes are not.

Fungal Culture

▼ ***Key Point*** Fungal culture is the most reliable and definitive method of identifying infected animals; it is the only method of identifying the species of fungi and should be performed in all suspected cases of dermatophytosis.

The ideal culture media for dermatophytes is dermatophyte test media (DTM), which is composed of Sabouraud's agar, antimicrobials to inhibit bacterial and fungal saprophyte growth, and phenol red as a pH indicator. DTM is available in screw-cap containers or in plates with DTM on one side and plain Sabouraud's agar on the other. The plates are preferred over the tubes because it is easier to obtain samples from the plates for species identification. Saprophytes are less likely to overgrow dermatophyte colonies on the plates than on the tube media. Plain Sabouraud's agar is better for evaluating colony morphology because DTM may suppress the formation of conidia and alter colony coloration.

Technique

1. Specimen collection of hair involves three steps:
   a. Clip hairs to 0.5 cm in an area of active inflammation; areas of broken, stubbly hairs of positive Wood's light fluorescence are ideal.
   b. Lightly swab the area with alcohol and allow to air-dry.

c. Gently remove the clipped hairs from the follicles; hemostats are ideal for this purpose.
2. Place hairs on the media (not deeply embedded).
3. In cases of onychomycosis, clip the proximal nail into small pieces for culture.
4. Place the sample (hairs or nail particles) in a dark environment, protected from ultraviolet light and desiccation. Maintain the cultures at a temperature between 24°C and 27°C (75°F and 81°F). Do not close the container tightly.
5. Observe the sample daily for colony growth and for a color change in the media.
6. As a general rule, dermatophytes turn DTM red simultaneously with colony growth, whereas saprophytes generally do not turn the media red until after a week or so after fungal growth commences. Therefore, inspect the culture daily.
7. Fungal colonies that are darkly pigmented (blue, green, black, or a combination) are *not* dermatophytes.

▼ ***Key Point*** Some species of fungi other than dermatophytes may turn the DTM media red within the first 7 to 10 days; therefore, microscopic examination of the mycelia is necessary to identify the fungus definitively as a dermatophyte.

Identification of Subclinically Infected Cats

- Identification of the dermatophytosis in the minimally symptomatic cat can be accomplished using a toothbrush technique. Vigorously brush the cat over the entire body with a new toothbrush.
- Tease the hair from the brush and place the collected hairs and scale onto the fungal culture media. Alternatively, the distal bristles can be cut from the brush and placed directly on the media with the attached hairs.

Identification of Dermatophyte Species from a Fungal Colony

The colony morphology in combination with the characteristic microscopic morphology allows identification of the dermatophyte species causing the infection (Table 42-3). The easiest and most practical method of observing microscopic morphology is the "acetate tape" method:

1. Gently touch a 2-cm strip of clear acetate tape to the surface of a mature culture colony (>5 days old). A colony on plain Sabouraud's agar is preferable, if available.
2. Then place the tape over a glass slide with a drop of lactophenol cotton blue or new methylene blue stain.
3. Observe the slide microscopically for identification of the dermatophyte species by conidia formation (Fig. 42-2).

Biopsy and Histopathology

Generally, it is not necessary to biopsy skin for identification of a dermatophyte infection. However, dermatophytes may be visible in hematoxylin-eosin (H&E)-stained sections and are readily detected with periodic acid-Schiff (PAS) and Gomori methenamine silver (GMS) stains. In cases of suspected dermatophyte onychomycosis, the nail itself may be submitted in 10% formalin for histopathologic evaluation.

TREATMENT

▼ ***Key Point*** Dermatophytosis is a zoonotic disease, and children and immunocompromised individuals are at increased risk; therefore, minimize exposure of people and other animals to the affected animal.

- Dermatophyte infections may be self-limiting, particularly in dogs; however, plan treatment with the goals of eliminating the infection in the animal and preventing the spread of infectious materials to other pets or people in the household.
- Treatment requires therapy for the infected pet, as well as methods to decontaminate the pet's environment.

Table 42-3. COLONY AND MICROSCOPIC MORPHOLOGY OF DERMATOPHYTE CULTURES ON SABOURAUD'S DEXTROSE AGAR

Organism	Colony Morphology	Microscopic Morphology*
Microsporum canis	The surface is cottony to woolly and white. The reverse side is yellow-orange.	Abundant spindle-shaped macroconidia with thick, spiny walls and a terminal knob are present. Six or more cells are found in the macroconidia. One-celled microconidia are uncommon.
Microsporum gypseum	The surface is flat, granular, and light tan to cinnamon in color with white mycelia. The reverse side is pale yellow to tan.	Abundant spindle-shaped macroconidia with no terminal knobs are present. Macroconidia contain up to six cells. Microconidia are uncommon.
Trichophyton mentagrophytes	The surface usually is cream-colored and powdery. The reverse side is tan to brown, or red.	Some strains produce spiral hyphae. Microconidia are numerous and often are arranged in grape-like clusters along the hyphae. Macroconidia are uncommon; if present, they are slender and cigar-shaped with smooth thin walls.

*See Figure 42-2.

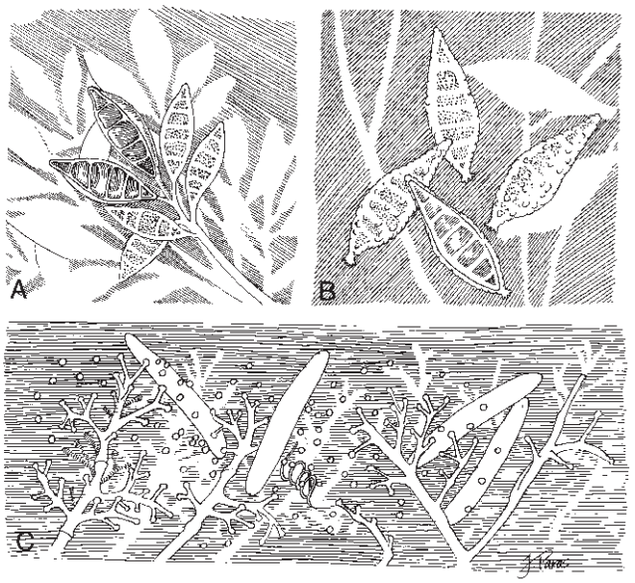

Figure 42-2. Identification of dermatophyte species from mature fungal colonies is possible by microscopically examining the conidia morphology: *A, Microsporum gypseum. B, Microsporum canis. C, Trichophyton mentagrophytes.*

- Cats are usually clinically asymptomatic prior to a mycologic cure—that is, the dermatophytes are still present after the animal is free of lesions. Thus two consecutive negative fungal cultures at 2-week intervals are necessary before the animal can be said to be cured.

▼ ***Key Point*** *Always* treat cats with dermatophytosis with systemic antifungal therapy. Dogs with localized lesions of dermatophytosis may be treated with topical therapy only; however, *always* use systemic antifungal therapy in dogs with onychomycosis, multiple lesions, or generalized lesions.

Topical Therapy

Topical Shampoo and Dip Therapy

Indications

- Topical therapy with whole-body shampoos or dips is most useful for decreasing the spread of disease, and this helps decrease the probability of the pet becoming re-infected from re-exposure to dermatophyte spores (particularly *M. canis*).
- Use topical therapy in every cat with dermatophytosis and in dogs with multifocal or generalized disease.

Clipping the Haircoat

- Clipping the haircoat is optimal, especially in cats with dermatophytosis. This helps decrease the release of infected hairs and spores into the environment.
- Clipping the coat may lead to a temporary worsening of the pet's condition by spreading the lesions. Warn the owner of this possibility.

Procedure

- Topical shampoos and dips may decrease the duration of systemic therapy and ultimately the cost of treatment.
- Few topical therapies have demonstrated antifungal activity in vivo or in vitro. Useful treatments include lime sulfur (1:16) (LymDyp, DVM Pharmaceuticals), enilconazole (10%), and miconazole shampoo. Enilconazole is not approved for use in dogs and cats in the United States. Miconazole shampoo is useful as an adjunct to systemic therapy.
- Because shampooing may spread the lesions through mechanical trauma, it would appear that the most effective topical whole-body therapy approved for use in the United States is lime sulfur. Apply the lime sulfur as a rinse, and gently sponge or pat (not rub) onto the animal. Lime sulfur dips should be applied once to twice weekly.
- If lime sulfur is used on a cat, place an Elizabethan collar after dipping to prevent ingestion of the substance. Warn owners that the dip may discolor the pet's haircoat, may dry the skin and coat, and in some cases may be irritating with repeated use.

Local Topical Therapy

- Localized topical therapy with creams and ointments containing miconazole, clotrimazole, or terbinafine seems to have limited value. Restrict use to localized lesions in dogs. This form of therapy may not speed resolution of the lesion, but it may help prevent dissemination of infective materials.
- Do not use creams and ointments in cats with dermatophytosis.

Systemic Therapy

- Systemic antifungal therapy (Table 42-4) is indicated in the treatment of all cats with dermatophytosis, dogs with generalized or multifocal dermatophytosis, and dogs and cats with onychomycosis.

Griseofulvin

▼ ***Key Point*** Griseofulvin, a fungistatic antimicrobial, is a commonly used drug in the treatment of dermatophytosis in dogs and cats.

- Absorption of the drug is enhanced when it is given with a fatty meal. Griseofulvin is available in microsize and ultramicrosize formulations in polyethylene glycol to enhance absorption so that lower doses can be used (see Table 42-4).
- Never administer griseofulvin, which is a teratogen, to pregnant animals.

Table 42-4. SYSTEMIC ANTIFUNGAL THERAPY FOR TREATMENT OF DERMATOPHYTOSIS

Drug	Brand Name (Manufacturer)	Dose/Application	Comments	Side Effects
Griseofulvin-microsize	Fulvicin U/F (Shering) Grifulvin V (Ortho)	25–50 mg/kg q24h Tablets, suspension	Not for use in cats infected with FIV	Idiosyncratic myelotoxicity, nausea, vomiting, ataxia, teratogenic
Griseofulvin-ultramicrosize	Gris-PEG (Dorsay)	5–10 mg/kg q24h Tablets	Not for use in cats infected with FIV	Idiosyncratic myelotoxicity, nausea, vomiting, ataxia, teratogenic
Ketoconazole	Nizoral (Janssen) Generic ketoconazole	10 mg/kg q24h Tablets	Not for use in cats, some strains of *M. canis* may be resistant	Gastric irritation, anorexia, nausea, idiosyncratic hepatoxicity, lightening of haircoat, teratogenic
Itraconazole	Sporanox (Janssen)	10 mg/kg q24h Capsules, suspension	Combined/continuous pulse therapy: 10 mg/kg daily for 28 days, then on alternate weeks Short-term cycle therapy: 10 mg/kg once daily for 15 days, followed by fungal culture. Cycle repeated until culture negative	Teratogenic, nausea, vomiting
Terbinafine	Lamisil (Novartis)	30–40 mg/kg once daily Tablets	May be used at this dose in combined/continuous pulse therapy or short-term cycle therapy as described above	Vomiting, nausea

- Common side effects include anorexia, vomiting, and diarrhea.
- Less common side effects, which appear to be idiosyncratic, include pyrexia, icterus, ataxia, angioedema, and myelosuppression.
- During therapy, monitor purebred cats, which may be pre-disposed to develop myelosuppression.

▼ ***Key Point*** Do not treat cats infected with FIV with griseofulvin, as they are very susceptible to toxicity from this drug and may suffer a severe, and sometimes fatal, neutropenia. Thus FIV testing is imperative before using griseofulvin in any cat.

Ketoconazole

Ketoconazole is a fungistatic imidazole derivative with broad-spectrum antifungal activity against both superficial and deep mycotic infections.

- Use this in dogs with griseofulvin-resistant dermatophytosis and for dogs that cannot tolerate griseofulvin therapy. Ketoconazole may not be effective against certain strains of *M. canis*. See Table 42-4 for the dosage.
- Because nausea and anorexia are frequently encountered in cats when using ketoconazole, and because *M. canis* may be resistant, do not use this in cats.

Itraconazole

Itraconazole is a triazole antifungal that is effective for the treatment of dermatophytosis. This is the therapy of choice for cats with dermatophytosis.

- Itraconazole is the drug of choice in FIV-positive cats.
- It is also effective in dogs; however, the expense of the drug may preclude its use in many cases.
- Itraconazole is teratogenic at high doses; therefore, do not use it in pregnant animals.
- Flexible dosing schedules (see Table 42-4) may be utilized with this drug since high levels are maintained in keratinized tissues (hair, nail, and stratum corneum).

Terbinafine

- Terbinafine is an allylamine antifungal agent that is fungicidal against dermatophytes.
- Terbinafine is well tolerated by cats and dogs. Vomiting is the most often reported side effect in pets.
- Terbinafine may be used on a daily basis (see Table 42-4) or with continuous/pulse therapy as with itraconazole.

Lufenuron

Lufenuron is used for control of pre-adult fleas. It disrupts chitin synthesis. Chitin is a component of the

fungal cell wall, and preliminary studies suggested that it may be useful in the treatment of dermatophytosis in dogs and cats. However, recent, controlled studies suggest that lufenuron will not prevent infection in exposed cats, nor will it alter the course of infection. I do not recommend the use of lufenuron for the treatment of dermatophytosis.

Antifungal Vaccine

There is a commercially available, killed vaccine for *M. canis* (Fel-O-Vax MC-K, Fort Dodge). The product insert claims its use is as an "aid in the prevention and treatment of clinical signs of disease caused by *Microsporum canis*." The vaccine is intended as an adjunct to traditional therapy, not a replacement. The insert also states that "vaccination has not been demonstrated to eliminate *M. canis* organisms from infected cats." Studies by the manufacturer indicate that there is a decrease in clinical signs in affected vaccinated cats compared with unvaccinated cats. However, there is no data to suggest that a cure is obtained faster when using this product or that this vaccine helps prevent infection in challenged animals.

Monitoring Therapy

Animals treated for dermatophytosis may appear clinically normal long before they are actually cured or culture negative. Reassess animals frequently to monitor response to therapy and to assess the need for modifications in therapy.

- Check animals on treatment at least every 3 to 4 weeks. Monitor for medication side effects.
- After 4 to 5 weeks of systemic therapy, check fungal cultures every 2 to 4 weeks depending upon clinical signs.
- Do not discontinue therapy until two negative cultures have been obtained.

PREVENTION

When planning and carrying out preventive measures, consider that dermatophyte spores can remain viable in the environment for many years.

Current Recommendations for Disinfection

The purpose of environmental disinfection is to prevent reinfection of the pet and to prevent infection of other household members. Unfortunately, many of the disinfectants that are in use today are not effective for killing dermatophyte spores. Evaluation of several different disinfectants found that only concentrated bleach and 1% formalin were 100% effective in killing spores. These products are not acceptable for routine environmental disinfection.

- Discard animal bedding, collars, brushes, and toys.
- Clean all draperies and bedding material.
- Remove and clean all furnace and air conditioning filters. Catteries or multiple cat households should consider having air ducts cleaned.
- Thoroughly vacuum floors, carpeting, and furniture to remove infected hairs. Do this at least 3 to 4 times weekly. Dust surfaces with an electrostatic dust-trapping cloth on a daily basis. Dispose of vacuum bags after each use.
- Clean surfaces that will not be damaged by the solution with a 1:10 dilution of bleach (sodium hypochlorite) on a weekly basis.
- Dispose of all grooming equipment.
- Wash hands thoroughly after handling infected animals.

Identification of the Source of Exposure

- Examine other animals in the household.
- Specific dermatophyte species that are cultured can provide helpful clues. For example, if *T. mentagrophytes* is isolated from a dog that spends most of the time indoors and there is a pet rodent in the household, brush culture the rodent for the presence of dermatophytes.
- Treat all infected animals in the household.

Preventive Measures in a Cattery

- Identify all infected animals. For best results, use the toothbrush culture technique described previously.
- Separate infected from culture-negative animals.
- Treat infected cats until tests are culture negative before reintroducing them into the general cat population.
- Disinfect cages on a regular basis and vacuum and disinfect air vents.
- Never use the same grooming equipment on both infected and culture-negative cats.
- Place all new animals brought into a cattery in isolation until culture-negative results have been obtained.

Chapter 43

Canine and Feline Demodicosis

Sarah Colombini Osborn

DEMODEX MITES

- Every animal harbors its own host-specific species of *Demodex* mite. *Demodex* mites, in low numbers, are normal inhabitants of the stratum corneum, hair follicles, and sebaceous glands.
- Demodicosis is the disease state associated with the abnormal proliferation of *Demodex* mites.
- Demodicosis occurs commonly in dogs and less commonly in cats. The feline mite resides more superficially on the skin than the canine mite.
- The entire life cycle (25–30 days) is completed on the host. Mites cannot survive off the host for more than a couple of hours.
- Four stages of the life cycle may be demonstrated in skin scrapings: eggs, larvae, nymphs, and adults.
- Transmission of the mite occurs by direct contact during nursing in the first 2 to 3 days of life.

CANINE DEMODICOSIS

Etiology

- Although *Demodex canis* is part of the normal fauna of canine skin and is the most common mite found in cases of demodicosis, two other *Demodex* mites have recently been identified. One is a short-tailed *Demodex* mite (unnamed as yet) and the other is a long-bodied *Demodex* mite *(Demodex injai).*
- More than one type of mite may be found on some dogs.
- The mites are present primarily in hair follicles and rarely in sebaceous glands, although the short-tailed mite resides on the skin surface.
- Treatment and prognosis appear similar between the various mite species.

Pathogenesis

- The pathogenesis of demodicosis is not completely understood.
- Affected animals probably have a mite-induced immunosuppressive disorder of T cells of varying severity in which the immunosuppression is proportional to the number of mites present.
- The tendency to develop juvenile-onset, generalized demodicosis is familial. Adult-onset and localized demodicosis are not. Although the mode of inheritance is not known with certainty, an autosomal recessive mode is suspected.
- Purebred dogs have a higher incidence of demodicosis, with the Shar-Pei, West Highland white terrier, Boston terrier, and English bulldog being among the most commonly affected breeds.
- In most cases, canine demodicosis is not contagious.

Clinical Signs

▼ ***Key Point*** Characterization of demodicosis in dogs is important to both treatment and prognosis. Demodicosis is classified as: (1) juvenile-onset or adult-onset, (2) squamous or pustular, and (3) localized or generalized.

Juvenile Onset

- Onset in animals less than 2 years of age is considered *juvenile onset* in most breeds. Onset in animals greater than 2 years of age is considered *adult onset.*
- Juvenile-onset, generalized demodicosis is a familial disease, and all affected animals should be neutered. The parents and siblings of the affected animal should also be removed from the breeding population.

Adult Onset

- Adult-onset demodicosis invariably results from immunosuppression. Approximately 50% of adult-onset demodicosis cases result from exogenous or endogenous glucocorticoids (iatrogenic or spontaneous hypercortisolism).
- Diagnosis of adult-onset, generalized demodicosis is cause for a thorough workup to evaluate for underlying immunosuppressive conditions, including hypothyroidism, hypercorticism, neoplasia, and administration of immunosuppressive medications.

Localized

- Localized demodicosis is classified as less than approximately six lesions or only one body region affected. The periocular and perioral regions are most commonly affected and pruritus may be present.
- Nearly 90% of localized demodicosis cases will spontaneously resolve in young animals, while 10% will become generalized regardless of treatment.
- Localized demodicosis is not familial.

Generalized Demodicosis

- Generalized demodicosis is classified as more than approximately six lesions, involvement of two or more body regions, or involvement of two or more feet (pododemodicosis).

Squamous Demodicosis

- Squamous demodicosis presents as patchy alopecia with no pyoderma. Fine scales may be present in the affected areas and close examination may reveal comedones (plugged hair follicles).

Pustular Demodicosis

- Pustular demodicosis presents with a secondary pyoderma, with *Staphylococcus intermedius* being the most common bacterial organism involved.

Pododemodicosis

- Pododemodicosis lesions are especially susceptible to develop secondary pyoderma.

Demodex Otitis

- Demodicosis of the ear canals associated with ceruminous otitis externa occurs rarely and may result in intense pruritus.

Diagnosis

- Obtain a thorough history and physical examination.
- For dogs with adult-onset demodicosis, obtain the following:
  - Complete blood count, chemistry panel, urinalysis
  - Further testing: Screening thoracic and abdominal radiographs (for neoplasia), thyroid profile, adrenocorticotropic hormone stimulation test, or low-dose dexamethasone test
- *Deep skin scraping* is the preferred means to diagnose demodicosis. If performed properly, mites should be present on skin scrapings in nearly all affected animals.
- If skin scrapings cannot be performed due to location (eyelid, etc.) or discomfort, perform a trichogram by plucking hairs in the affected areas and examining them microscopically in the same manner as skin scrapings. This technique, however, can yield false-negative results in mildly affected dogs.

Skin Scraping Technique

- Squeeze the skin prior to and during the scrapings to facilitate mite collection.
- Apply a few drops of mineral oil to the sites that will be scraped.
- Scrape the skin in the direction of hair growth with a dull #10 scalpel blade.
- Scrape until capillary oozing occurs.
- Collect debris and blood from the site and place on a slide with mineral oil.
- Moistening the blade with mineral oil may facilitate collection of material.
- Apply a cover slip to the slide and examine microscopically under the low power objective (4×, 10×) (Fig. 43-1).
- Obtain scrapings from a minimum of four or five locations, including lesions, lip folds, and interdigital regions.
- Scrapes should be positive if the animal has demodicosis and the correct technique is employed. Exceptions are the Shar-Pei or dogs with chronic fibrotic lesions (especially of the interdigital skin) that may require biopsy.
- Quantify the number of eggs, juveniles, and adult mites from each location to determine the severity of the disease and for later evaluation of response to treatment.
- A single mite on skin scrapings may be normal, but perform multiple follow-up skin scrapings to rule out demodicosis.

Skin Biopsy

- Skin biopsy and histopathology may be indicated in the Shar-Pei or from dogs with chronic, fibrotic lesions (see Chapter 37). This is especially true of dogs with chronic pododemodicosis.

Figure 43-1. *Demodex canis.*

Treatment

Localized Demodicosis

▼ ***Key Point*** No therapy is necessary for localized demodicosis, as there is no difference in resolution rates between treated and untreated cases.

- There is no evidence that topical treatment of localized lesions prevents the disease from becoming generalized.
- If treatment of localized demodicosis is to be initiated, use topical spot treatments such as benzoyl peroxide gels, amitraz (Mitaban, Pharmacia & Upjohn) in mineral oil (1:9), or 1% rotenone ointment (Goodwinol, Goodwinol Products).
- An amitraz collar (Preventic, Virbac) may also be considered appropriate treatment for localized demodicosis.
- Topical treatment may cause increased alopecia and erythema.
- For cases of demodicosis localized to the external ear canal, amitraz in mineral oil (1:9) can be very effective (6–8 drops in the ear canal q24h).

▼ ***Key Point*** Never treat localized demodicosis with systemic or full-body topical parasiticides as it increases the potential for resistance and impairs the ability to determine if the disease would have become generalized, making neutering of the pet essential.

Generalized Demodicosis

- More than 30% to 50% of dogs less than 1 year of age with generalized demodicosis will spontaneously recover. If a dog continues to have clinical lesions beyond 1 year of age, then spontaneous resolution becomes unlikely.
- It appears that the shorter the haircoat, the better the prognosis.

▼ ***Key Point*** In cases of pustular demodicosis, always treat with appropriate systemic antimicrobial therapy as pyoderma contributes to the mite-specific immunosuppression and makes resolution of the demodicosis more difficult. Extended courses of antibiotic therapy are typically indicated (4–8 weeks).

- Medicated bathing with a benzoyl peroxide shampoo on a weekly basis is beneficial.
- Corticosteroids are contraindicated in all forms of demodicosis.

Amitraz

- Amitraz remains the only licensed product by the U.S. Food and Drug Administration for treatment of generalized demodicosis in the dog.
- The label instructions are to use a 250-ppm concentration (1 bottle in 2 gallons of water) once every 2 weeks.
- It is not an approved treatment for localized demodicosis.
- Dips may be performed at the veterinary clinic or by the owners. Be very familiar with the precautions that appear on the label instructions and the possible side effects for humans in contact with the dip (see below).

Amitraz Dip Procedure

- Keep the haircoat cut short during treatment to improve the efficacy of amitraz dips.
- Remove all crusts and bathe the entire dog with a benzoyl peroxide shampoo prior to dipping.
- The dips must be prepared fresh prior to each dip as the product looses efficacy and breaks down to more toxic products once the vial is opened.
- A 15-minute contact time is extremely important, especially on the feet and face. The dip should be sponged over the entire body area for the full duration.
- Do not rinse or towel-dry following the dip.
- Avoid getting the patient wet in between dips (i.e., prevent them from swimming, do not bathe with any shampoo, and do not allow them to be outside if it rains).
- Efficacy is increased significantly when dips are increased to once weekly, and increasing the concentration (e.g., 500 ppm) of the dips may improve efficacy. However, this is extra-label use of the product, and the potential for side effects may increase.
- Most dogs require an average of six to nine dips to achieve resolution of demodicosis—some cases may need more dips before resolution occurs.

Minimizing Side Effects of Amitraz Dips

- Depression, lethargy, and hypothermia are the most common side effects of amitraz dips. Patients should be monitored for these side effects. Less common side effects include pruritus, neurologic signs, and bradycardia.
- Especially for small-breed (e.g., Yorkshire terriers and Chihuahuas) or young dogs, dilution of the dip to half strength for the first couple of dips may help determine how the patient will tolerate the dips. The dip then needs to be increased to full strength to resolve the mites and help prevent development of resistance.
- Yohimbine (Yobine, Lloyd Labs) at 0.11 mg/kg may be used pre- and/or post-dipping to help prevent or reverse side effects of the dips.
- Amitraz shows an increasing frequency of side effects as the topical concentration increases.

▼ ***Key Point*** Do not apply the dip if you are asthmatic, diabetic, have cardiovascular disease, or are taking alpha 2-agonists.

Amitraz Collar

- Amitraz collars may be beneficial as an adjunctive treatment for generalized demodicosis or a sole treatment for localized demodicosis.
- It is not effective as the sole treatment for generalized demodicosis.

Ivermectin

- Ivermectin (Ivomec, Merial) remains an extra-label alternative for the treatment of canine generalized demodicosis. Use for those patients that do not respond to or tolerate amitraz dips.
- Obtain signed owner consent for the use of ivermectin in the pet.
- Avoid ivermectin in collies, shelties, and herding breeds, as they are very susceptible to developing signs of ivermectin toxicity.
- The target dose of ivermectin is 400 to 600 mg/kg orally once daily. Slowly increase the dose by 100 mg/kg/day to allow close monitoring for potential side effects.
- Length of treatment ranges from 60 to 120+ days.
- Every-other-day therapy has been reported to be effective, although the duration of treatment appears to be prolonged.

Ivermectin Toxicity

- Signs of ivermectin toxicity may occur in any breed, although collies, shelties, and herding breeds are most susceptible. Of collies, 30% to 40% will show adverse effects to ivermectin administration, which may prove fatal.
- Side effects include mydriasis or miosis, salivation, depression or lethargy, anorexia, vomiting, ataxia, stupor or coma, and possibly death.
- Immediately withdraw ivermectin and administer symptomatic therapy should signs of toxicity occur. There is no antidote for ivermectin toxicity.

Milbemycin

- Milbemycin oxime (Interceptor, Ciba-Geigy) is in the same drug family as ivermectin and is also *not* approved by the Food and Drug Administration for the treatment of canine demodicosis.
- It may be safer in sensitive breeds as it requires a higher dose to produce side effects.
- The recommended dose is 1 to 2 mg/kg orally once daily.
- Cure rates appear to be higher with higher dosages, and dogs with adult-onset demodicosis respond less favorably then those with juvenile-onset demodicosis.
- The tablet is easier to administer than ivermectin, especially in small dogs.
- Milbemycin has the disadvantage of being 3 to 4 times more expensive than ivermectin.
- moxidectin, another milbemycin, has also been reported to be effective in the treatment of canine demodicosis at doses of 0.2 to 0.4 mg/kg/day. This is also off-label use; only consider using when dogs cannot be treated with amitraz or the disease is resistant to amitraz.

Combination Therapy with Amitraz and Ivermectin or Milbemycin

- Daily ivermectin or milbemycin therapy combined with weekly amitraz dips results in an extremely high incidence of severe neurotoxicity.
- Once weekly administration of ivermectin with weekly or every-other-week amitraz dips appears safer but is likely no more effective than amitraz dips alone.
- Do not use combination therapy.

End Point of Treatment

- Regardless of the type of therapy selected, perform multiple deep skin scrapings prior to and every 2 to 4 weeks throughout treatment.
- Scrape the same four or five areas and record the number of eggs, juveniles, and adult mites to monitor response to treatment.

▼ ***Key Point*** Dogs will achieve clinical cure prior to parasitologic cure (skin scrape negative). Even the finding of dead mites is considered a positive scraping. Continue treatment for at least 4 weeks beyond negative skin scrapings. Premature cessation of therapy is the most common cause for recurrence of demodicosis.

- If a dog is going to relapse, most do so within the first 6 months following the cessation of therapy. The dog is only considered cured after 12 months free of disease.

Unsuccessful Treatment or Recurrence of Demodicosis

- Maintenance therapy is necessary in up to 20% of demodicosis patients. This is especially true for cases of adult-onset, generalized demodicosis in which the underlying immunosuppressive condition cannot be determined or corrected.
- Treatment options to keep the *Demodex* mite numbers under control and clinical signs to a minimum must be tailored to the patient.
- Options include amitraz dips every 2 to 6 weeks or ivermectin or milbemycin administered every other

day, once daily every other week, or the first week of every month.
- Immunostimulants such as levamisole, thiabendazole, and vitamin E have shown no effect on the resolution of canine demodicosis and are not recommended.

FELINE DEMODICOSIS

Etiology

- Feline demodicosis is caused by either *Demodex cati* (long-tailed mite) or *Demodex gatoi* (short-tailed mite).
- A third possible *Demodex* mite has also been reported.
- *D. cati* is found in hair follicles and has a similar appearance to *D. canis* in the dog. The feline mites, however, have a slimmer, elongated body compared with the canine mites.
- *D. gatoi* is a superficial mite found in the stratum corneum, with a short, broad, blunted abdomen.
- Generalized demodicosis with *D. cati* is rare, and an underlying immunosuppressive disease (diabetes, feline leukemia or feline immunodeficiency virus, hyperadrenocorticism, respiratory infection, etc.) should always be suspected in affected cats.

▼ ***Key Point*** *D. gatoi* is contagious among cats and generalized infection with this mite is not typically associated with underlying disease.

Clinical Signs

- The clinical signs of feline demodicosis are quite variable and some cats may serve as asymptomatic carriers.
- Localized demodicosis may present as a single area of alopecia and scaling, primarily affecting the periocular, head, and neck regions.
- Occasionally, the mites may be confined to the external ear canals, with ceruminous otitis externa being the only clinical sign. Large numbers of mites have also been found on skin scrapings from the ear canals of asymptomatic cats.
- Clinical signs of generalized demodicosis include multifocal to generalized alopecia, scaling, erythema, and hyperpigmentation.
- Bilaterally symmetrical alopecia can be a common clinical finding with generalized demodicosis, making differentiation from allergic dermatitis and psychogenic dermatosis difficult.
- Pruritus with *D. cati* is variable and usually minimal. Pruritus with *D. gatoi* is typically much more pronounced, with excessive grooming and subsequent alopecia being the primary presenting complaints.

Diagnosis

- Multiple superficial skin scrapings are the diagnostic tools of choice.

▼ ***Key Point*** Feline *Demodex* mites can be very difficult to find on skin scrapings (much like canine scabies), and treatment is recommended whenever feline demodicosis is suspected.

- Due to the small size and translucency of *D. gatoi,* use the 10× objective when searching microscopically for the mite. Reduce the intensity of the light to increase the contrast.
- The number of mites present in the skin appears to be dramatically reduced in those cats that are pruritic, likely due to over-grooming.
- If *D. cati* is found on skin scrapings, search for an underlying disease. Perform complete blood count, serum chemistry panel, urinalysis, and tests for feline leukemia and feline immunodeficiency virus.

Treatment

- The treatment of choice for both species of feline *Demodex* mites is lime sulfur dips (LymDyp, DVM Pharmaceuticals) every 5 to 7 days for six treatments.
- If a cat has demodicosis or lime sulfur dips are being administered as a therapeutic trial, improvement should be evident following three to four dips.
- The superficial location of the mites in the skin of cats compared with that of dogs likely accounts for the good response to lime sulfur dips.
- If *D. gatoi* is present or the mite cannot be found on skin scrapings, treat all contact cats simultaneously as some cats may serve as asymptomatic carriers of the mite.
- Treatment of localized demodicosis confined to the ear canals includes lime sulfur, ear mite preparations, and amitraz in mineral oil (1:9) applied to the ear canal.
- Do not use amitraz dips for the treatment of feline demodicosis due to the effectiveness of more benign therapy and the significant potential for side effects.
- Recent findings suggest that clinical signs of demodicosis may resolve with weekly application of selamectin (Revolution, Pfizer) but that mites are still present on skin scrapings. When application of selamectin is decreased or discontinued, the clinical signs of demodicosis recur.
- Ivermectin has not been shown to be reliably effective unless administered on a daily basis. Further clinical studies are needed to determine the most effective dosing regimen of ivermectin before this medication can be recommended as an appropriate treatment for feline demodicosis.

Chapter

44 Scabies, Notoedric Mange, and Cheyletiellosis

Lauren R. Pinchbeck / Andrew Hillier

Sarcoptic mange, notoedric mange, and cheyletiellosis are parasitic dermatoses caused by acarine mites living on or within the skin of the host animal. Exposure to these mites and the corresponding incidence of parasitic dermatoses are closely related to environmental factors, especially animal contact and living in endemic areas. Although these mites are not completely host specific, they exhibit host preference and have zoonotic potential for causing dermatoses in humans.

Ectoparasitism is a differential diagnosis in all veterinary patients presenting with a primary problem or clinical signs suggestive of pruritus. The level of pruritus can be variable, especially among cats, and the recognition of pruritus may be underappreciated by owners. Assess parasitism prior to pursuing primary allergic diseases such as atopic dermatitis or cutaneous adverse food reaction. Parasitism is generally a curable disease, and the diagnosis of a primary allergy can only be definitively diagnosed after parasitism is ruled out.

Lesions resulting from infestation with these mites are primarily due to self trauma. In addition, lesions may be due to mechanical damage from burrowing of the mite into the superficial layers of the skin, pruritogenic substances secreted by the mite, or the hypersensitivity reaction developed against extracellular products of the mite. The variability of clinical manifestations of these dermatoses probably reflects variations in duration and intensity of the hypersensitivity reaction and variations in the capacity of the host to limit parasite multiplication.

▼ ***Key Point*** Always consider parasites in patients presenting with pruritus.

SCABIES

Etiology

- Scabies (sarcoptic mange) is a non-seasonal, intensely pruritic papulocrustous dermatosis of dogs caused by the epidermal mite *Sarcoptes scabiei* var. *canis* (Fig. 44-1). Although fairly host specific, the mite can affect cats, foxes, and humans. Sarcoptic acarosis is rare in the cat, and an underlying immunosuppressive disease (i.e., feline immunodeficiency virus infection) is likely to be concurrent and should be investigated.
- The adult mite is microscopic (200–400 µm), roughly circular in shape. It is characterized by two pairs of short legs anteriorly that bear long, unjointed stalks with suckers and two pairs of rudimentary legs posteriorly that do not extend beyond the border of the body.
- The parasite completes its life cycle (egg–larva–nymph–adult) in 12 to 21 days in tunnels and molting pockets in the stratum corneum of the epidermis. Mites burrow into the lower stratum corneum but rarely penetrate further. The female may reach the stratum spinosum as she creates the tunnel and deposits eggs.
- Although scabies mites live in the superficial layers of the skin, the mite antigen can reach the lower epidermal and dermal skin and induce a humoral and cell-mediated immune response. Dogs may develop a protective immunity after successful treatment and cure of a scabies mite infestation. Thus, subsequent reinfestation may not result in clinical signs. The exact mechanism of protective immunity is not fully understood, and its elucidation is further complicated by crossreactivity and cross-sensitization to house dust mites.
- Although the parasite is susceptible to high temperature and drying, it can live in the environment for up to 21 days under ideal environmental conditions.
- Scabies is highly contagious and is primarily transmitted by direct contact with an infested animal. Fomite and fur transmission to humans or other animals can occur via contact with grooming equipment or at kennels.
- The incubation period is highly variable and is dependent on factors such as the number of mites present, the time required for the development of hypersensitivity, and the treatments prescribed. The use of systemic corticosteroids may allow the mite population to increase more rapidly.
- Observable dermatologic changes are often out of proportion with the number of mites present on the

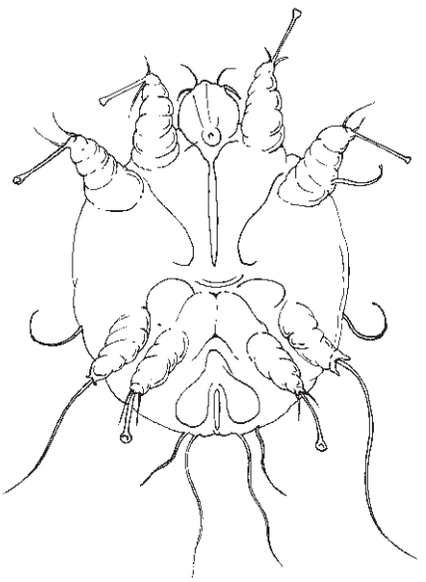

Figure 44-1. *Sarcoptes scabiei.*

animal, suggesting that cutaneous hypersensitivity to mite antigen plays an important role in the course of disease.

Clinical Signs

▼ ***Key Point*** Scabies is typically characterized by papular dermatitis and intense pruritus that is incompletely or minimally responsive to corticosteroids.

- The body sites typically involved include the ear pinnae margins, elbows, hocks, and ventral chest. Lesions and pruritus can become widespread, but the dorsum is usually spared.
- Early lesions are characterized by erythematous papular eruptions that develop thick crusts that may be yellow in color. With time, self-excoriation results in patchy to widespread alopecia, and generalized papulocrustous dermatitis develops. Hyperpigmentation and lichenification are the most dominant lesions in chronic cases due to constant self trauma at affected body sites.
- Some dogs are intensely pruritic but have few, if any, lesions other than mild erythema and occasional excoriations. Others may have less severe pruritus with many mites present (so-called Norwegian scabies).

Diagnosis

- Major differential diagnoses include cutaneous adverse food reaction (CAFR) and flea bite hypersensitivity (FBH), as these diseases can also be intensely pruritic. The distribution patterns characteristic of CAFR, FBH, and scabies can mimic each other in chronic cases, especially if secondary infections are present.
- Additional differentials to consider include cheyletiellosis, *Otodectes cyanotis* dermatitis, dirofilariasis, *Pelodora* dermatitis, atopic dermatitis, and contact dermatitis.
- *Malassezia* dermatitis and superficial pyoderma are also important differentials, and these secondary infections should be considered at the initial presentation. These infections can be intensely pruritic in animals hypersensitive to the organisms. Dermatophytosis is not usually pruritic, but it should be pursued as a differential if therapy does not resolve the clinical signs.

History

- Rapid onset of intense pruritus and rapid progression of lesions with inconsistent response to corticosteroids.
- Likely source of infection. Inquire about visits to training or boarding facilities, dog shows, dog parks, grooming parlors, etc., approximately 1 month prior to the onset of the pruritus.
- Potential exposure of the affected animal to other species known to harbor the mite, especially fox.
- Pruritic dermatitis involving dogs and humans in contact with the affected animal. The absence of pruritus in in-contact animals does not rule out the possibility of infestation.

Physical Examination

- Characteristic cutaneous lesions and typical distribution pattern as described.
- Generalized peripheral lymphadenopathy may be palpated in an affected dog.

Diagnostic Tests

- To make a definitive diagnosis, the clinician must demonstrate the presence of any life stage of the mite and/or eggs. Perform superficial skin scrapings and fecal flotation. Remember that the mite is often very difficult to find, even with multiple skin scrapings.

▼ ***Key Point*** Failure to find the mite does not eliminate the diagnosis of scabies. Always use trial therapy if the diagnosis remains in question and the degree of suspicion is high enough to justify its use.

- To obtain superficial skin scrapings, identify non-excoriated and recently affected body sites where crusted papules are visible. Avoid lesions of chronic pruritus, such as severe lichenification. Usually the

ear pinnae, elbows, hocks, and ventral thorax are best. Apply a liberal amount of mineral oil to the skin surface and scrape a wide anatomic area with a #10 scalpel blade. Transfer the collected material to a glass slide and examine under 10-power magnification and reduced light. Carefully evaluate all microscope fields for any life stage of the mite. Even finding an egg or brown, oval fecal pellets in the material is diagnostic.

▼ ***Key Point*** Obtaining multiple superficial skin scrapings, performed over wide areas of recently affected body sites, will increase the chances of finding mites.

- Of dogs with scabies and ear pinna lesions, 75% to 90% have a positive pinnal-pedal reflex. In one study, this test had a sensitivity of 81.8% and a specificity of 93.8%.
  - To perform this test, maneuver the tip of an affected ear pinna and rub it vigorously against the base of the ear for at least 5 seconds. At the same time, observe the ipsilateral hind limb. If the dog moves the limb in an attempt to scratch, the test is positive.
  - A positive reflex alone is not diagnostic, and a negative result does not rule out scabies.
- Most dogs develop a humoral antibody response between 2 and 5 weeks after infection with scabies. An enzyme-linked immunosorbent assay (ELISA) used to detect serum immunoglobulin G (IgG) antibodies to *Sarcoptes* mite antigen is available (Imovet Sarcoptic). The test has a reported diagnostic sensitivity of 83% to 92% and a specificity of 89.5% to 96%. It may be helpful in the diagnosis of canine scabies when the disease is suspected, but mites cannot be identified.
  - Send labeled serum (1 ml) on ice packs with submission form overnight to the following address:

    Attn: Dana Ambrose
    Athens Diagnostic Laboratory
    University of Georgia College of Veterinary Medicine
    Athens, Georgia 30602-7383
  - Submission forms may be downloaded from the Athens Diagnostic Laboratory website at http://hospital.vet.uga.edu/dlab/athens/access.pdf.
  - Seroconversion may take up to 5 weeks, so do not submit serum for this test in acute cases. Currently, this test is recommended only if clinical signs have been present for at least 2 weeks.
- House dust mite, a common allergen in dogs with atopic dermatitis, shares some antigens with *S. scabiei*. Patients with scabies may have positive intradermal and serum allergy test results to house dust mite allergens. Thus, rule out scabies definitively prior to making a diagnosis of atopic dermatitis and performing allergy testing.

Treatment

- Emergence of resistant strains of the *Sarcoptes* organism and an array of available commercial products make selection of parasiticides difficult. Products highly efficacious in one geographic location may be ineffective in another.
- A number of acaricidal products have demonstrated efficacy in the treatment of sarcoptic mange. Many of these products have real potential for toxicity and adverse reactions in certain breeds or species. Idiosyncratic reactions have also been reported in certain breeds at therapeutic doses.
- Initially, use a product approved and licensed by the U.S. Food and Drug Administration (FDA) for the target animal species and disease being treated. Any other application is extra-label usage of that drug. The FDA recognizes the need for extra-label usage in veterinary medicine, but you should obtain informed consent from the owner. If the FDA product cannot be used in a particular animal, attempt to use a drug that is approved for the species you are treating but for another disease.
- For scabies, treat all in-contact animals concurrently.
- Evaluate heartworm status in all dogs prior to treatment. Some topical treatments are systemically absorbed.
- Systemic therapies are emerging and proving to be efficacious in the treatment of scabies in dogs. The macrocyclic lactones ivermectin (Ivomec, Merial Animal Health), milbemycin oxime (Interceptor, Novartis Animal Health), moxidectin (Cydectin, Fort Dodge Animal Health), and selamectin (Revolution, Pfizer Animal Health) are effective.

Selamectin

- Selamectin is a novel semisynthetic avermectin produced by *Streptomyces avermitilis*. In the United States, it is approved for the prevention of canine heartworm, flea control, deworming, and the treatment of sarcoptic mange and *Otodectes cyanotis* in dogs. It is also licensed for the control of *Dermacentor variabilis* infestations. For cats, it is labeled in the United States for the prevention of dirofilaria, fleas, and *Otodectes cyanotis*. It is also used for gastrointestinal nematodes in cats. In cats and dogs, selamectin may be given at 6 weeks of age at the label dosage of 6 to 12 mg/kg applied to the skin.

▼ ***Key Point*** Selamectin (Revolution, Pfizer Animal Health) is the only product licensed by the FDA for the treatment and control of scabies.

  - Selamectin is apparently safe in collies, related breeds, and their crosses.
  - Two treatments with selamectin 30 days apart at a dose of 6 to 12 mg/kg applied to the skin on the

dorsal neck is reported by the manufacturer to be 100% efficacious for the treatment of scabies by day 60. Field and laboratory trials were comparable to a reference positive-control product. We frequently use selamectin every 14 days for two to three treatments for the treatment of confirmed or suspected scabies acarosis. This regimen would be extra-label usage. Environmental treatment may not be necessary.

Milbemycin Oxime

- Milbemycin oxime (Interceptor, Novartis Animal Health) is a macrolide antibiotic made from the fermentation of *Streptomyces hygroscopicus* and is approved for monthly heartworm prophylaxis. It is not approved by the FDA for the treatment of scabies, but it may be an alternative treatment, especially in breeds of dogs in which ivermectin is contraindicated and the FDA-approved product cannot be used.
  - Dosing regimens of either 2 mg/kg PO twice at 14-day intervals or 2 mg/kg PO at 7-day intervals for 3 to 5 weeks have been effective. Other regimens that may be effective include 1 mg/kg PO every 2 days for eight treatments and 2 mg/kg PO twice weekly for 3 to 4 weeks.
  - Accurate dosing of milbemycin oxime is essential in at-risk breeds. When administered at doses of less than 3 mg/kg, adverse effects are rare. Milbemycin is fairly well tolerated in collies and related breeds, but some dogs may be sensitive even at doses of less than 3 mg/kg. Always use caution in at-risk breeds and their crosses.
  - Lack of response to milbemycin when mites are not observed on scrapings does not necessarily rule out the disease. Reevaluate patients after the second or third treatment to look for clinical improvement. Treatment duration may need to be extended.

Ivermectin

- Ivermectin (Ivomec, Merial Animal Health) is very effective in the treatment of scabies, but it is not approved by the FDA for the treatment of scabies. Ivermectin is only licensed in the dog for the prevention of dirofilariasis at a dosage of 0.006 mg/kg PO monthly. For cats the dosage is 0.024 mg/kg PO monthly. Extra-label doses of ivermectin preparations that are marketed for use in other species are reported for the treatment of scabies.
  - A dosage of 0.2 to 0.4 mg/kg PO every 7 days for three to four treatments or SC every 14 days for two to three treatments is effective.
  - Any dog may have an idiosyncratic reaction to ivermectin. Some recommend a step-up dose regimen to identify dogs that are sensitive. Do not administer to collies, Shetland sheepdogs, Old English sheepdogs, Australian shepherds, or their crosses.
  - Adverse reactions to ivermectin may include tremors, ataxia, mydriasis, stupor, coma, and death. As there is no known antidote for ivermectin toxicity, only supportive therapy (fluids, parenteral nutrition) is available.
  - The 0.5% pour-on preparation of ivermectin is effective at 0.5 mg/kg applied topically to the dorsum twice 14 days apart. This may be considered if a large number of dogs must be treated. Systemic absorption must be considered, and the same precautions should be taken.

Fipronil Spray

- A 0.25% fipronil spray (Frontline Spray; Merial Animal Health) at a dose of 3 ml/kg applied every 21 days for three treatments has been safe and effective in 4-week-old puppies. Decreased pruritus was recognized 1 week after the first application. It has also been used effectively as a sponge-on preparation in dogs when applied at a dose of 6 ml/kg applied twice 7 days apart. These treatments would be extra-label usage. Recently, use of this product has been recommended only for early cases of scabies or for use in pets for which alternative products are contraindicated.

Dips

- Dips traditionally were routine in the treatment of scabies. Although less commonly used today, dips may be indicated in certain situations. Clip the hair when the dog has medium to long hair or a dense coat. When scale and crust are present, bath with a keratolytic shampoo prior to dipping. Treat the entire coat; spot treatment is ineffective.
- Dips known to be effective include the following:
  - *Lime sulfur* (LymDyp, DVM Pharmaceuticals): A 2.5% to 5% solution every 5 to 7 days. It is the safest dip for young animals or sick and debilitated patients. The animal may appear worse after the first treatment but will likely be 50% to 75% improved after the second application. Reevaluate after the third dip and continue treatment until the dog is asymptomatic and negative skin scrapings are obtained. The foul odor and potential for staining light haircoats, fabrics, paints, metal, and jewelry make lime sulfur less appealing. These problems are not significant once the coat is dry. Staining of the pet's haircoat is temporary, and the discoloration and associated dry skin resolve once treatment is discontinued.
  - *Amitraz* (Mitaban, Pfizer Animal Health): A 0.025% solution applied 3 times 14 days apart. This treatment would be extra-label usage. A response is usually seen after the second application. Care and appropriate precautions must be taken in applying the dip. Do not use amitraz in toy breeds, pregnant or nursing bitches, or puppies less than 3 months

of age. Inform owners of side effects and signs to monitor for at home after dip application. Have the dip performed by trained personnel in a setting where the animal can be monitored for side effects after the application. Yohimbine and atipamezole are antidotes.

Other Treatments

- Doramectin at a dose 0.2 mg/kg SC or IM administered once.
- Moxidectin 1% injectable at a dosage of 0.2 to 0.25 mg/kg PO or SC every 7 days for 3 to 6 weeks. Side effects of this medication may include urticaria, angioedema, and ataxia. Side effects seem to occur more frequently when administered subcutaneously, so the oral route is preferred.
- These treatments would be extra-label usage.

Treatment Principles

- Treat all dogs in contact with the affected animal. Do not allow affected and in-contact animals to socialize with other dogs or travel where there may be fur-bearing animals.
- Cats may be reservoirs but do not usually need to be treated. If there are cats in the household, treat with selamectin every 2 to 4 weeks while the affected dogs in the household are being treated.
- Mites die after a few days when off the host, but general cleanup of the environment and application of a parasiticide containing permethrin may be beneficial when a number of animals are affected (e.g., a kennel or pet shop). Environmental treatment may prevent reinfestation from point sources. Consider environmental treatment if there is a poor response to parasiticidal therapy in proven cases or in recurrences.
- If a therapeutic trial does not result in the reduction and subsequent resolution of clinical signs within 3 to 4 weeks, reassess the animal for other causes of pruritus (most notably infection and allergic dermatitis) and pursue further diagnostics.

NOTOEDRIC MANGE

Etiology

- Notoedric mange (feline scabies) is an intensely pruritic, crusting dermatosis of cats caused by the sarcoptiform mite, *Notoedres cati* (Fig. 44-2). The mite may also infest dogs, fox, and rabbits and may cause transient lesions in humans.
- Notoedric mange is uncommonly diagnosed, but it may be endemic in a few localities.
- This obligate parasite is a burrowing mite similar to *S. scabiei,* and the life cycle is approximately 17 to 21 days.

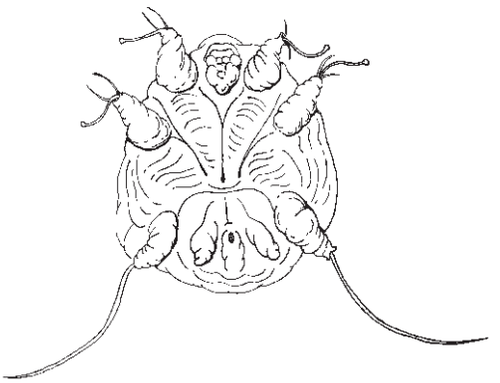

Figure 44-2. *Notoedres cati.*

- In comparison to *S. scabiei* var. *canis, N. cati* is smaller; has medium-length, unjointed sucker-bearing stalks on the legs; and has more body striations. The major differentiating characteristic is the dorsally located anus in *N. cati.*

▼ ***Key Point*** Notoedric mange is highly contagious and is usually transmitted by direct contact.

- It commonly affects entire litters and all in-contact adult cats in cattery situations. Characteristically, it is a disease of adult cats, but it may present as a fulminating dermatitis in kittens.
- *N. cati* survive for only a few days off the host, but fomite transmission should be considered in cases that do not respond to therapy.
- The exact pathogenesis of notoedric mange is unknown, but the intense pruritus and inflammation may be due to the proximity of the burrowing tunnels to the nerve endings in the skin.

Clinical Signs

- Classically, the ear pinnae, head, and neck are the affected body sites.
- Initially there are erythematous papular eruptions on the medial aspect of the pinnae as the mites burrow between hair follicles. The papules may have a well-defined center representing the location of the burrow.
- Lesions can then spread rapidly to the head, neck, perineum, and feet. This distribution is consistent with the grooming and nesting behaviors of most cats. The abdomen, flanks, base of tail, and inner thighs become affected with time.
- As the disease progresses, the affected body sites become thickly crusted. The intense pruritus results in self-excoriation that leads to alopecia and lichenification. A matted haircoat may be noted in medium- and long-haired cats.
- Persistent self-trauma can lead to secondary infection.
- Peripheral lymphadenopathy is usually present.

Diagnosis

- Diagnosis is suggestive if there is a compatible history, intense pruritus, and characteristic distribution of lesions. Definitive diagnosis can only be made by finding mites on superficial skin scrapings.
- Differential diagnoses include both primary and secondary causes of pruritus in cats. Other parasitic dermatoses such as *Otodectes cyanotis* dermatitis and cheyletiellosis can have similar clinical signs. CAFR, FBH, and atopic dermatitis are allergic diseases that should remain differentials until the appropriate therapeutic and diagnostic trials are completed. Infectious diseases such as dermatophytosis can present with lesions that mimic notoedric mange but are not normally intensely pruritic infections. Perform fungal cultures at the initial evaluation to rule out dermatophytosis early. Cats with autoimmune diseases may present with papulocrusting dermatitis, so include pemphigus foliaceus, pemphigus erythematosus, and systemic lupus erythematosus on the differential list, although these diseases are typically not associated with pruritus.

Diagnostic Tests

- Diagnostic tests include superficial skin scrapings and fecal flotation to look for ova or ingested adult mites.
- Superficial skin scrapings are examined using the 10-power objective with reduced light as for scabies.

▼ ***Key Point*** In contrast to scabies, large numbers of mites are typically found on affected animals with superficial skin scrapings. Cats that are hypersensitive may have severe clinical signs but very few mites. Asymptomatic carriers may be detected in a multi-cat environment. The absence of pruritus in in-contact cats does not rule out the possibility of *N. cati* infestation.

- Consider a therapeutic trial to provide supportive evidence for a diagnosis of notoedric mange, although definitive diagnosis can only be made by demonstrating the live mites. The best areas to scrape are lesions on the ears and face.

Treatment

- Concurrently treat all in-contact animals due to the possibility of asymptomatic and transiently infested carriers.
- Reevaluate cats every 14 days and repeat superficial skin scrapings at each visit to determine the treatment end point.

Dips

- Dips have been the traditional mode of therapy.
  - Sedation may be necessary for safe handling of the cats during treatment.
  - Clip medium- to long-haired cats.
  - Bathe cats with a keratolytic shampoo before dipping to loosen and remove adherent surface crusts.
  - Place an Elizabethan collar after dipping to prevent ingestion of the substance.
- Dips that may be effective include the following:
  - *Lime sulfur* (LymDyp, DVM Pharmaceuticals): 2% solution applied every 5 to 7 days for 6 to 8 weeks. This is the safest dip for young kittens or sick and debilitated animals. Continue dips until there is resolution of the clinical signs and negative superficial skin scrapings.
  - *Amitraz* (Mitaban, Pfizer Animal Health): 0.025% solution applied once and repeated in 2 weeks. This treatment would be extra-label usage. Use extreme caution in cats.

Systemic Therapy

- *Selamectin* (Revolution, Pfizer Animal Health) is effective at a dose of 6 to 12 mg/kg applied to the skin on the dorsal neck 1 to 2 times 30 days apart. This treatment would be extra-label usage.
- *Ivermectin* (Ivomec, Merial Animal Health) is effective at a dosage of 0.3 mg/kg PO every 14 days for three treatments. It has also been used at dosages of 0.2 to 0.3 mg/kg SC every 14 days for two to three treatments and 0.4 mg/kg SC on a single occasion. These treatments would be extra-label usage. Use extreme caution in cats.
- Recently, *doramectin* was used for the treatment of notoedric mange in five cats. The use of doramectin has been studied in ruminants and swine. Doramectin has the same spectrum of activity as ivermectin, but the plasma half-life is twice as long. The longer plasma half-life is due to the oil formulation and the non-polar structure of the ivermectin ring. These features may provide residual activity during treatment, and a single dose may therefore be used.
- Doramectin at a dose from 0.2 to 0.3 mg/kg SC administered once is effective. Precise dosing may be difficult with the 1% solution. This treatment would be extra-label usage. Use extreme caution in cats.
- Because the mite does not persist long off the host, a single thorough cleaning of the environment is all that is usually necessary. One application of a parasiticide in a cattery where multiple animals are infested with the mite is helpful, but treatment with an acaricidal compound is not mandatory.

CHEYLETIELLOSIS

Etiology

- Cheyletiellosis (*Cheyletiella* dermatitis) is a highly contagious, variably pruritic, and dorsally distributed papulocrustous or scaling dermatosis caused by the

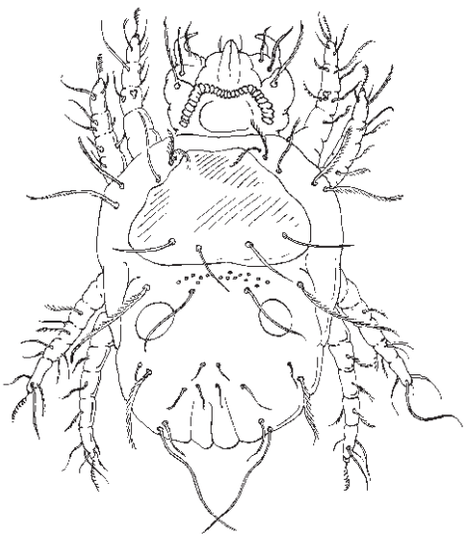

Figure 44-3. *Cheyletiella yasguri.*

surface-dwelling mites *Cheyletiella yasguri* (dog) (Fig. 44-3), *C. blakei* (cat), and *C. parasitovorax* (rabbit).

- The cheyletiellidae are obligate parasites that are not strictly host specific and may travel freely to various host species, including humans. Humans in contact with animals carrying *Cheyletiella* spp. may become transiently infected and develop a pruritic papular dermatitis of the arms, abdomen, or chest.
- *Cheyletiella* mites are large (500 µm × 350 µm) and saddle-shaped. They can be identified by prominent hook-like accessory mouthparts (palpi). All four pairs of legs extend beyond the body margin and bear terminal combs, not claws.
- They have been found on cats, dogs, foxes, rabbits, squirrels, and poultry.
- The entire life cycle (egg–larva–nymph–adult) is spent on the host and is completed in approximately 3 to 6 weeks. Female mites may live free of their hosts for as long as 10 days.
- *Cheyletiella* spp. are non-burrowing epidermal mites that dwell on the skin surface. In the keratin layer, they reside in pseudotunnels they create, and they periodically pierce the skin to feed on tissue fluids (lymph).
- Cheyletiellosis is highly contagious, especially between young animals, and is zoonotic. Transmission is typically by direct contact, but indirect transmission via fomites may be as important. Eggs attach to hair, and hair shed into the environment can be a source for reinfestation.
- In some animals, the intensity of the pruritus and severity of lesions are out of proportion with the low number of mites present, theoretically suggesting a hypersensitivity reaction to the mite or mechanical irritation. The excessive scale may be due to the mite's burrowing, but, more likely, the significant scale is the result of a host defense mechanism. Epidermal cell turnover will increase in response to an insult to the epidermal barrier.

Clinical Signs

- The hallmark of cheyletiellosis is excessive scaling and associated pruritus. A crusting or papular dermatitis may also characterize the disease. The haircoat may be greasy. Cats may have a papulocrustous eruption (miliary dermatitis).
- Dorsal truncal distribution is typical in dogs and cats, but a generalized distribution may occur. Puppies tend to be affected over the caudal dorsum initially, and the lesions then spread up the back to the head.
- Pruritus is highly variable, ranging from absent to constant. Asymptomatic carriers can also exist. Introduction of a susceptible pet into the household may be the first indication that there is a carrier animal.

▼ ***Key Point*** The most common clinical presentation of cheyletiellosis is a puppy or kitten recently acquired from a pet shop, kennel, or cattery with a pruritic, dorsal papulocrustous or scaling dermatosis.

Diagnosis

- The variability in clinical presentation, along with the difficulty of finding the mite, can make cheyletiellosis a challenging condition to definitively diagnose. Its prevalence is probably underappreciated, especially when pets are on flea control products year-round.
- Differential diagnoses include all diseases that cause pruritus and/or scale. Other mite infestations such as sarcoptic mange, notoedric mange, and pediculosis are included. Consider allergic diseases and include FBH, CAFR, and atopic dermatitis. Superficial pyoderma and *Malassezia* dermatitis are also differentials. All causes of seborrhea and miliary dermatitis in the cat are additional differentials.
- Rule out *Cheyletiella* before making a diagnosis of idiopathic seborrhea or a primary keratinization disorder. This is especially important in pets that frequent grooming, day-care, or boarding facilities.
- Suspect cheyletiellosis based on the following:
  - The nature and distribution of the cutaneous lesions, as previously described.
  - Exposure of the patient to other animals just prior to the onset of clinical signs.
  - Involvement of in-contact animals and humans. Clinical signs in affected humans are often characteristic (pruritic papules with central necrosis) and may be the only evidence that the animal in the household is infested.
- Consider cheyletiellosis in every pruritic cat. In addition, consider cheyletiellosis in every cat presented with miliary dermatitis and symmetrical alopecia.

- Make a definitive diagnosis by demonstration of the mite or egg on the animal. Mites are usually present in high numbers, but occasionally they can be difficult to detect. The absence of mites does not rule out this disease when there are compatible clinical signs.

Diagnostic Tests

- Several diagnostic tests may be needed. Techniques used to demonstrate the mite or its eggs include the following:
  - *Direct examination* of the surface of the skin and haircoat using a magnifying lens. The mites are very large; hence the name "walking dandruff."
  - *Flea combing* is the most reliable method for finding mites in both symptomatic and asymptomatic patients. Comb the entire coat for several minutes. Brushing the collected material onto a dark background may facilitate recognition of mites. If no mites are found at the initial diagnostic appointment, instruct the owner to similarly brush the coat of the pet several times a day for several days and collect the material in a container for examination at the clinic.
  - *Superficial skin scrapings* performed as previously described for scabies and notoedric mange. In animals with thick coats, clip an area so that the affected hair and skin can be visualized and sampled.
  - *Adhesive acetate tape* (Scotch tape) *preparation* is the classic diagnostic test; however, it only samples a small area. If used, sample several sites. Press a small piece of tape repeatedly over affected hair and skin. Place the tape strip onto a glass slide with a few drops of mineral oil.
  - *Potassium hydroxide (KOH) digestion.* Mix epidermal material collected with flea combing with 10% KOH and heat for 10 to 20 minutes. Centrifuge with a saturated sugar solution and examine microscopically under 40-power magnification.
  - *Fecal flotation.* Double centrifugation with a standard sucrose solution may be performed to examine feces for ova and ingested mites. This may provide supportive evidence for the diagnosis of cheyletiellosis in pets with low mite numbers.

▼ ***Key Point*** The most effective diagnostic techniques for cheyletiellosis are the acetate tape preparation and the collection of epidermal debris with a flea comb.

- In some cases, the mite or its eggs cannot be demonstrated, and a therapeutic trial is indicated. Such trials can only definitively rule out cheyletiellosis.

Treatment

- Although *Cheyletiella* mites appear to be susceptible to most insecticides, they may be extremely difficult to eradicate. Treatment of the patient, all in-contact animals, and the premises is mandatory. Successful treatment plans are 6 to 8 weeks in duration.
- There are no veterinary products specifically licensed by the FDA for the treatment of cheyletiellosis in dogs or cats.
- Flea shampoos, powders, foams, and sprays have not been efficacious as sole therapies for cheyletiellosis. Historically, organophosphates, carbamates, and amitraz have been advocated. However, there are newer treatments that provide an effective and safer alternative.
- Dips traditionally were routine in the treatment of cheyletiellosis and may still be indicated in certain situations. Clip the hair when the animal has medium to long hair or a dense coat. When scale and crust are present, bathing with a keratolytic shampoo prior to dipping is beneficial. The entire coat must be treated; spot treatment is ineffective.

Treatments for cheyletiellosis that have been effective include the following:

- *Lime sulfur* (LymDyp; DVM Pharmaceuticals) as a 2% solution applied as a dip every 7 days for six to eight treatments. Lime sulfur can be used safely in kittens, puppies, pregnant or lactating animals, or debilitated animals.
- Weekly *pyrethrin sprays* or L-pyrethrin dips diluted according to label instructions. Products used on cats should be approved for use in this species and should always be diluted according to the label instructions.
- *Amitraz* (Mitaban, Pfizer Animal Health) as a 0.025% solution applied as a dip every 14 days for four treatments. This treatment would be extra-label usage. Use extreme caution in cats. Monitor as described for scabies.
- *Ivermectin* (Ivomec; Merial Animal Health) at a dosage of 0.2 to 0.3 mg/kg PO every 7 days or SC every 14 days for 6 to 8 weeks in dogs and cats.
  - This treatment would be extra-label usage. Consider risks of adverse reaction, and have the owner give informed consent. Due to the low cost, ivermectin may be appealing if there is a kennel or multi-pet environment. Consider safer alternatives first.
  - Evaluate heartworm status before administration.
  - Do not administer to herding breeds such as collies, collie crosses, Shetland sheepdogs, Old English sheepdogs, or Australian shepherds. Any patient can show clinical signs of ivermectin toxicity, so careful patient monitoring is indicated. Clinical signs of toxicity include vomiting or diarrhea, mydriasis, depression, persistent lethargy, ataxia, tremors, ptyalism, recumbency, excitability, stupor, coma, and death.
  - Administration of the bovine 0.5% alcohol-based ivermectin (Ivomec Pour-On for cattle, Merial Canada) applied topically to the interscapular skin.

This was recently reported in cats using a dose of 0.5 mg/kg (0.1 ml/kg). Four to six treatments may be required. This treatment would be extra-label usage.

- *Fipronil spray,* 0.25%, at a dose of 3 ml/kg or the 10% concentrated solution (Frontline Spot-on Dog, Merial Animal Health) applied every 30 days for two to three treatments. Frontline Plus (Merial Animal Health) should be similarly effective. This treatment would be extra-label usage.
- *Selamectin* (Revolution, Pfizer Animal Health). For cheyletiellosis, apply every 30 days for three treatments. This treatment would be extra-label usage. We routinely use selamectin every 2 weeks for three treatments in adult cats and dogs.
  - Selamectin is reportedly safe in ivermectin-sensitive collies.
- *Milbemycin oxime* (Interceptor, Novartis Animal Health) at a dosage of 2 mg/kg PO every 7 days in dogs. Treatment may take 9 weeks. The efficacy of milbemycin oxime has not been demonstrated in cats. This treatment would be extra-label usage.
- Clean and spray the animal's quarters and bedding with a residual insecticide appropriate for killing adult fleas. Discard any bedding or grooming supplies that cannot be effectively cleaned to prevent fomite-mediated reinfestation. Launder washable fabrics at 55°C and then treat. Professional exterminators may be required. Perform frequent vacuuming with disposal of the collected material.
- Treat all in-contact animals throughout the treatment period and reevaluate the affected animals at regular intervals to assess for mites and eggs. Continue treating for 2 to 4 weeks beyond resolution of clinical signs and pruritus and until a negative examination for mites and eggs has been made.
- Treat the environment every 2 weeks with a premise spray appropriate for killing fleas. In addition, the car may need to be treated if the pet rides in the vehicle. Treat any visiting fur-bearing mammals.
- Client compliance is central in the effective resolution of *Cheyletiella* dermatitis and environmental contamination. If a treatment failure is suspected, first ensure that all instructions were followed as prescribed. Always ask the clients if they are able to perform rinses or dips at home. Alternatively, these can be performed in the hospital by trained technicians.

Chapter 45

Flea Allergy Dermatitis

Craig E. Griffin

Flea allergy dermatitis (FAD) is a hypersensitivity reaction to one or more components of fleas, especially allergens in flea saliva. Several types of hypersensitivities, such as cutaneous basophil hypersensitivity, immunoglobulin E (IgE)-mediated immediate hypersensitivity, late-onset IgE reactions, and delayed-type hypersensitivity, can occur alone or in combination. The hypersensitivity reactions cause inflammation leading to pruritus and the generation of most of the lesions.

In most geographic areas, FAD is still a common cause of skin disease in dogs and cats. During the summer it is often the most common disease seen by the small animal practitioner and is a common reason for exacerbation of pruritus in patients with concurrent FAD and atopic dermatitis. In some areas, and when indoor infestations occur, FAD may be non-seasonal. The advent of newer, more effective flea control products has been both beneficial and detrimental to clinical practice. The new products have greatly minimized the impact of FAD in many practices and allowed much more effective flea control. At the same time, many clients utilizing these products no longer believe fleas can be the cause of disease. Thus, establishing the diagnosis and client acceptance of the diagnosis is more troublesome, as clients do not see fleas but FAD is still occurring.

Atopic dermatitis or adverse food reactions ("food allergy") may occur in combination with FAD, and occasionally all three reactions will be present in one patient. The prevalence of FAD in patients with atopic dermatitis is generally higher; up to 80% of dogs with atopic dermatitis that are exposed to fleas were reported to have FAD.

ETIOLOGY

- *Ctenocephalides felis* is the species that usually infests both dogs and cats. *Pulex irritans* and less commonly *Ctenocephalides canis* may be responsible in some areas.
- Investigations with purified flea saliva led to the discovery of several antigens, and one named Cte f 1 has been cloned. Eighty percent of clinical flea-allergic dogs have an IgE response to Cte f 1, making this a major allergen involved in the pathogenesis. It is not the only allergen, and some flea-allergic dogs do not react to Cte f 1, nor do all have IgE-mediated disease.

Important Flea Life Stages

Effective control of flea populations and prevention of exposure to adult fleas requires an understanding of many aspects of the flea life cycle and biology. Adult fleas only represent a small percentage of the total flea population. Eggs, larvae, and pupae make up the vast majority.

Larval Stage

- Larvae are positively geotactic and negatively phototaxic and therefore migrate deep into carpets and under furniture.

Pupal Stage

- Of the pre-adult stages, the pupal stage is most troublesome.
- This stage is most resistant to environmental changes, such as low humidity, and is also most resistant to environmentally applied insecticides, partly due to their location deep in the carpet. The pupa's external sticky cocoon attracts a coating of environmental debris that also helps protect the developing adult inside the cocoon from insecticides.
- The pre-emerged adult flea inside the cocoon will wait for optimal environmental and local host factors before emerging. Emergence of the adult from the cocoon may be delayed up to 5 months and can be responsible for pet owners seeing young adult fleas even after environmental therapy. Delayed emergence and resurgence of fleas after effective use of environmental insecticides has been termed the *pupal window.*

Newly Emerged Adult Fleas

- The newly emerged adult flea will rapidly find its host in response to stimuli such as positive phototaxis, carbon dioxide, body heat, light changes from movement, and negative geotaxis.

- Even residual types of environmental insecticides and insect growth regulators (IGRs) are not rapid enough in killing fleas to prevent these newly emerged adults from finding their host. The time necessary for even effective topical or systemic therapies to eliminate all the developing stages from an enclosed environment has been termed the *developmental window*. As a result of these pupal and developmental windows, owners may see emerging young adult fleas and feel that the products are not beneficial, leading to poor compliance or premature termination of treatments that would eventually be effective.

Other Environmental Sources of Fleas

Other environmental sources for newly emerged or mature adult fleas must also be considered.

- *C. felis* commonly infest opossums, raccoons, skunks, coyotes, foxes, and some rodents. Areas outdoors frequented by these other hosts will keep flea populations present in locations that pets may frequent, exposing the pet to more fleas.
- In these circumstances, even the use of the newer topical or systemic flea-killing products may not prevent clinical allergy from occurring. As the products with the most rapid killing effect take 4 to 6 hours to kill newly emerged adult fleas, enough of these newly emerged fleas (or fleas from other environmental sources) may be present to keep significant disease occurring for days. Thus, active FAD may be present even though an infestation in the pet's home environment may be prevented.

CLINICAL SIGNS

- Pruritus is the primary clinical sign, which the owner may observe as chewing (as if eating corn on the cob), rubbing, rolling, or scratching. Cats may groom excessively or pull out their hair. Severe chewing may lead to excessive wear of the incisor and canine teeth.
- Primary lesions are papules and erythematous macules in dogs and focal crusted erosions or papules (miliary eczema) in cats. Exudation and crusting may be seen.
- Secondary lesions result from the chronic inflammation and pruritus-induced trauma and include alopecia, excoriations, broken hairs, dry hair, scaling, hyperpigmentation, and lichenification.

Pattern of Involvement

Lesions are localized to areas of flea bites, and distant lesions and significant disease from one flea bite is unlikely. Generalized disease does not occur without generalized biting.

- Involvement of the tail-base and dorsal lumbar region has been shown to be highly discriminant for the diagnosis of FAD. The caudal thighs, groin, and abdomen are frequently affected, although less severely than the dorsal lumbar region. In chronic and severe cases, there is extension of the lesions cranially on the trunk.
- Ear disease, otitis externa, perioral lesions, and pododermatitis (especially of the front paws) are usually not seen and are highly discriminant for a diagnosis other than FAD. When these signs are present in a dog suspected of FAD, they suggest either that flea allergy is not present or that flea allergy is present with a concurrent disease, such as atopic dermatitis or food adverse reaction.
- Cats with FAD commonly have miliary crusts in the cervical as well as the dorsal lumbar region. Lesions may be limited to the abdomen and groin or cervical area.

Secondary Problems

Secondary problems that may occur often represent focal sites of infection; foci of severe trauma, possibly from the itch-scratch cycle; or a different pathologic reaction.

- Acute moist dermatitis (hot spots), acral pruritic nodules, eosinophilic plaques, and eosinophilic granulomas may be seen in dogs and cats.
- Superficial or deep pyoderma may develop, especially in animals repeatedly treated with corticosteroids.
- Animals with superficial pyoderma will present with pustules, crusted papules, or circular spreading rings of crust over erythematous erosions, lichenified plaques, or papules.
- Deep pyoderma may be present as furuncles, hemorrhagic bullae, fistulous tracts, crusted ulcers, and proliferative pruritic nodules.

DIAGNOSIS

FAD is diagnosed presumptively in pruritic animals with typical patterns of involvement. Flea involvement that may be determined by finding fleas, flea feces, or a history of possible exposure to fleas is supportive of the diagnosis. In cases with no direct evidence of fleas, response to flea control is used as evidence that fleas were present. Always consider the presence of coexistent allergies as they are frequently overlooked.

▼ ***Key Point*** The most definitive diagnosis of FAD requires typical lesions, a typical pattern, a positive intradermal or in vitro test to Cte f 1 (flea antigen), and a complete response to effective flea control.

History

- Identify typical patterns of involvement and seasonality compatible with fleas.

- A history of otitis externa or paw licking suggests that other or concurrent allergies are present.
- Obtain information regarding the number and type of pets, housing, the type of floor covering, current pesticide use, and client concerns regarding the use of pesticides.
- Possible sources of exposure to fleas should also be investigated. A history of cats living in the same environment also has a positive correlation with a diagnosis of FAD. Investigate how much time is spent outside, the type of outdoor environments the pet has access to, and the possible presence of stray or feral cats as well as opossums and other wildlife.
- A history of prior favorable response to flea control also supports a diagnosis of FAD. Adverse food reaction is one of the few differential diagnoses for the lesions and pattern of involvement seen in FAD, and a gastrointestinal history (bowel movements, borborygmus, flatulence, etc.) may be helpful in this regard.

Physical Examination

- Examine for fleas or flea dirt in longhaired animals by brushing the pet over white paper; in shorthaired animals, flea combing may be helpful.
- Closely examine areas of involvement typical for other allergies (see Chapters 46 and 47) for evidence of coexisting disease.
- Closely examine the dorsal lumbar area for papules, which are the primary lesions seen in canine FAD.
- Carefully palpate the skin in cats; this is important because the typical small, crusted papules (miliary crusts) often are more easily felt than seen.
- Shave the haircoat to allow closer observation of the lesions.
- Examine for lymphadenopathy in cats, a common finding in chronic FAD.

Dermatopathology

Dermatopathology is not specific (but may be suggestive) with FAD. Superficial, mixed perivascular dermatitis with eosinophils is typical in FAD, and occasionally intraepidermal eosinophilic microabcesses may be seen; these changes may be seen in other allergic dermatoses. Typically, histopathology is not necessary in the diagnosis of FAD.

Intradermal Testing

Intradermal testing with 1/1000 wt/vol flea antigen (Greer Labs) has been documented as a reliable test for diagnosing FAD when evaluated at all possible reaction times.

- Positive reactions may occur in 15 minutes (immediate), 6 to 8 hours (late onset), or 24 to 48 hours (delayed).
- A positive test indicates that flea hypersensitivity is present, but it does not document that all clinical signs are related to fleas, that is, there may be subclinical hypersensitivity.
- A negative test at all observation times usually indicates (approximately 90%) that flea allergy is not present.
- False-negative results may occur if glucocorticoids and antihistamines are not properly withdrawn before testing.

Serum In Vitro Testing

Recent advances have led to an in vitro test that is valuable in the diagnosis of FAD (Heska Corporation). This test utilizes a recombinant flea salivary antigen.

- A positive test is strongly correlated with FAD.
- A negative test does not preclude a diagnosis as some dogs and cats react to a different allergen or have FAD by other allergic mechanisms.

Response to Therapy

A favorable response following parasiticidal therapy directed against fleas is helpful in making a diagnosis of FAD. It does not eliminate the diagnosis of coexisting diseases.

TREATMENT

FAD is best treated by eliminating exposure to the flea allergen (i.e., effective flea control). When a complete flea control program is used, more than 90% of cases can be controlled without additional treatment. Raising the allergic and pruritic thresholds by treating coexistent problems also may be helpful. In cases in which adequate flea control cannot be achieved, blocking the allergic reaction with systemic therapy is required.

Decrease Allergic Load (Flea Control)

Modern flea control utilizes a variety of chemicals directed at many different parts of the flea life cycle (Table 45-1). Many products are typical insecticides in that they kill adult fleas. In the flea-allergic dog that gets exposed to adult fleas, the speed of kill becomes relevant because the longer fleas live on the FAD pet, the more bites and allergens the pet is exposed to. Repellent activity is especially beneficial for decreasing allergen exposure. It is believed, although not yet proven, that permethrin (a known mosquito repellent) may also have some repellent activity against adult fleas. IGRs do not kill adult fleas and do not prevent biting, but they interfere with the development of eggs into larvae or pupae by mimicking insect juvenile hormone. The two available in the United States are methoprene and pyriproxyfen. The insect development inhibitor (IDI),

Table 45-1. CHEMICALS USED FOR FLEA CONTROL

Chemical Name	Example of Brand/ Manufacturer	Main Area Used and Stage Targeted	Treatment Regimen	Advantages	Disadvantages
Borates	Dustmite and Flea Control/Aveho Biosciences Rx for Fleas/ Fleabusters	Environment, ingests and desiccates larvae.	Wettable powder sprayed on or added to carpet shampooer. Powder applied and brushed into carpets.	Long-term effects, safety.	Powder can be messy, and both are labor intensive to apply.
Fipronil	Frontline/Merial	Dogs and cats topical, adulticide.	Monthly topical spot application spreads over body and spray.	Rapid kill.* Shown to resist depletion by shampooing or water.	Cannot be applied more often than monthly. External insecticide.
Fipronil/ methoprene	Frontline Plus/ Merial	Dogs and cats topical, adulticide and IGR.	Monthly topical spot application spreads over body.	Rapid kill. One product delivers integrated flea control.	As above, and IGR not photostable.
Imidacloprid	Advantage/Bayer	Dogs and cats topical, adulticide.	Monthly up to weekly topical spot application spreads over body and spreads local into environment where pets sleep.	Rapid kill. More frequent application can make it more effective in FAD dogs and cats.	Expense when used more often than monthly. External insecticide.
Imidacloprid/ permethrin	Advantix/Bayer	*Dogs only.* Two types of adulticide, possible repellent.	Monthly topical spot application.	As above, plus integrated flea control and suspected to have flea repellent effect.	As above. *Not for cats.*
Lufenuron	Program/Novartis Animal Health	Dogs and cats oral or injectable. IDI larvae.	Oral for dogs and cats, and long-acting injection for cats.	Systemic very effective for whole month and not affected by topical therapy. No external drug.	Not adulticidal and not as effective for FAD as sole therapy in dogs and cats that spend much time outdoors.
Methoprene	Various	Dogs and cats topical, systemic, and environment. IGR to multiple stages.	Varies on delivery system and what is treated.	Effective against multiple stages with large margin of safety.	UV susceptibility limits environmental use.
Nitenpyram	Capstar/Novartis Animal Health	Dogs and cats oral, adulticide.	Oral systemic therapy. To maintain levels, q24h in cats and q48h in dogs.	Extremely rapid kill† and safe to use daily makes it most effective as trial therapy and short-term prevention. No external insecticide on pet.	Short half-life limits long-term use due to expense.
Permethrin	Multiple	Dogs only most formulations. Topical and environment.	Varies with product type and where applied.	Suspected repellent effect makes particularly useful for FAD-affected dogs. UV resistant. Longer effect than pyrethrin.	Most products not allowed on cats, and ones allowed must be low concentration.
Pyrethrin	Various shampoos and spray	Topical and environmental products, adulticide.	Apply up to daily to pets or environment.	Rapid kill and large safety margin makes it useful on puppies, kittens, and environment where it is allowed when many other products are not.	Short residual action and rapid UV degradation.
Pyriproxyfen	Various	Dogs and cats topical and environment. IGR multiple stages.	Varies with form and use.	Photostable, so longer-term effect.	Concern for effect on other insects since long-term environment persistence.
Selamectin	Revolution/Pfizer	Dogs and cats topical.	Monthly topical administration, which is absorbed systemically.	Rapid kill. Not readily washed off for long. Broad spectrum, so multiple-use product.	Expense if only use is for fleas. Although rapid kill, some suggest still slower than other rapid kill.

*Rapid kill means over 90% of fleas applied to the pet's haircoat are killed in 24 hours or less.
†Extremely rapid kill is over 90% of fleas killed in 4–6 hours.
FAD, flea allergy dermatitis; IDI, insect development inhibitor; IGR, insect growth regulator; UV, ultraviolet.

lufenuron inhibits chitin synthesis and also prevents the development of larvae.

Complete flea control requires treating the affected pet, other pets in the same environment, and the pet's environment. Modern product developments have totally changed the approach to flea control in the last few years (see Table 45-1). Compliance and flea control success have greatly improved because of long-acting, total-body protection that can be achieved with topical focal spot applications, systemic therapy from monthly oral or topical spot formulations, and improved flea collar technology. These products have made the use of flea shampoos, dips, and sprays for on-pet use obsolete for long-term flea control. Pyrethrin shampoos may still be used to rapidly remove fleas in infested puppies, kittens, or adults when quick elimination of fleas on a pet is required. However, they are not routinely recommended as compliance and efficacy are less than newer products.

Resistance to some flea products has been seen in the past. The cat flea has been described as the most resistant of the flea species, and to more types of products. Integrated pest management decreases the probability of this developing to the newer products now being used extensively. The international imidacloprid flea susceptibility monitoring program developed an in vitro assay to test for the development of flea resistance. Evaluations of natural strains of fleas from around the world have not yet detected any resistance.

Compliance is still a key component of a successful flea control program. Even the newer products require regular use to prevent the development of viable eggs from being laid. Therefore, to assure that the flea life cycle is broken, owners must be diligent about proper application of these products at correct intervals. This involves the use of different ingredients or techniques on pets and in the environment. In severely infested environments, effective control may take 4 to 8 weeks to achieve. Once flea control is achieved, clients may find that only one or two aspects of flea control are sufficient for maintenance, but the long-term use of an integrated pest control plan is optimum.

▼ ***Key Point*** The optimum control will utilize integrated pest management as the most effective way to eliminate multiple stages of the flea life cycle and decrease the chance that resistant strains of fleas will develop.

Environmental Treatment for Indoor Areas

Because the majority of flea eggs, larvae, and pupae are located in the environment, it is essential to treat environmental areas. Treatment of indoor areas is critical when the affected animal spends most of the time indoors. This is the habitat that can be controlled most effectively. The main life stages being targeted are the larvae and eggs.

- These stages are mainly found in carpets and cracks or spaces in flooring. Most tile, linoleum, and smooth wood floors do not readily support flea development. Therefore, treatment can be applied to carpeted areas, pet bedding, and upholstered furniture that pets have access to.
- Since larvae are mobile and negatively phototaxic, treatment under furniture and behind doors is an important aspect of control.
- Hand-held application is preferred for making sure products reach the important areas.
- Vacuuming, especially with vacuums that have beater bars, is also helpful in decreasing the number of eggs and larvae. The cleaner bags should be removed following vacuuming to prevent any fleas from returning to the environment.
- Treat linoleum and tile floors by frequently mopping with routine disinfectants.

Insect Growth Regulators

The newer systemic and topical formulations with IGRs for rapid adult kill in under 24 hours are also very helpful in keeping an indoor environment flea free (see Table 45-1). Imidacloprid has also been shown to be transferred to treated pets bedding and is an effective ovicidal and larvacidal agent if the bedding is not laundered. IGR-containing products that have residual effects and bind to the pets hair are likely to also have an environmental effect.

Borate Products

In houses in which floors are primarily carpeted, borate products are most effective, lasting up to 1 year. They are also safe, with no reported toxicity.

- An electrostatically charged sodium polyborate powder (Rx for Fleas, Fleabusters) is applied as a powder and brushed into carpets and pet-exposed furniture.
- Disodium octaborate tetrahydrate (Dustmite and Flea Control, Aveho Biosciences) is a wettable powder that once mixed with water is sprayed on. It may also be added to carpet shampooers or steam cleaners providing excellent penetration to deeper carpet fibers.

Permethrin or Pyrethrin Combined with Insect Growth Regulators

Another alternative is spraying all carpeted surfaces and furniture that pets have access to with permethrin or with pyrethrin in conjunction with an IGR.

- Effective products include methoprene, permethrin, phenothrin (Vet Kem Siphotrol Plus II House Treatment, Wellmark), pyriproxyfen, pyrethrin and permethrin (Virbac Knockout ES Area Treatment,

Virbac), and tetramethrin with pyriproxyfen (Ectokyl IGR Pressurized Spray, DVM Pharmaceuticals).
- Frequency of use varies with products selected, but in general these IGR combinations last at least 1 month.

Environmental Treatment for Outdoor Areas

Treat outdoor pens and similar enclosures weekly for 3 weeks and then monthly.

- A liquid application of chlorpyrifos, permethrin, or diazinon is preferred.
- Although helpful in long-term control, granular and microencapsulated insecticides have been less beneficial for obtaining initial control.
- Pyrethrins are safe and have minimal environmental impact, but weekly applications are required as they have no residual activity.
- The IGR pyriproxyfen is photostable and therefore a useful adjunct to outdoor therapy when used with adulticides.
- Consideration should also be given to areas that are occupied by both pets and wildlife that may carry fleas, for example, under trees that may harbor opossums or raccoons.

Treatment of Unaffected Pets

Treat unaffected animals in the same environment with adulticidal and/or insect development inhibitor flea products that lack flea repellent effects.

- Regular use of the topical adulticides fipronil or imidacloprid or of lufenuron helps prevent unaffected animals from contributing to reintroduction of fleas into the home environment. Combination products or combining IGR products will improve environmental control of population levels and is an integrated pest control strategy.
- In cases in which topical treatments are not wanted by owners or pets react, systemic products such as lufenuron or collars may be helpful.
- Use an approved flea collar with at least an IGR on cats that cannot be treated with topical spot applications, dips, sprays, or foams.

Treatment of Affected Pets

Treat affected animals with an adulticidal product and repellents as frequently as allowed for these products.

- The new topical adulticides, fipronil, imidacloprid, and selamectin, have been shown to be efficacious for treating FAD in dogs and cats, even when environmental treatment is not done. Fipronil in the spray formulation appears to be more efficacious than the spot application and is preferred for the affected pet if client compliance is not a problem.
- Nitenpyram is the most rapid flea-killing systemic product available, with the drawback of a short half-life. This means there is duration of only 1 day in cats and 2 days in dogs. It may be used when pets are known to be going into areas where fleas may be present. It is also helpful as a trial therapy to see if flea control is effective and help establish FAD as the diagnosis.
- The newest generation products have improved these products by combining another topical agent that works by another mechanism. Fipronil is combined with an IGR methoprene and imidacloprid is combined with an adulticide and repellent permethrin. Repellent activity for mosquitoes has been documented; effectiveness for repelling fleas is still to be determined.
- Permethrin is toxic for cats and cannot be used on cats. Use water-based pyrethrin spray for cats, and for dogs use either pyrethrin or permethrin sprays (Duocide LA, Allerderm/Virbac) that contain a repellent. Apply daily if approved for such use.

Increase Allergic/Pruritic Threshold

- Control concurrent allergic diseases such as atopic dermatitis and food allergy.
- Treat secondary pyoderma, which often increases pruritus, with systemic antibiotics (see Chapter 38).
- Eliminate dry skin by use of baths, moisturizing sprays or rinses, and fatty acid supplements.
- Remove other irritants or allergens on the skin surface, which may aggravate inflamed skin, by frequently bathing the animal. Use this option cautiously with most topical treatments, although fipronil and imidacloprid and selamectin still have efficacy if bathing is 48 hours from application time. Selamectin is absorbed systemically, excreted in epidermal secretions, and replenished, although bathing may temporarily decrease surface levels. Do not bath for 48 hours following application.

Block Allergic Reactions

A variety of systemic drugs may be used to alter the allergic reaction. This approach is often used at the beginning of the flea control program and to break the itch-scratch cycle. Resort to long-term use of systemic drugs only when clients cannot effectively control fleas. This most often occurs with outdoor or roaming pets, especially cats.

Glucocorticoids

- Topical triamcinolone 0.015% spray (Genesis spray, Virbac) has been shown to be effective in the management of experimentally induced FAD and has been effective in some clinical cases.
- Systemic glucocorticoids are often effective. Initially, use prednisone or prednisolone, 1 to 2 mg/kg PO q12–24h, to stop the pruritus associated with FAD.
- Use either oral triamcinolone acetonide (Vetalog, Fort Dodge), 0.25 to 0.5 mg/kg q12–24h, or methyl-

prednisolone (Medrol, Pfizer), 0.8 to 1.6 mg/kg q12–24h, if polyuria, polydipsia, or polyphagia associated with prednisone or prednisolone is unacceptable to the client.
- When pruritus is controlled, change to an alternate-day program and then taper to the lowest effective dose.

Cyclosporine

Although not approved for FAD, some dogs with FAD have responded well to this new treatment for atopic dermatitis. Relative effectiveness compared to glucocorticoids is not known. Atopica (Novartis) at 5 mg/kg q24h has been effective with fewer side effects than glucocorticoids.

Antihistamines

Antihistamines are infrequently effective for FAD. They may be used in conjunction with glucocorticoids and have a synergistic effect that makes possible a reduction in the glucocorticoid dose.

- Diphenhydramine HCl, 2 mg/kg PO q8h; hydroxyzine HCl or pamoate, 2 mg/kg PO q8h; doxepin HCl, 1 to 2 mg/kg PO q12h; or clemastine, 0.05 to 0.1 mg/kg q12h PO may be useful in dogs.
- Chlorpheniramine may be helpful in dogs at a total dosage of 2 to 6 mg PO q8–12h. It is especially useful in cats at a total dosage of 2 mg PO q12h.

Fatty Acid Supplements

Fatty acid supplements containing omega-3 fatty acids and dihomogammalinolenic acid alone rarely control FAD. However, they may be helpful in controlling concurrent atopy, alleviating dry skin, and modulating the production of inflammatory mediators. These effects may raise the pruritic/allergic threshold and have a synergistic effect with other treatments, allowing a reduction in the glucocorticoid dose.

Allergen-Specific Immunotherapy

Allergen-specific immunotherapy (ASIT), previously referred to as hyposensitization with standard allergens and protocols, has not been shown to be efficacious in studies. However, ASIT has been reported to be occasionally effective in individual cases, but it is not considered cost effective for most clients, considering the low level of efficacy. A recent trial with flea salivary antigen did show efficacy in a blinded, controlled trial, suggesting that if done in type I allergic dogs with the exact allergen they tested positive to, then this form of therapy may be beneficial. This is not commercially available at this time.

PREVENTION

Prevention is achieved by long-term continuation of a flea control program. Long-term treatment may not have to be as complete or as frequent as the initial treatment program. Another option is to use prevention by anticipating increases in flea population and increasing the use of parasiticidal therapy just before the onset of environmental conditions favoring these increases.

Chapter 46

Atopic Dermatitis

Andrew Hillier

Atopic dermatitis (AD) is a genetically predisposed inflammatory and pruritic allergic skin disease with characteristic clinical features. It is associated most commonly with immunoglobulin E (IgE) antibodies to environmental allergens: dust mites (house dust and storage mites), pollens (trees, grasses, and weeds), mold spores, danders, insects (moth, cockroach, etc.), and other miscellaneous allergens.

In dogs, this results in skin disease in most cases, with occasional concurrent involvement of other organ systems. Cats generally develop dermatitis as well, but they may also develop asthma-like respiratory tract disease in association with IgE antibodies to environmental allergens. However, the link between feline asthma and AD is uncertain.

ETIOLOGY

AD is a classic example of an IgE-mediated, type I hypersensitivity reaction. Patients may have hypersensitivity to one, a few, or many allergens. AD is a complex skin disease, and a state of "cutaneous hyperreactivity" often exists. The following factors may contribute to clinical disease:

- Environmental allergens
- Staphylococcal pyoderma
- *Malassezia* (yeast) dermatitis
- Concurrent flea allergy or food allergy
- Irritants such as chemicals, plants, and medications
- Temperature and humidity
- Local skin factors such as dry skin, excoriations, etc.

Recognition of factors contributing to disease in each individual patient is critical in the development of successful treatment strategies. As there is a *summation of effects* (added effects of multiple stimuli), elimination of some of the most significant stimuli may reduce the skin inflammation below the patient's *pruritic threshold* (the point at which pruritic stimuli induce skin disease and pruritus) without a need to address all factors that may be contributing to the pruritus.

Incidence in Dogs

AD is a common skin disease that affects 10% to 15% of the dog population. Data from 52 general practices in the United States documented that AD was diagnosed in 8.7% of all canine patients and in 21.6% of all dogs presented with skin or ear disease. In regions where fleas are not a significant problem, AD is likely the most common allergic disease of dogs and cats.

Age and Sex Predilection

- *Age at onset:* Clinical signs are first seen between the ages of 6 months and 3 years in the majority of dogs. AD will rarely develop for the first time once animals are over 7 years of age.
- *Sex predilection:* None known.

Breed Predilection

AD can affect dogs of *any breed* as well as mixed-breed dogs.

- *High-risk breeds:* Beauceron, Boston terrier, boxer, Cairn terrier, Chinese Shar-Pei, cocker spaniel, Dalmatian, English bulldog, English setter, fox terrier, golden retriever, Irish setter, Labrador retriever, Labrit, Lhasa apso, miniature schnauzer, pug, Scottish terrier, Sealyham terrier, West Highland white terrier, wirehaired fox terrier, and Yorkshire terrier.
- *Low-risk breeds:* Dachshund, Doberman pinscher, German shepherd, German short-haired pointer, and poodle.

Seasonal Incidence

Typically, AD is seasonal in nature initially, but the majority of dogs progress over a period of years to develop non-seasonal (year-round) disease. However, many dogs with non-seasonal AD have seasonal exacerbations due to pollen allergies or concurrent flea allergy dermatitis.

Incidence in Cats

There is no reported sex or breed predilection, although Abyssinian cats were suggested in one review to have a higher incidence of AD. The age of onset of clinical signs is similar to dogs.

CLINICAL SIGNS

AD should be considered a differential diagnosis in any dog with the following:

- Pruritus
- Recurrent staphylococcal or *Malassezia* dermatitis
- Otitis externa

Pruritus

Pruritus is the initial and most outstanding clinical sign of AD in dogs and cats. Pruritus is mild to moderate in most cases but may become severe in some chronically affected dogs. It is responsive to glucocorticoid therapy, at least initially.

- The pruritus in AD typically involves one or more of the following body locations:
  - *Face*—Especially periocular, muzzle and chin
  - *Ears*—Most commonly the ear canal but sometimes also the ear pinna and skin at the base of the ear
  - *Ventrum*—Including the neck, axilla, abdomen, and groin
  - *Distal limbs*—Including the carpal and tarsal area, digits, and interdigitally
- Other locations sometimes affected include the perineum and the flexural surface of the elbows and hocks.
- Pruritus may become generalized with chronicity or when a secondary infection is present.

Staphylococcal and Malassezia Dermatitis

AD in dogs is commonly complicated by recurrent staphylococcal pyoderma (see Chapter 38) and *Malassezia* yeast dermatitis (see Chapter 41).

- Both infections contribute to the skin disease and pruritus. Once the infections are treated and resolved, pruritus is usually diminished, sometimes significantly. However, residual pruritus typically remains—a strong clue to a primary underlying allergic dermatitis. Rarely, treatment of the secondary infection leads to resolution of the pruritus as well—these patients only have pruritus when the infection flares and is active.
- Staphylococcal infections tend to involve the trunk, while *Malassezia* infections are more frequently found in the ventral neck, interdigital area, and nail folds. Either infection may become generalized.

Otitis Externa

Otitis externa is common in dogs with AD—one study reported that 86% of cases had otitis. One or both ears may be affected.

- Early cases have mild erythema of the ear pinna and ear canals. As the disease progresses, hyperplasia of the epithelium and ceruminous exudation usually develop.
- Most frequently, allergic otitis becomes complicated by secondary bacterial and yeast infections (see Chapter 59).

Skin Lesions

There is currently debate about the skin lesions that typify AD (assuming that secondary infections are not present).

- Some dogs with AD have no primary lesions, while others may have a macular to papular dermatitis (i.e., a rash).
- Chronic self-trauma as a result of the allergic inflammation eventually leads to secondary lesions such as alopecia, lichenification, hyperpigmentation, and seborrhea. The most important aspect of these lesions is whether their location on the body is typical for AD. Similar secondary lesions are seen in other pruritic but non-allergic dermatoses; however, the lesions are not in the locations on the body that are associated with AD.

Clinical Signs in Cats

Pruritus is the hallmark of the disease in cats as well. However, the other characteristics of AD in cats do not mimic the disease in dogs very closely.

- Pruritus due to AD in cats may manifest as *symmetric alopecia, miliary dermatitis,* or one of the *eosinophilic granuloma complex lesions.* These cutaneous reaction patterns may also be observed in cats with non-atopic pruritic skin disease as well (see Chapters 52 and 53 for differential diagnoses).
- Secondary bacterial or yeast infections and otitis are less common than in dogs but may be present in some atopic cats and must be considered part of the diagnostic workup.

DIAGNOSIS

The diagnosis of AD in dogs and cats is based on the following:

- Typical historical features
- Presence of characteristic clinical signs
- Exclusion of other differential diagnoses

Differential Diagnoses

The following are the most significant differential diagnoses that need to be considered.

Seasonal Disease

- Flea allergy dermatitis
- Insect bite hypersensitivity

Non-seasonal Disease

- Food allergy
- Scabies
- Contact dermatitis

Diagnostic Approach

Use the following three-step approach in patients with suspected AD.

Step 1

- Diagnose and treat secondary infections.
- Diagnose and treat concurrent flea allergy.
- Diagnose and treat scabies.

Step 2

- Confirm that secondary infections, flea allergy, and scabies have been ruled out.
- Determine that residual pruritus is still present.
- If pruritus is seasonal and flea allergy has been ruled out, the patient has AD.
- If pruritus is non-seasonal, perform a food trial to rule out food allergy (see Chapter 47).

Step 3

- If pruritus resolves with a food trial, the likely diagnosis is food allergy, and it is confirmed when pruritus recurs with a challenge trial using the former diet.
- If partial response occurs with a food trial, a combination of food allergy and AD is likely.
- If no response occurs with a food trial, the patient has AD.

Allergy Testing

Perform allergy testing only after a diagnosis of AD has been made and when allergen-specific immunotherapy (ASIT) is anticipated in the treatment plan. The true utility of allergy testing is in the selection of allergens for ASIT.

▼ ***Key Point*** Do not use allergy testing as the basis for diagnosis of AD.

Both intradermal tests (IDTs) (or skin tests) and serum allergy tests (SATs) detect the presence of allergen-specific IgE. A positive allergy test indicates the presence of excessive amounts of IgE to an allergen and may be associated with the following:

- Subclinical hypersensitivity (and not causing disease)
- Clinical allergy (and leading to AD)

Correlation with Seasons

The clinical significance of a positive allergy test can only be ascertained once all other possible causes for the dermatitis have been ruled out and if the positively reacting allergens are known to be in high quantities at the time of year that the individual patient has exacerbations of skin disease (i.e., correlation of seasons of the allergens and the disease in the patient). Thus, once the result of the allergy test is available, it is essential to review the patient's history to consider the seasonal or non-seasonal nature of the disease and the patient's environment. In general, allergens may be categorized as follows (there may be significant geographic variation):

- *Non-seasonal*—House dust mites *(Dermatophagoides farinae, Dermatophagoides pteronyssinus),* storage mites *(Tyrophagus putrescentiae, Lepidoglyphus destructor),* cockroach, moth, danders/epidermals, indoor molds *(Penicillium, Aspergillus, Rhizopus, Mucor)*
- *Spring*—Tree pollens
- *Summer*—Grass pollens, outdoor molds *(Alternaria, Cladosporium)*
- *Fall*—Weed pollens, outdoor molds

Intradermal Versus Serum Allergy Tests

- Neither type of test has been proven to be more accurate than the other, although IDTs have been regarded the "gold standard." Both tests, if performed appropriately, may provide useful information.
- I prefer to perform both tests in all patients with AD where ASIT is anticipated. However, it is not essential and the results of either test will provide clinically useful information in many patients.
- There are numerous laboratories that perform serum allergy tests. It should be emphasized that none of the commercially available serum allergy tests has been proven to be more accurate than any other in peer-reviewed publications. The following factors should be considered when choosing an SAT:
  - Scientific basis of the assay
  - Published results of studies using these assays
  - Laboratory's involvement in allergy research
  - Quality and efficiency of the service
  - Availability of qualified technical staff for consultation
  - Cost
  - Recommendations from experts
  - Personal experience

Allergy Screening Test

- A simple, rapid screening test is available for in-clinic use by veterinarians (Allercept E-Screen, Heska).
- It is important to realize that this test does not screen for allergy (i.e., clinical disease) but does screen for the presence of above-normal levels of IgE to major allergens.
- This screening test has good predictive value for the likely result of the full and complete regional panel. Thus, if the screening test is positive, then there is a high likelihood of at least one positive reaction on the full panel. Similarly, if the screening test is negative, it is unlikely that there will be a positive reaction on the full panel.

Interpretation of a "Positive" Intradermal or Serum Allergy Test

Indicative of AD is when the positively reacting allergens are known to be present in the environment at the time of year when the patient has skin disease or has exacerbations of skin disease.

Interpretation of a "Negative" Intradermal or Serum Allergy Test

Consider the following interpretations for negative allergy test results:

- The patient does not have AD—Reconsider other differential diagnoses.
- The alternative type of allergy test may be more informative (i.e., an IDT if an SAT was performed, or vice versa).
- Drug interference—Glucocorticoids and antihistamines may interfere with an IDT, while an SAT is reportedly unaffected (however, a small percentage of dogs on glucocorticoids may have a less-than-optimal SAT).
- Time of year—The best results with an IDT are often seen at the end of the patient's allergy season, while the best results of an SAT are often seen at the peak of the patient's allergy season.
- Allergens of significance for the patient were not tested—This may be the case in a small percentage of dogs. Most IDTs and SATs include all known major allergens.
- A small percentage of dogs with AD never have positive allergy tests (may be the equivalent of intrinsic AD in humans).

TREATMENT

Current treatment options for AD include the following:

1. ASIT
2. Anti-inflammatory therapy
3. Antimicrobial therapy
4. Allergen avoidance

General Treatment Guidelines and Overview

The choice of treatment options to institute in the individual patient will depend on the following:

- Nature and intensity of clinical signs
- Presence of flare factors (pyoderma, yeast dermatitis, otitis, etc.)
- Patient acceptance of repeated topical, oral, or injectable treatment
- Owner willingness to accept time, effort, and expense of treatment

Thus, there is no "cookbook formula" for treatment of AD in all patients as these factors differ between patients. Most patients can be successfully controlled with a combination of treatments.

1. Antimicrobial therapy:
   - Use antibiotics for active infections and prophylactically.
2. Flea control:
   - Use flea control whether the patient is flea allergic or not.
3. ASIT:
   - Recommend ASIT in *all* cases of AD unless the clinical signs are very mild (i.e., easily controlled with anti-inflammatory therapy without side effects) or have a very limited season.
4. Crisis management during therapeutic trials:
   - Use "crisis busting" prednisone, 0.5 to 1.0 mg/kg q24hrs for 3 days only.
5. Initial therapy (best for dogs with mild disease):
   - ASIT
   - Hypoallergenic or moisturizing shampoo as often as possible
   - Omega-3 fatty acids once daily for 3 months
   - Antihistamine trial—Try two or three for 10 days each
   - Topical lotion or spray for localized areas once daily (preferably with residual activity, such as leave-on conditioners)
6. If poor response to initial therapy or moderate disease is present:
   - Reconsider ASIT
   - Topical triamcinolone spray for 3 weeks
   - Temaril-P (loading then taper)
   - Prednisone loading then taper (methylprednisolone if unacceptable mineralocorticoid side effects from prednisone)
   - Topical tacrolimus for focal areas of severe pruritus
7. If still poor response or severe disease is present:
   - *Refer* the case to a dermatologist!
   - Reconsider the diagnosis
   - Reconsider ASIT
   - Cyclosporine
   - E-collars, T-shirts, body suits

Allergen-Specific Immunotherapy

ASIT (also known as hyposensitization or desensitization) is the practice of administering gradually increasing quantities of an allergen extract to an allergic subject to ameliorate the symptoms associated with subsequent exposure to the causative allergen. Allergens are given by subcutaneous injection in increasing doses up to a maintenance dose or a patient-determined maximum dose.

Indications

- All dogs and cats with non-seasonal AD.
- Dogs and cats with seasonal AD where anti-inflammatory therapy is ineffective, associated with unacceptable side effects, or unsustainable.
- ASIT should not be reserved only for severe cases of AD; that is, it is not a last resort treatment. Limited evidence suggests better efficacy in younger dogs with AD that do not have advanced skin disease.

Efficacy

- True efficacy of ASIT has not been studied in randomized controlled clinical studies.
- Generally, it appears that between 60% and 75% of patients will have 50% improvement in their clinical signs with ASIT.
- As a general guideline for pet owners, one-third of patients have an excellent response, one-third have a good response, and one-third have a poor or no response.
- Owners must understand that it will likely be a number of months (usually 2–6 months and possibly as long as 12 months) before improvement is seen.
- The efficacy of ASIT in cats has not been established but is likely to be similar to that in dogs.

Protocols

- A wide range of protocols for ASIT exists. Generally, a loading phase (increasing concentrations of allergen over a period of weeks to months) is followed by a maintenance phase (once the maximum concentration of allergen has been reached).
- No particular protocol has been proven to be more effective than another. I recommend following the protocol that is supplied by the dermatologist or laboratory performing the allergy test.
- Current studies are evaluating *rush immunotherapy,* where the loading phase is very rapid (increasing concentrations of allergen administered every 30 to 60 minutes in a hospital environment) and the maintenance phase is reached within 24 to 48 hours. Whether rush immunotherapy is as effective (or more effective) than conventional immunotherapy is unknown. There may be a potential for increased risk of adverse reactions (anaphylaxis in particular) with this protocol.

Recheck Evaluations on ASIT

Studies have indicated that as many as 40% to 50% of pet owners discontinue ASIT without consulting their veterinarian. This is likely due to a lack of communication concerning the expectations and the time necessary before a response is seen. Recheck at least after 3 and 12 months of ASIT. Evaluate for the following:

- Recurrence of skin infections.
- Control of concurrent diseases (e.g., flea allergy dermatitis).
- Changes in pruritus at the time of each injection: If there is a temporary (a few days to a week or two) increase in pruritus, the dose may be too high; a temporary decrease in pruritus may indicate that the injection needs to be given more frequently.

Anti-inflammatory Therapy

Drugs used for symptomatic control of AD are categorized as follows (see Table 46-1).

Drugs with Weak Evidence of Efficacy

- Widely recommended and used
- Generally safe and inexpensive
- Highly effective in a few patients but ineffective in the majority of patients

Drugs with Fair Evidence of Efficacy

- Effective in about 50% of patients
- Limited number of studies with low numbers of subjects (await further evaluation)

Drugs with Strong Evidence of Efficacy

- Effective in a majority of patients
- Higher risk of significant side effects
- May be more expensive

Drugs Used to Treat Atopic Dermatitis

Consider the following comments and specific recommendations for the drugs listed in Table 46-1.

Antihistamines

- Try each for a 7- to 10-day trial.
- Failure to respond to one antihistamine does not predict failure to respond to other antihistamines.

Tricyclic Antidepressants

- I typically use tricyclic antidepressants (TCAs) for patients that are "highly strung"—the anxiolytic effect may be of benefit in these patients.
- Doxepin may be effective because of potent antihistaminic effects.

Table 46-1. PHARMACOLOGIC AGENTS USED FOR THE SYMPTOMATIC CONTROL OF CLINICAL SIGNS OF ATOPIC DERMATITIS IN DOGS

Drugs with Weak Evidence for Efficacy in Treatment of AD			
Antihistamines	Diphenhydramine	Benadryl/generics	2 mg/kg q8h
	Hydroxyzine	Atarax/generics	2 mg/kg q8h
	Chlorpheniramine	Chlortrimeton/generics	0.2–0.5 mg/kg q8h
	Clemastine	Tavist/generics	0.1 mg/kg q12h
	Cyproheptadine	Periactin/generics	1 mg/kg q12h
Tricyclic antidepressants	Doxepin	Generics	1–2 mg/kg q12h
	Amitriptyline	Elavil	1 mg/kg q12h
Fatty acids	Omega-3 fatty acids	Generic fish oil caps	180 mg EPA/5 kg q24h
		3V Caps HP	Label instruction
Topical moisturizers	Moisturizers	Various	As often as possible
		HyLyt EFA	
Topical anti-inflammatory drugs	Various: Pramoxine hydrocortisone oatmeal, diphenhydramine	Various	Daily–weekly
Drugs with Fair Evidence for Efficacy in Treatment of AD			
Tacrolimus		Protopic	Every 24 hours
Topical triamcinolone		Genesis spray	q12h for 1 week, then q24h for 1 week, then q48h
Misoprostol		Cytotec	3–6 µg/kg q8h
Pentoxifylline		Trental/generics	10–15 mg/kg q8–12h
Drugs with Strong Evidence for Efficacy in Treatment of AD			
Glucocorticoids	Prednisone	Generics	Crisis buster: 1 mg/kg q24h for 3 days Long term: 1 mg/kg q24h for 7 days, taper to <0.5 mg/kg q48h
	Methylprednisolone	Medrol	0.8 mg/kg q24h for 7 days, taper to <0.4 mg/kg q48h
Calcineurin inhibitors	Cyclosporine	Atopica	5 mg/kg q24h for 30 days, taper to q48–72h

AD, atopic dermatitis; EPA, eicosapentaenoic acid.

Fatty Acids

- Both omega-6 (vegetable oils) and omega-3 (fish oil and flaxseed oil) have been recommended.
- I prefer omega-3 fatty acids for anti-inflammatory effects.
- Omega-6 fatty acids may be of benefit in restoration of the lipid barrier.

Topical Moisturizers

- A lipid barrier defect has been documented in dogs with AD.
- Restoration of the lipid barrier may prevent penetration of allergens, infectious agents, and irritants.
- The use of moisturizers with frequent bathing (daily to weekly) may have the added benefits of "clearing" the skin of allergens, infectious agents, and irritants.
- I prefer the HyLyt EFA (DVM Pharmaceuticals) products as they contain omega-6 fatty acids along with the moisturizers.

Topical Anti-inflammatory Drugs

- There are numerous topical medications with added anti-inflammatory agents (oatmeal, local anesthetics, glucocorticoids, antihistamines, etc.).
- I prefer leave-on conditioners with glucocorticoids or local anesthetics (e.g., ResiCort and ResiProx, Virbac).

Tacrolimus

- Useful for treatment of localized areas of pruritus.
- Available as an ointment (Protopic 0.03% and 0.1%, Fujisawa—the higher concentration is preferable). Each tube of ointment is expensive, but if used only on focal lesions, it may last a few months.

Topical Triamcinolone

- Useful if large areas are to be treated
- Preferable to systemic glucocorticoids
- Genesis spray (Virbac)

Misoprostol

- Limited reports indicate that it may be of benefit in some patients, but I have no experience with this agent.

Pentoxifylline

- I have found this to be beneficial in only a few patients.
- Use the higher dose (15 mg/kg) at least q12h, and preferably q8h.

Glucocorticoids in Dogs

- Unfortunately, some AD patients are "steroid dependent."
- In this case, try Temaril-P (Pfizer) at label doses. The tablet is a combination of an antihistamine (trimeprazine) and glucocorticoid (prednisolone). Typically, less glucocorticoid is necessary to control AD with Temaril-P than with glucocorticoids alone.
- I frequently use a "crisis-busting" dosage of prednisone (1 mg/kg for 3 days only) in dogs when severe exacerbations of pruritus occur.
- If prednisone is necessary long-term, aim for a maintenance dosage of <0.5 mg/kg q48h.
- There is rarely a need for long-acting depot injectable glucocorticoids in dogs. Although they are often effective initially, reasons to avoid these include the risk of serious side effects, the development of bacterial infections of the skin and lower urinary tract, and the possibility of adult-onset demodicosis.

Glucocorticoids in Cats

- For cats, dexamethasone is my preferred oral glucocorticoid. The crisis-busting dosage is 0.5 to 1.0 mg once daily for 3 days. If maintenance dexamethasone is necessary, aim for <0.25 mg/kg every 3 to 4 days.
- Depot injectable glucocorticoids (e.g., methylprednisolone acetate, Depo-Medrol, or triamcinolone, Vetalog) may be acceptable in cats for temporary remission of pruritus in cats with seasonal disease.

Cyclosporine

- Cyclosporine may be as effective as glucocorticoids for the control of AD in dogs and cats.
- I prefer a dosage of at least 5 mg/kg q24h on an empty stomach.
- Treat for a minimum of 30 days before assessing the response.
- Side effects are common, including vomiting (30% of cases), diarrhea (20% of cases), gingival hyperplasia, hypertrichosis, and pyoderma.
- The drug is very expensive and is likely to be most commonly used in smaller-breed dogs and cats to treat refractory or severe disease.

Chapter

47 Food Hypersensitivity

Stephen D. White

Adverse reactions to foods have been well documented in small animals. The terms *food allergy* and *food hypersensitivity* have been used interchangeably in the human and veterinary medical literature to describe clinical signs induced by food ingestion in which there are demonstrable or highly suspected immunologic reactions. The terms *food intolerance* and occasionally *food sensitivity* have been used when an immunologic etiology is unlikely or has not been established. Although the causes of abnormal reactions to ingested foods have not been well established in small animals, food hypersensitivity and food allergy are the terms commonly used. I prefer the former as being more accurate in describing an abnormal response of the immune system. Allergies to inhalant aeroallergens cause atopic dermatitis (see Chapter 46).

ETIOLOGY

- The exact mechanisms of food hypersensitivity have not been delineated in dogs and cats. Reactions to food have been noted in dogs and cats that could be termed immediate (i.e., hypersensitivity type I, occurring within minutes to hours after ingestion) or delayed (i.e., type IV, occurring within hours to days of ingestion). Recent reports (Ishida et al., 2003 and 2004) lend credence to both IgE- and cell-mediated mechanisms. A spontaneous canine model of IgE-mediated food hypersensitivity has been developed (Jackson and Hammerberg, 2002). However, documentation of the mechanisms involved in the development of food hypersensitivity in pet animals is still lacking.
- In dogs, the most common confirmed dietary allergens are beef, soy, dairy products, and cereal. Other allergens reported include cheese, chicken, chicken eggs, lamb, and chocolate.
- In cats, beef, milk, and fish are the most common dietary allergens. I have identified fish as an offending allergen in 50% of cats with food hypersensitivity.
- The vast array of foodstuffs used in commercial pet foods, as well as variable processing methods, probably accounts for the large numbers of allergens reported. Any dietary protein, even in small (mg) quantities may be the cause of food hypersensitivity.
- Food contaminants such as pathogenic bacteria and toxins, food additives such as tartrazines, and vasoactive amines such as tyramine in cheese have all been implicated or suspected as mimicking food hypersensitivity in humans. Their importance in small animals is unknown and is likely to be low.

CLINICAL SIGNS

▼ ***Key Point*** Although the age of onset is variable, predisposition is noted for young dogs (≤1 year of age). Owners seldom relate the onset of clinical signs to any change in diet.

- No sex predilections have been noted in dogs or cats with food hypersensitivity. Terriers and Siamese cats may be predisposed. Clinical signs are variable.
- Pruritus is the most common sign in dogs; rarely, nonpruritic animals are reported. The pruritus is often distributed similar to that for atopic dermatitis (i.e., feet, ears, face, and axillae) and these two diseases are clinically virtually indistinguishable if the pruritus is non-seasonal (year-round). The pruritus may be severe from very early in the disease. Animals with food hypersensitivity have been described as having glucocorticoid-resistant pruritus; however, this should not be regarded as a feature of food hypersensitivity as some animals are responsive to glucocorticoid administration.
- Cutaneous lesions noted in dogs include papules, erythema, epidermal collarettes, pododermatitis, seborrhea, and otitis externa. Rarely, sloughed or cracking claws may be caused by food hypersensitivity.
- In cats with food hypersensitivity, clinical signs include generalized pruritus, miliary dermatitis, facial and head pruritus, pruritic angioedema-urticaria, eosinophilic plaque, eosinophilic ulcer, mural folliculitis, and erythema.
- Gastrointestinal signs (vomiting, diarrhea) have also been noted (see Chapters 67 and 69). These may be more common than previously thought. Dogs in par-

ticular may show signs suggestive of colitis. In cats, food hypersensitivity has been manifested as lymphocytic-plasmacytic enteritis or colitis.
- Neurologic signs (epileptiform seizures, malaise) and respiratory distress (asthma-like syndromes) occasionally have been reported.
- Multiple organ involvement is uncommon.

DIAGNOSIS

Suspect food hypersensitivity in the following situations:

- Non-seasonal occurrence of pruritic skin lesions
- Recurrent pyoderma and yeast infection and recurrent otitis
- Lack of response to steroidal or other anti-inflammatory drugs in dogs and cats, although efficacy of corticosteroids in controlling pruritus does not rule out a diagnosis of food hypersensitivity
- Lack of response to progestational drugs in cats

Laboratory Findings

There are no consistent laboratory findings in small animals with food hypersensitivity. Peripheral eosinophilia may or may not be present.

Histopathologic Findings

Histopathologic findings are nonspecific and nondiagnostic, usually characterized by perivascular dermatitis with neutrophils or mononuclear cells predominating and variable secondary suppurative changes. Tissue eosinophilia is uncommon but has been reported. Histopathology is rarely needed as part of the diagnostic workup in cases of suspected food hypersensitivity.

Intradermal Testing

Intradermal skin testing with food extracts usually has been unrewarding in humans and small animals, possibly owing to changes in composition of the allergen with digestion or to improper dilution of the test allergen.

Serologic Diagnostic Tests

Serologic diagnostics using the radioallergosorbent test (RAST) or the enzyme-linked immunosorbent assay (ELISA) for reaginic antibodies in humans correlate with history and provocative exposure tests in over 50% of cases reported. However, the data from two studies, one utilizing RAST (White and Mason, 1990) and one utilizing the ELISA test (Jeffers et al., 1991), have shown that these tests are of no value in small animals. Most commercial laboratories that perform serologic allergy testing offer tests with "food panels." I do not use these tests as an aid in the diagnosis of food hypersensitivity and recommend that clinicians should not do so at this point in time.

▼ ***Key Point*** The most valid and most often recommended method for diagnosis of food hypersensitivity is the restricted ("hypoallergenic" or "elimination") test diet.

Restricted Diet Test

Home-Prepared Diets

- An appropriate restricted diet generally contains one protein and one starch. These must be based on avoidance of previously fed dietary ingredients, including snacks, treats, table scraps, cat food, and flavored medications. Remember that dogs living in households with cats tend to have been exposed to fish through their consumption of either cat food or cat feces. I often start dogs on home-cooked diets with pork and potatoes, although pinto beans and potatoes may also be used. Based on non-exposure, rabbit, duck, and tuna are also options. I have also used "exotic" foods like elk when feasible. Other than fresh water, nothing else should be fed to the dog during the restricted diet trial. This means that vitamins and chewing toys must be eliminated and that flavored medications (such as certain ectoparasite and endoparasite preventatives and vitamin supplements) should be replaced by other, equally effective non-flavored preparations. Protein-flavored toothpaste should be replaced by the malt-flavored variety. Because the restricted diet is not a balanced one, owners should be warned that the dog may lose weight, develop a "dull" haircoat or scaling, or be hungrier than usual.
- In cats, pork and tapioca pudding (the latter prepared with water, not milk) is usually palatable.
- Restricted diets should be free of colorings, preservatives, and flavorings. Do not give palatable medications, such as certain heartworm preventatives (substitute another type of heartworm preventative for the duration of the diet), and omit all vitamin and mineral supplements.
- Do not use vegetables during the trial as a treat unless you are certain that the animal has never been exposed to that vegetable. I am aware of at least two dogs that were allergic to carrots, and a dog has been reported with an allergic response to tomato.

Commercial Limited-Antigen Diets

- Owners may be unable or unwilling to cook for their pet for the time period needed. In such cases, commercially available limited-antigen diets may be used.
- For dogs these would include Purina LA (salmonid); Iams FP (fish and potato) and KO (kangaroo and oats); IVD duck, venison, whitefish, or rabbit plus potato; Hills D/D (duck or fish and rice); or Waltham fish and rice.
- For cats these would include IVD duck, venison, or rabbit plus green pea; Hills D/D feline; or Iams lamb and barley.

- Commercially prepared pet foods, including diets containing no preservatives and diets marketed as "natural," are *not* adequate test diets. These products do not meet the criteria for a true restricted test diet because of the many foodstuffs they contain and the processing of these ingredients.
- Use of a commercially prepared diet will give an approximately 90% chance of determining a food allergy; however, none of these diets will work for all animals, and failure of an animal to improve on such a diet may warrant trying another one or a home-cooked diet in another trial.

Hydrolyzed Protein Diets

- Another option for animals who already have been fed many foods, or whose dietary history is unknown, is the use of hydrolyzed protein diets, in which the protein source is hydrolyzed to small molecular weights, thus avoiding the body's "immunologic radar." Such foods for dogs include Purina HA (hydrolyzed soy and corn starch), Hills Z/D Ultra (hydrolyzed chicken and chicken liver and corn starch), and Hills Z/D Low allergen (hydrolyzed chicken and chicken liver and potato). For cats I have used Hills feline Z/D Low allergen (hydrolyzed chicken and chicken liver and rice protein) or Purina HA (not yet available at the time of writing of this chapter).

Concurrent Medical Therapy

- Occasionally, an animal may be presented to the clinician with pruritus so severe that administration of oral corticosteroids is justified while the diet is in progress. Administer prednisone or prednisolone, 0.5 to 1.0 mg/kg PO q24h, for 10 to 14 days, and then stop. Continue the diet for a minimum of 2 weeks beyond discontinuation of the medication in order to properly evaluate response to diet.
- Identification, treatment, and resolution of secondary bacterial and yeast infections are critical if the clinician is to be able to evaluate the response to the restricted diets.

Interpreting Results

- Clinical improvement is observed in most animals within 24 hours to 4 weeks after starting the restricted diet. It may take longer than this for complete resolution of pruritus.
- In my experience, 8 weeks is a reasonable length of time in which to expect some improvement. Improvement is best defined as a reduction of pruritus (or other clinical signs if pruritus is absent).
- If only partial improvement is noted, the diet may not have been given long enough for full effectiveness.
- Alternatively, evaluate the restricted diet's content and consider a change (e.g., substitute potatoes for rice).
- Consider other, concurrent hypersensitivities, such as fleas and atopic dermatitis. Literature reports indicate that approximately 30% of dogs with food hypersensitivity have concurrent atopic dermatitis; in these patients, residual pruritus is to be expected and is associated with the atopic dermatitis.

TREATMENT

Once improvement is noted, several treatment alternatives are open to the clinician.

- Challenge the animal with its original diet in order to substantiate the diagnosis. A recurrence of clinical signs is usually seen within 72 hours of initiating the dietary challenge, but it may take as long as 2 weeks, particularly when a hypersensitivity to cereals is involved.
- This rechallenge procedure is particularly important when the clinical improvement with the restriction test occurred over the course of a change in season, as this may cause a decreased exposure to environmental aeroallergens; that is, pollens may have led to improvement in a pet with atopic dermatitis, rather than improvement from the change in diet.
- If clinical signs recur with the original diet and food hypersensitivity is confirmed, then revert back to the restricted diet. Once clinical signs have resolved again, add individual foodstuffs to the restricted diet at 5- to 10-day intervals until a balanced diet is achieved or the offending allergen(s) is discovered.
- Many owners are unwilling to exacerbate a clinically improved animal or separate various components of foods to determine potential allergens. Instead, they are more interested in achieving a balanced, less expensive diet as soon as possible.
- Once the diagnosis of food hypersensitivity is confirmed, if the pet's restricted diet has been homemade, the diet may be changed to one of the commercially available limited-allergen diets mentioned in the previous section (see "Restricted Diet Test"). If the new diet is not tolerated, most animals show a recurrence of clinical signs within 72 hours, although a few pets may take longer.
- If the animal cannot tolerate a commercial diet, use a home-prepared diet consisting of a protein and carbohydrate source supplemented with vitamins, minerals, and, for cats, 60 to 100 mg of taurine daily. Supplementation with 0.5 teaspoon of clam juice per day, recommended by some, is *not* adequate taurine supplementation. For further information on additive-free supplements for homemade hypoallergenic diets, see the article by Roudebush and Cowell (1992). Consultation with a veterinary nutritionist is strongly advised in the formulation of home-prepared diets.

Chapter

48 Immune-Mediated Dermatoses

Karen Helton-Rhodes

Immune-mediated dermatoses are relatively uncommon diseases in domestic animals. This group may be divided into autoimmune and immune-mediated categories according to immunopathogenesis.

- Autoimmune diseases include the pemphigus complex, bullous pemphigoid, mucous membrane pemphigus, and uveodermatologic syndrome (Vogt-Koyanagi-Harada syndrome). These are characterized by a specific antibody-mediated or cell-mediated immune response directed against a normal component of the skin or body.
- Immune-mediated dermatoses include systemic lupus erythematosus and cutaneous (discoid) lupus erythematosus. In these diseases, antigen-antibody complexes are formed and then deposited in various locations (vessel walls, glomeruli of the kidney, or basement membrane zone of the skin). This deposition of immune complexes may then trigger an inflammatory response that results in tissue destruction.
- Vasculitis can be either autoimmune or immune mediated, depending on the underlying etiology.

PEMPHIGUS COMPLEX

The pemphigus complex of diseases includes pemphigus foliaceus, pemphigus erythematosus, pemphigus vulgaris, pemphigus vegetans, panepidermal pustular pemphigus, paraneoplastic pemphigus, and drug-related pemphigus.

▼ ***Key Point*** Pemphigus foliaceus is the most common autoimmune skin disorder in dogs and cats.

- Pemphigus erythematosus is considered a variant of pemphigus foliaceus. It may have clinical and histopathologic features of lupus erythematosus and is therefore considered a "crossover" between the pemphigus and the lupus erythematosus complexes.
- Pemphigus vegetans is an extremely rare variant of pemphigus vulgaris that is distinguished clinically from the other autoimmune diseases by the production of lesions that are vegetative (i.e., proliferative) rather than pustular or ulcerative.

Etiology

The exact cause or stimulant for the production of the pemphigus antibody is unknown. Theories involve either abnormal immune regulation or abnormal antigen stimulation.

- A virus spread by an insect vector has been proposed as the initial stimulus. This theory gains support from an endemic form of pemphigus (fogo selvagem) in humans in South America.
- Genetic factors may be equally important as there are breed predilections for the disease.
- In humans, once formed, the antibody binds with components found in the core of the desmosome (desmoglein I or plakoglobin). Desmosomes function as attachment areas between keratinocytes of the skin. This binding stimulates plasminogen activators (i.e., serine proteases), which subsequently cause the conversion of plasminogen to plasmin.
- The production of plasmin causes the disruption of the desmosome attachments and therefore a loss of keratinocyte adhesion. This loss of adhesion between adjacent cells is called *acantholysis,* and the individual cells are termed *acantholytic cells.*
- All of the diseases in the pemphigus complex appear to have the same immunopathogenesis, but the target protein will vary depending on the type of pemphigus. The location of the bulla or separation within the epidermis differs; for example, pemphigus foliaceus has a more superficial bulla than pemphigus vulgaris.

Clinical Signs

Pemphigus Foliaceus

- Breeds that are predisposed include Akitas, chow chows, bearded collies, dachshunds, Doberman pinschers, schipperkes, and rottweilers.
- Lesions consist of erythematous macules that progress rapidly to a pustular phase and then appear as a dry,

yellow crust. These lesions may be limited to the pinnal, perioral, periocular, dorsal muzzle, nasal planum, and/or nail bed regions, or they may be generalized. Although pustules are the primary lesions, these are uncommonly seen and the clinician is more typically presented with a crusting dermatitis.
- Animals may present with marked hyperkeratosis (scaling) or crusting of the foot pads with or without nail bed involvement. The nails usually are normal.
- Cats commonly exhibit a marked paronychia that appears as a thick "cheesy" core of exudate when the nails are extruded manually.
- Mucocutaneous and oral lesions are rare.
- Pruritus is variable—the appearance of lesions precedes the pruritus (in contrast to allergic dermatoses, where pruritus is the first clinical sign).

Pemphigus Erythematosus

- Pemphigus erythematosus is a rarely recognized variant of pemphigus foliaceus.
- Collies appear to be at risk (this disease is one of several differential diagnoses for "collie nose").
- Lesions are similar to those of pemphigus foliaceus but are limited to the face.
- Some animals may show depigmentation of the planum nasale.

Pemphigus Vulgaris

- Lesions are characterized as vesicobullous eruptions that rapidly ulcerate, leaving thick crusts.
- Lesions may be primarily mucocutaneous in location or generalized.
- Onychomadesis (loss or shedding of the nails) and foot pad ulcerations are common.
- Ulceration of the oral cavity may be an initial presenting sign in over 50% of cases and is eventually present in 90% of cases. Drooling and difficulty in eating may be presenting signs.
- Pruritus and pain are variable.

Pemphigus Vegetans

- Pemphigus vegetans is an extremely rare variant of pemphigus vulgaris.
- Lesions usually are generalized rather than mucocutaneous.
- Lesions are vegetative (proliferative) or verrucous (wart-like).

Panepidermal Pustular Pemphigus

- Lesions are limited to the face.
- Pustules are found at all levels within the epidermis and follicular epithelium.
- Lesions are short-lived pustules that rupture and form a thick, adherent crust.

Paraneoplastic Pemphigus

- Rare form of pemphigus recognized in association with canine lymphoma and one case of Sertoli cell tumor.
- Oral cavity is often affected.

Drug-Related Pemphigus

- Pemphigus may be drug induced or drug triggered.
- The drug-induced form often resolves when the medication is withdrawn, while the drug-triggered form usually requires immunosuppressive therapy.
- Trimethoprim-sulfa is the most common drug associated with pemphigus.
- Feline cases are associated with itraconazole, methimazole, and lime sulfur dips.

Diagnosis

▼ ***Key Point*** Histopathologic examination of skin biopsies gives the most valuable diagnostic information. Obtain at least three biopsies of the freshest pustules, vesicles, or bullae or from the edge of an ulcerated lesion.

- In all of the pemphigus complex diseases, the complete blood count (CBC), serum biochemical profile, and urinalysis are non-diagnostic.
- Anti-nuclear antibody (ANA) tests are positive at low titers in 50% of pemphigus erythematosus patients, but in other forms of pemphigus the ANA tests are generally negative.

▼ ***Key Point*** False-positive ANA titers may be seen in animals with pemphigus, rheumatoid arthritis, idiopathic thrombocytopenia, autoimmune hemolytic anemia, thyroiditis, endocarditis, cancer, hepatotoxicity, feline leukemia, feline infectious peritonitis, dirofilariasis, demodicosis, and flea allergy dermatitis; they even may be seen in clinically normal animals.

Pemphigus Foliaceus

- Direct smear of an intact pustule or surface beneath a thick crust reveals numerous acantholytic cells.
- Histopathologic findings include subcorneal and/or intragranular pustules with acantholytic cells.
- Direct immunofluorescent antibody (IFA) tests and direct immunoperoxidase staining (IPS) tests are positive, with intercellular staining of immunoglobulin and/or complement in the upper one-third of the epidermis.

▼ ***Key Point*** IFA is positive in only 50% of autoimmune cases, whereas IPS is very sensitive and is positive in 95% of confirmed cases.

- IPS is not very specific; positive results are obtained in 73% of animals with pyoderma, 67% with dermatophytes, 50% with demodicosis, and 100% with scabies. Also, IPS is positive with the immunoreactant immunoglobulin G in an intercellular pattern in biopsies obtained from normal canine planum nasale and foot pads. IFA is positive with the immunoreactant immunoglobulin M in a basement membrane zone pattern in 75% of normal canine nasal biopsies and 45% of biopsies of normal foot pads, thus yielding false-positive results.

▼ ***Key Point*** Indirect pemphigus titers using serum are unreliable in dogs and cats.

Pemphigus Erythematosus

- Direct smears are similar to those of pemphigus foliaceus.
- ANA tests are positive, with low titers, in 50% of cases.
- Histopathologic findings include subcorneal and/or intragranular pustules, hydropic degeneration of the basal cell layer, and dyskeratotic cells.
- IFA and IPS are positive (see the preceding section), with staining in the intercellular pattern with or without concurrent staining in the basement membrane zone.

Pemphigus Vulgaris

- Direct smears are similar to those of pemphigus foliaceus.
- Histopathologic findings include suprabasilar pustules with acantholysis.
- IFA and IPS are positive (see "Pemphigus Foliaceus"), with intercellular deposition of immunoglobulin or complement in the lower one-third of the epidermis.

Pemphigus Vegetans

- Direct smears are similar to those of pemphigus foliaceus.
- Histopathologic findings include intraepidermal acantholytic eosinophilic microabscesses with significant surface crusting and verrucous vegetations and papillomatous proliferations.
- IFA and IPS are positive (see "Pemphigus Foliaceus"), with an intercellular staining pattern.

Panepidermal Pustular Pemphigus

- Histopathology findings include sterile pustules involving the subgranular layers of the epidermis and outer root sheath of the hair follicle, suppurative crusts with acantholytic cells, irregular epidermal hyperplasia, and a superficial perivascular and interstitial inflammatory response.

Paraneoplastic Pemphigus

- Histologic lesions appear to be a mixture of pemphigus foliaceus (PF), pemphigus vulgaris (PV), and erythema multiforme.
- Autoantibody targeted appears to be different than those recognized in PF and PV (desmoplakin II and a 190 kDa protein).

Drug-Related Pemphigus

- Most cases resemble pemphigus foliaceus.

Differential Diagnoses

The major differential diagnoses for pemphigus foliaceus include the following.

Generalized Pustular Crusting

- Bacterial pyoderma (it is essential to rule out pyoderma before making a diagnosis of pemphigus foliaceus based on negative cytology, negative culture, and poor response to antibiotics)
- Dermatophytosis
- Demodicosis
- Cutaneous drug reaction
- Dermatophilosis
- Subcorneal pustular dermatoses
- Sterile eosinophilic pustulosis

Pedal Lesions

- Superficial necrolytic dermatitis
- Systemic lupus erythematosus/discoid lupus erythematosus
- Zinc-responsive dermatoses
- Contact dermatitis
- Digital hyperkeratosis

Nasal or Facial Lesions

- Bacterial pyoderma
- Dermatophytosis
- Demodicosis
- Cutaneous drug reaction
- Dermatomyositis
- Pemphigus erythematosus
- Discoid lupus erythematosus

Treatment

General Considerations

Management is similar for each of the diseases in the pemphigus complex.

▼ ***Key Point*** The goal in treating autoimmune skin diseases is to keep the condition in satisfactory remission on a "safe" dose of medication. It is better for the animal to have a few remaining lesions on low-dose alternate-day glucocorticoids than to have normal skin on high daily doses of glucocorticoids.

- For initial therapy, choose prednisone. If the response is poor, add a chemotherapeutic agent such as azathioprine to the protocol.
- For more rapid and complete resolution of clinical signs with less resistance to therapy, start with a regimen of prednisone and an adjunctive chemotherapeutic drug.
- Maintain medications at a high dose until clinical signs have resolved at least 75% to 85%, then gradually decrease dosages while monitoring for exacerbation of disease.
- Taper either the prednisone or the chemotherapeutic agent first, depending on side effects noted.
- Another option is to alternate the dosage reductions of the two medications until there is complete remission and therapy is no longer necessary or until the minimum dosage of drug needed to control the disease is found.
- Initially, monitor CBC and platelet count every 2 weeks. After the disease is controlled and the level of medication is being tapered, gradually decrease the frequency of monitoring to every 1 to 2 months. Evaluate periodic (every 3–6 months) urine cultures for occult lower urinary tract infections.
- It is typically very difficult to induce remission of lesions without the initial use of glucocorticoids.

Prednisone as a Single Therapeutic Agent

- Prednisone, 1 to 2 mg/kg PO q12h (dogs) or 1 to 3 mg/kg PO q12h (cats).
- Use in conjunction with over-the-counter sunscreens and topical glucocorticoids and/or topical tacrolimus (see later section).
- Treatment of choice for pemphigus erythematosus.

Prednisone with Azathioprine

- Prednisone, 1 to 2 mg/kg PO q12h in combination with azathioprine (Imuran, Burroughs-Wellcome), 1 to 2 mg/kg PO q24–48h (dogs).
- Treatment of choice for pemphigus foliaceus, pemphigus vulgaris, and pemphigus vegetans when lesions are advanced.
- Side effects of azathioprine include vomiting, diarrhea, pancreatitis, dermatitis, anemia, bone marrow suppression, and hepatotoxicity.
- Monitor CBC and platelet count every 3 to 4 weeks.

▼ ***Key Point*** Do not use azathioprine in cats because of idiosyncratic reactions characterized by severe, non-responsive leukopenia and thrombocytopenia most pronounced in feline leukemia virus– and feline immunodeficiency virus–positive cats.

Prednisone with Chlorambucil

- Prednisone, 1 to 2 mg/kg PO q12h in combination with chlorambucil (Leukeran, Burroughs Wellcome), 0.2 mg/kg PO q24–48h.
- Treatment of choice for pemphigus complex in small dogs and all cats when lesions are severe.
- Toxicity from this protocol is mild and includes vomiting, anorexia, and diarrhea (usually resolves when the dosage is changed from a daily to an alternate-day regimen), as well as a mild, gradual, and rapidly reversible myelosuppressive effect.
- Monitor CBC and platelet count every 2 weeks.

Tetracycline and Niacinamide

- Used for mild or localized cases.
