- Tetracycline has anti-inflammatory properties affecting complement activation, antibody production, chemotaxis, prostaglandin synthesis, lipases, and collagenases.
- Niacinamide inhibits mast cell degranulation and phosphodiesterase.
- Adverse reactions include vomiting, diarrhea, anorexia, and increased serum liver enzymes.
- In dogs with >10-kg body weight, give 500 mg of each drug q8h (higher doses have been used in some large- and giant-breed dogs).
- In dogs with <10-kg body weight, give 250 mg of each drug q8h.
- Clinical response may take 1 to 3 months; then taper the medication dose according to clinical response.

Cyclosporine

- Cyclosporine blocks regulatory proteins that upregulate activation genes of T-helper inducer and cytotoxic cells.
- The clinical response is variable in autoimmune and immune-mediated diseases.
- Give 5 mg/kg/day PO without food (2 hours before and after dosing).
- May be used with glucocorticoids if needed.
- Side effects include vomiting, diarrhea, anorexia, weight loss, hepatotoxicity, gingival hyperplasia, involuntary shaking, hirsutism, and papillomatosis.
- Use caution when using in conjunction with other drugs that influence the hepatic microsomal isoenzyme P450 system (e.g., ketoconazole)—use half the dose of cyclosporine to avoid toxicity.
- Monitor the serum chemistry panel every 3 months.
- Cyclosporine is very expensive, especially in medium- to large-breed dogs. As the reported success rate of this therapy is not very high, it should be regarded as a distant choice of treatment.

Tacrolimus (Topical)

- 0.1% topical formulation
- Often used for pemphigus erythematosus and discoid lupus erythematosus but in focal cases only, especially involving the face

Dapsone

- Dapsone (Jacobus) is rarely used for pemphigus and may be combined with glucocorticoids.
- Dapsone decreases complement activation, antibody production, lysosomal enzyme synthesis, and neutrophil chemotaxis.
- Dosage is 1.0 mg/kg q8h; use for *dogs only*.
- Lag phase of 4 to 8 weeks.
- Side effects include anemia, neutropenia, thrombocytopenia, hepatotoxicity, gastrointestinal signs, neuropathies, and cutaneous drug eruptions.
- Monitor CBC, platelet counts, serum chemistries, and urinalysis every 3 weeks for the first 4 months.

Sulfasalazine

- Sulfasalazine (Azulfidine, Pharmacia) is rarely used for pemphigus and may be combined with glucocorticoids.
- Sulfasalazine has anti-inflammatory properties.
- Dosage is 10 to 40 mg/kg q8h; consider it for cases with marked neutrophilic component.
- Monitor as for dapsone and check tear production (keratoconjunctivitis sicca is common side effect).

Gold Therapy

- Aurothiomalate (gold salts) (Myochrysine, Merck) is rarely used, and no published reports exist regarding its effectiveness in animal patients.
- Prednisone, 1 mg/kg PO q12h, also may be needed until remission is achieved.
- Gold therapy is suitable for both dogs and cats; however, results appear to be much better in cats.
- Auranofin (Ridaura, SmithKline Beecham), an oral form of gold salts, has been tried in a limited number of cases but needs further investigation for use in dogs and cats.
- Side effects include thrombocytopenia, aplastic anemia, toxic epidermal necrolysis, stomatitis, nephrotic syndrome, hepatotoxicity, dermatitis, and pancreatitis. Eosinophilia may herald toxicity.
- Monitor CBC, platelet count, and urinalysis every 2 weeks during the first 3 months of treatment and a serum chemistry panel monthly.

Prognosis

- The prognosis for control of pemphigus foliaceus is fair to good.
- If glucocorticoids cannot be administered, then the prognosis is poor to guarded.
- It is important that the clinician always remember the following:
  - The drugs are more likely to kill the patient than the disease.
  - 100% control of all lesions is not always necessary.

SUBEPIDERMAL BLISTERING DERMATOSES

This category includes bullous pemphigoid, mucous membrane pemphigoid, and epidermolysis bullosa acquisita.

Etiology

The immunopathogenesis of bullous pemphigoid and mucocutaneous pemphigoid involves antibody production directed against the hemidesmosomes located in the lamina lucida (BPA II/ collagen type XVII) region of the basement membrane zone of the skin. The complement cascade is then activated, causing the release of components C3a and C5a, which triggers mast cell degranulation. Mast cell mediators attract inflammatory cells that release lysosomal enzymes, resulting in tissue destruction and subepidermal blisters. The target antigen for epidermolysis bullosa acquisita is the anchoring fibrils of the lamina densa (type VII collagen).

Clinical Signs

Bullous Pemphigoid

- This is a relatively uncommon autoimmune dermatosis.
- Collies, Doberman pinschers, and Shetland sheepdogs may be predisposed.
- Clinical signs and lesions mimic those of pemphigus vulgaris.
- Vesicles and bullae of bullous pemphigoid are more stable than those seen with pemphigus, most likely due to the depth of the lesion.
- Oral cavity lesions are common and occur in 80% of cases, but they are not usually the initial presenting clinical sign. Cutaneous or mucocutaneous vesicobullous lesions generally precede oral cavity involvement.
- Pruritus and pain are variable.

Mucous Membrane Pemphigoid (Cicatricial Pemphigoid)

- This is relatively common, accounting for half of the reported subepidermal blistering diseases.
- Common in the German shepherd breed; no age or sex predilection.
- Transient vesicles that rapidly evolve into erosions, ulcers, and crusts.
- Lesions concentrate around the oral cavity, nasal planum, eyes, ear canals, genitalia, and anus.
- Oral mucosal lesions are common and are often present from the outset of disease.

Epidermolysis Bullosa Acquisita

- This is extremely rare. It is mostly seen in young dogs and is clinically similar to bullous pemphigoid.

- Great Danes appear to be at a greater risk than other breeds.
- Lesion is deeper in the skin since the anchoring fibrils (type VII collagen) of the lamina densa are the target antigen.

Diagnosis

- Direct smears are negative for acantholytic cells because this disease does not affect intercellular adhesion.
- CBC, serum biochemical profile, and urinalysis are non-diagnostic.
- ANA test is negative.
- Histopathologic findings include a subepidermal cleft or bulla with a lichenoid infiltrate of neutrophils and/or eosinophils.
- IFA and IPS are positive (see under "Pemphigus Foliaceus"), with a linear band of staining along the basement membrane zone.

Treatment

Therapeutic options for subepidermal blistering diseases are the same as those available for the pemphigus (see "Treatment" under "Pemphigus Complex").

UVEODERMATOLOGIC SYNDROME

This disease is also known as the Vogt-Koyanagi-Harada (VKH) syndrome.

Etiology

The exact immunopathogenesis of VKH syndrome is unknown. In humans, circulating lymphocytes from patients with VKH syndrome show significant cytotoxic activity against P-36 human melanoma cells. The factors responsible for the cellular hyperactivity against melanin-containing cells have not been determined. Deficiency of T-suppressor cells, viral inducement of immunologic abnormality, and genetic factors have all been implicated.

Clinical Signs

- Akitas, Samoyeds, and Siberian huskies appear to be predisposed.
- In humans, three phases have been recognized:
  - *Meningoencephalitic phase*—Fever, malaise, headache, nausea, vomiting, and tinnitus
  - *Ophthalmic phase*—Photophobia, uveitis, and blindness
  - *Dermatologic phase*—Leukoderma (acquired lack of skin pigment) and leukotrichia (acquired lack of hair pigment)
- Dogs appear to exhibit primarily the ophthalmic and dermatologic phases.
- Dermatologic lesions (leukoderma, leukotrichia) affect primarily the nose, lips, foot pads, eyelids, and anus.
- Erosions and ulcerations may or may not be present in conjunction with leukoderma.

Diagnosis

- Direct smears are negative.
- CBC, serum biochemical profile, and urinalysis are non-diagnostic.
- ANA test is negative.
- Histopathologic findings include a histiocytic interface dermatitis with pigmentary incontinence (histiocytes contain fine melanin granules).
- IFA and IPS are negative.

Treatment

- Treatment is similar to that for the pemphigus (see "Treatment" under "Pemphigus Complex").
- VKH syndrome is very difficult to control and usually requires high levels of prednisone and azathioprine.
- Ocular changes usually dictate the therapeutic course. For treatment of uveitis, see Chapter 136.

LUPUS ERYTHEMATOSUS COMPLEX

This includes discoid lupus erythematosus (DLE), systemic lupus erythematosus (SLE), exfoliative cutaneous lupus erythematosus (ECLE), vesicular cutaneous lupus erythematous (VCLE), and canine lupoid onychitis (CLO).

Etiology

The exact immunopathogenesis of this group of diseases is unknown. Antigen-antibody complexes are produced and subsequently lodge in small vessels and the basement membrane zone of the skin (SLE and DLE) and in various organ systems (SLE). Genetic factors, T cell defects, B cell hyperactivity, hormonal alterations, and viral inducement of antigen-antibody complex formation have all been implicated. (See Chapter 24 for more information about SLE.)

Clinical Signs

Discoid Lupus Erythematosus

- Collies, Shetland sheepdogs, German shepherds, and Siberian huskies are predisposed.
- There are no internal manifestations of disease except in very rare "potential" crossover cases that, in time, become more consistent with SLE.
- The initial lesion is an area of depigmentation or erythema that slowly progresses to loss of the normal cobblestone appearance of the nasal planum and eventual development of erosions, ulcers, and crusts.

- The planum nasale is the area most commonly affected, although lesions have been noted on the eyelids, lips, foot pads, and concave surface of the pinnae and in the oral cavity.
- Profuse hemorrhage may occur following minor trauma to the planum nasale.
- Sunlight exacerbates the lesions and may play a role in the pathogenesis of DLE.

Systemic Lupus Erythematosus

- Collies and Shetland sheepdogs are predisposed.
- SLE is a multiorgan disease with dermatologic manifestations in 32% to 54% of cases.
- Cutaneous signs associated with SLE include ulcerative stomatitis, seborrhea, mucocutaneous ulceration, foot pad ulceration, panniculitis (lupus profundus), urticaria, and purpura.
- Non-cutaneous signs of SLE (see Chapter 24) include polyarthritis, fever, glomerulonephritis, hemolytic anemia, thrombocytopenia, polymyositis, neurologic signs, pleuritis, myocarditis, and lymphadenopathy.

Exfoliative Cutaneous Lupus Erythematosus

- This hereditary disease (autosomal recessive) is also known as *lupoid dermatosis* of German shorthaired pointers. It usually occurs in the first year of life.
- It is characterized by localized to generalized scale with follicular casting and alopecia. Pruritus is minimal. The course may wax and wane.
- Dogs may also have blood dyscrasias, joint disease, and features of sebaceous denitis.

Vesicular Cutaneous Lupus Erythematosus

- This is also known as *ulcerative dermatosis* of collies and Shetland sheepdogs and was previously thought to be a variant of dermatomyositis. It has an adult onset.
- Lesions are annular, polycyclic, and serpiginous (wavy, indented) ulcerations and are located primarily in the inguinal and axillary regions.

Canine Lupoid Onychitis

- This is primarily a disease that affects the claw with "lifting" of the nail due to separation from the basement membrane. Lesions may also affect the tail and planum nasale.
- Dogs rarely experience associated pain and seem to be more comfortable once the nail has fallen off.
- The nail will often remain misshapen and fail to form a more normal appearing nail.
- Pyonychia is absent.

Diagnosis

Discoid Lupus Erythematosus

- Direct smears are non-diagnostic.
- CBC, serum biochemical profile, and urinalysis are non-diagnostic.
- ANA test is positive in 5% of cases of DLE. This may indicate those animals with the potential for conversion to SLE that therefore should be closely monitored.
- Histopathologic findings include a lichenoid interface dermatitis composed primarily of lymphocytes and plasma cells, thickened basement membrane zone, hydropic degeneration of the basal cell layer, apoptotic keratinocytes in the lower layers of the epidermis, pigmentary incontinence, and excess of dermal mucin.
- IFA and IPS are positive, with a granular or rough band of immunoglobulin and/or complement deposited at the basement membrane zone.

Systemic Lupus Erythematosus

- Direct smears are non-diagnostic.
- CBC, serum biochemical profile, and urinalysis may show a variety of abnormalities, depending on the non-cutaneous organs involved (see Chapter 24).
- ANA test is positive in 85% to 90% of cases.
- The negative titers in 10% to 15% of ANA tests may be a laboratory "fault" because of the current inability of most laboratories to test for extractable nuclear antigens.
- The lupus erythematosus cell preparation is unreliable and not routinely used in veterinary medicine.
- Histopathologic findings include epidermal and dermal lesions similar to those seen in DLE and may include leukocytoclastic vasculitis and mononuclear panniculitis.
- IFA and IPS are positive, with a band of staining at the basement membrane zone of the skin and involved dermal and subcutaneous vessels.

Exfoliative Cutaneous Lupus Erythematosus

- Histopathology reveals hyperkeratosis, basal cell degeneration, and apoptotic epidermal cells, as well as features of sebaceous adenitis.

Vesicular Cutaneous Lupus Erythematosus

- Histopathology reveals an interface dermatitis and folliculitis composed predominantly of lymphocytes with vesiculation of the dermal-epidermal junction.

Canine Lupoid Onychitis

- This is a clinical diagnosis. Histopathology is rarely diagnostic.

Treatment

Lupus Erythematosus Complex

- To treat SLE, give prednisone, 1 mg/kg PO q12h.
- Systemic glucocorticoids are rarely necessary in DLE; thus, only use them in severe DLE that is unresponsive to other therapies.

- Apply topical glucocorticoids to the planum nasale. This may be the only form of corticosteroid needed to treat and control mild cases.
- Topical tacrolimus (Protopic 0.03% or 0.1%) may be beneficial.
- Apply topical sunscreens to the planum nasale during periods of sun exposure.
- Administer vitamin E 400 IU PO q12h. Give 2 hours before or after a meal.
  - Vitamin E has a 30- to 60-day lag phase, and therapy usually is maintained for the life of the dog.
  - No side effects have been reported in dogs. Problems noted in humans include thrombophlebitis, hypertension, fatigue, cardiac disease, and diabetes mellitus.
- Tetracycline and niacinamide in combination may be effective. In dogs over 10 kg, the initial dosage is 500 mg of each drug PO q8h, and in dogs under 10 kg, the dosage is 250 mg of each drug PO q8h. Once response is noted, the dosage can be decreased to q12h and then to q24h. Side effects include anorexia, vomiting, and diarrhea.
- Severe cases may require the use of azathioprine, as described for the pemphigus complex (see "Prednisone with Azathioprine").
- Gold salts are contraindicated in SLE because of the potential for both the drug and the disease to produce glomerulonephritis.
- In severe cases of anemia and thrombocytopenia, splenectomy may be indicated (see Chapter 25).
- Trental (pentoxifylline) has been helpful in rare cases, especially for lupoid onychitis.
- Essential fatty acid supplementation may be used as an adjunct therapy for all of the disorders.

VASCULITIS

Etiology

- Most of the recognized vasculitic syndromes are caused by deposition of immune complexes within vessel walls. Complement components are then activated and act as chemoattractants for neutrophils. Neutrophils infiltrate the vessel wall and release lysosomal enzymes such as elastase and collagenase, which damage the vessel wall. Thrombosis, occlusion, hemorrhage, and necrosis may develop. Blood flow turbulence and hydrostatic tension may also play a role in the immunopathogenesis of vasculitis.
- Inciting causes of vasculitis are varied and include allergic diseases, bacterial and viral infections, drug reactions, chemicals, neoplasia, SLE, rickettsial diseases, polyarteritis nodosa, rheumatoid arthritis, and cold hemagglutinin disease. (See Chapter 153 for more information on vasculitis.)

Clinical Signs

- Vasculitis is a polysystemic disease.
- Dermatologic signs include petechiae, ecchymoses, hemorrhagic bullae, ulcerations, urticaria, and edema.
- Non-cutaneous signs are similar to those described for SLE.

Diagnosis

- Direct smears are non-diagnostic.
- Diascopy, the application of a glass slide pressed to an erythematous lesion, may help rule out vascular fragility. The lesion clears if the erythema is due to vascular dilatation but remains if hemorrhage or vascular leakage has occurred.
- CBC, serum biochemical profile, and urinalysis changes are dependent on the underlying etiology and on the target organ system.
- ANA test is negative unless SLE is the underlying cause of the vasculitis.
- Histopathologic findings include leukocytoclastic vasculitis, fibrinoid degeneration of vessel walls, thrombosis, and endothelial swelling.
- IFA and IPS may be positive in early lesions, with immunoglobulin and complement detected in and around vessel walls. Affected animals have high levels of circulating immune complexes and low levels of complement.

Treatment

- Treatment is similar to that described for the pemphigus (see "Treatment" under "Pemphigus Complex").
- Do not use glucocorticoids if there is an infectious etiology.
- Dapsone (Jacobus), 1 mg/kg PO q24h, may be used in cases of idiopathic neutrophilic vasculitis.

Chapter 49

Necrotizing Skin Diseases

Gail A. Kunkle

Necrotizing dermatitis refers to those skin conditions in which there is death of tissue. With many cases of necrotizing dermatitis, eschar (slough) formation and ulceration is often the visible clinical sign, and it occurs when there is cell death, especially within the epidermis and the hair follicles. In other necrotizing skin diseases, the tissue destruction may arise in the dermis or even from compromise of deeper vessels. In these cases the first clinical signs may be discoloration, swelling, or coolness to the skin followed later by cutaneous ulceration. Causes of necrotizing skin disease are categorized in Table 49-1.

▼ ***Key Point*** Dependent on the depth of necrosis or the percentage of surface area which is ulcerated, necrotizing dermatoses can be life-threatening.

An overview of necrotizing dermatitis will be presented in this chapter, followed by discussion of the specific diseases that cause the disorder.

CLINICAL SIGNS

Necrotizing skin diseases are characterized clinically by well-defined areas of devitalized skin (eschar), which may vary from pinpoint sized to involving of a large portion of the skin surface. The area may be discolored, ranging from dark red to purple to yellow to black. There may be swelling and even gas production within the tissues. In time, the devitalized skin develops into a thick adherent crust, revealing deep ulceration if removed. Common sequelae are systemic signs of toxicity.

PRINCIPLES OF DIAGNOSIS

Significant necrosis of the skin is a dermatologic emergency and may result in death; thus, initiate the diagnostic approach to necrotizing skin disease as quickly as possible.

Early identification of an underlying cause and specific treatment generally allows a better clinical outcome. The diagnostic approach should be as thorough as possible from the outset to increase the chance of a definitive diagnosis.

▼ ***Key Point*** Specific diagnosis is best made by routine histopathology from representative primary skin lesions and/or tissue samples adjacent to necrosis, in conjunction with a careful history and thorough physical examination.

History

- Identify or exclude several of the potential causes of necrotizing dermatoses.
- Record a thorough drug history and take note of environmental factors.
- Record a careful timetable of events in addition to the owner's description of the earliest cutaneous lesions and their temporal relationship to any noted systemic signs.

Physical Examination

- Thoroughly examine all of the skin, including the inside of the ears, the oral cavity (and other mucosal surfaces), and haired as well as non-haired skin.
- Note any primary lesions.
- Look for secondary lesions and for evidence of how they may have developed.
- Palpate all peripheral lymph nodes for enlargement.
- Take the body temperature.
- Perform a general physical examination, including examination of the eyes, auscultation of the thorax and palpation of the abdomen, to evaluate for systemic signs.

Serum Biochemical Profile, Urinalysis, and Complete Blood Count

- Evaluate these in animals with systemic signs such as anorexia, fever, and depression. This minimum database may even be justified in animals with extensive necrotizing dermatitis but without overt clinical signs of systemic disease.
- Use these as baseline information when progressive disease is suspected.

Table 49–1. CLASSIFICATION AND CAUSES OF NECROTIZING DERMATOSES

Category	Cause
Vasculitis	Sepsis Systemic infectious disease Drug-induced Neoplasia Immune-mediated Focal (rabies vaccination) Post-vaccination ischemic dermatopathy Dermatomyositis Idiopathic
Neoplasia	Squamous cell carcinoma (see Chapter 30) Mast cell (see Chapter 28) Lymphoma (see Chapter 27) Lymphatoid granulomatosis Other tumors (see Chapter 30)
Drug-induced	Antibiotics Biologicals Barbiturates Phenylbutazone Gold salts
Toxic epidermal necrolysis	Drug-induced Systemic disease
Erythema multiforme	Neoplasia Idiopathic
Superficial necrolytic dermatitis	Glucagonoma Hepatopathy
Environmental	Contact irritant Snake bite Spider bite Radiation Burns Frostbite Decubitus ulcers
Immune-mediated	Systemic lupus erythematosus (see Chapter 24) Bullous pemphigoid (see Chapter 24) Pemphigus complex (see Chapter 24) Cold agglutinin disease Vasculitis Vesicular cutaneous lupus erythematosus
Infectious	Bacterial cellulitis (see Chapter 38) Deep fungal infection (see Chapter 40)
Vascular compromise	Thrombovascular necrosis Mechanical occlusion Diabetes mellitus (see Chapter 34)

Tests for Systemic Immune-Mediated Diseases

- When clinical signs suggest systemic disease, perform antinuclear antibody (ANA) testing of serum to assess the presence or absence of antibodies directed against multiple nuclear antigens.
- Other immune tests such as Coombs testing and cryoglobulin identification may be indicated in cases in which specific diseases are suspected.
- See Chapter 24 for further discussion of testing for systemic immune-mediated diseases.

Skin Biopsy

- Skin biopsy is usually a critically important diagnostic tool in necrotizing skin diseases (see Chapter 37). Sampling of early primary lesions is most likely to be rewarding. When vasculitis is suspected, obtain deep wedge biopsies for diagnosis—deep tissue may not be obtained if only punch biopsy tissue specimens are collected.
- Collect lesions that are primary eruptions and/or skin immediately adjacent to necrotic skin.
- Use formalin as a fixative and obtain representative tissue samples from various types of lesions. A pathologist familiar with dermatopathology often can determine if systemic or topical disease is present.
- Most pathologists now use formalin-fixed tissue for immunohistochemistry for the presence of antibody. However, absence of antibody does not rule out autoimmunity as a cause.

Skin and Blood Cultures

- Evaluate the patient for infection by culturing the skin for bacterial (aerobic and anaerobic) and fungal agents.
- For systemic diseases, blood cultures may be indicated.

Other Diagnostic Evaluations

- Evaluate rickettsial serum titers and other disease-specific hematologic tests as indicated.
- Perform liver function tests (pre- and post-prandial serum bile acids) and abdominal ultrasound (to evaluate the liver and pancreas) to assess a suspected case of superficial necrolytic dermatitis.
- Radiography and ultrasonography are useful if cutaneous lesions are suspected to be secondary to malignancy or systemic disease.
- In rare cases, response to therapy or removal of a suspected inciting drug confirms the diagnosis.

PRINCIPLES OF TREATMENT

▼ ***Key Point*** Therapy is most effective when a specific cause is identified; treatment can then be focused on the elimination or modification of the underlying cause.

Cutaneous necrosis is best managed aggressively with treatment directed against a definitive cause. If there is a possibility that drugs are implicated, discontinue all drugs until a definitive or probable diagnosis is established. Secondary infection is likely and best treated with a broad-spectrum antibiotic (preferably one that the patient has not previously received). Toxins associated with tissue necrosis can have systemic effects; therefore, debride tissues and flush frequently with sterile

saline. When the cause cannot be identified, supportive care is the mainstay of treatment. Hydration and provision of a high-quality protein diet are important aspects of therapy.

SPECIFIC NECROTIZING DERMATOSES

Vasculitis/Vasculopathy

Etiology

Vasculitis is an inflammatory process that occurs within blood vessel walls and that can lead to necrosis of the vessels and subsequent death of the adjacent tissue. Histopathologic evidence of vasculitis can be subtle and transient. When surrounding tissues suggest vascular compromise or there is vessel wall damage without cells, many pathologists refer to this as vasculopathy. Acute cutaneous vasculitis is most likely to result in necrotizing skin signs including hemorrhage (ecchymoses or purpura), hemorrhagic bullae, necrosis (eschar), and punched out ulcers. Hemorrhage can be confirmed clinically by diascopy (the skin remains discolored when pressure is applied with a glass slide. In comparison, erythema blanches under pressure). Chronic vasculitis or cell-poor vasculitis (vasculopathy) is more likely to present with ischemic changes such as alopecia, scaling, hyperpigmentation and some erythema. Both often involve the ears, tail tip, face, and extremities. Cutaneous vasculitis and vasculopathies are rarely primary in the dog. The list of secondary causes is quite extensive; for prognosis and treatment purposes it is useful to separate these into infectious and non-infectious etiologies. In spite of an extensive search for an underlying cause, many cases are idiopathic.

Non-immunologic Causes

- Necrotizing vasculitis can be seen with a variety of infections caused by bacteria, viruses, disseminated fungi, and tickborne organisms such as Rickettsia rickettsii. Bacteria may directly invade the vessel walls, especially with sepsis. Other infections such as E. coli can produce toxins that result in specific signs of vasculopathy as seen in the cutaneous and renal glomerular vasculopathy of greyhounds.
- Neoplasia can result in vessel wall necrosis through toxin production or direct invasion of the vessel wall by neoplastic cells.
- Specific drugs can induce lesions of vasculitis in animals; the antifungal drug, itraconazole, at a dosage of 5 mg/kg q12h PO has been observed to cause vasculitis in some dogs.

Immunologic Causes

- With autoimmune disease immune complex deposition may occur in vessel walls. Antibodies or cytotoxic cells may attack components of the vessel walls in other connective tissue conditions.
- Focal cutaneous vasculitis has been reported at the site of rabies vaccination. This is usually a deep panniculitis, and the cutaneous clinical sign most often is alopecia instead of necrosis. Similar lesions may develop later at sites distant from the site of vaccination.
- Post-vaccination ischemic dermatopathy and familial dermatomyositis in the acute stages may exhibit erosions or ulcerated lesions on the extremities in association with vasculitis. However, in the majority of these cases the signs are more chronic and are evidence of a vasculopathy.

Clinical Signs

- Vasculitis signs usually consist of necrosis and ulceration. These commonly occur on the pressure points, foot pads, pinnae, and extremities. Mucocutaneous ulcerations may be present as well as fever, lymphadenopathy, anorexia, and depression. Acute signs are more often necrotic or erosive lesions whereas chronic signs may show alopecia and scarring.

Treatment

- Vasculitis/vasculopathy is best managed by treatment of the underlying disease. Unfortunately, a specific cause of vasculitis/vasculopathy cannot be identified in a significant number of cases.
- If sepsis or generalized bacterial, fungal, or rickettsial disease is identified, treat the infectious agent.
- If the vasculitis is drug induced, discontinue the offending drug immediately. Corticosteroids at anti-inflammatory dosages (prednisone or prednisolone, 1.1 mg/kg q12–24h PO) are advocated by some for the management of drug-induced vasculitis.
- If immune complexes are being deposited in vessel walls, give immunosuppressive doses of glucocorticoids (2–4 mg/kg q12–24hr PO) or other drugs.
- Corticosteroids may be beneficial in some cases of vasculitis/vasculopathy. Other cases are self-limiting. In some, alternative treatments may be beneficial. Pentoxyfylline (10–15mg/kg q8h PO) has a wide range of properties, few side effects, and can be used for successful management in idiopathic cases. Dapsone (Avlosulfone, Jacobus) (dogs only) as well as sulfasalazine reportedly have been effective. The initial dosage of dapsone is 1 mg/kg q8–12h PO; when the disease is controlled, gradually reduce the dosage. Both of these drugs have potential side effects, and should be used accordingly.

Neoplasia-Related Skin Necrosis

- Neoplasia can cause skin necrosis and cutaneous ulceration through a variety of mechanisms. As mentioned previously, neoplasia can cause vasculitis.

Through release of necrosis factors generated by tumor cells, there may be local death of tissues. Also, the encroaching growth of a rapidly advancing lesion may cause circulatory compromise, leading to cutaneous tissue necrosis. There are several neoplastic conditions that may result in dermal necrosis, including cutaneous lymphoma.

Clinical Signs

- Clinical signs depend on the type and location of the tumor as well as the stage of the disease. In epidermotropic lymphoma and in some cases of cutaneous lymphoma, ulceration and necrosis of the tissues at the mucocutaneous junctions and inside the oral cavity may be seen with or without well-defined tumors. In other cases of cutaneous lymphoma, multifocal cutaneous necrotic lesions may occur without mucocutaneous lesions. In lymphomatoid granulomatosis (angiotropic lymphoma) neoplastic cells are noted around and within the walls of vessels with the result of ischemic necrosis.

Treatment

- Neoplasia treatment depends on the type of tumor, its potential for metastasis, and its biologic behavior. Surgical resection is indicated for solitary lesions. Treatment of other tumors should be based on current recommendations for the individual type of neoplasia. (See Chapters 27–30.)

Drug-Induced Necrosis

- Drug-induced necrosis of the skin followed by ulceration may occur with various drugs. Hypersensitivity may be responsible in many of these cases, but proving this can be difficult. Vesiculobullous drug eruptions may precede ulceration, and purpura may occur before there is apparent tissue death.

Clinical Signs

- Drug-induced necrosis of the skin can cause a wide variety of clinical signs and can mimic almost any condition.
- When this is due to a systemically administered drug, the cutaneous lesions frequently start out focally but rapidly progress to generalized. *Fixed drug eruption* is an exception to this because on subsequent exposures it always occurs in the same local area. Fixed drug reaction can result in focal ulceration. Most drug eruptions begin with generalized erythroderma or erythematous macules, followed by vesiculation and then necrosis or ulceration of the skin. These eruptions may occur during the first exposure to a drug. If they occur with first exposure, they do not usually develop clinically until after 5 to 7 days of drug administration.
- Drug reactions to topically applied drugs can occur if the animal has an idiosyncratic reaction or, more often, if prior exposure has induced hypersensitivity. Contact allergic dermatitis can be the result of a topical drug, and extensive ulceration can occur, especially if the diagnosis is not made early.

Treatment

- For treatment of drug-induced necrosis, discontinue the offending drug immediately. New lesions may continue to develop after discontinuation of the drug. If the adverse effects resolve and are known to be dosage dependent, resume therapy at a much lower dosage if the primary disease mandates continuation of the drug. In most instances, it is preferable to substitute a different drug and to avoid giving the suspect drug to the animal in the future. The efficacy of corticosteroids, both at immunosuppressive and at anti-inflammatory levels, for drug reactions is highly controversial. Assess each case individually for potential advantages and disadvantages.

Toxic Epidermal Necrolysis and Erythema Multiforme

Toxic epidermal necrolysis (TEN) and erythema multiforme (EM) are both necrotizing skin diseases most often caused by drugs. These conditions may also be the result of systemic diseases such as cholangiohepatitis, hepatic necrosis, and endocarditis. Other etiologies include infections, immune-mediated diseases, neoplasia, and idiopathic causes. Although they may have similar etiologies, the histopathology and clinical course of TEN and EM are often quite separate. Some of the drugs that have been implicated in TEN and EM in dogs and cats include levamisole, penicillins, cephalosporins, sulfonamides, gold salts, 5-fluorocytosine, and antiserum.

Toxic Epidermal Necrolysis

- TEN may mimic EM in its early signs, but it is a much more serious disease. The histological lesion of TEN is full thickness coagulative necrosis of the epidermis which may extend into the hair follicles. In early lesions and prior to secondary infection the dermis is not necrotic and inflammation is minimal. In this way TEN can be differentiated from chemical or thermal injuries if the lesions are biopsied early.

Clinical Signs

- Eventually full-thickness necrosis and sloughing of the skin occur, often involving large areas of skin. The clinical appearance can mimic a burn. There may be a positive Nikolsky sign in which normal-appearing skin can be separated away from the underlying dermis with firm manual pressure. The patient usually shows systemic signs of malaise and fever.

▼ ***Key Point*** Because of the extensiveness of TEN, it is crucial to pursue an early diagnosis and to eliminate the inciting cause as quickly as possible while providing aggressive supportive therapy.

Treatment

- Toxic epidermal necrolysis represents a true dermatologic emergency. Immediately discontinue any suspect drugs and search for systemic disease or neoplasia. Once full-thickness necrosis of the skin begins, start aggressive supportive care with intravenous (IV) fluids such as lactated Ringer's solution to replace estimated fluid loss. Keep affected tissues clean and debrided; and cover with a topical cream such as silver sulfadiazine (Silvadene, Marion) to decrease evaporation from large denuded areas. Secondary infection can result in sepsis and hypoproteinemia may be a concern when large areas are affected. Corticosteroids (prednisone or prednisolone, 2.2 to 4.4 mg/kg q12h PO initially, and then taper the dosage) are recommended by some, especially early in the course of the disease.
- The prognosis is guarded, and in spite of removal of the causative agent or disease, TEN can continue to progress and may be fatal.

Erythema Multiforme

- EM tends to be less severe than TEN. Histological examination generally shows single cell necrosis of epidermal cells at all levels of the epidermis. There often is an inflammatory infiltrate noted, even in early lesions. Occasionally, in more severe forms of EM, there can be an overlap of the histopathological findings with a confluence of cells dying, mimicking TEN.

Clinical Signs

- Multifocal clinical lesions may appear papular, macular, vesicular, bullous, or target-like, with central areas of redness surrounded by an erythematous ring. Cutaneous lesions usually progress to multifocal ulcerations and these are often in arciform or polycyclic conformations. Mucocutaneous areas are generally affected.

Treatment

- Erythema multiforme is treated by discontinuation of any potential causative drugs as soon as possible and giving supportive care. Symptoms may continue for several days past withdrawal of the offending agent, and pain and scarring may occur.
- The prognosis for survival is better if the primary causative condition is not life-threatening.
- Although not as serious a disease as TEN, the initial prognosis for EM is guarded. The disease is progressive in some dogs and difficult to control in others.

Superficial Necrolytic Dermatitis

- Superficial Necrolytic Dermatitis (SND) *(necrolytic migratory erythema [NME], metabolic epidermal necrosis [MEN], and hepatocutaneous syndrome)* is an uncommon canine skin disease which is a manifestation of a poorly defined error in metabolism. The histologic picture is similar to glucagonoma syndrome in humans. The histopathological findings include a marked parakeratotic epidermis with inter- and intracellular edema, keratinocyte degeneration in the upper epidermis, and hyperplastic basal cells, forming a characteristic "red, white, and blue" histological lesion diagnostic for this syndrome.
- In a recent retrospective study affected SND dogs had a high frequency of chronic phenobarbital usage administered for idiopathic epilepsy. Liver enzyme values, especially alkaline phosphatase, are often elevated.
- Some cases (<10% of cases reported in the literature) have had glucagonomas (i.e., endocrine tumor of the pancreas similar to the disease in humans).
- Mean plasma amino acid concentrations for dogs with SND reportedly are lower than normal dogs or dogs with hepatitis, some amino acids are <20% of the normal values. A metabolic hepatopathy with increased hepatic catabolism of amino acids is hypothesized as the cause of this syndrome, but the exact metabolic etiology is still undefined.

Clinical Signs

- The clinical findings in SND are erythema, crusting, exudation, and ulceration of the skin of the footpads, mucocutaneous junctions, and pressure points. Classically there is crusting, ulceration, and fissuring of the footpads with some patients being reluctant to walk due to pain. Although this condition may clinically mimic EM, the footpad lesions are more suggestive of SND. Systemic SND signs are quite varied and may include clinical signs of concurrent diabetes mellitus and/or hyperadrenalcorticism.

Treatment

- Treatment with dietary supplementation of protein (high protein diets or egg yolks) or amino acid supplements (e.g., Promod 1 scoop/10 kg), fatty acids, and zinc have generally not been rewarding. Intravenous solutions of amino acids (e.g., Aminosin 500 ml weekly) have caused transient improvement in some cases.
- There is frequently a secondary bacterial and/or yeast infection of the lesions (especially interdigitally). Recognition and control of the infection (topical and systemic antimicrobial therapy) provides significant benefit (and temporarily improved quality of life) to some dogs although the primary disease will progress.

- The medium- to long-term prognosis is generally poor, and an outcome of euthanasia is common, often due to the painful feet of the patient. The reported mean survival time from diagnosis is less than 6 months, but some dogs live for months with waxing and waning of their symptoms.

Environmental Injury of the Skin

Environmental factors can cause necrosis and ulceration of the skin. The clinical signs of environmental injuries of the skin vary depending on the specific etiology and location of exposure.

Contact Irritant Chemicals

- Contact irritant chemicals can caustically burn or necrose the skin after topical exposure. The list of primary irritants is extensive and includes soaps, detergents, insecticidal sprays, fertilizers, and caustics such as strong acids or alkalies. Medications and hypertonic solutions delivered extravascularly can also result in necrosis of the underlying tissue and the skin.

Clinical Signs

- Lesions of cutaneous necrosis can occur wherever the skin was exposed to the irritant. Usually the feet, scrotum, and ventral abdomen are involved if the animal walked or lay down on the causative agent. The muzzle or oral cavity may be involved if the animal tried to remove the compound by licking.

Treatment

- Treatment requires removal of the irritant followed by supportive care.

Snake Bite

- Snakes, including pit vipers (copperhead, cottonmouth, and rattlesnake) and coral snakes, produce venoms that alter the integrity of blood vessels, blood cells, and coagulation; affect the nervous system; and result in necrosis at the site of envenomation.
- Snake bites most frequently occur during the warmer months in geographic areas with an indigenous population of venomous snakes.

Clinical Signs

- The face and extremities are the common sites of involvement. Initial signs are localized soft tissue swelling that spreads rapidly. Local hemorrhage occurs, followed by necrosis of tissue and sloughing.

Treatment

- Treatment of snake bite varies with the severity of the clinical signs, location of the bite, type of snake, and length of time since the bite. Initially, immobilize the lesion and keep the patient quiet. Application of tourniquets is controversial, as is glucocorticoid therapy. When polyvalent antivenom (Antivenin, Fort Dodge) is indicated, give one vial slowly IV as soon as possible after the bite and repeat injections as necessary. Monitor the patient closely for anaphylaxis. Broad-spectrum antibiotics are generally indicated because both anaerobic and aerobic infections are often sequelae to the bite. Keep the lesions clean and debride wounds regularly.

Spider Bite

- Spiders (e.g., brown recluse and brown spider) cause necrotizing skin lesions by injection of a potent dermonecrotic toxin into the tissue when they bite. The enzymes in the venom and the immunologic response of the host both play a role in dictating the clinical response.
- These toxins can continue to damage the surrounding tissue for an extended time after the bite.

Treatment

- Excise the bite wound if the lesion is identified early as a bite from one of these spiders.
- Corticosteroids and antivenom do not appear to reduce local necrosis.
- When systemic signs are present, corticosteroids combined with supportive care are beneficial. Intravascular hemolysis and renal failure are possible sequelae.

Radiation Injury

- Radiation injuries may be acute or chronic, and necrosis and ulceration of the tissue can occur days to weeks after exposure.
- Radiation injury occurs in the anatomic area previously exposed to radiation.

Clinical Signs

- The clinical signs include erythema of the skin, moist desquamation, pigmentation or change in hair color, and loss of hair.

Treatment

- Treat acute radiation damage with gentle topical cleansing, followed by topical creams. Use medications to control pain as needed.
- Chronic radiation injury and areas of cutaneous atrophy caused by acute damage may later necrose and slough. This condition usually is progressive. Supportive care is the primary treatment.

Burn Injury

- Burn injuries can result from heat, sun, flames, scalding liquids, friction, and electricity. The history usually identifies the source of injury.

- Burns can cause significant necrosis and loss of skin. Depending on the depth of the burn, necrosis may involve only the epidermis or may extend deeper into the tissues.

Clinical Signs

- Clinical signs usually include pain, erythema, and eschar formation with full-thickness burns. Deeper burns may result in shock, electrolyte and protein disturbances, and life-threatening secondary bacterial infection.

Treatment

- Treat burns according to their depth (partial- or full-thickness) and extent over the body. Apply intensive and aggressive topical therapy in severe cases. Give medications such as morphine to control pain. Cleanse, debride, and cover burns with an antibacterial cream (e.g., Silvadene or Marion) (see Chapter 56 for management of open wounds). Fluid replacement and protein supplementation are important. Because secondary bacterial (e.g., Pseudomonas) infection is common, systemic broad-spectrum antimicrobial drug therapy is essential. Skin grafts may be necessary for extensive full-thickness burns (see Chapter 57).
- The prognosis depends on the extent of the surface area involved.

Frostbite

- Frostbite occurs when exposure to environmental cold results in vasoconstriction so severe that the effects are not totally reversible on rewarming of the tissues.

Clinical Signs

- Frostbite most often results in necrosis and sloughing of the tips of the ears or tail. In the dog, the scrotum can also be affected. Debilitated animals are more susceptible because of immobility and poor circulation.

Treatment

- Frostbite-affected animals usually are presented long after the damage has occurred, and supportive care with debridement may be necessary. In early cases, rapidly rewarm the tissues in water heated to 40–42°C. Whirlpool therapy can be helpful. Medication for pain may be necessary. If self-trauma can be minimized, the lesions are best left uncovered. Administer systemic antibiotics to manage secondary infection.

Decubitus Ulcers

- Decubitus ulcers are a form of vascular compromise related to environmental conditions, characterized by loss of soft tissue cushion over bony prominences.
- Decubitus ulcers usually are secondary to pressure necrosis in recumbent animals.

Clinical Signs

- Pressure points, especially stifles, elbows, hocks and hips, are common sites. These lesions are well demarcated, with full-thickness necrosis usually extending to the underlying musculature.

Treatment

- Decubitus ulcers are best treated by making the patient ambulatory, but if this is not possible, then supportive care is required. Clean and rotate the patient often. Soft bedding or a water mattress is useful. Keep ulcerated areas free of fecal and urine contamination. If possible, cover affected areas with clean dressings. Tie-over bandages are very useful for these lesions (see Chapter 56). A wide variety of agents are available for topical use. In some cases, surgical debridement and reconstruction are indicated (see Chapter 56).

Immune-Mediated Dermatoses

- Immune-mediated dermatoses are one group of conditions that may present with substantial areas of cutaneous necrosis. In general these diseases have blister (or pustule) and cleft formation, followed by separation within the viable skin. Ulceration and erosion then occur as this portion of the skin dies and lifts off.
- Autoimmune diseases that affect the skin include systemic diseases, such as systemic lupus erythematosus, cold agglutinin disease, and immune-mediated vasculitis, and the more cutaneous conditions of bullous pemphigoid and pemphigus complex. These are discussed elsewhere (see Chapter 24).

Clinical Signs

- Immune-mediated dermatoses usually cause acute lesions that may include vesicles, bullae, ulcers, hemorrhagic nodules, and erosions. The mucocutaneous junctions may be involved. The animal is generally middle-aged or older and may have systemic signs. See Chapter 24 for discussion of autoimmune diseases.

Treatment

- Treatment depends on the type of immune-mediated disease and the severity and extent of the lesions. Initially, give systemic corticosteroids at immunosuppressive dosages (prednisone or prednisolone at 2.2 to 4.4 mg/kg q12–24h PO for dogs; approximately twice that dosage for cats). Other immunosuppressive drugs such as azathioprine (Imuran, Burroughs-Wellcome) [dogs only], cyclophosphamide (Cytoxan,

Bristol-Myer), and chlorambucil (Leukeran, Burroughs-Wellcome) may be necessary in severe or refractory cases.

Infection-Induced Necrosis

- Infection from deep bacterial or fungal invasion can lead to local areas of cellulitis or abscessation and subsequent necrosis of surrounding tissues.
- Both streptococcal and staphylococcal infections n the dog can result in a rapidly progressing deep necrotizing fasciitis. Although staphylococcus can produce exfoliative toxins that result in a more superficial peeling of the skin (staph scalded skin syndrome), staphylococcus and streptococcus can produce exotoxins similar to those that produce toxic shock syndrome in humans.

Clinical Signs

Canine patients with necrotizing fasciitis will have intense pain, swelling, and necrosis of the fascia, fat and overlying skin. These patients can rapidly deteriorate and die if aggressive treatment is not elected.

- Embedded foreign bodies may result in central necrosis of the tissue due to release of neutrophilic enzymes. The lesion ruptures and drains externally at the most necrotic site.
- Infection can also cause sepsis and vasculitis resulting in necrolytic dermatitis.

Treatment

- Treat by administering systemic antimicrobial agents against the offending etiologic agent, based on culture and sensitivity testing. Establish and maintain local drainage.

Vascular Compromise

- Vascular compromise can occur whenever there is interruption of the normal circulation to an area of tissue. This is involved in many of the aforementioned conditions and also can be the result of a thrombus, vasculopathy, or mechanical or pressure constriction (e.g., elastic bands).
- There is a unique thrombovascular problem in some dachshunds that affects the dependent portion of the aural pinnae.
- In diabetes mellitus, vasculopathies may occur rarely in the extremities of dogs and cats. In these cases a chronic ulcerated lesion on an extremity usually fails to heal even with symptomatic treatment.

Clinical Signs

- Vascular compromise can lead to sloughing or ulcerated lesions. In mechanical occlusion of the circulation, the necrotic lesion is distal or beneath the obstruction. For example, an elastic band tightened around the tail over time causes underlying tissue death and sloughing of the distal tail.

Treatment

- Treat vascular compromise based on the etiology and the location of the necrosis. In thrombovascular necrosis of the ears, resect all affected tissue. When mechanical occlusion causes incomplete circulation to the tissue, remove the mechanical device. In diabetes mellitus, the optimal approach to the vasculopathy is to carefully monitor and control the diabetes.

Keratinization Defects

Kenneth W. Kwochka

PRIMARY DEFECTS OF KERATINIZATION

Primary defects of keratinization are dermatoses that are manifested clinically by localized or generalized excess scale formation. The scale may be formed from the interfollicular epidermis or may emanate from hair follicles as comedones and follicular casts. Histologically, the most striking abnormalities involve the keratinizing structures of the body including the epidermis, hair follicle outer root sheath, and hair cuticle.

▼ ***Key Point*** Cutaneous scaling of dogs is a very common clinical sign. In most cases, it is not due to a primary keratinization defect but is secondary to other dermatologic diseases. Common conditions causing secondary scaling include demodicosis, scabies, cheyletiellosis, atopic dermatitis, adverse food reaction ("food allergy"), flea allergy, pyoderma, yeast infection, dermatophytosis, hypothyroidism, hyperadrenocorticism, sex hormone abnormalities, pemphigus foliaceus, mycosis fungoides, and environmental influences. The veterinarian must determine whether the scaling is secondary to one of these conditions or associated with a primary keratinization defect. A primary keratinization defect is never diagnosed until the secondary causes of scaling have first been considered.

In this chapter, an overview of the etiology, clinical signs, diagnosis, and treatment of keratinization disorders is presented, followed by a description of each specific disease.

Etiology

- For most of the diseases classified as primary keratinization defects, the pathophysiology is unknown. For others, the cause is known and the primary pathophysiology involves a defect in the keratinizing epithelium or the cutaneous glandular function.

Clinical Signs

- Disorders of keratinization are characterized clinically by mild-to-severe dry, waxy, or greasy scales. Some degree of "seborrheic odor" may be associated with the skin condition. Because hair follicles and glandular structures may also be involved, it is not unusual to see comedones and follicular casts. Comedones are blackheads resulting from dilation of hair follicles with keratin plugs. Follicular casts are tightly adherent scales around hair shafts, giving the so-called candle wax appearance. Common secondary findings include alopecia, inflammation, crusts, pruritus with secondary excoriations, and pyoderma. Secondary *Malassezia* colonization may also be associated with primary and secondary causes of scaling, especially with greasy scales.

▼ ***Key Point*** Primary keratinization defects are usually hereditary and appear during the first 2 to 3 years of life. A breed incidence for these disorders is known. An observant owner usually indicates that the scaling was present before the development of secondary signs.

Diagnosis

No specific laboratory test exists for definitive diagnosis of a primary keratinization disorder. A combination of factors is used, including age of onset, breed, history, diagnostic elimination of more common secondary causes of scaling, findings on histologic examination of skin biopsies, and response to therapy.

▼ ***Key Point*** Skin biopsy is the most important diagnostic tool for primary keratinization defects (see Chapter 37). Biopsy results not only help make a definitive diagnosis but also help rule out dermatoses associated with secondary scaling.

Take several biopsies from lesions of various ages. Send samples to a veterinary pathologist who specializes in dermatopathology.

Treatment

After a definitive diagnosis of a primary keratinization defect is established, warn owners that the condition is most likely controllable but not curable.

▼ ***Key Point*** Some type of topical and systemic treatment will probably be needed for the remainder of the patient's life.

▼ ***Key Point*** It is imperative to treat any secondary bacterial and/or yeast infections before a decision is made on the type of specific treatment that will be needed for the primary keratinization disorder.

PRIMARY IDIOPATHIC SEBORRHEA

Primary idiopathic seborrhea is the most common chronic keratinization disorder encountered in dogs. Predisposed breeds include cocker spaniels, English springer spaniels, West Highland white terriers, basset hounds, Irish setters, German shepherds, dachshunds, Doberman pinschers, Chinese Shar-Peis, and Labrador retrievers.

Etiology

- In cocker spaniels and Irish setters, at least part of the pathophysiology of scale formation involves hyperproliferation of basal epidermal keratinocytes.

▼ ***Key Point*** Many dogs with primary idiopathic seborrhea will have concurrent dermatoses that contribute to the severity of the cutaneous scale and inflammation.

For example, it is not unusual to see a seborrheic cocker spaniel with concurrent allergic dermatosis and secondary pyoderma and/or yeast dermatitis. When these conditions are diagnosed and treated properly, the remaining scale caused by the primary seborrhea is much less severe and easier to control.

Clinical Signs

- Depending on the breed, clinical signs may range anywhere from dry scaling (seborrhea sicca), to greasy scaling (seborrhea oleosa), to scaling and greasiness with inflammation and pruritus (seborrheic dermatitis), and any combination of these clinical abnormalities on the same animal. Breeds affected with the seborrhea sicca form of idiopathic seborrhea include Doberman pinschers, Irish setters, German shepherds, and dachshunds. Breeds most predisposed to the seborrhea oleosa form include cocker spaniels, English springer spaniels, basset hounds, West Highland white terriers, Chinese Shar-Peis, and Labrador retrievers.

Diagnosis

- A definitive diagnosis of primary idiopathic seborrhea requires a number of different supporting factors, including age of onset, breed, history, diagnostic elimination of secondary causes of scaling, and findings on histopathologic examination of skin biopsy specimens.
- The most important aspect of the diagnostic plan is a full investigation for secondary causes of scaling. The primary differentials are allergic dermatitis, scabies, dermatophytosis, demodicosis, bacterial folliculitis, *Malassezia* dermatitis, hypothyroidism, and vitamin A–responsive dermatosis. Additional differentials in Doberman pinschers are color-dilution alopecia and adult-onset follicular dysplasia.
- Biopsy samples are usually characterized by orthokeratotic and parakeratotic hyperkeratosis, follicular hyperkeratosis, and dyskeratosis. Often, the follicular abnormalities are more impressive than are the changes in the surface epidermis.

Treatment

Topical Therapy

- As in most primary keratinization disorders, the treatment goal in primary idiopathic seborrhea is to control scale formation, not to cure the disease. Moisturize the skin and haircoat when dry scaling is present. This task is accomplished with twice-weekly moisturizing hypoallergenic shampoos (HyLyt EFA, DVM Pharmaceuticals; Allergroom, Virbac; Micro Pearls Advantage Hydra-Pearls, EVSCO) and frequent moisturizing rinses (HyLyt EFA Bath Oil Coat Conditioner, DVM Pharmaceuticals; Humilac, Virbac) after each shampoo.
- When dry scaling is severe and some keratolytic activity is needed, the treatment usually consists of sulfur and salicylic acid shampoos (SebaLyt and SeboRex, DVM Pharmaceuticals; Sebolux, Virbac; Micro Pearls Advantage SebaMoist and SebaHex, EVSCO) followed by moisturizing rinses. Dietary supplementation with an omega-6 and omega-3 essential fatty acid combination is also beneficial (e.g., DermCaps, DVM Pharmaceuticals).
- Use keratolytic and keratoplastic degreasing shampoos to control the scale and odor associated with seborrhea oleosa. Effective topical agents include coal tar (NuSal-T, DVM Pharmaceuticals; T-Lux, Virbac; LyTar, DVM Pharmaceuticals; Allerseb-T, Virbac), benzoyl peroxide (OxyDex and Sulf OxyDex, DVM Pharmaceuticals; Pyoben, Virbac; Micro Pearls Advantage Benzoyl Plus, EVSCO), and selenium sulfide (Selsun Blue, Ross). If significant bacterial and/or yeast infections are playing a major role in the greasy scaling dermatitis, it is better to use an antibacterial and antifungal shampoo combination (Malaseb Shampoo, DVM Pharmaceuticals;

KetoChlor Shampoo, Virbac) alone or alternated with one of the keratolytic degreasers.

Systemic Therapy

- The synthetic retinoid etretinate (Tegison, Roche) had been effective for idiopathic seborrhea in cocker spaniels, springer spaniels, Irish setters, golden retrievers, and mixed-breed dogs at 1 mg/kg PO q24h. Etretinate has been replaced by acitretin (Soriatane, Roche) at a dosage from 0.5 to 1.0 mg/kg PO q24h. Response is seen within 2 months and consists of decreased scale, odor and pruritus, and softening and thinning of seborrheic plaques. Some dogs have been maintained without signs of toxicity over several months on alternate-day therapy.

▼ ***Key Point*** The synthetic retinoids are associated with teratogenicity. Do not use in breeding animals, and warn clients about the serious potential risks from accidental human ingestion. Other potential side effects include keratoconjunctivitis sicca; leg and joint pain; and mild elevations in cholesterol, triglycerides, and liver enzyme levels. These are usually reversible on discontinuation of therapy or lowering the dosage. Perform Schirmer tear tests and liver panels every 2 to 4 weeks initially and then every 3 months during maintenance therapy. Unfortunately, the synthetic retinoids are prohibitively expensive for most owners.

- Calcitriol (Rocalcitrol, Roche) has been effective for idiopathic seborrhea in cocker spaniels at 10 ng/kg PO q24h. Give the medication as far removed as possible from the main meal of the day to decrease the possibility of hypercalcemia. Response is seen within 2 to 3 months. Continue treatment for life with monitoring of calcium and parathyroid hormone levels.
- Cyclosporine (Atopica, Novartis) at a dosage from 5 to 10 mg/kg PO q24h has been effective for some dogs with severe idiopathic seborrheic dermatitis. It is suspected that these dogs may be those with a strong allergic component to their disease.
- A 7- to 10-day course of prednisone or prednisolone at an anti-inflammatory dose may occasionally be needed during periods of severe inflammation and pruritus in dogs with seborrheic dermatitis.

VITAMIN A–RESPONSIVE DERMATOSIS

Vitamin A–responsive dermatosis is a rare, nutritionally responsive scaling disorder of primarily cocker spaniels. Similar syndromes have been reported in other breeds, including miniature schnauzers, Labrador retrievers, and Chinese Shar-Peis in Europe.

Etiology

This condition is not a systemic vitamin A deficiency but probably represents a local deficiency in the epidermis, a problem with uptake in the skin, a disorder of cutaneous utilization, or a positive pharmacologic effect of high doses on the epidermis.

Clinical Signs

- Vitamin A–responsive dermatosis has clinical signs consisting of refractory generalized scaling, dry haircoat with easy epilation, prominent comedones, and hyperkeratotic plaques with large "fronds" of keratinous material protruding from the follicular ostia. The plaques are usually on the ventral and lateral thorax and abdomen, but the neck and face may also be involved. Other clinical features include a rancid odor from the skin, ceruminous otitis externa, and varying degrees of pruritus. Gordon setters have a dorsal pruritic papular dermatitis that responds partially to antibiotic treatment, but relapses without vitamin A supplementation.

Diagnosis

- Vitamin A–responsive dermatosis is characterized clinically by an early age of onset of refractory generalized scaling with ventral follicular hyperkeratosis and hyperkeratotic plaques with large "fronds" of keratinous material protruding from the follicular ostia in cocker spaniels. Gordon setters have a dorsal pruritic papular dermatitis that responds partially to antibiotic treatment but relapses without vitamin A supplementation.
- The major diagnostic differentials for this condition include primary idiopathic seborrhea, zinc-responsive dermatosis, generic dog food dermatosis, sebaceous adenitis, and superficial necrolytic dermatitis.
- A more definitive diagnosis can be made with skin biopsy findings consisting of marked follicular hyperkeratosis and very distended follicular ostia, mild orthokeratotic hyperkeratosis of the epidermis, and mild irregular epidermal hyperplasia. Even with classic clinical and histologic findings, a definitive diagnosis can be confirmed only by response to supplementation with vitamin A.

Treatment

- Treat patients with vitamin A–responsive dermatosis with 625 to 800 IU/kg PO q24h of vitamin A. Improvement is seen within 4 to 6 weeks, complete remission is obtained by 10 weeks, and treatment is needed for life. Vitamin A at this dosage is well tolerated in dogs; therefore, no clinicopathologic monitoring is necessary. Keratolytic shampoos containing benzoyl peroxide have excellent follicular flushing activity. Twice-weekly treatment helps remove keratinous debris from follicles and hastens recovery.

ZINC-RESPONSIVE DERMATOSIS

Etiology

- *Zinc-responsive dermatosis* is a rare, nutritionally responsive scaling disease of several breeds of dogs, especially Alaskan malamutes and Siberian huskies. The incidence of this disease seems to be decreasing.

Clinical Signs

Zinc-responsive dermatosis is typically divided into the following two clinical syndromes:

- *Zinc-responsive dermatosis of Siberian huskies and Alaskan malamutes* is the first syndrome. It is also reported in American Eskimo dogs, Samoyeds, Doberman pinschers, and Great Danes. Alaskan malamutes have a genetic defect affecting zinc absorption from the intestines. Thus, the condition may occur even while the dog is on a well-balanced commercial diet. Zinc-responsive dermatosis may be precipitated by stress, estrus, and gastrointestinal disorders affecting absorption. Diets high in calcium and phytate (plant-derived protein especially high in cereals) may also precipitate the disorder by binding zinc in the gastrointestinal tract. A condition resembling zinc-responsive dermatosis has been described in dogs fed nutritionally incomplete generic dog food.
  - Lesions usually develop in dogs before puberty or in young adulthood. They include alopecia, erythema, scaling, and crusting involving the face, head, scrotum, and legs. Lesions often encircle the mouth, chin, eyes, ears, prepuce, and vulva. Thick crusts may be found on the elbows and other pressure points of the body. The foot pads may be hyperkeratotic. The haircoat is generally dull and dry.
- *Zinc-responsive dermatosis of rapidly growing puppies* on zinc-deficient diets or oversupplemented with vitamins and minerals, especially calcium, is the second syndrome. It is also seen with diets high in phytate. Commonly affected breeds include Great Danes, Doberman pinschers, beagles, German shepherds, German shorthaired pointers, Labrador retrievers, and Rhodesian ridgebacks. In addition to scaling and crusting, these dogs exhibit secondary infections, lymphadenopathy, depression, and anorexia. The most obvious cutaneous lesions involve the head, elbows, other joints, and foot pads.

Diagnosis

- Zinc-responsive dermatosis is diagnosed clinically by early age of onset, dietary history, breed, and physical examination findings. A firmer diagnosis is made with skin biopsy results of a marked, diffuse surface and follicular parakeratotic hyperkeratosis and a hyperplastic superficial dermatitis. A definitive diagnosis can be confirmed only by response to dietary zinc supplementation. Important diagnostic differentials for this syndrome include demodicosis, dermatophytosis, pemphigus foliaceus, generic dog food dermatosis, and superficial necrolytic dermatitis.

Treatment

- Treatment of zinc-responsive dermatosis depends on the specific syndrome.
  - The first syndrome of zinc-responsive dermatosis usually responds to zinc sulfate at 4.5 mg/kg (elemental zinc dose) PO q24h or divided q12h with food. A better alternative is zinc methionine at a dosage of 1 to 3 mg/kg (elemental zinc dose) PO q24h because it is better absorbed in dogs and causes less gastrointestinal upset. Correct dietary imbalances (e.g., high calcium and phytate, generic diets). Symptoms resolve rapidly, but lifetime therapy is usually needed. Zinc may cause vomiting, in which case lower the dose and give the medication with food.
  - The second syndrome in puppies usually responds over time to dietary corrections alone. However, recovery may be hastened by supplementation as discussed for the first syndrome. Some puppies may need supplementation until maturity.

EPIDERMAL DYSPLASIA

Epidermal dysplasia is an extremely severe keratinization disorder reported only in West Highland white terriers.

Etiology

- It may be a genetic keratinization abnormality or a severe inflammatory or hypersensitivity reaction associated with atopic dermatitis, adverse food reaction, or infections such as *Malassezia pachydermatis*.

Clinical Signs

- Epidermal dysplasia of West Highland white terriers develops in either sex, usually during the first year of life. Clinical signs begin with erythema and pruritus of the ventrum and extremities. These rapidly progress to a generalized disorder ("armadillo disease") with severe erythema and pruritus, alopecia, hyperpigmentation, lichenification, lymphadenopathy, greasy skin and haircoat, rancid odor, ceruminous otitis, and secondary bacterial infection. Some dogs have secondary *Malassezia pachydermatis* colonization of the surface and infundibular keratin, which may contribute to the severity of the disease.

▼ ***Key Point*** Secondary staphylococcal and *Malassezia* infections may be associated with any of the primary and secondary causes of scaling. Always

look for the presence of bacteria and yeast with skin cytologic examination (see Chapter 37).

Diagnosis

- Epidermal dysplasia is diagnosed clinically by early age of onset of severe ventral erythema and pruritus rapidly progressing to chronic lesions in West Highland white terriers. This diagnosis is supported by skin biopsy findings consisting of hyperplastic perivascular dermatitis with epidermal abnormalities, including hyperchromasia, excessive keratinocyte mitosis, crowding of basilar keratinocytes, epidermal "buds," loss of epidermal cell polarity, and parakeratosis. Budding yeast organisms and gram-positive cocci may also be found in surface and infundibular keratin.
- The principal diagnostic challenge in these dogs is to determine if the condition is caused by epidermal dysplasia, some other pruritic skin disease, or a combination. Primary diagnostic differentials that must be considered include atopic dermatitis, adverse food reaction dermatitis, scabies, and primary idiopathic seborrhea. Evaluate all of these by appropriate testing or response to therapy in the diagnostic workup.
- A definitive diagnosis of epidermal dysplasia can be made only with characteristic clinical and histologic findings and elimination of other diagnostic differentials. Another challenge is to determine how much secondary bacterial infection or *Malassezia* colonization is contributing to the severity of the clinical condition. This can only be assessed by evaluating response after treatment with appropriate topical and systemic antimicrobial agents.

Treatment

- Epidermal dysplasia has generally been thought to be nonresponsive to medical therapy. However, this observation has changed with the realization that most of these dogs manifest the syndrome secondary to allergies and skin infections, especially yeast.
- In patients with secondary *Malassezia* colonization, there may be significant improvement in pruritus and skin condition with ketoconazole (Nizoral, Janssen), 5 to 10 mg/kg PO q24h, or itraconazole (Sporanox, Janssen), 5 mg/kg PO q24h, and twice-weekly application of a topical antifungal shampoo. Alternate-day or twice-weekly pulse dosing with the systemic antifungal agents may be used after initial treatment for long-term control of redevelopment of the infection.
- Similar to what was described above for dogs with idiopathic seborrhea, cyclosporine (Atopica, Novartis) at a dosage of 5 to 10 mg/kg PO q24h has been effective because of the strong allergic component associated with this disease.

LICHENOID-PSORIASIFORM DERMATOSIS

Etiology

- *Lichenoid-psoriasiform dermatosis* is an extremely rare, probably inherited, keratinization defect reported only in English springer spaniels.

Clinical Signs

- Clinical signs include non-pruritic, erythematous, lichenoid papules and plaques involving the pinnae, external ear canal, preauricular and periorbital skin, lips, prepuce, and inguinal region. Chronic cases have papillomatous-type lesions, which may involve the face, ventral trunk, and perineum. A more generalized distribution of greasy scales and crusts may also be present.

Diagnosis

- Lichenoid-psoriasiform dermatosis is diagnosed clinically by early age of onset of refractory, plaque-like lesions involving the face, ears, and ventrum in English springer spaniels. Perform skin scrapings and fungal culture to rule out demodicosis and dermatophytosis.
- The definitive diagnosis is based on skin biopsy results. Histologic examination reveals lichenoid dermatitis (i.e., a band of mononuclear cells in the superficial dermis) with psoriasiform epidermal hyperplasia, intraepidermal microabscesses, and Munro microabscesses. Advanced lesions may show papillated epidermal hyperplasia and papillomatosis.

Treatment

- Lichenoid-psoriasiform dermatosis is a waxing and waning dermatitis. Minimal responses usually follow medical therapy with most antibiotics, low-dose glucocorticoids, vitamin A, levamisole, dapsone, autogenous vaccines, and topical antiseborrheic agents. Cephalexin may be helpful when secondary pyoderma is present. Prednisone at 2.2 mg/kg PO q24h has improved lesions in some cases but has not resulted in complete remission.

SCHNAUZER COMEDO SYNDROME

Etiology

- *Schnauzer comedo syndrome* is a follicular keratinization defect of miniature schnauzers characterized clinically by multiple comedones along the dorsal midline of the back. The etiology is probably genetic because of the exclusive occurrence in miniature schnauzers. A developmental defect may affect the hair follicle, leading to abnormal keratinization, comedo forma-

tion, follicular plugging and dilation, and secondary bacterial folliculitis.

Clinical Signs

- Schnauzer comedo syndrome usually develops in young adult dogs. Clinical signs include crusted, papular comedones (blackheads) along the dorsal midline of the back from the neck to the tail. In the early stages and in mild cases, lesions are difficult to see through the haircoat but are more easily palpated as "bumps" down the back. Animals with advanced disease frequently have secondary bacterial folliculitis and, rarely, furunculosis. The lesions may be accompanied by pruritus and pain. The infection leads to alopecia, with a "moth-eaten" appearance to the coat. The condition is chronic—for the life of the dog. Dogs with advanced disease should be evaluated for hypothyroidism and hyperadrenocorticism.

Diagnosis

- Schnauzer comedo syndrome is characterized clinically by dorsal follicular comedones in miniature schnauzers.
- Diagnostic differentials include demodicosis, dermatophytosis, and bacterial folliculitis. Obtain a complete drug history in miniature schnauzers with comedo syndrome. Glucocorticoids are comedogenic, and long-term administration may precipitate or worsen the condition. Older miniature schnauzers with endogenous Cushing disease and hypothyroidism may develop dorsal comedones. Confirm the diagnosis by skin biopsy, which shows dilated hair follicles filled with keratinous debris. Dilated or cystic sebaceous or apocrine glands, folliculitis, perifolliculitis, or furunculosis may be found.

Treatment

Topical Therapy

- The majority of cases of schnauzer comedo syndrome can be controlled with periodic application of benzoyl peroxide shampoos (OxyDex, DVM Pharmaceuticals; Pyoben, Virbac) to flush follicles and control secondary bacterial folliculitis. A combination benzoyl peroxide and sulfur shampoo (Sulf OxyDex, DVM Pharmaceuticals) is especially effective because of enhanced keratolytic activity. Benzoyl peroxide gels (OxyDex Gel, DVM Pharmaceuticals; Pyoben Gel, Virbac) are helpful to remove tightly adherent comedones. Gentle agitation with a mildly abrasive sponge (Buff-Puff, Johnson & Johnson) helps mechanically remove adherent comedones. Systemic antibiotics for a minimum of 3 weeks are indicated to control secondary staphylococcal folliculitis.

Systemic Therapy

- If there is no response to topical therapy, the synthetic retinoid isotretinoin (Accutane, Roche), 1 to 2 mg/kg PO q24h, has been very effective. Rapid response is seen within 3 to 4 weeks. After lesions resolve, most dogs can be maintained in remission without signs of toxicity on alternate-day therapy.

ICHTHYOSIS

Etiology

- *Ichthyosis* is an extremely rare, congenital keratinization defect of dogs, especially terriers, characterized by very severe scaling of the skin and foot pads. Lamellar ichthyosis results in severe scaling with moderate to marked hyperkeratosis and a thickened granular layer histologically. It may be an autosomal recessive trait in dogs (as it is in humans), although the exact genetics have not been studied.

Clinical Signs

- Ichthyosis is reported most commonly in terriers and terrier crosses. In most cases, the entire body is covered with tightly adherent, fine, white scales, some of which may appear as feathered keratinous projections. Extensive alopecia, hyperpigmentation, and lichenification may occur. Large quantities of waxy adherent scales may also be produced, especially in the flexural creases and intertriginous regions. Severe foot pad hyperkeratosis may be present with the margins more severely involved.

Diagnosis

- Canine ichthyosis is diagnosed clinically by congenital, severe cutaneous scaling and foot pad hyperkeratosis in terriers. Skin biopsy and histologic findings confirm the diagnosis. They include increased mitotic activity in the basal keratinocytes, prominent stratum granulosum, severe laminated orthokeratotic hyperkeratosis, vacuolated keratinocytes in the superficial epidermis, and follicular hyperkeratosis and plugging.
- Because of the congenital nature of this disorder, it is rarely confused diagnostically with other keratinization defects. However, if its presence at birth cannot be firmly established, the diagnostic differentials include zinc-responsive dermatosis, nasodigital hyperkeratosis, primary idiopathic seborrhea, canine distemper virus, pemphigus foliaceus, lupus erythematosus, hypothyroidism, generic dog food dermatosis, and superficial necrolytic dermatitis.

Treatment

Topical Therapy

- Topical therapy is helpful, including warm water soaks to help remove scales, antiseborrheic shampoos (SebaLyt, DVM Pharmaceuticals; Sebolux, Virbac), antiseborrheic gels (KeraSolv, DVM Pharmaceuticals; Retin-A, Ortho) for locally severe lesions, lactic acid as a total body rinse or spray (Humilac, Virbac; Micro Pearls Humectant Spray, EVSCO), and a combination rinse of 75% propylene glycol and 25% humectants (Humilac, Virbac). Topical therapy other than shampoos is used twice daily until the scale and odor are controlled and then is used as often as necessary for maintenance.

Systemic Therapy

- Excellent results have been obtained with isotretinoin (Accutane, Roche) at a dosage of 1 to 2 mg/kg PO q24h. Remission occurs usually within 8 to 12 weeks, although it may take up to 6 months. Some dogs can be maintained on alternate-day therapy.
- The long-term prognosis for ichthyosis is poor because of the severe scale formation and the continual therapy that will be needed for the entire life of the patient.

SEBACEOUS ADENITIS

Etiology

- *Sebaceous adenitis* is an inflammatory disease process directed against the sebaceous glands of the skin. Predisposed breeds include standard poodles, Akitas, Samoyeds, and vizslas. The pathophysiology is unknown but may include an inherited defect of sebaceous gland development, immune-mediated sebaceous gland destruction, a primary follicular keratinization defect with obstruction of sebaceous ducts and inflammation, and abnormal lipid metabolism affecting sebaceous secretions and keratinization.

Clinical Signs

- Sebaceous adenitis has two different clinical presentations related to coat length as follows:
  - Long-coated breeds, such as standard poodles, Akitas, and Samoyeds, have non-pruritic patchy or symmetrical alopecia with excess scale formation and dull, brittle hairs. Specific areas include the dorsal planum of the nose, top of the head, dorsal neck and trunk, tail, and pinnae. Advanced lesions include tightly adherent silver-white scales, follicular casts, matted hair, and secondary bacterial folliculitis.
  - Short-coated breeds, such as Vizslas, have circular areas of alopecia and scaling of the head, ears, trunk, and extremities. These areas may enlarge and eventually coalesce into serpiginous patterns or diffuse alopecia.

Diagnosis

- A tentative clinical diagnosis of sebaceous adenitis is made based on breed, history, and clinical findings. The definitive diagnosis is based on skin biopsy specimens revealing nodular granulomatous to pyogranulomatous inflammation at the level of the sebaceous glands. Advanced lesions are characterized histologically by a complete loss of sebaceous glands with periadnexal fibrosis.

Treatment

- Response to therapy for sebaceous adenitis depends on the stage and severity of the disease. Immunosuppressive dosages of glucocorticoids may be effective very early in the course of the disease when severe inflammation is present.
- Isotretinoin (Accutane, Roche) at 1 mg/kg PO q12–24h may be effective in refractory cases, especially in short-coated breeds. After remission is obtained, the goal is to gradually decrease the dosage to 1 mg/kg PO q48h. Cyclosporine (Atopica, Novartis) has also been used in refractory cases at 5 mg/kg PO q12h.
- Topical therapy with sprays or rinses consisting of 75% propylene glycol and 25% humectants (Humilac, Virbac) is helpful when applied once daily. Other therapy consists of essential fatty acid dietary supplements, antiseborrheic shampoos and emollients, antibiotics, and antibacterial and follicular flushing shampoos.

IDIOPATHIC NASODIGITAL HYPERKERATOSIS

Etiology

- *Idiopathic nasodigital hyperkeratosis* is a primary keratinization disorder characterized by excess keratin accumulation on the planum nasale, foot pads, or both. It is most commonly seen in cocker spaniels and English springer spaniels, although any breed may be affected.

Clinical Signs

- Idiopathic nasodigital hyperkeratosis may have focal or diffuse lesions characterized by tightly adherent, thick accumulations of keratin on the nasal planum, foot pads, or both. This material is usually extremely dry and may be accompanied by cracks, fissures, erosions, and ulcers. Severe foot pad involvement may result in pain and lameness.

Diagnosis

- Idiopathic nasodigital hyperkeratosis is diagnosed by finding nasal and/or digital hyperkeratosis without evidence of other concurrent diseases. Consider all diseases that may cause the lesions. Unfortunately, the list is long and includes canine distemper virus, pemphigus foliaceus, pemphigus erythematosus, lupus erythematosus, nasal solar dermatitis, hypothyroidism, zinc-responsive dermatosis, generic dog food dermatosis, and superficial necrolytic dermatitis. Pemphigus foliaceus, superficial necrolytic dermatitis (hepatocutaneous syndrome), and lupus erythematosus are the most common causes of nasal and digital hyperkeratosis.
- Perform extensive diagnostic tests only when the condition is severe or when clinical signs suggest that one of the other more serious diseases listed previously is present.

▼ ***Key Point*** Idiopathic nasodigital hyperkeratosis is merely cosmetic for most dogs and requires neither extensive diagnostic workup nor treatment.

- When warranted, perform a complete diagnostic evaluation including a good history, complete blood count (CBC), serum biochemical profile, thyroid evaluation with baseline thyroxine and a thyroid-stimulating hormone level, and biopsy for histologic evaluation. Histopathologic findings are most helpful in ruling out the diagnostic differentials. Abnormalities for idiopathic nasodigital hyperkeratosis are nonspecific and consist of irregular epidermal hyperplasia with severe orthokeratotic and parakeratotic hyperkeratosis.

Treatment

- Medical treatment of idiopathic nasodigital hyperkeratosis includes hydration of the hyperkeratotic tissue by water soakings or wet dressings followed by application of petrolatum jelly as an occlusive agent to help seal moisture into the stratum corneum.
- Although simple hydration may be adequate for mild lesions, more severe hyperkeratosis requires a topical agent with keratolytic activity. A gel containing salicylic acid, lactic acid, and urea (KeraSolv Gel, DVM Pharmaceuticals) is helpful, as is topical 0.025% or 0.01% tretinoin gel (Retin-A, Ortho). Apply the gel q12h until the condition is controlled, then use as needed for long-term maintenance. Irritation may be a problem, especially with tretinoin. Corticosteroid and antibiotic ointments, creams, or gels may be needed when severe inflammation or secondary infection is present.
- When very severe projections of keratin are present, especially on foot pads and causing lameness, they may be surgically removed by trimming the dead tissue with scissors.

CANINE EAR MARGIN DERMATOSIS

Etiology

- *Canine ear margin dermatosis* is a rare, idiopathic keratinization defect characterized by greasy plugs that adhere to the skin and hairs of the pinnae of the ears in a bilaterally symmetrical pattern. This dermatosis occurs primarily in dachshunds but is also occasionally seen in other breeds with pendulous ears. (See Chapter 58 for a discussion of pinnal diseases.)

Clinical Signs

- Canine ear margin dermatosis has greasy plugs adhering tightly to the skin surface and hair shafts on the pinnal margins. Alopecia may develop with time. Pruritus is usually absent. In severe untreated cases, a progression to ulceration and necrosis has been reported that is due to thrombosis of capillaries that supply blood to the pinnal margins. This condition may result in severe scarring and fissures.

Diagnosis

- Canine ear margin dermatosis is tentatively diagnosed in the early stages when only scale is present by breed and clinical signs alone. Perform skin scrapings and fungal culture to rule out scabies (a consideration only if pruritus is present), demodicosis, and dermatophytosis. Skin biopsy findings reveal prominent orthokeratotic and parakeratotic hyperkeratosis. However, biopsy is unnecessary and the ear margin is a difficult part of the body from which to remove tissue.
- When the condition has progressed to ulceration and necrosis, the number of differential diagnoses to consider is more extensive and includes lupus erythematosus, pemphigus complex, cutaneous vasculitis, dermatomyositis, cold agglutinin disease, frostbite, drug reactions, and lymphoreticular neoplasms. Diagnostic procedures to differentiate these diseases include CBC, serum biochemical profile, urinalysis, skin biopsy for routine histologic examination and direct immunofluorescence, Coombs testing, and antinuclear antibody testing.
- Skin biopsy specimens reveal necrosis and ulceration. Some sections may demonstrate vascular thrombosis. However, the changes are nonspecific and may be seen with many of the diagnostic differentials. Therefore, all of the suggested diagnostic tests are recommended to eliminate the differentials and to establish a definitive diagnosis of canine ear margin dermatosis.

Treatment

- The mild scaling form of ear margin dermatosis is usually controllable but rarely curable with topical

therapy. Periodic use of an antiseborrheic shampoo to remove the scales and waxy accumulations is all that is needed to control the mild form of the condition. Helpful agents include sulfur and salicylic acid (SebaLyt, DVM Pharmaceuticals; Sebolux, Virbac) and benzoyl peroxide (OxyDex, DVM Pharmaceuticals; Sulf OxyDex, DVM Pharmaceuticals; Pyoben, Virbac). A topical glucocorticoid cream may be needed in severe unresponsive cases or in those with severe inflammation.

- The advanced ulcerative and necrotic stage may be responsive to pentoxifylline (Trental, Hoechst Marion Roussel) at a dosage of 10 to 15 mg/kg PO q8–12h if there is a component of vasculitis present.

Chapter 51

Sex Hormone and Endocrine Look-alike Dermatoses

Linda A. Frank

▼ ***Key Point*** Bilaterally symmetrical alopecia sparing the head and extremities is usually associated with an endocrine cause such as hypothyroidism or hyperadrenocorticism; however, this same pattern of alopecia is seen with sex hormone dermatoses and various other dermatoses described in this chapter.

The differential diagnoses for an "endocrine" pattern of alopecia (other than hypothyroidism and hyperadrenocorticism) include sex hormone aberrations, follicular arrest (Alopecia X), cyclic flank alopecia, pattern baldness, and post-clipping alopecia. In addition, more generalized non-inflammatory alopecias may be associated with follicular dysplasias and telogen defluxion.

SEX HORMONE DERMATOSES

Etiology

Sex hormones are produced primarily from cholesterol by the zona reticularis of the adrenal cortex and by the gonads. Sex hormones are also produced in the tissues by peripheral conversion. Sex hormone dermatoses are uncommon in the dog and are attributed to an overproduction of one or more of the sex hormones. This overproduction may arise endogenously from the adrenal glands or gonads or exogenously from administration of a hormone product. The alopecia results from the effects of hormones on the hair follicle, inhibiting the normal cyclic pattern of hair growth.

Hyperestrogenism

- The source of excess estrogen production is from cystic ovaries, ovarian granulosa cell tumors, or testicular tumors (especially Sertoli cell tumors). Iatrogenic estrogen supplementation (such as for treating urinary incontinence) can also be a source.
- Estrogen inhibits initiation of anagen, the hair growth phase.

Hyperandrogenism

- The source of excess androgen production is from testicular tumors (e.g., interstitial cell tumors, seminomas) and possibly from adrenal tumors.
- Hyperandrogenism is uncommonly associated with alopecia in dogs. Excess androgen is more often associated with hyperplasia and hypersecretion of the sebaceous and circumanal or hepatoid glands.

Hyperprogesteronism

- An endocrine pattern of alopecia caused by a progesterone-secreting Sertoli cell tumor was reported in one dog.
- Progesterone may bind to glucocorticoid receptors, thus blocking hair growth.
- Progesterone may also cross with testosterone receptors, resulting in either down-regulation or up-regulation of the receptors.

Clinical Signs

▼ ***Key Point*** The classic endocrine pattern of alopecia is a bilaterally symmetrical *diffuse* alopecia sparing the head and extremities caused by non-inflammatory endocrine dermatoses. Focal or patchy alopecias are more likely caused by inflammatory dermatoses, such as pyoderma, demodicosis, or dermatophytosis.

Hyperestrogenism

Cutaneous Signs

- These dogs often present with bilaterally symmetrical alopecia sparing the head and extremities. The alopecia may begin in the perineal, inguinal, and flank regions and then progress to involve the entire trunk.
- Comedones may be seen in the inguinal region.
- The coat may have a generalized dry or oily seborrhea.
- Hyperpigmentation may be seen as diffuse pigmentation in the areas of alopecia, or it may appear as macular lesions with a ventral distribution.

- In male dogs, a clinical sign highly suggestive of excess estrogen production is linear preputial dermatosis that appears as a narrow strip of hyperpigmentation along the ventral midline from the prepuce toward the scrotum.

Female Reproductive Signs

- The nipples and vulva may be enlarged, similar to a normal heat cycle.
- The heat cycles may be abnormal, especially persistent or irregular estrus.

Male Reproductive Signs

- The testes may be palpably abnormal.
- The nipples may enlarge, similar to what occurs in females.
- Males may attract other male dogs.

Other Signs

- Hyperestrogenism can cause serious bone marrow suppression and aplastic anemia.

Hyperandrogenism

- Intact male dogs are most commonly affected. Testes are palpably normal in most cases, but a testicular tumor may be identified.
- Hyperandrogenism is only rarely associated with alopecia.
- Typical lesions include perianal gland hyperplasia, resulting in a "donut" ring around the anus. This can result in anal sac impaction.
- Generalized seborrhea oleosa is a presenting sign in some dogs.
- Local hyperplasia of the supracaudal gland may appear as alopecia and seborrhea of the dorsal aspect of the tail approximately one-third the distance from the tail base.

Hyperprogesteronism

- Bilaterally symmetrical alopecia sparing the head and extremities has been attributed to elevated progesterone in one dog.

Diagnosis

Suspect sex hormone dermatoses in dogs that have typical clinical signs after routine diagnostic testing has ruled out the more common causes of endocrine alopecia, such as hypothyroidism or hyperadrenocorticism (see Chapters 31 and 33). In intact dogs, the resolution of clinical signs in response to neutering confirms the diagnosis. In neutered dogs with sex hormone dermatosis, adrenal testing is required.

Diagnosis of Gonadal Causes in Intact Dogs

- In intact animals, the excess sex hormone is most likely gonadal in origin. Measure baseline concentrations of estradiol, progesterone, and testosterone to establish a presumptive diagnosis. If any of these hormones is *substantially* increased out of the normal range, then there is good reason to suspect this is causing the dermatosis.
- Use diagnostic imaging, especially ultrasonography, to identify gonadal tumors.
- Evaluate a complete blood count to assess bone marrow status when hyperestrogenism is suspected.
- Confirm the diagnosis based on resolution of clinical signs in response to neutering or ovariohysterectomy.
- The intact animal may also respond to treatment with an antagonistic hormone, such as androgen to treat hyperestrogenism; however, this approach is not recommended since the primary cause of the sex hormone imbalance is a gonadal tumor.

Diagnosis of Adrenal Tumors

- Adrenal tumors have been associated with abnormal sex hormone production; thus, in neutered dogs with clinical signs suggestive of a sex hormone dermatosis, the excess sex hormones are most likely arising from the adrenal glands.
- Perform abdominal ultrasonography to identify adrenal tumors.
- Measure the serum concentration of the sex hormones as well as cortisol, before and after adrenocorticotropic hormone (ACTH) stimulation, to identify *substantial* increases in one or more of these adrenal hormones. Hyperandrogenism sometimes occurs concurrently with hypercortisolemia. To perform the ACTH stimulation test, obtain baseline and, 1 hour post-ACTH, serum samples. ACTH is administered at 5 µg/kg IV. The serum samples need to be frozen and mailed overnight to the following address: Clinical Endocrinology Service, 2407 River Drive, Rm A105 Veterinary Teaching Hospital, University of Tennessee, Knoxville, TN 37996-4543 (telephone: 865-974-5638).

Skin Biopsy

A skin biopsy may support the diagnosis of a sex hormone imbalance; however, the findings are nonspecific. The biopsy can only document the presence of a non-inflammatory alopecia accompanied by hairs that are not cycling (typical endocrine histopathology pattern). This is not specific for endocrine disease; it also is seen in many of the endocrine "look-alike" alopecias discussed in the later sections of this chapter.

▼ ***Key Point*** A biopsy result indicating an endocrine pattern of alopecia simply means that there is no inflammation to explain the alopecia, the thickness of the dermis and epidermis is normal to decreased, and the hairs are in telogen phase (not cycling). Think of this as a non-inflammatory pattern of alopecia that can be associated with endocrine or endocrine look-alike dermatoses rather than strictly an endocrine pattern of alopecia.

Treatment

- If the dog is intact, the treatment of choice is neutering.
- Under certain circumstances, treatment using an antagonistic hormone may result in resolution of clinical signs; however, this is not recommended since surgical excision is a preferable treatment for gonadal tumors.
- If the abnormal sex hormones are arising from adrenal hyperplasia, treatment with mitotane may abolish the hormone-secreting tissue and result in resolution of clinical signs (treatment of hyperadrenocorticism is described in Chapter 33).
- If there is an adrenal tumor, surgery is the treatment of choice (see Chapter 33).

ENDOCRINE LOOK-ALIKE DERMATOSES

Various dermatoses with an endocrine pattern of alopecia include Alopecia X, pattern baldness, cyclic flank alopecia, and post-clipping alopecia. Endocrine alopecia caused by hypothyroidism (see Chapter 31) and hyperadrenocorticism (see Chapter 33) is seen more commonly than the endocrine look-alike causes of alopecia.

▼ ***Key Point*** Endocrine look-alike dermatoses cannot be definitively diagnosed without first ruling out hypothyroidism and hyperadrenocorticism.

Alopecia Associated with Follicular Arrest (Alopecia X)

Etiology

- This disease is also known as adrenal hyperplasia-like syndrome, growth hormone-responsive alopecia, biopsy-responsive alopecia, pseudo-Cushing's syndrome, and other names.
- The pathomechanism of the disease is unknown. A defect in anagen initiation of the hair cycle at the level of the follicle is suspected. The role that adrenal steroid hormone intermediates play in this disease is currently under debate.

Clinical Signs

- This is most commonly seen in the "plush-coated" breeds such as Pomeranians, malamutes, huskies, chow chows, Samoyeds, keeshonds, and American Eskimo dogs and in miniature poodles.
- This occurs in adult male and female dogs between 1 and 10 years of age irrespective of neuter status.
- The dog presents with the typical endocrine pattern of alopecia. Initially there is loss of guard hairs that progresses to complete alopecia of the neck, tail, rump, perineum, caudal thighs, and ultimately trunk.
- The skin may become intensely hyperpigmented in areas of alopecia.

Diagnosis

- First rule out other endocrine dermatoses such as hypothyroidism, hyperadrenocorticism, and sex hormone dermatosis.
- A biopsy will categorize the alopecia as non-inflammatory (endocrine pattern) and rule out conditions such as sebaceous adenitis or folliculitis as causes of the alopecia.
- There is no confirmatory diagnostic test.

▼ ***Key Point*** With few exceptions, histopathology cannot differentiate among various endocrine dermatoses and cannot be used to definitively diagnose Alopecia X.

Treatment

- This is a "responsive dermatosis." Several treatment approaches can produce hair regrowth, but unfortunately, this is seldom permanent. Many dogs lose their hair again during subsequent hair cycles.
- If the dog is intact, neutering results in hair regrowth in some cases.
- Melatonin (3 mg q12h for small dogs and 6–12 mg q12h for large dogs) results in some degree of hair growth in approximately half of the cases. Because this treatment is very safe, it is currently recommended as a first approach to treating dogs with Alopecia X after neutering. The only contraindication is treating dogs with diabetes mellitus, as melatonin may cause insulin resistance.
- Mitotane results in hair regrowth in some cases. The recommended dosage is lower than that used for hyperadrenocorticism (25 mg/kg, PO, q24h or divided q12h for 5–7 days, then divided twice weekly for maintenance).
- Testosterone results in hair regrowth in some dogs. Adverse effects of this treatment can include cholangiohepatitis or aggressive behavior.
- When the condition was thought to be growth-hormone related, treatment with growth hormone resulted in hair regrowth. Unfortunately, growth hormone can result in diabetes mellitus and is difficult to obtain.

Cyclic Flank Alopecia

Etiology

- This is a seasonal truncal alopecia that occurs primarily during periods of decreasing day length. Therefore, the hair loss usually occurs during the winter to spring months, although this can be quite variable. The condition appears to be more prevalent in the northern states and Canada, possibly due to shorter day lengths.
- The condition may recur yearly, sporadically, or never again. The actual mechanism of the alopecia is not known.

Clinical Signs

- Breeds predisposed to this condition include Airedales, boxers, and English bulldogs, but the condition has been reported in many different breeds.
- The age of onset is usually between 1.5 and 4.5 years.
- The condition occurs in intact or neutered dogs of either sex.
- Dogs present with alopecia of the flanks and/or lateral thorax that is usually symmetrical. The alopecia can progress to involve the thoracolumbar region. The alopecia is usually more delineated than that seen with hyperadrenocorticism; however, early in the condition, the haired regions of the flank may appear diffusely thinned.
- The skin in the alopecic areas is often hyperpigmented. Hyperpigmentation on the bridge of the nose is occasionally associated with this condition.

Diagnosis

- First rule out endocrinopathies such as hypothyroidism and hyperadrenocorticism.
- Biopsy is often helpful. Characteristic findings, in addition to a non-inflammatory pattern of alopecia, include follicular keratosis with deformed ("witch's foot") follicles and variable melanization of sebaceous glands and ducts.

Treatment

- Melatonin may shorten the duration of the alopecia and prevent its recurrence. Use the same dosage as for Alopecia X (see the preceding section).

▼ ***Key Point*** Melatonin is a useful treatment for many of the endocrine look-alike alopecias.

Pattern Baldness

Etiology

- This is a tardive hypotrichosis in dogs that usually begins at less than 1 year of age and progresses throughout their lives.
- The pathomechanism is unknown, but a genetic defect is suspected.

Clinical Signs

There are four patterns of alopecia that can be included in this category.

Pinnal Alopecia of Dachshunds

- Pinnal alopecia of dachshunds occurs most commonly in male dogs.
- The alopecia affects both pinnae and is usually first noticed when the dog is less than 1 year of age.
- The alopecia is progressive, with the pinnae becoming hyperpigmented and "leathery" in texture over time.

Caudal Thigh Alopecia of Greyhounds

- Greyhounds frequently develop alopecia of the caudal thighs (bald thigh syndrome).
- This occurs in young to middle-aged adults, irrespective of sex or neuter status.

Ventral and Caudal Thigh Alopecia of Various Breeds

- Ventral and caudal thigh alopecia is frequently seen in dachshunds and Boston terriers. Other breeds including whippets and Italian greyhounds may also be affected.
- The alopecia is usually first noticed when the dog is less than 1 year of age.

Patterned Alopecia of Portuguese Water Dogs and American Water Spaniels

- Portuguese water dogs and American water spaniels may develop a patterned alopecia of the ventral neck, caudomedial thighs, and tail.
- This is usually first noticed when the dogs are less than 1 year of age.

Diagnosis

- Pattern alopecia (baldness) is usually diagnosed based on signalment and clinical signs.
- Because of the young age of onset, endocrinopathies are unlikely. However, hypothyroidism and hyperadrenocorticism should be ruled out in greyhounds with alopecia of the caudal thighs since this tends to develop at a later age.
- Biopsies may help differentiate pattern alopecia from "endocrine" alopecia if taken early in the disease process. Hair follicles and adnexa are decreased in size (miniaturized) with small anagen hair bulbs still present. Later in the course of disease, there is a decrease in the number of hair follicles and adnexa, and few, if any, anagen hair bulbs remain.

Treatment

- There is no known treatment for canine pattern alopecia.

- Interestingly, some respond to melatonin (see the "Alopecia X" section), suggesting that the alopecia may be associated with hair cycle arrest, similar to the other endocrine look-alikes discussed.

Post-Clipping Alopecia

Etiology

- Failure to regrow hair following clipping is a common sequel to the "summer cut" and surgical site preparation. Possible explanations for this include an arrest of the cycling hair follicle due to the clipping or surgical procedure or the clipping of the coat during a normal telogen phase of the hair cycle in dogs with very seasonal growth phases.
- It may be seen more frequently with clip sites of epidural anesthesia.

Clinical Signs

- Delayed hair regrowth is seen at clipped areas. This tends to be most noticeable over the trunk, causing it to be easily confused with endocrine dermatoses.
- Many times some hairs have regrown within the alopecic area while the rest remain inactive.

Diagnosis

- History of a recent clip and clinical signs are highly suggestive of this condition.
- Because endocrinopathies may be associated with lack of hair regrowth following clipping, it is important to rule out hypothyroidism and hyperadrenocorticism.
- Biopsy supports a non-inflammatory cause of the alopecia. Biopsy may show telogen arrest with all hairs in telogen. In some cases the biopsy is very similar to normal-haired areas of the same dog, suggesting that the dog's hair growth cycle was in a normal resting phase. The biopsy may show anagen hairs, indicating that hair regrowth has started.

Treatment

- This condition is self-limiting and does not require treatment. Hair usually grows back within 1 year, especially after the dog completes a heavy shedding cycle.
- Melatonin appears to help stimulate hair regrowth, although controlled studies have not been done (see the "Alopecia X" section for dosages).

Follicular Dysplasias

Follicular dysplasias include color dilution alopecia and black hair follicular dysplasia.

Etiology

- This condition appears to be congenital and/or genetic.
- The pathomechanism of the alopecia is unknown; however, it may involve defective melanization and/or a hair defect.

Clinical Signs

Color Dilution Alopecia

- Color dilution alopecia is seen in dogs with diluted haircoat colors such as blue Doberman pinschers or fawn Irish setters. It also occurs in Yorkshire terriers. Any breed of dog with a color dilution can in theory have this condition.

Black Hair Follicular Dysplasia

- In black hair follicular dysplasia, the alopecia is restricted to the black-haired areas of the coat. This condition is usually seen in piebald dogs (dogs with large patches of white and black) throughout the coat, although it has also been seen in black Doberman pinschers.
- Alopecia occurs in dogs less than 3 years of age and progresses. Seborrhea and pyoderma are often associated with areas of alopecia.

Diagnosis

- Suspect this condition when alopecia is restricted to a specific color region of the haircoat.
- Microscopic examination of the hair (trichogram) is useful only in dogs with color dilution alopecia. This reveals large and irregular melanin aggregates within the hair shaft resulting in distortion and breakage of the shaft.
- Histopathology is useful for both conditions, revealing abnormal melanin clumping within the hair shafts and periadnexally within the dermis.

Treatment

- Symptomatic treatment of seborrhea and pyoderma is essential.
- There is no known treatment to reverse the clinical alopecia. There are anecdotal reports of partial response to retinoids and melatonin.

Telogen Defluxion

Etiology

- Illness or severe stress causes abrupt cessation of anagen and synchronizes hair follicles into the telogen (resting) stage of hair growth.
- Telogen hairs synchronously shed in 1 to 3 months as the new anagen hair cycle begins.

Clinical Signs

- Hairs begin to shed in abnormal amounts, resulting in alopecic patches, usually 1 to 3 months following a stressful incident or illness.

- Hairs epilate easily. The skin appears otherwise healthy with no evidence of pyoderma or inflammation.

Diagnosis

- Suspect telogen defluxion based on history and clinical signs.
- A trichogram of the epilated hairs will confirm that all hairs are in telogen.
- Biopsy will support a non-inflammatory alopecia and either confirm all hairs to be in telogen or reveal early regrowth of a new wave of anagen hairs.

Treatment

- Telogen defluxion is self-limiting, and hair eventually regrows normally without treatment.

Chapter 52

Feline Symmetrical Alopecia

Vicki J. Scheidt / Andrew Hillier

Alopecia is defined as the absence of hair from skin areas where it is normally present. Feline symmetric alopecia (FSA) is a cutaneous reaction pattern with many possible etiologies; FSA should not be a final diagnosis, and it is important to determine the primary cause for the most appropriate therapy to be instituted.

In order to properly define the clinical problem and formulate an appropriate list of differential diagnosis, it is helpful to further categorize alopecia as follows:

- Whether the alopecia is self-induced (i.e., a result of pruritus) or not
- Distribution of lesions (body locations involved, localized or generalized)
- Duration (permanent or transient)
- Degree (partial or complete)

Alopecia in the cat, whether symmetric or asymmetric, is most often associated with varying degrees of pruritus and skin reactivity depending on the underlying disease.

▼ ***Key Point*** Although self-trauma (pruritus) due to underlying inflammatory skin disease is the most common cause of FSA, visible skin inflammation may be minimal or absent, even in cases of severe pruritus and alopecia.

NORMAL SHEDDING OF HAIR

In animals, the haircoat aids in thermal regulation, protects the skin, and has important aesthetic qualities. Cats are fastidious and spend a great deal of time grooming their coats. Normal grooming behavior aids in hair removal and normal shedding. However, when grooming becomes excessive, it may accentuate hair damage and skin disease. It may be difficult for some owners who are inexperienced in the grooming behavior of cats to be able to distinguish between normal grooming and excessive grooming due to pruritus.

Hair follicles have specific cycles of growth (anagen) and rest (telogen) that are primarily stimulated by changes in the photoperiod and to a lesser extent by temperature. From winter to late spring in temperate climates, minimal hair growth occurs and the thick winter coat is shed. Therefore, cats that live outside in colder climates may shed excessively in late spring and develop a transient thinning of the coat (hypotrichosis). Secondary hairs undergo a growth phase in the fall and winter that results in the thick, heavy coat needed for colder temperatures. Seasonal changes are less dramatic in tropical regions or in environments with artificial lighting (e.g., cats confined indoors). Under these conditions, a small amount of hair loss may occur continuously.

ETIOLOGY OF ALOPECIA

Multiple factors play a role in normal hair follicle development and growth (Table 52-1). Absence or changes in one or more of the factors can alter the normal hair growth process and result in alopecia. The underlying causes of FSA can vary depending on the area or region of the body affected. This chapter focuses on the causes of FSA that are primarily confined to the trunk (dorsum, perineum, caudal thighs, flanks, ventral abdomen, and thorax). The underlying causes of FSA affecting the trunk region have been classified into those that are associated with self-trauma or pruritus (e.g., licking or scratching) and those that are nonpruritic (Table 52-2).

▼ ***Key Point*** Determine whether pruritus and concurrent skin inflammation are present when formulating a differential diagnosis for FSA in the cat.

Self-induced (Pruritic) Alopecia

Allergic dermatitis and parasitic infestations are the most common causes of self-induced alopecia. Other cutaneous reaction patterns associated with allergic and parasitic dermatoses are feline miliary dermatitis (see Chapter 53) and eosinophilic granuloma complex lesions (see Chapter 53). Allergic causes of self-induced alopecia in cats typically do not have as strong a regional distribution (i.e., involvement of specific body locations) as is the case in dogs.

Table 52-1. INTERNAL AND EXTERNAL FACTORS INFLUENCING HAIR FOLLICLE GROWTH AND DEVELOPMENT

Internal Factors	External Factors
Genetic	Nutritional
Hormonal	Infectious
Immunologic	Bacterial
Neoplastic	Fungal (dermatophytes)
Stress	Parasitic
	Physical (traumatic)
	Chemical (toxins, drug therapy)

Table 52-2. CAUSES OF FELINE SYMMETRIC ALOPECIA OF THE TRUNK

Self-induced (Pruritic)	Non–self-induced (Nonpruritic) (All Rare)
Allergic dermatoses	Feline endocrine alopecia
Food allergy	Sex hormone-related
Atopy	Hyperthyroidism/hypothyroidism
Flea allergy	Hyperadrenocorticism
Demodicosis	Systemic disease
Dermatophytosis	Diabetes mellitus
Otodectic mange	Renal disease
Notoedric mange	FeLV and FIV
Bacterial skin infection	Telogen effluvium/anagen defluxion
Yeast *(Malassezia)* skin infection	Paraneoplastic alopecia
	Thymoma
Psychogenic alopecia	
Intestinal parasite hypersensitivity (rare)	
Chronic cystitis (rare)	

Flea Infestation and Flea Allergy Dermatitis

When associated with mild pruritus and minimal dermatitis, fleas can cause a symmetric alopecia of the dorsum, proximal tail, flanks, perineum, and ventral abdomen. Although a similar presentation can be seen in cats with flea allergy dermatitis, the alopecia and pruritus are much more severe in flea-allergic cats, and they typically have concurrent skin lesions (miliary dermatitis) along the dorsum, tail base, and ventral abdomen (see Chapter 45). Some flea-allergic cats do not have involvement of the typical body locations as mentioned; other body locations maybe involved, and flea allergy dermatitis should remain a differential diagnosis for cats with pruritus and alopecia even if the typical body locations are not involved.

Fleas and/or their feces are usually present on examination. However, in some cases the fleas and feces are removed during the excessive grooming (fleas may be found on fecal flotation in these cases) and the absence of fleas or flea feces should *not* rule out the possibility of flea allergy dermatitis.

Food Allergy

Food allergy in cats is associated with non-seasonal pruritus and a variety of clinical presentations, including FSA. The skin lesions and severe pruritus may be generalized or confined to the face and ears or trunk. Alopecia, whether diffuse or symmetric, results from excessive pruritus triggered by an allergic reaction to specific food items ingested (see Chapter 47). Stubbled or broken hairs, with or without concurrent focal erythema, papules, and crusting (miliary dermatitis), are usually present. Food allergy should be considered a differential diagnosis in any cat with non-seasonal pruritus and alopecia.

Feline Atopic Dermatitis

Atopic dermatitis in cats may be associated with seasonal or non-seasonal alopecia and pruritus (see Chapter 46). Similar to that seen in feline food allergy, the alopecia is secondary to pruritus and is associated with broken or stubbled hairs and concurrent skin lesions. The alopecia may be generalized or confined to the head and neck or distal extremities. Food allergy and atopic dermatitis are virtually indistinguishable on clinical examination in cats with non-seasonal pruritus.

Dermatophytosis

This is a common cause of localized or generalized alopecia in cats (see Chapter 42). Fungal organisms invade the hair shaft and grow downward but do not penetrate the mitotic region of the hair. Alopecia is not permanent unless the follicle is destroyed by secondary inflammation. A wide spectrum of clinical presentations can be seen with feline dermatophytosis, including the asymptomatic carrier state, particularly in longhaired cats. Classically, the alopecia is focal to diffuse with small numbers of fractured or stubbled hairs and mild epidermal erythema and scaling. The majority of dermatophyte infections in cats are caused by the zoophilic fungus *Microsporum canis*. Pruritus is variable in dermatophytosis and when present is typically mild and rarely moderate to severe.

Demodicosis

Demodicosis is an uncommon cause of alopecia in cats (see Chapter 43). The pathogenesis of feline demodicosis is reported to be similar to that described in the dog and caused by either *Demodex cati* (follicular mite) or *Demodex gatoi* (skin surface mite). *D. cati* is a normal inhabitant of feline skin, which under favorable conditions proliferates in hair follicles. Lesions consist of focal to diffuse alopecia, erythema, scaling, and crusts that may be localized and self-limiting or generalized. In some cases, these lesions may mimic feline endocrine alopecia. Generalized demodicosis due to *D. cati* infestation is usually associated with an underlying immunosuppressive disease, such as feline leukemia virus

(FeLV), feline immunodeficiency virus (FIV), diabetes mellitus, or neoplasia.

A pruritic, symmetric alopecia of the trunk caused by *D. gatoi* has been described in cats. Other body locations may occasionally be affected.

Otodectic Mange

Otodectes mites are the most common cause of otitis externa in cats (see Chapter 59). Otodectic mites can live on the skin surface and infrequently cause a symmetric alopecia over the lower back and tail base. Concurrent otitis externa may or may not be present. The degree of pruritus is variable.

Notoedric Mange

Notoedres mites cause a severely inflammatory and pruritic dermatitis involving the head, pinna, and neck in particular. Typically, miliary dermatitis is seen, but FSA may be an uncommon manifestation of infestation with this mite.

Bacterial Infection (Pyoderma)

Bacterial infection (usually staphylococci bacteria) is usually secondary to underlying primary disease, for example, allergic dermatitis, parasitic infestations, or endocrinopathy. Secondary bacterial skin infections are far less common in cats compared with in dogs. However, occasional cats may have a secondary bacterial infection that will mask response to flea control or food trials if not detected and treated to resolution.

Yeast (Malassezia) Dermatitis

Similar to bacterial infections, yeast dermatitis is usually a secondary problem associated with primary skin disease (allergy, parasites, endocrine, etc.) and is also far less common in cats compared with dogs. However, when present, yeast infections may induce moderate to severe pruritus in their own right, even when the underlying primary disease is non-pruritic (e.g., endocrine). Once again, failure to detect and resolve yeast skin infections will make it difficult to appreciate response to flea control, food trials, immunotherapy, etc.

Psychogenic Alopecia

This condition is often an enigma. Alopecia develops because the cat excessively licks, bites, or pulls out hair from those areas normally groomed (perineum, ventral abdomen, flank). In most cases, a stressful event such as moving to a new surrounding, being hospitalized or boarded, loss of a favorite companion, or introduction of a new pet or person (baby) into the environment precipitates the disease. Psychogenic alopecia is most common in nervous or "high-strung" cats, such as Siamese, Abyssinian, or black-colored cats. Typically, the areas affected are regions the cat can easily lick, such as the dorsal lumbosacral region, tail, medial and caudal thighs, ventral abdomen, flanks, and perineum. Partial to complete alopecia and stubbled hairs are observed, and concurrent skin changes (e.g., erythema, erosions, exudation, and crusting) are rare.

▼ ***Key Point*** As with most psychogenic conditions, it is critical to rule out the more common and likely pathologic causes of FSA before a diagnosis of psychogenic alopecia can be confirmed.

Non–self-induced (Nonpruritic) Alopecia

Feline Endocrine Alopecia

This is a disease of unknown cause. It is presumed to result from hormonal imbalances or deficiencies based on the positive response observed following treatment with specific hormones. The condition is characterized by non-pruritic, symmetric hair loss on the perineum, ventral abdomen, and caudal or medial thighs. Although the alopecia may spread to the flanks, lateral thorax, and proximal tail, the dorsum is usually spared. A thinning of the hair, rather than complete baldness, with normal, non-inflamed skin is the classic presentation. Feline endocrine alopecia primarily affects neutered females and males. However, this syndrome has been reported in intact cats.

Significant controversy exists regarding the relationship of hypothyroidism to feline endocrine alopecia. Affected cats usually have normal baseline serum thyroxine (T_4) levels; however, serum T_4 levels at 6 hours following stimulation with thyroid-stimulating hormone (TSH) have been low compared with TSH stimulation results in normal cats. These findings suggest that some cats with feline endocrine alopecia may have a low thyroid reserve.

Some cats with hyperthyroidism may develop truncal alopecia, although typically the skin lesions of hyperthyroidism are uncommon and more often associated with a dull, greasy, lusterless haircoat.

Feline hyperadrenocorticism is rare; however, spontaneous and iatrogenic Cushing disease can produce FSA of the trunk or pinnae associated with thin hypotonic skin.

Telogen Effluvium

This is a syndrome in which the anagen cycle is shortened and a wave of hairs simultaneously enters the resting phase. Conditions associated with physiologic stress (e.g., fever, shock, pregnancy and lactation, malnutrition, adverse drug reactions, or a severe debilitating disease) can precipitate rapid shedding in animals. The resultant alopecia can be partial to complete, localized or generalized, and usually non-pruritic. Affected hairs are easily epilated by friction or grooming.

Anagen Defluxion

This is a syndrome in which there is a sudden interruption of growth of anagen hairs, causing deformity

and fragility of the hair, which is then subject to breaking, and leading to alopecia. Causes of anagen interruption may include severe disease and fever. A wave of hair loss occurs shortly after the precipitating event.

Systemic Disease

Diffuse, symmetric, or asymmetric hair loss in the cat can be caused by systemic disease. Hair follicles are sensitive to pathologic and physiologic changes resulting from systemic diseases, such as end-stage kidney disease, chronic hepatitis, diabetes mellitus, and viral infections (FeLV, FIV). The degree of pruritus and skin lesions associated with the alopecia is variable.

CLINICAL SIGNS

- FSA is either self-induced (pruritic) (a direct result of the cat excessively licking or pulling the hair out) or non-pruritic (hair follicles fall out independently). The finding of stubbled or broken hairs suggests self-trauma. However, invasion of organisms, such as dermatophytes, into the hair shaft can also produce fractured or stubbled hairs. A trichogram (examination of hairs under low-power microscopy) may help demonstrate broken hair shafts or fungal elements.
- A history of frequent vomiting of hairballs or hair in the feces (or hair impaction of feces) may also support the possibility of self-induced alopecia and excessive grooming.
- Excoriations, erosions, and/or ulcerations in conjunction with stubbled hairs usually imply that the hair loss and skin changes are self-inflicted. These lesions may also be secondary manifestations of a primary vesicular or bullous disease; however, these lesions are usually associated only with rarely seen dermatoses.
- Pruritic or self-inflicted alopecia that is responsive to systemic corticosteroid therapy suggests an underlying allergic or parasitic etiology. Alopecia that is responsive to systemic progestational therapy, however, may have a hormonal, an allergic, or a psychogenic basis.
- Cats that are nervous, poorly adjusted, or high strung are more likely to develop excessive grooming behavior (e.g., psychogenic alopecia) and subsequent alopecia.
- Systemic signs (e.g., anorexia, vomiting, weight loss, polydipsia, polyphagia, or polyuria) may be present when the alopecia is associated with either a primary systemic disease (e.g., renal disease or diabetes mellitus) or a secondary hormonal imbalance (e.g., iatrogenic Cushing disease).

DIAGNOSIS

▼ ***Key Point*** FSA can be classified as either self-induced (pruritic) or non-pruritic based on the history and gross appearance of the haircoat and skin. The goal of diagnostic evaluations is to identify the underlying disease.

When self-induced alopecia is suspected but not supported by history and physical findings, preventing the cat from licking the body, using an Elizabethan collar continually for 2 to 4 weeks, is often conclusive. In such cases, obtain baseline diagnostic tests first (e.g., skin scrapings and fungal culture).

History

Evaluate for pruritus, the general psychological state of the cat, environmental changes that preceded the alopecia, past and current hormonal status of the cat, concurrent systemic signs, and possible nutritional or therapy-related causes.

Physical Examination

Perform a thorough examination of the integument and all internal organ systems.

- Examine hair shafts and follicles from affected areas, grossly and microscopically, for structural abnormalities (e.g., fractures, bulges, and constrictions). Telogen hairs plucked from the skin have a fusiform appearance and a dry, white, club-shaped root on gross or microscopic examination. In contrast, growing or anagen hairs have a blunt end that is glistening, pigmented, and surrounded by a root sheath.
- Examine the skin in both alopecic and normal areas for primary (erythema, papules) and secondary (crusts, scale, hyperpigmentation) lesions. Note the thickness and elasticity of the skin.
- Search for external parasites (fleas and flea dirt—use a flea comb over the entire trunk).
- Note abnormalities in other organ systems.

Diagnostic Tests

Tests for Bacteria and Yeast

- Perform *skin surface cytology* (see Chapter 37) to check for bacterial and yeast secondary infections.

Tests for Mites

- Perform *deep skin scrapings* to rule out *D. cati* infestations.
- Perform *superficial or surface skin scrapings* to rule out *D. gatoi, Otodectes cyanotis, Notoedres,* or other external mite infestations.
- Collect *ear smears* from cats with concurrent otitis externa or those with a history of recurrent otodectic mange (ear mites).

Tests for Dermatophytes

- Perform *fungal culture* to identify a dermatophyte infection. Examine affected hairs with an ultraviolet light (Wood's lamp). Approximately 50% of the cases of *M. canis* fluoresce. Use hairs that fluoresce an apple-green color, both for culturing and for microscopic examination for fungal spores or hyphae, using a clearing agent (KOH). Refer to Chapter 42 for details concerning the diagnosis of dermatophytosis.

Allergy Testing

- In cats with non-seasonal FSA, institute an *elimination diet* trial (see Chapter 47). The diagnosis of food allergy is confirmed with amelioration of the pruritus and/or excessive licking during a 4- to 8-week diet trial and recurrence of signs following provocative exposure to the original diet or offending antigen.
- Perform *intradermal skin testing* or *in vitro allergy testing* for flea and environmental allergens in cats with a history of seasonal (spring to fall) and non-seasonal pruritus, especially if there is a history of response to systemic corticosteroid therapy. Correlate positive reactions with the history of allergen exposure and seasonality.

Flea Control

- Appropriate flea control (see below) should be instituted in any cat with FSA involving any body location, but especially if the caudal dorsum, tail base, perineum, caudal or medial thighs, ventral abdomen, and/or inguinal regions are involved.

Skin Biopsy

- Skin biopsy of affected and unaffected areas is helpful in evaluating the growing stages of hair follicles and in identifying any concurrent follicular inflammation—whether infectious, parasitic, or allergic. (See Chapter 37 for skin biopsy technique.)

▼ ***Key Point*** Histopathology of affected skin is not usually helpful in making a specific diagnosis. Most often the pathologist will be able to indicate if there is a primary inflammatory or primary endocrine disease, at best. Thus, histopathology is typically of little benefit in the workup of FSA.

Endocrine Tests

- Obtain *baseline serum thyroid hormone* levels or perform a *TSH stimulation test* in cats with non-pruritic alopecia and histopathologic findings consistent with an endocrine-based alopecia. A TSH stimulation test is superior to serum baseline T_4 levels for diagnosing hypothyroidism in the dog and cat and is the test of choice (see Chapter 31).
- Perform an *adrenocorticotropic hormone (ACTH) stimulation test* in cats with non-pruritic alopecia and concurrent polyuria, polydipsia, polyphagia, lethargy, pendulous abdomen, and/or thin, easily torn skin to rule out iatrogenic or naturally occurring hyperadrenocorticism (see Chapter 33).

Ancillary Laboratory Tests

- Perform a *complete blood count, serum biochemical profile,* and *urinalysis* in cats with symmetric alopecia and concurrent systemic signs (e.g., fever, depression, anorexia, and polyuria-polydipsia) to identify any underlying primary disease (e.g., diabetes mellitus) or adverse reaction to previous therapy (e.g., iatrogenic Cushing disease resulting from prolonged systemic corticosteroid or progestational therapy).
- The finding of peripheral eosinophilia in a cat with seasonal or non-seasonal pruritus and/or licking is suggestive of an allergic or parasitic dermatitis.
- Perform *FeLV and FIV tests* in cats with generalized demodicosis, non-healing skin infections, or protracted systemic signs (see Chapters 6 and 7).

TREATMENT

FSA is often managed with "scientific neglect" during the early stages when hair loss is mild and pruritus is absent. However, if the alopecia progresses or is observed to be self-induced, pursue an underlying cause and prescribe appropriate treatment. Determine from the onset whether the hair loss is due to self-induced behavior (licking, chewing, hair pulling) or to an underlying, non-pruritic disease (hormonal, systemic disease). Many cats are "closet lickers"; therefore, the owners may not observe excessive licking or chewing. In such cases, applying an Elizabethan collar for 2 to 4 weeks can be very helpful in identifying whether or not the cat is actually licking the hair out. Chronic cases of FSA that are associated with secondary skin changes and pruritus often require symptomatic treatment with anti-inflammatory agents during the initial stages of the diagnostic workup. Avoid prolonged corticosteroid therapy until the primary etiology has been identified and appropriately treated.

Specific Therapy

Hypoallergenic Diet

Feed a hypoallergenic diet to cats with symmetric alopecia caused by a dietary allergy (see Chapter 47). Many cats are finicky eaters and will not eat home-cooked diets. Pureeing the foods often increases the palatability of home-cooked diets. Use a daily multiple mineral-vitamin supplement when home-cooked diets are used for a prolonged period. Several commercial diets are well tolerated by food-allergic cats, including canned

Response Formula LB/Feline (Eukanuba Veterinary Diets) and canned or dry Limited Diets Feline/venison and green pea/rabbit and green pea (Innovative Veterinary Diets).

Immunotherapy

Allergen-specific immunotherapy (ASIT) (hyposensitization) has been reported to be an effective treatment for feline atopic dermatitis (see Chapter 46). In a recent study, Halliwell found an improvement of at least 50% in 42 cats with various dermatologic manifestations of feline atopic dermatitis following ASIT. The percentage of response for each dermatologic manifestation varied, ranging from 60% to 94%.

Flea Control

Flea control is a critical part of the management of feline flea allergy and infestation. Currently, there are several topical and/or systemic products available for use in cats and dogs that are so effective that environmental treatment is often not necessary (see Chapter 45). Lufenuron (Program, Novartis), given orally at a dosage of 10 to 15 mg/kg once a month, prevents the synthesis of chitin, which is needed for normal flea development. Eggs laid by fleas that feed on treated cats or dogs fail to hatch, and new larvae fail to molt. It has no affect on adult fleas. In contrast, topical solutions containing imidacloprid (Advantage, Bayer), fipronil (Frontline Top Spot, Rhone Merieux), or selamectin (Revolution, Pfizer), when applied once a month to the skin surface, kill adult fleas before they have a chance to lay eggs, eliminating the need for concurrent environmental flea treatment. For rapid elimination of fleas, oral nitenpyram (Capstar, Novartis) may be useful.

Antibacterial and Antiyeast Therapy

If a secondary bacterial infection is present, a 3-week course of antibiotics is essential. Commonly prescribed antibiotics include cephalexin (generics) (22 mg/kg twice daily) and amoxicillin/clavulanic acid (Clavamox, Pfizer) (13.5 mg/kg twice daily).

In the case of secondary yeast infections, systemic itraconazole (Sporanox, Janssen) at 5 mg/kg once daily is usually effective at eliminating the infection.

For both secondary bacterial and yeast infections, topical therapy with chlorhexidine +/− miconazole (e.g., Malaseb, DVM Pharmaceuticals) provides additional useful adjunctive therapeutic support. If the secondary infection is localized, topical therapy alone may be adequate.

Antifungal Therapy

Clinical management of feline dermatophytosis includes clipping and cleansing of the affected areas, generalized topical antifungal therapy, isolation and appropriate sanitation, and systemic antifungal therapy (griseofulvin, ketoconazole, itraconazole) in severe generalized cases. Refer to Chapter 42 for details concerning the treatment of feline dermatophytosis.

Miticidal Therapy

- Apply miticidal solutions containing 2% lime sulfur (LymDyp, DVM Pharmaceuticals) once weekly for six treatments for FSA caused by *D. cati* or *D. gatoi*.
- Treat FSA caused by otodectic mange with topical or systemic ivermectin (Ivomec, MSD Agvet) at a dosage of 0.2 to 0.4 mg/kg PO or SC weekly for 4 to 6 weeks or with application of selamectin (Revolution, Pfizer) to the back of the neck every 2 weeks for three treatments. Because of the contagious nature of *O. cyanotis,* both the affected cat and all contact animals are treated for 4 to 6 weeks with a miticidal otic preparation or ivermectin.

Antiinflammatory Therapy

Use antiinflammatory drugs in cats with symmetric alopecia and concurrent pruritus that are suspected of having an underlying allergic disease (e.g., food allergy, atopic dermatitis, or flea allergy). Short-term treatment with systemic antihistamines or corticosteroids may be used during the initial stages until the causative allergen is identified (diet trial, intradermal or serum allergy testing) and is eliminated or appropriately controlled (hypoallergenic diet, immunotherapy, flea control).

Systemic Antihistamines

Compared with systemic corticosteroid use, systemic antihistamine use is generally not as effective in controlling pruritus in cats. Chlorpheniramine maleate, given at 2 mg/cat q12h PO, can be an effective treatment in cats with pruritus of an unknown or idiopathic nature. We have found hydroxyzine hydrochloride, given at 10 mg/cat q12h PO, to be effective for control of pruritus in cats with feline atopic dermatitis.

Fatty Acid Supplements

DVM Derm Caps (DVM Pharmaceuticals), 0.11 ml/kg q24h PO, are occasionally effective in controlling pruritus in cats when given alone or in combination with an antihistamine (chlorpheniramine, hydroxyzine). However, 4 to 8 weeks may be required before improvement is noted.

Systemic Corticosteroids

Corticosteroids are very effective in the management of pruritus in cats. Cats require much higher doses than dogs to suppress or control pruritus of an allergic nature. Compared with other species, cats appear to be more resistant to the harmful side effects of systemic corticosteroid therapy and the development of

iatrogenic Cushing disease. Administer dexamethasone at a dosage of 0.25 to 1.0 mg/cat once daily with a taper to 2 to 3 times weekly, or prednisolone at a dosage of 2 mg/kg q24h PO for 7 to 14 days with a taper to an alternate-day schedule, and gradually taper to the lowest effective dose. Methylprednisolone acetate (Depo-Medrol, Upjohn) given at a dose of 4 to 5 mg/kg or 20 mg/cat SC is also effective when administered every 2 to 3 weeks. When giving repeated corticosteroid injections (Depo-Medrol) every 2 to 3 weeks, do not exceed four treatments at this interval. If pruritus persists, it is imperative to find the underlying disease or look for alternative treatments.

Systemic Progestational Compounds

These compounds have been used for years to treat various feline skin diseases, including FSA, both pruritic (e.g., atopy and psychogenic alopecia) and non-pruritic (e.g., feline endocrine alopecia). In cats, progestational compounds such as megestrol acetate (Ovaban, Schering-Plough) are immunosuppressive and have potent anti-inflammatory activity. They exhibit a wide spectrum of actions and side effects. Serious side effects in the cat include decreased spermatogenesis, pyometra, mammary gland fibroadenomatous hyperplasia and mammary neoplasia in both male and female intact and neutered animals, permanent or transient diabetes mellitus, adrenocortical suppression, and various behavioral abnormalities (e.g., polyphagia with subsequent weight gain, polyuria, polydipsia, and lethargy). The oral dosage in cats is variable and starts with an induction dose of 2.5 to 5 mg per cat q24h for 5 days, decreases to every other day, and is tapered to 2.5 to 5 mg every 5 to 7 days for 1 to 2 months.

▼ ***Key Point*** Progestational compounds are not approved for use in cats. Because of this and their numerous side effects, they are administered only as the last choice.

Hormonal Therapy

Hormonal therapy has been successfully used in the cat to treat non-pruritic, FSA that is associated with normal-appearing skin and classified as endocrine in origin. Although various hormones have been effective in the treatment of feline endocrine alopecia, relapses are common and intermittent lifelong therapy is often necessary.

Combined Estrogen and Testosterone

These have been used successfully in both neutered male and female cats with feline endocrine alopecia. Repositol testosterone (12.5 mg/cat) and repositol diethylstilbestrol (0.625 mg/cat) are given IM separately or in combination. Although hair regrowth is usually present by 6 weeks, relapses are common. Side effects, including signs of estrus in females, aggressive behavior or urine spraying in males, and hepatobiliary disease in both, have been reported following androgen and/or estrogen therapy.

Thyroid Hormone

Supplemental thyroid hormone has been found to be effective in cats with feline endocrine alopecia, despite normal serum baseline thyroid levels. Sodium levothyroxine is effective at a dosage of 0.05 to 0.1 mg q12–24h PO. Sodium liothyronine (Tertroxin, Glaxo) given at 50 µg q12h PO has been reported to produce complete hair regrowth in 73% of cats treated (Thoday, 1989).

Progestational Compounds

These compounds can be effective in the management of feline endocrine alopecia. Megestrol acetate (2.5–5.0 mg/cat PO once every other day for 1–2 months) is preferred over repositol progesterone due to potential side effects of the latter in cats.

Adrenalectomy

Either unilateral or bilateral adrenalectomy is the treatment of choice for naturally occurring hyperadrenocorticism in the cat (see Chapter 33). Discontinue and avoid future treatment with systemic corticosteroids and progestational compounds in cats with iatrogenic hyperadrenocorticism.

Antianxiety Drugs and Tranquilizers

These drugs can be used in conjunction with behavior modification to treat cats with stress-induced symmetric alopecia or psychogenic alopecia. Because response to systemic antianxiety medication is variable in cats and requires much patience and effort on the part of the owner, identification and removal (if possible) of the predisposing cause is crucial. Use these drugs as adjunctive therapy to behavioral modification. The main goal is to calm the cat and eventually discontinue the antianxiety medication.

- Examples include clomipramine, alprazolam, fluoxetine, and amitriptyline.

Chapter 53

Miliary Dermatitis and Eosinophilic Granuloma Complex

Wayne S. Rosenkrantz

Miliary dermatitis (MD) and eosinophilic granuloma complex (EGC) are extremely common cutaneous reaction patterns in the cat. The term *miliary* is a descriptive one, and it implies that the papules and crusts characteristic of the syndrome resemble millet seeds. The term *eosinophilic granuloma* is also descriptive of a group of lesions affecting the skin and oral cavity of the cat. The three clinical histologic syndromes included in this complex are eosinophilic ulcer, eosinophilic plaque, and eosinophilic (collagenolytic) granuloma.

ETIOLOGY

▼ ***Key Point*** MD and EGC are neither final diagnoses nor pathognomonic for any one disease. Many etiologies exist for both reaction patterns. The ability to control or cure chronic or recurrent cases is dependent on pursuing the underlying cause. The two conditions share similar etiologies and therefore are discussed together in this chapter.

Underlying causes or predisposing factors for MD and EGC (Table 53-1) include (1) allergies, (2) parasites, (3) infectious diseases, and (4) miscellaneous conditions.

Allergies

Allergies to biting insects (e.g., fleas, mosquitoes, and flies), foods, environmental allergens, and rarely contact substances (irritants and allergens) have been associated with MD in the cat. With the exception of contact allergies, all of these reactions have also been associated with EGC. In particular, flea and other biting insect hypersensitivities have been emphasized as etiologies in EGC.

Parasites

Parasites, such as fleas, *Demodex, Cheyletiella, Notoedres,* chiggers, *Otodectes,* lice, cat fur mites, and endoparasites, have been associated with MD. Fleas have also been implicated in EGC as a cause of a hypersensitivity reaction. These parasites also produce lesions in MD by way of a hypersensitivity reaction. Refer to the respective chapters concerning these various parasites for additional information.

Infectious Diseases

Infectious causes for both entities include bacterial infections and dermatophytosis. In EGC, viral infections are an additional consideration and for MD consider *Malassezia* (yeast) infections (see Chapter 41).

- The most common bacteria isolated in both entities include *Staphylococcus,* hemolytic *Streptococcus, Pasteurella,* and *Bacteroides* species. Presence of bacteria on cytology and positive clinical response to a variety of antibiotics in both MD and EGC gives support to a bacterial etiology. Although secondary bacterial infections are uncommon in cats (less common than in dogs), their role in disease and contribution to clinical signs is easily overlooked.
- The major dermatophyte species isolated from cats is *Microsporum canis* (see Chapter 42). This dermatophyte can produce MD, but it can also be found on cats without MD. This dermatophyte is rarely isolated from EGC lesions, and its significance in this complex is questionable.

Miscellaneous Causes

Miscellaneous conditions causing MD include genetic factors, immune-mediated diseases, drug reactions, nutritional factors, epitheliotropic lymphoma, and idiopathic causes. Genetic factors, immune-mediated disease, and idiopathic causes have received attention as etiologies in EGC.

- *Hereditary (genetic) factors* have been implicated based on reports of offspring from affected cats, which have developed similar MD or EGC lesions.
- *Immune-mediated disorders,* such as pemphigus foliaceus, can produce MD-like lesions. Immune-mediated disease has not received much consideration in EGC, although antiepithelial antibodies

Table 53-1. ETIOLOGIES OF MILIARY DERMATITIS AND EOSINOPHILIC GRANULOMA COMPLEX

(immunoglobulin G) have been documented in cats with eosinophilic ulcers.

- *Drug reactions* can mimic any skin disease. Cases of drug-induced MD lesions have been seen but are rare. Drug-induced EGC lesions are questionable; however, some of the dorsal cervical eosinophilic ulcerative lesions can be due to injection-site reactions.
- *Nutritional factors* related to fatty acid or biotin deficiencies have been reported in the older literature as causes of MD. Such deficiencies are unlikely in cats on commercial, well-balanced diets.
- *Cutaneous neoplasms* (squamous cell carcinoma, mast cell tumor, lymphoma) can mimic MD and/or EGC.
- *Idiopathic forms* exist for both MD and EGC. Such cases most likely reflect the inability to identify one of the aforementioned diseases. Undefined allergic reactions may account for a number of these idiopathic cases.

CLINICAL SIGNS

Miliary Dermatitis

- The lesions of MD are usually small erythematous papules (1–2 mm) that develop into crusts. Secondary lesions result from self-trauma and produce alopecia, erosions, excoriations, and acute pyotraumatic dermatitis. The distribution can be localized to a specific area or generalized. The dorsal lumbosacral, cervical, and inguinal areas are the most common sites affected.
- Additional physical signs that may be noted in MD include the following:
  - Peripheral lymphadenopathy of the inguinal lymph nodes
  - Personality changes such as depression and hiding
  - Pain or twitching over affected sites
  - Concurrent lesions of EGC

Eosinophilic Granuloma Complex

The lesions of EGC are variable and are classified into three types.

Eosinophilic Ulcer

- *Eosinophilic ulcer* (indolent, rodent, and lip ulcer) is a well-circumscribed, red-brown to yellow, ulcerated lesion most commonly found on the upper lip of the cat. The lesions are generally non-painful and non-pruritic.

Eosinophilic Plaque

- *Eosinophilic plaque* is a well-circumscribed, raised exudative lesion that is highly pruritic and generally found on the abdomen or inguinal region. This lesion is the most common form of EGC in cats with concurrent MD.

Eosinophilic Collagenolytic Granuloma

- *Eosinophilic collagenolytic granuloma* is seen primarily in young cats and is a well-circumscribed, raised, erythematous to yellow linear, papular, or nodular lesion. It is most commonly found in a linear pattern (linear granuloma) over the caudal thighs and in a nodular pattern on the lower lip and in the oral cavity. Other sites include the bridge of the nose, chin, lips, pinnae, footpads, paws, and perianal region.

DIAGNOSIS

History

History helps identify seasonal allergies, such as flea and other insect hypersensitivities, atopic dermatitis, and

chiggers. A history of pruritus with MD lesions is more typical of parasitic and allergic hypersensitivity disorders.

Physical Examination

Physical examination can also help narrow the differential diagnosis in both MD and EGC by identification of the specific lesion and by the body location of the lesions.

Miliary Dermatitis

The distribution of MD lesions favors some etiologies over others:

- Dorsal distribution (especially the lumbosacral area) favors flea hypersensitivity. Cheyletiellosis can also have a dorsal distribution.
- When the head and neck are affected, consider notoedric mange, otodectic mange, food allergy, atopic dermatitis, pyoderma, or pemphigus foliaceus.

Eosinophilic Granuloma Complex

The distribution of EGC lesions is less helpful in limiting the differential diagnoses.

- Nasal and pinnal forms of eosinophilic collagenolytic granuloma tend to support the diagnosis of insect bite reactions (i.e., mosquito and black fly).
- Eosinophilic plaques on the abdomen and inguinal region suggest the diagnosis of flea hypersensitivity.
- Pruritic cervical EGC lesions are more commonly seen in food allergy, atopic dermatitis, bacterial infection, or injection-site reactions.

Minimum Database

- *Skin scrapings, Scotch tape preparations,* and *combings of hair and dander* for fleas and mites are very important in the initial MD diagnostic evaluation.
- *Skin cytology* can be of value to determine the presence of infectious organisms and inflammatory cells. Skin cytologic specimens are obtained by fine-needle aspirate of the lesion, by touching a glass slide to the lesion, or by surface scraping of the lesion (see Chapter 37). Tissue eosinophilia suggests the diagnosis of parasitic and allergic disorders.
- *Dermatophyte culture* is the best way to rule out a dermatophyte as the cause of MD (see Chapter 42).

Bacterial Culture

Bacterial culture and sensitivity tests, performed from an intact pustule, bulla, furuncle, or skin biopsy sample, can give additional information on etiology and choice of correct antibiotic for therapy. Bacterial culture is necessary if initial empirical antibiotic therapy has failed and a bacterial infection is still suspected.

Routine Blood Tests

- *Complete blood counts* may reveal peripheral eosinophilia associated with parasitic and allergic disorders, especially flea allergy. Peripheral eosinophilia tends to be seen in most cases of eosinophilic plaque and in many cases of eosinophilic collagenolytic granuloma, especially with oral lesions.
- *Serum biochemical analysis* helps rule out other concurrent medical problems.
- *Viral testing* for feline leukemia virus and feline immunodeficiency virus are recommended in recurrent cases of MD and EGC (see Chapters 8 and 9). Results of both chemistry and viral screens will influence treatment and prognosis.

Skin Biopsy

Dermatopathology is one of the most important diagnostic tests performed. Findings may support the clinical assessment, suggest additional diagnoses, provide a specific diagnosis, and rule out differential diagnoses (such as neoplasia with EGC lesions). With EGC, specific histologic patterns have been associated with the three clinical entities:

- *Eosinophilic ulcer* is usually characterized by a chronic ulcerative suppurative dermatitis. In some cases histopathology may reveal eosinophilic collagenolytic dermatitis with palisading granulomatous inflammation.
- *Eosinophilic plaque* is characterized by marked intercellular edema (spongiotic dermatitis) and tissue eosinophilia. Surface crusting with degenerating inflammatory cells with focal areas of erosions, ulceration, or necrosis are not uncommon. This is similar to what is seen histologically in some MD lesions.
- *Eosinophilic collagenolytic granuloma* is characterized by eosinophilic collagenolytic dermatitis with palisading granulomatous inflammation.

Allergy Testing

Food Elimination Diets

A food elimination diet is the only way to accurately rule out food allergy (see Chapter 47). Such a diet consists of a protein source that the cat does not or has not eaten routinely.

- The common choice is lamb baby food, but ham baby food, home-cooked chicken, turkey, fish, rabbit, and other protein sources have been provided successfully (see Chapter 47). If baby food is used, feed a product that does not contain onion powder (i.e., Beech-Nut products) to avoid potential for Heinz body anemia.
- Alternative commercially available diets include Hills (Feline z/d), Innovative Veterinary Diets (rabbit or venison with green pea), Waltham (Hypoallergenic

HP), Royal Canin (Sensitivity VR and RD) and Eukanuba (Response LB) diets. The elimination diet is fed strictly for 6 to 8 weeks.

Intradermal Allergy Testing

Intradermal testing (IDT) helps demonstrate hypersensitivity to insect and environmental allergies. Allergy testing in the cat is more difficult to perform and interpret than in the dog. Testing is, therefore, best done by an experienced veterinary allergist (see Chapter 46).

Serum In Vitro Allergy Testing

Serum in vitro allergy testing (SIAT) has improved significantly in the cat. I have had results comparable to skin testing using a liquid-phase enzymo-immunometric assay (Veterinary Allergy Reference Laboratory; Pasadena, CA) for selecting antigens for allergen-specific immunotherapy (ASIT).

▼ ***Key Point*** Positive allergy test results (IDT or SIAT) should not form the basis for a diagnosis of atopic dermatitis—positive results will help confirm the clinical diagnosis of atopic dermatitis and are essential in the selection of allergens for inclusion in immunotherapy. Allergy tests have not been shown to be useful in the diagnosis of food allergy in cats.

TREATMENT

▼ ***Key Point*** Many forms of therapy have been described for both MD and EGC. The best long-term management is achieved when a definitive diagnosis of the underlying cause has been established and specific therapy for that disease is prescribed.

Avoidance of Inciting Etiologies

Avoidance strategies are commonly used for flea bite hypersensitivities, other ectoparasitic hypersensitivities, food hypersensitivities, epithelial allergens (feathers, cat, dog, or human dander) or mold allergies and most recently for house dust mite (HDM) hypersensitivities.

Control of House Dust Mites

In my practice, HDM *(Dermatophagoides farinae)* is the most common non-seasonal allergic reaction seen in the feline.

- HDM detection can be performed by using an in-home swipe test on any textile surface (MITE-T-Fast Allergen Detection System, Aveho Biosciences). In many cases testing is not necessary and treatment can be based upon the presence of a positive allergy test or a strong clinical suspicion.
- Although treatment options for environmental allergen and mite reduction (Allerase and Dustmite, Aveho Biosciences) are available, their efficacy has not been determined in the feline. However, I commonly recommend the use of environmental control based on positive experiences seen in HDM allergy in the canine.
- In addition to treating the premises, it is also recommended to install a room air conditioner and dehumidifier in the bedroom if the home does not have central air conditioning. Lowering humidity reduces the number of mites, as well as mold and other allergens.
- It is also recommended to use wood, vinyl, or leather furniture instead of upholstery furniture; vacuum frequently; avoid pet foam beds; and wash all bedding materials in hot water (>130°F) weekly.

Glucocorticoid Therapy

This therapy can be tried in first-time cases of MD and EGC. In chronic recurrent cases, alternative therapy is given based on information from an appropriate workup. Even with proper workup, refractory allergies or idiopathic cases of both MD and EGC may require long-term glucocorticoid therapy. A variety of glucocorticoids can be tried.

- Methylprednisolone acetate (Depo-Medrol, Pfizer) at 4 mg/kg IM is a commonly used, and often efficacious, long-acting injectable glucocorticoid. Cases of refractory EGC may need three injections at 2-week intervals. In general, after remission, do not use methylprednisolone acetate more often than every 3 months.
- As an alternative to methylprednisolone acetate, give anti-inflammatory doses of prednisolone or methylprednisolone at 2.2 mg/kg PO q24h for resolution of lesions. Decrease the dose to 1 to 2 mg/kg PO q48h for maintenance.
- Some cases can be successfully managed with initial injections of methylprednisolone acetate and then maintained with oral prednisone, prednisolone, or methylprednisolone at a dosage of 1 to 2 mg/kg PO q48h.
- Other oral glucocorticoids can be tried in refractory cases. Use triamcinolone at a dosage of 0.4 to 0.6 mg/kg PO q24h, then tapering to 0.2 to 0.3 mg/kg PO q48h–72h for maintenance; or use dexamethasone at a dosage of 0.25 to 0.75 mg PO q24h, then tapering to 0.25 to 0.125 mg q48h–72h for maintenance.
- Use intralesional triamcinolone (Vetalog, Squibb) in refractory EGC lesions at a dose of 1 to 4 mg injected intralesionally.

Antihistamine Therapy

Antihistamines can be tried in atopic dermatitis, flea allergy, and idiopathic MD and EGC:

- Chlorpheniramine, 2 to 4 mg PO q12h, appears to be the most effective antihistamine in cats and has fewer sedative or excitatory side effects, although results are not as good as with glucocorticoids.
- Other antihistamine choices are the following:
  - Cyproheptadine (Periactin), 2 to 4 mg PO q12–24h
  - Amitriptyline (Elavil), 10 mg PO q12–24h
  - Trimeprazine (Temaril), 0.5 to 1 mg/kg q8–12h
  - Cetirizine (Zyrtec), 5mg/cat q12h
  - Fexofenadine (Allegra), 10mg/cat q12h
  - Hydroxyzine hydrochloride or pamoate, 10 mg PO q12h

Food Allergy Management

After determining that a cat has a food allergy, manage with a balanced home-cooked diet or a commercial diet that is tolerated (see Chapter 47).

Allergen-Specific Immunotherapy

ASIT, based on in vitro or in vivo testing, is becoming more promising in cases of EGC and MD in which atopic dermatitis is the underlying cause. Currently, SIAT is my preferred method of allergy testing in the cat. In a limited number of cases, ASIT can manage recurrent EGC and MD lesions (see Chapter 46). Flea immunotherapy has had little benefit in controlling flea allergy in the cat. Protocols are similar to those in dogs.

Parasiticidal Therapy

Because parasites directly or indirectly, via a hypersensitivity reaction, contribute to the lesions in MD and EGC, the control of parasites on the pet and in the environment is extremely important. Integrated strategies for flea control are described in Chapter 45. Treatment of *Notoedres* and *Cheyletiella* is described in Chapter 44.

Antimicrobial Therapy

Use antibiotic therapy for primary or secondary infections in both MD and EGC. Initially, select antibiotics empirically based on cytologic findings. In chronic cases, culture and sensitivity results are employed. Therapy for dermatophytosis is described in detail in Chapter 42. Antibiotics for empirical therapy are listed here; continue treatment for a minimum of 2 weeks and 10 days past clinical cure:

- Trimethoprim-potentiated sulfas, 30 mg/kg PO q12h.
- Cefadroxil (Cefa-Drops, Fort Dodge), 20 mg/kg PO q12h.
- Amoxicillin-clavulanate (Clavamox, Pfizer), 12 to 15 mg/kg PO q12h.
- Clindamycin (Anirobe, Pfizer), 5 to 10 mg/kg PO q12h.
- Fluoroquinolones (occasionally); for example, enrofloxacin (Baytril, Bayer), 2.5 to 5 mg/kg PO q24h, or marbofloxacin (Zeniquin, Pfizer), 2.5 mg/kg PO q24h. Dosages greater than 5 mg/kg should be avoided with enrofloxacin due to the potential development of a rare idiopathic blindness syndrome.

Immunomodulating Therapy

Drugs that either stimulate or suppress the immune response have been tried with EGC. Chlorambucil (Leukeran, Glaxo Wellcome), 0.1 to 0.2 mg/kg PO q48h, or aurothiomalate (Myochrysine, Merck), 2 mg/kg IM weekly, may be used in refractory EGC. Both drugs have long lag phases before response is seen and can create side effects (e.g., bone marrow suppression) that should be monitored.

Interferon alpha-2a (Roferon, Hoffman La Roche) has also been tried in refractory EGC cases at a dose of 30 IU/cat PO once daily for 7 days on a one-week-on/one-week-off schedule, with limited success.

Cyclosporine and Tacrolimus

Cyclosporine (Atopica or Neoral oral suspension, Novartis) and tacrolimus (Protopic topical preparations 0.03% and 0.1%, Fujisawa USA) are immunosuppressant agents that have been used extensively in human medicine, primarily to prevent organ transplant rejection. However, I have used these drugs occasionally in the treatment of EGC and MD allergy-induced cases.

- Both drugs are activated by binding to specific intracellular receptors, called immunophilins. They inhibit calcium-dependent pathways, particularly affecting the enzymatic action of calcineurin, resulting in blocking of regulatory proteins that activate T-helper inducer and cytotoxic cells. Many cytokines are affected, especially interleukin-2 (IL-2).
- Cyclosporine is given at 5 mg/kg PO q24h. It may take up to 6 weeks to completely evaluate responses.
- Currently, due to the much greater potency and potential toxicity of tacrolimus and lack of adequate dosing regimes, systemic administration is not recommended and only topical use is recommended. Tacrolimus can be used topically to lesions on a daily basis, and if effective, responses should be seen within 7 to 10 days.
- Both drugs appear to be well tolerated in the cat with gastrointestinal symptoms, the major side effect from oral cyclosporine or ingestion of topically applied tacrolimus.

Progestational Therapy

Progestational compounds have been advocated for treating both MD and EGC. Most veterinary dermatologists do not use or recommend these products because of their potential for severe side effects. They are not approved for use in cats. With the effectiveness of other forms of therapy, progestational drug therapy is undesirable because of the potentially severe and

life-threatening side effects (including pyometra, diabetes mellitus, and mammary neoplasia).

Chapter

54 Surgery of Intertriginous Dermatoses

Jamie R. Bellah

Intertriginous dermatoses are surface pyodermas that are associated with skin folds. Chronic skin apposition results in friction, minor trauma, and poor air circulation along with a moist environment conducive to colonization and infection by bacteria and yeasts.

▼ ***Key Point*** Inflammation and exudates associated with skin fold pyoderma cause pain, pruritus, and malodor. Conservative treatment is only palliative. Resolution of these conditions can be accomplished only by surgery.

ETIOLOGY

Normal skin defense mechanisms are as follows:

- Intact epidermis and stratum corneum
- Sebum that contains antibacterial and antifungal fatty acids
- Skin microflora that may secrete antibiotic-like substances

Skin fold pyoderma is classified as a surface pyoderma. (See Chapter 38 for a complete discussion of pyoderma.)

- Bacteria and yeasts remain on top of the skin.
- Warm, moist environment within recess of the skin fold allows colonization by *Staphylococcus intermedius* or *Malassezia pachydermatis.*
- Other infecting organisms include *Streptococcus, Escherichia coli, Pseudomonas, Proteus,* and *Candida.*
- Surface bacteria and yeasts act on trapped secretions and sebum, producing breakdown products that are irritating and odoriferous.
- Superficial skin erosions and inflammation result.
- Self-trauma and obesity tend to worsen the condition.

Locations, characteristics, and breeds associated with intertriginous dermatoses include the following.

Facial or Nasal Fold

- Frequently associated with secondary ulcerative keratitis
- Brachycephalic breeds: Pekingese, English bulldog, pug, French bulldog, Boston terrier
- Persian cats

Lip Fold

- Common in dogs with excessive mandibular labial tissue, such as spaniels, Saint Bernard, Irish setter, Newfoundland, golden retriever, and Labrador retriever.
- Redundant lip fold is usually located behind the mandibular canine tooth.
- Can be bilateral.
- Causes severe halitosis.
- May occur after partial mandibulectomy or maxillectomy if a skin fold is created during wound closure.

Body Fold

- Usually affects obese or Chinese shar-pei dogs.
- With shar-pei puppies, body folds become less redundant with growth but persist on the head and face.
- May occur in female dogs or cats along the abdominal midline if mammary glands or body fat creates a skin fold.
- Moist seborrhea predisposes the animal to body fold pyoderma.
- Pendulous cervical skin may result in body fold pyoderma, especially if generalized skin disease exists.
- Folds left after surgery (i.e., total ear canal ablation) or created by surgery may result in residual fold pyoderma.

Vulvar Fold

- Most common in older, obese, spayed female dogs and rarely cats.
- Seen in younger dogs with infantile vulvas.
- Accumulation of urine and vaginal secretions occur.

▼ ***Key Point*** Chronic or relapsing urinary tract infection is commonly secondary to vulvar fold pyoderma and recessed vulva.

Tail Fold ("Screw Tail")

- Common in English bulldog, pug, Boston terrier, and schipperke breeds.
- Also seen in Manx cats.
- Caused by redundant skin around the tail and the corkscrew conformation of the terminal coccygeal vertebrae.
- A full-thickness ulcer may be present in the skin under the ventrally deviating tail. This can be very painful and uncomfortable for affected dogs.
- Contamination by fecal flora causes fulminating pyoderma.
- Self-trauma and scooting exacerbate the condition.

PREOPERATIVE CONSIDERATIONS

- Conservative treatment, including clipping hair from the skin fold and cleansing with dilute antibacterial solutions, medicated soaps, antiseborrheic shampoos, astringents, and topical and systemic antibiotics, is palliative only.
- Medical treatment may be advisable before surgery in some animals to lessen the amount of wound exudate and to lower bacterial numbers at the time of surgery (see Chapter 38).
- In the presence of severe infection (i.e., tail fold pyoderma), use a perioperative antimicrobial (e.g., cephalosporins) to help prevent a postoperative wound infection.
- When show animals are affected, counsel the owner with regard to the expected postoperative appearance and consult breed requirements for show.
- Perform urine culture and treat urinary tract infection prior to vulvar fold excision.

SURGICAL PROCEDURES

Objectives

- En bloc excision of the skin fold and associated pyoderma
- Wound closure without excessive tension
- Resolution of wound infection

Equipment

- Standard general surgical pack.
- Suture material appropriate for infected wounds (e.g., polydioxanone for subcutaneous tissues and monofilament nylon for skin).
- Bone-holding forceps aid manipulation of the tail during caudectomy for screw tail.
- Bone-cutting forceps or Gigli saw for caudectomy.
- Penrose drains (most commonly for screw tail excision).
- Sterile skin marking pen

Technique

1. Facial or Nasal Fold Excision

a. Position the animal in ventral recumbency.
b. Protect the eyes with an ophthalmic ointment during preparation and surgery.
c. Clip hair from the facial skin folds and ventral eyelids sufficient to drape an appropriate margin around the fold to be excised.
d. Plan and mark (with sterile marking pen) the boundaries of the incision so that removal of too much skin is avoided. Skin is needed for closure without tension (Fig. 54-1*A*).
e. With two paired incisions, excise enough of the facial fold to alleviate the recess created by the fold and to eliminate any chance of hair contacting the eye.

▼ ***Key Point*** Stay at least 1 cm from the medial canthus of the eye, and avoid lacrimal structures and large vessels in the region.

f. Undermine skin edges gently and carefully, if required.
g. Close in two layers using fine (3-0 or 4-0) absorbable suture for subcutaneous tissue and fine monofilament suture for skin closure (Fig. 54-1*B*).

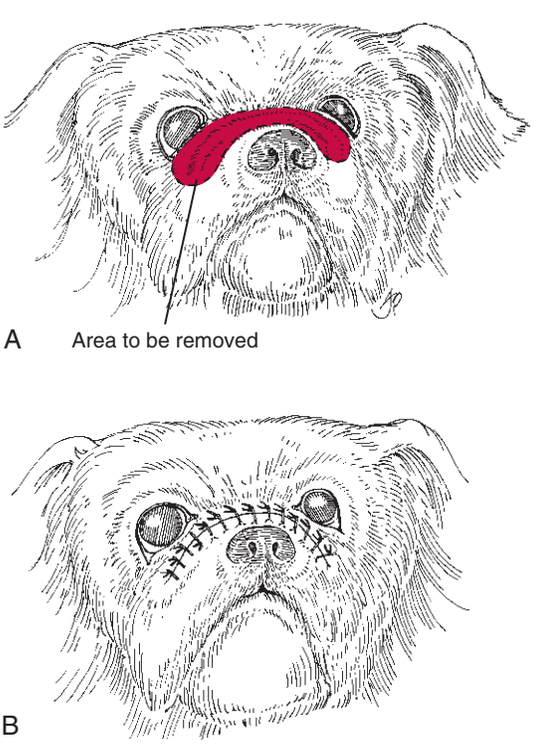

Figure 54-1. Facial fold excision. *A,* Incision boundaries (dotted lines) are planned so that enough skin for closure without tension remains. *B,* Final suture pattern.

h. Cut the suture ends short so that they do not contact the cornea.
i. Alternatively, use an intradermal pattern using fine absorbable suture, eliminating the need for suture removal.

2. Lip Fold Excision (Cheiloplasty)

a. Position the animal in dorsal recumbency.
b. Clip and prepare the skin over the mandible from its rostral tip to the mandibular angle (Fig. 54-2*A*).
c. Make an elliptical incision around the lip fold, and remove the entire fold and infected region (Fig. 54-2*B*).
d. It is very rare that the mucosal surface of the lip needs to be incised.
e. Try to avoid incising the underlying muscles of the lip.
f. Close the incision in two layers using fine absorbable suture for subcutaneous tissue and fine non-absorbable suture for skin (Fig. 54-2*C*).
g. Close the buccal mucosa, if incised, with fine, interrupted absorbable sutures.

3. Body Fold Excision

a. Position the dog so that optimal access to the body fold to be removed is accomplished.
b. Prepare the skin wide enough so the fold can be excised in its entirety.
c. Make two incisions parallel to the fold near its base, being certain to leave sufficient skin for closure.
d. Closure is done in two layers using fine absorbable suture for subcutaneous tissues and interrupted non-absorbable sutures for skin apposition.
e. Mastectomy (see Chapter 29) may be required to resolve body fold pyoderma that has resulted from rolls of abdominal fat or from pendulous mammary tissue.

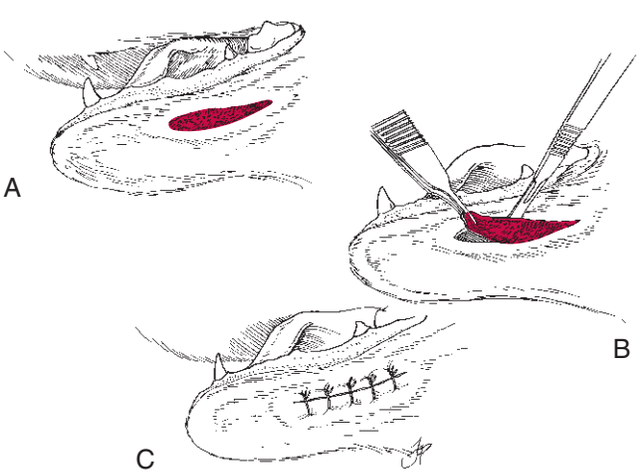

Figure 54-2. Lip fold excision (cheiloplasty). *A,* Preparation of skin. *B,* Excision of fold. *C,* Closure pattern.

4. Vulvar Fold Excision (Episioplasty)

a. Place the animal in ventral recumbency with the perineal region at the end of the table. If the rear legs are draped over the end of the table, be sure to pad them sufficiently.
b. Express the anal sacs, and place a purse-string suture around the anus.
c. Prepare the perivulvar region for aseptic surgery.
d. Mark the proposed skin incision. Make an elliptical incision around the base of the vulvar fold, then undermine and remove the incised area of skin (Fig. 54-3*A*).
e. Starting with the most dorsal suture, place simple, interrupted cuticular sutures equidistant from one another around the incision to approximate the wound margins (Fig. 54-3*B*). This step helps determine if adequate skin and subcutaneous fat have been removed.
f. Close the skin in two layers using fine absorbable suture for subcutaneous tissue and fine non-absorbable sutures for skin (Fig. 54-3*C*).
g. Remove the purse-string suture.

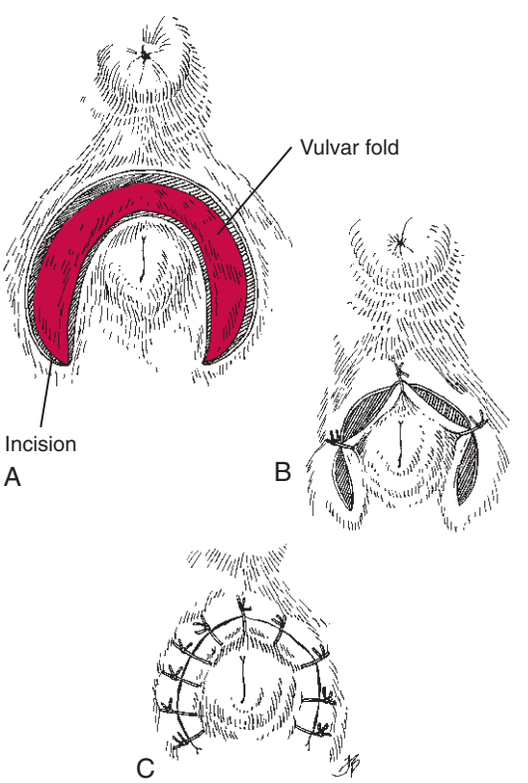

Figure 54-3. Vulvar fold excision (episioplasty). *A,* Incision pattern around the base of the vulvar fold. *B,* Simple sutures approximate the wound margin. *C,* Suture pattern.

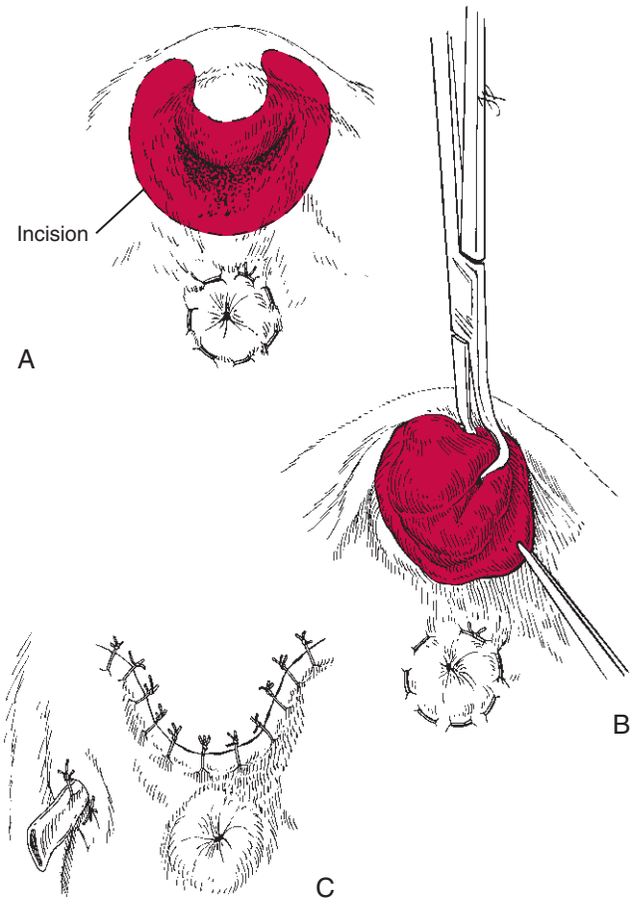

Figure 54-4. Tail fold excision and caudectomy. *A,* Place a purse-string suture around the anus, and incise the tail fold region as shown. *B,* Manipulate the tail with tail-holding forceps. *C,* Wound closure pattern and drain.

5. Tail Fold Excision and Caudectomy

a. Place the animal in ventral recumbency with the perineum facing the end of the table. A frog-leg position is used for this procedure.
b. Express the anal sacs, and place a purse-string suture around the anus.
c. Clip the entire perineum and tail-head region.
d. It is difficult to clip hair from the fold region adequately; therefore, give an antimicrobial drug perioperatively.
e. Make an incision around the tail and tail fold. Skin dorsal to the tail may be preserved and aids in cosmetic skin closure (Fig. 54-4*A*).
f. Attempt to dissect around the tail and skin fold without penetrating the fold.
g. Sometimes, because ventral deviation of the tail causes full-thickness erosion through the skin and en bloc excision cannot be performed, layered debridement must be done.
h. Manipulate the tail using bone-holding forceps (Fig. 54-4*B*).
i. Incise coccygeal and levator ani muscular attachments.
j. Using a Gigli wire or bone-cutting forceps, transect the tail rostral to its ventral deviation.

▼ ***Key Point*** Be careful during transection of the tail not to traumatize the rectum, which is just ventral to the tail base. The rectum may not be easily seen because of overlying muscle and granulation tissue associated with the ulcerated wound that sometimes underlies the ventrally deviated tail.

k. Liberally flush the surgical site with sterile saline.
l. Use several interrupted absorbable sutures to close dead space.
m. Place Penrose drains at this time, if necessary.
n. Close the wound in two layers, using fine absorbable sutures for subcutaneous tissues and fine non-absorbable sutures for skin apposition (Fig. 54-4*C*).
o. Remove the purse-string suture.

POSTOPERATIVE CARE AND COMPLICATIONS

Postoperative Care

- Prevent self-trauma (place an Elizabethan collar).
- Antimicrobial therapy may be given, based on culture and sensitivity testing, if deemed necessary.
- Keep oral incisions free of food and saliva by gentle cleansing.
- Keep perineal incisions clean, and remove fecal contamination.
- Remove Penrose drains in 3 to 5 days.
- Reassess urinary tract infection after vulvar fold excision (episioplasty) by reculture of the urine 2 to 3 weeks postoperatively.

Complications

- Self-trauma
- Wound infection
- Dehiscence
- Ectropion (aggressive facial fold removal)
- Insufficient skin fold removal (relapse of pyoderma)

Chapter 55

Management of the Traumatic Wound by Primary Closure

Mark W. Bohling / Steven F. Swaim

Following proper initial management of a traumatic wound by debridement and lavage, the wound may be closed. Sufficient viable tissue must be present to allow closure without excessive tension. Wounds may be closed by primary closure, delayed primary closure, or secondary closure. See Chapter 56 for a discussion of open wound management.

ANATOMY

- Dogs and cats have abundant skin on the trunk and neck but a sparsity of skin on the distal limbs, tail, ear, and rostral areas of the head.
- Direct cutaneous vessels run parallel to the skin's surface and supply the subdermal plexus of the skin. See Chapter 57 for more details regarding blood supply to the skin.
- Some areas of the body have panniculus musculature underlying the skin. The skin's blood supply runs both superficial and deep to this musculature.
- Other areas of the body have loose areolar fascia deep to the dermis in which vasculature is located, and in other areas the skin is closely associated with underlying fascia.

PREOPERATIVE CONSIDERATIONS

▼ ***Key Point*** If a traumatically induced wound is to be closed, it is imperative that the tissues be viable and clean enough that wound healing can progress uneventfully. Perform adequate debridement and lavage.

- Perform a thorough physical examination and appropriate diagnostic tests on all traumatized animals to rule out associated injuries.
- Perform primary closure when:
  - The animal is in good condition.
  - A short time (6–12 hours) has elapsed since injury.
  - Minimal contamination and tissue trauma have occurred.
  - Adequate debridement and lavage have been done.
  - Adequate hemostasis has been attained.
- Perform delayed primary closure when:
  - Wounds show evidence of heavy contamination, purulent exudate, residual necrotic or questionable tissue, edema, erythema at the wound margins, lymphangitis, and skin tension.
  - Local infection has been controlled by staged debridement, lavage, topical and/or systemic antibiotics, and appropriate bandages. This is usually 3 to 5 days after wounding.
- Perform a secondary closure when:
  - The wound is in the reparative stage of healing at presentation, with a healthy bed of granulation tissue and evidence of epithelialization.
  - The wound has disrupted and has subsequently developed a healthy bed of granulation tissue.
  - It has been necessary to leave the wound open for longer than 5 days to control infection (see Preoperative Considerations, Delayed Primary Closure, Local Infection Control).

SURGICAL PROCEDURES

Primary or Delayed Primary Closure without Tension

Objectives

- Close the wound.
- Provide drainage if necessary.

Equipment

- Standard general surgical pack
- Undyed polyglactin 910, polyglecaprone, dyed or undyed polydioxanone, 2-0 to 4-0 (Vicryl, Monocryl, or PDS II; Ethicon, Somerville, NJ.) and polypropylene or nylon, 2-0 and 3-0 (Prolene or Ethilon, Ethicon, Somerville, NJ.)
- Wound lavage solution of 0.05% chlorhexidine diacetate or gluconate (Nolvasan Solution, Fort Dodge, IA. or ChlorhexiDerm Disinfectant, DVM Pharmaceuticals, Miami, FL.)

Technique

1. Pack the wound with sterile surgical sponges moistened with physiologic saline, or with water-soluble sterile lubricant (K-Y Jelly, Johnson & Johnson, New Brunswick, NJ.) or water-soluble sterile lubricant that contains chlorhexidine gluconate (Surgilube, E. Fougera & Co., Mellville, NY.)
2. Prepare the area around the wound for aseptic surgery.
3. Remove the wound packing or sterile lubricant.
4. Lavage the wound frequently with sterile isotonic fluids (or a solution of 0.05% chlorhexidine diacetate or gluconate) during surgery along with removal of devitalized tissue and debris as indicated.
5. Use as few simple interrupted absorbable sutures as necessary to close dead space in deep layers of the wound.
6. Be careful not to entrap major vessels or nerves in the sutures.
7. Place a drain (Penrose drain, or a closed suction drain [Jackson-Pratt]) if there is any possibility of residual dead space and/or wound drainage.
8. Place a simple continuous suture in the subcutaneous tissue at the wound edge using absorbable suture material.
9. Close the skin with non-absorbable simple interrupted sutures.

Postoperative Care and Complications

- Postoperative care
  - Place absorbent surgical sponges over the suture line, with extra sponges over the end of a Penrose drain.
  - Apply an absorbent secondary wrap to the area, followed by an outer wrap of porous adhesive tape.
  - Change the bandage every second or third day if there is no concern about possible complications. Change the bandage daily if there is concern about possible complications and/or a drain has been placed. The amount and nature of drainage should be assessed at each bandage change.
  - Remove the drain and discontinue bandaging when the drainage becomes minimal and is the same in quantity at successive bandage changes.
  - Remove the skin sutures 7 to 10 days postoperatively.
- Complications: Hematoma, seroma, or infection may result from improper wound evaluation, debridement, lavage, closure, or drain management.

Primary, Delayed Primary, or Secondary Closure with Tension

Objectives

- Close the wound.
- Relieve tension on the skin edges.
- Provide drainage if necessary.

Equipment

- See equipment under Primary or Delayed Primary Closure *Without* Tension.

Technique

1. The general techniques for closure of wounds with tension are the same as those for primary or delayed primary closure without tension (see previous section), with the exception of suture pattern (see tension-relieving suture patterns discussed subsequently).
2. Wounds that are in the reparative stage of healing with healthy granulation tissue and epithelialization.
   a. Excise epithelium from the edge of the wound, leaving healthy granulation tissue in the center.
   b. Gently clean the surface of the granulation tissue with 0.05% chlorhexidine solution (Fig. 55-1).
3. Gently undermine the skin surrounding the wound.
   a. Undermine bluntly, using Metzenbaum scissors, leaving some loose areolar connective tissue on the dermis or undermine beneath panniculus musculature if present.
   b. Undermine sharply with scissors or scalpel blade in areas where skin is closely associated with the underlying fascia.

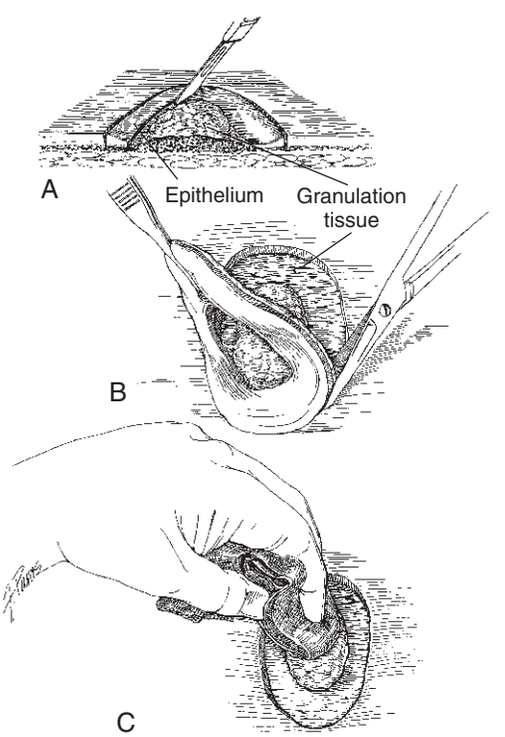

Figure 55-1. Preparation of a wound in the reparative stage of healing for secondary closure. *A,* Incising the epithelium. *B,* Removing the epithelium. *C,* Cleaning the surface of the healthy granulation tissue.

▼ ***Key Point*** Leave large identifiable blood vessels (i.e., direct cutaneous blood vessels) intact when undermining. Use good judgment when manipulating recently traumatized skin to avoid added insult to skin vasculature, which could result in skin slough.

4. One of the following tension-relieving suture patterns may be used to close the wound.
   a. Place "walking" sutures (our choice for closing wounds under tension) with absorbable material in staggered parallel rows, with bites oriented perpendicular to the wound edges to help preserve blood supply. Begin just in front of the plane where undermining stopped. Place a simple continuous subcuticular absorbable suture along the wound edge before skin closure with non-absorbable simple interrupted sutures (Fig. 55-2).
   b. Place an absorbable intradermal continuous horizontal mattress suture to appose the skin edges. This can be reinforced with non-absorbable simple interrupted skin sutures (Fig. 55-3).

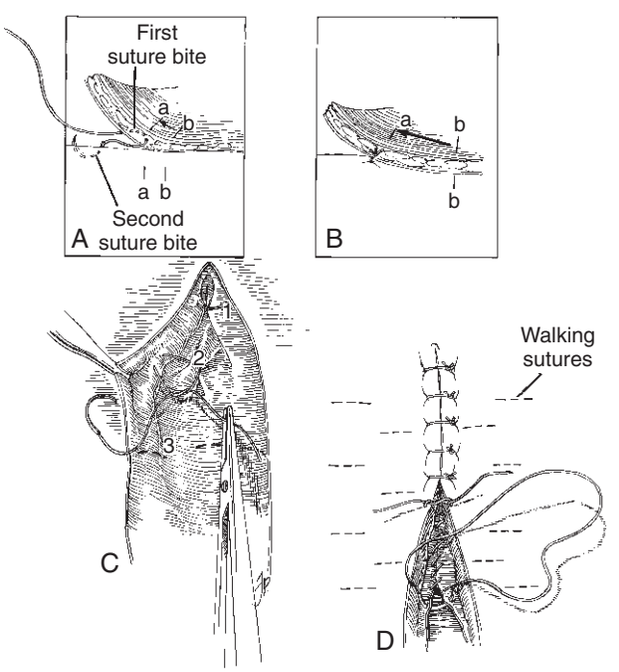

Figure 55-2. "Walking" sutures. *A,* Placing first and second suture bites. Segment of skin to be stretched (from a to b). *B,* Tying a "walking" suture advances the skin toward the center of the wound (a to b increased). *C,* "Walking" sutures placed in rows. 1, Walking suture tied; 2, placing a walking suture; 3, areas where bites will be taken for a walking suture *(broken lines). D,* Placing a simple continuous subcuticular suture along the wound edge, and simple interrupted skin apposition sutures. Broken lines are buried walking sutures. (After Swaim SF: The repair of the skin: Techniques of plastic and reconstructive surgery. *In* Bedford PGC, ed.: Atlas of Canine Surgical Techniques. Oxford: Blackwell Scientific Publications, 1984, p 49; and Swaim SF, Henderson RA: Small Animal Wound Management, 2nd Ed. Baltimore: Williams & Wilkins, 1997, p 154.)

   c. Place non-absorbable vertical mattress sutures near the wound edge over segments of Penrose drain. Use simple interrupted non-absorbable sutures to appose skin edges (Fig. 55-4).
   d. Place non-absorbable "far-near-near-far" or "far-far-near-near" sutures in the order of their names to act as apposition and tension sutures (Fig. 55-5).
   e. Preplace non-absorbable stent sutures deep to the wound tissues prior to closure of the wound. These sutures are then tied over a roll of surgical

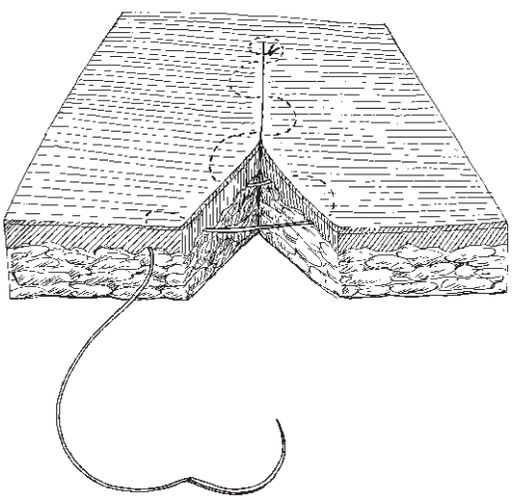

Figure 55-3. Intradermal sutures. Using 3-0 or smaller absorbable suture material in a continuous pattern, place intradermal sutures with each bite being passed horizontally. Figure 55-5. Combination apposition and tension sutures. *A,* "Far-near-near-far" sutures. *B,* "Far-far-near-near" sutures. (After Swaim SF, Henderson RA: Small Animal Wound Management, 2nd Ed. Baltimore: Williams & Wilkins, 1997, p 165.)

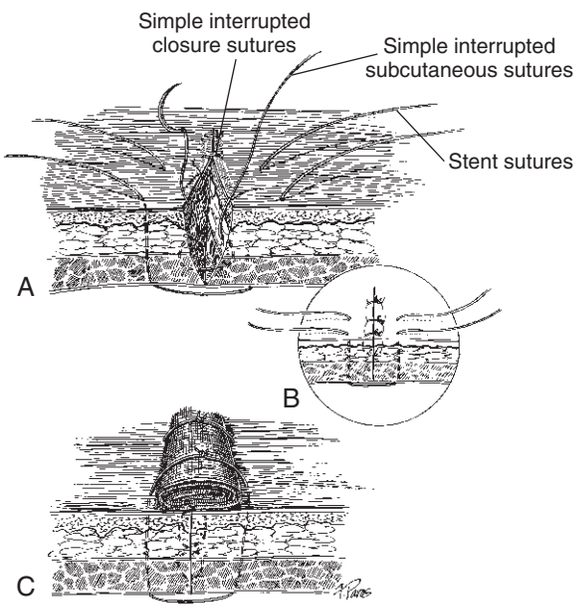

Figure 55-6. Stent sutures. *A,* Preplace stent sutures deep to the wound tissues. *B,* Wound tissues are closed. *C,* Tie stent sutures over a roll of gauze or rolled towel.

sponges or a rolled towel to act as a tension suture as well as to obliterate dead space (Fig. 55-6).

f. Place nonabsorbable Lembert sutures in the skin adjacent to the wound the day before surgery. The sutures are tied under tension. The following day, the "presutures" are removed and the wound is closed using the prestretched skin (Fig. 55-7).

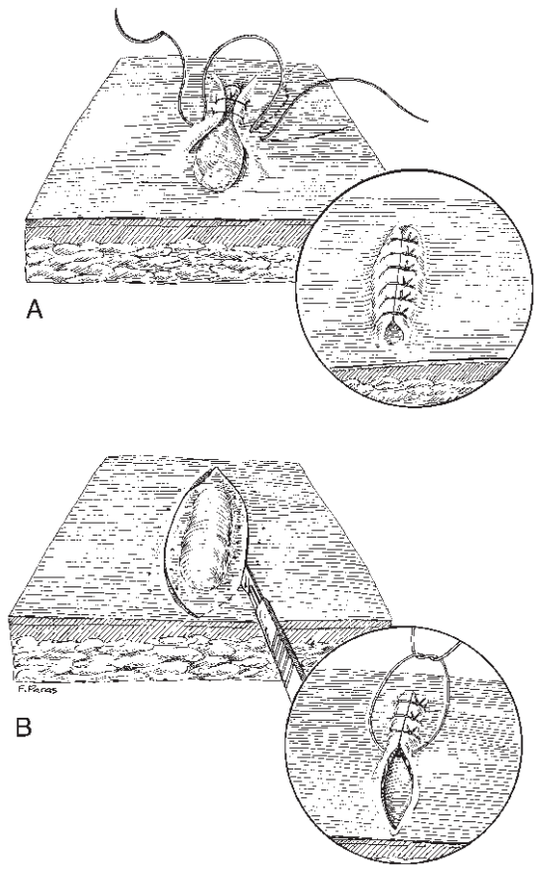

Figure 55-7. Presutures. *A,* The day before surgery, suture the skin adjacent to the lesion over the lesion using a Lembert suture pattern. *B,* The following day, remove the presutures and excise the lesion. *Inset,* Close the resulting defect or wound using the stretched skin made available by the presutures. (Redrawn from Scardino MS, Swaim SF, Henderson RA, Wilson ER: Enhancing wound closure on the limbs. Compend Contin Educ 18:919, 1996.)

g. On wounds that cannot be closed, or to help prevent further wound edge retraction, place a monofilament non-absorbable intradermal continuous horizontal mattress suture. The ends are left untied and a button and two fishing weights (split shot) are placed on each end of the suture. Traction is placed on each free suture end daily to advance the edges toward each other. Two new split shots are placed on the suture adjacent to the button after each tightening to hold the edges under tension and advance them toward the wound center (Fig. 55-8). Use "environmentally friendly" (tin) split shots to prevent lead toxicity in case the patient should chew at the wound site and swallow the split shots.

h. Another technique for closing wounds that are under considerable tension is the "pulley" suture (Fig. 55-9). This is a 4-bite buried interrupted

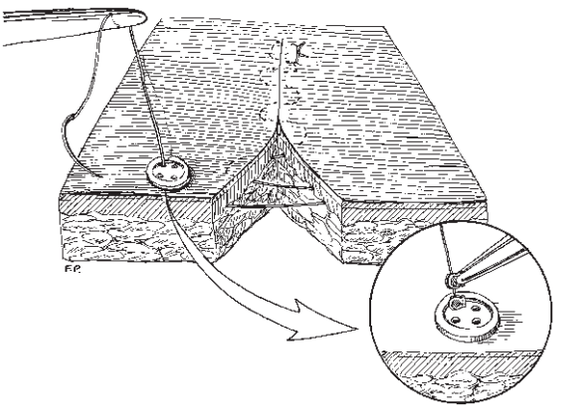

Figure 55-8. A half-buried horizontal mattress suture starts the suture at one end. Then advance the suture as an intradermal horizontal mattress suture with each bite slightly advanced. On the final bite, pass the needle through the entire thickness of the skin and through a hole in a sterile button. After the wound edges are advanced as far as possible, use two split shots to hold the suture tight (see *inset*). (Redrawn from Scardino MS, Swaim SF, Henderson RA, Wilson ER: Enhancing wound closure on the limbs. Compend Contin Educ 18:919, 1996.)

pattern with bites engaging the deep layer (underside) of the dermis. A monofilament absorbable suture such as PDS is used, in sizes 3-0 or 2-0. Multiple bites produce a mechanical advantage, like a pulley, that reduces the tension required to close the wound.

5. Use one of the following relaxing incisions for additional tension release.
   a. Make unilateral or bilateral bipedicle flaps when undermining does not provide enough relaxation for wound closure. Make an incision parallel to the wound's long axis but slightly curved toward the wound, with the width of the created flaps being equal to the wound width. Use absorbable "walking" sutures to advance and tack the flaps in place and a regular or tension-relieving suture pattern to suture the skin. Close the defects that resulted from moving the flaps (Fig. 55-10).
   b. Make unilateral or bilateral simple relaxing incisions as in creating a bipedicle flap. Move the flaps and suture in place as with bipedicle flaps. Do not close the defects that remain from moving the flaps, but leave them to heal as open wounds (Fig. 55-11).

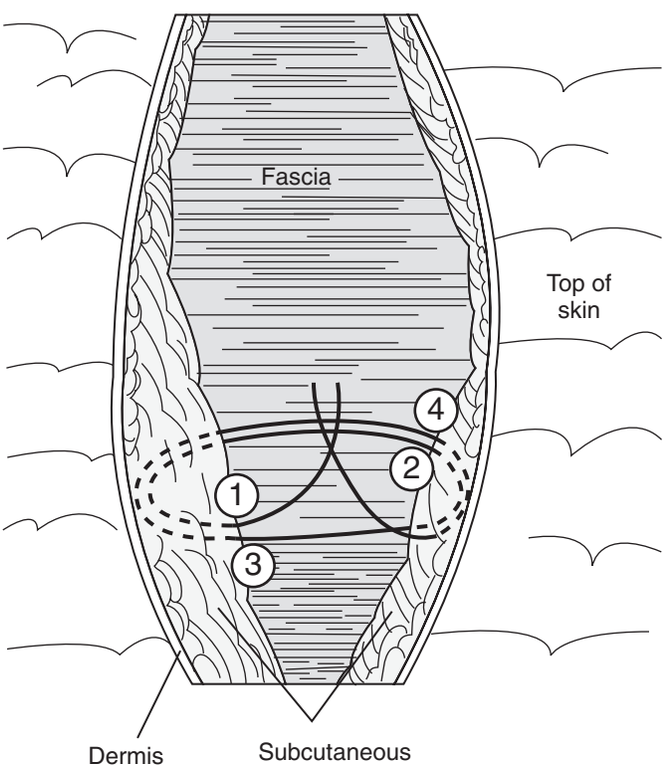

Figure 55-9. Pulley suture. This is the same as a "buried" simple interrupted suture, except that four suture bites (two on each side of the incision) are taken instead of two, creating two loops through the tissue instead of the usual single one. All bites are placed in the deep layer (underside) of the dermis to provide solid purchase in the tissue for closure against tension.

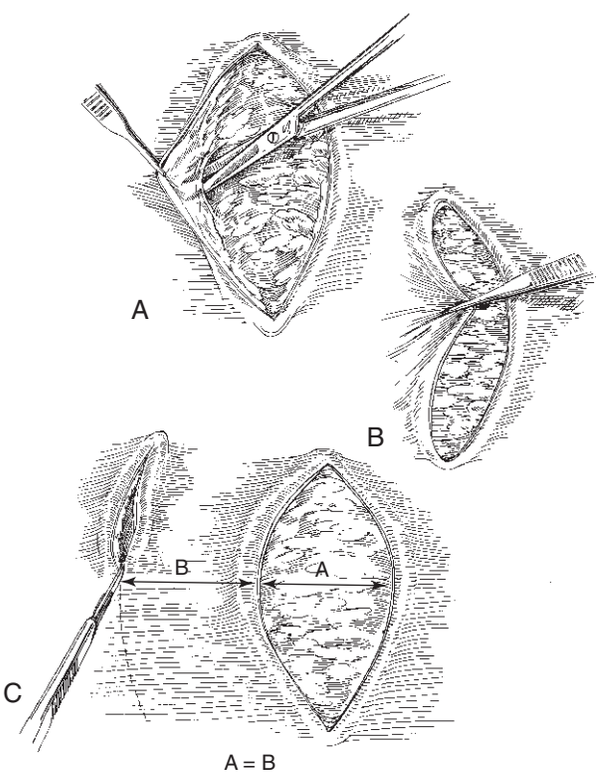

Figure 55-10. Unilateral bipedicle flap. *A,* Undermining the skin on the side of defect from which the flap will come. *B,* Checking to see if undermining provided sufficient skin for wound closure. *C,* Making an incision to create a bipedicle flap. Wound and flap width are equal (A = B).

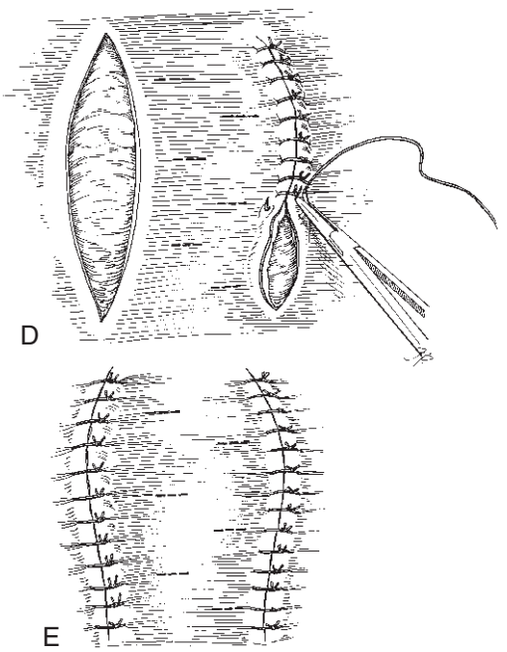

Figure 55-10, cont'd *D,* Flap being sutured into position after walking sutures have advanced it *(broken lines). E,* Donor site sutured. (After Swaim SF, Henderson RA: Small Animal Wound Management. 2nd Ed. Philadelphia: Williams & Wilkins, 1997, p 176.)

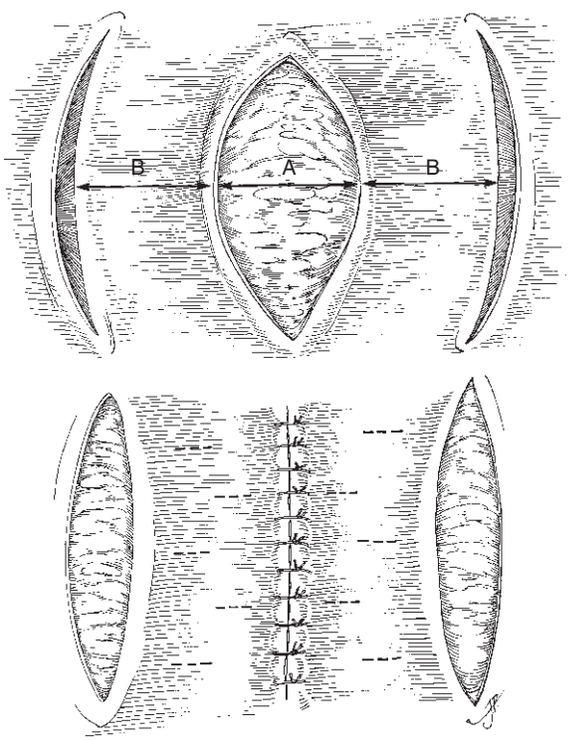

Figure 55-11. Bilateral simple relaxing incisions. *Top,* One bipedicle flap has been created on each side of the wound, with flaps equal in width to the defect width (A = B). *Bottom,* After undermining and moving the flaps with walking sutures *(broken lines)* to close the wound, leave the relaxing incision defects to heal as open wounds. (After Swaim SF, Henderson RA: Small Animal Wound Management. 2nd Ed. Philadelphia: Williams & Wilkins, 1997, p 177.)

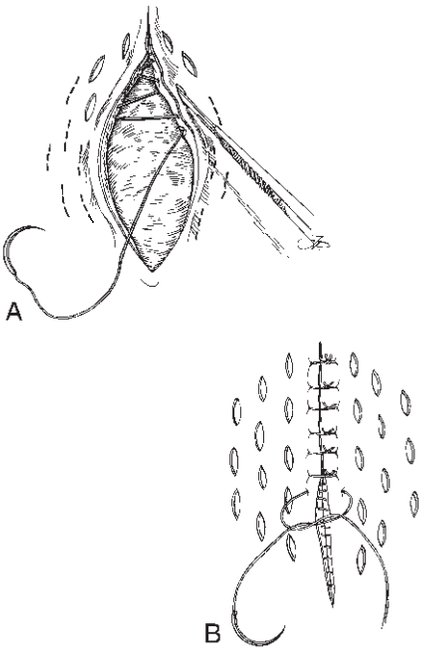

Figure 55-12. Multiple punctate relaxing incisions. *A,* Make parallel staggered rows of incisions as needed on both sides of a wound while a simple continuous intradermal suture is placed and tightened. *B,* Final wound apposition with simple interrupted sutures. (After Swaim SF, Henderson RA: Small Animal Wound Management. 2nd Ed. Philadelphia: Williams & Wilkins, 1997, pp 189–190.)

c. Make multiple, punctate, relaxing incisions 1 cm long and 0.5 cm apart in parallel, staggered rows bilaterally, as needed to allow wound closure as a simple continuous intradermal absorbable suture is placed and tightened. Final skin apposition is with simple interrupted, non-absorbable sutures (Fig. 55-12).
d. Design and incise a 60-degree equal angle, equal limb-length Z-plasty adjacent to the wound with the central limb of the Z in the direction in which relaxation is needed. After undermining the skin edges and Z-plasty flaps, close the wound using regular or tension sutures. Suture the Z-plasty flaps into their new positions (Fig. 55-13).
e. Make a V-shaped incision adjacent to the wound with the point of the V away from the wound. After undermining the resulting skin flap, use absorbable walking sutures to advance and tack the flap in place. A regular or tension suture pattern is used to suture the original skin defect. Close the V with simple interrupted non-absorbable sutures, beginning at the ends. When tension develops, close the remainder of the defect, beginning at the point of the V to form a Y-shaped suture line (Fig. 55-14).
f. Many traumatic wounds result in a large circular or nearly circular skin defect, especially after debridement is completed. Closure of these

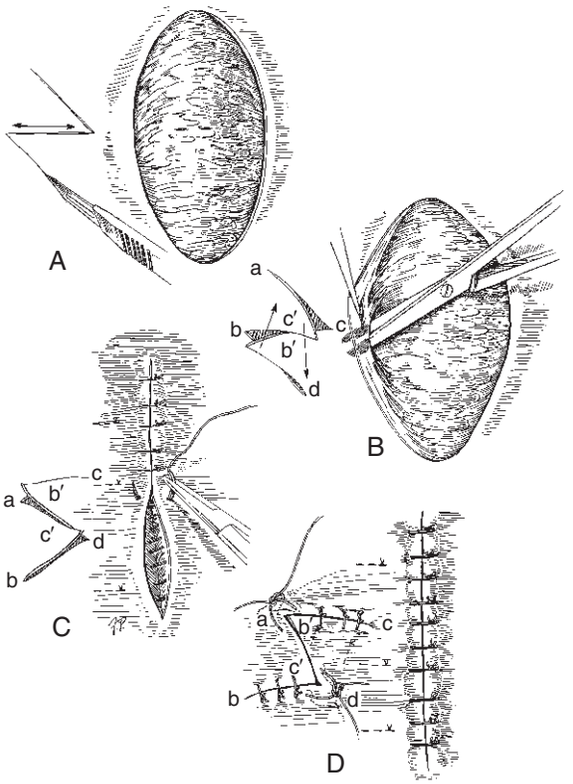

Figure 55-13. Z-plasty as a relaxing incision for wound closure. *A,* Make a 60 degree equal-angle, equal-limb-length Z-plasty designed adjacent to a wound, with the central limb in the direction relaxation is needed. *B,* Z-plasty has been cut. Undermine Z-plasty flaps and adjacent skin (*arrows* indicate Z-plasty flap transposition). *C,* Closure of the defect with automatic transposition of Z-plasty flaps. *D,* Suturing the Z-plasty flaps into their new positions. (After Swaim SF, Henderson RA: Small Animal Wound Management. 2nd Ed. Philadelphia: Williams & Wilkins, 1997, p 186.)

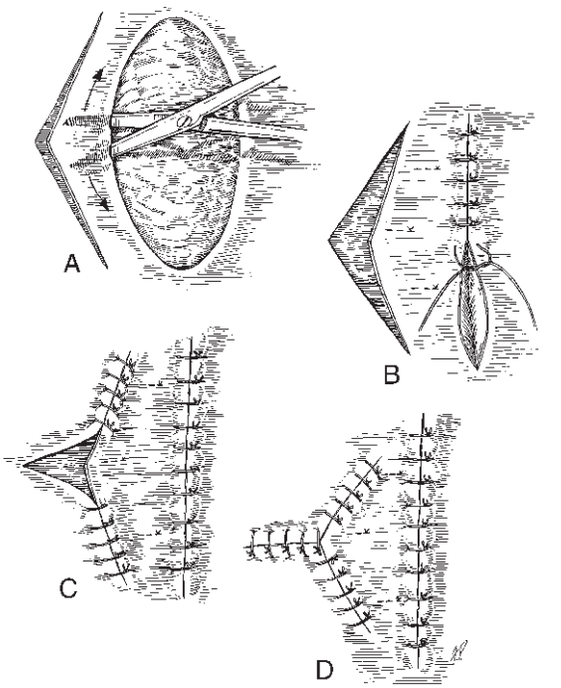

Figure 55-14. V-to-Y plasty relaxing incision. *A,* Make a V-shaped incision adjacent to the defect with point of the V away from the defect. Undermine skin between the defect and incision. *B,* Closure of the defect with walking sutures holding the flap in position *(broken lines). C,* Closure of the V-shaped incision, beginning at the ends. *D,* Closure of the stem of the Y. (After Swaim SF, Henderson RA: Small Animal Wound Management. 2nd Ed. Philadelphia: Williams & Wilkins, 1997, pp 181–182.)

defects can be problematic, particularly when they are located on a limb or other location lacking abundant adjacent skin for closure. The combined-V closure (Fig. 55-15) is often useful for such situations. Two V-shaped flaps, with width and length equal to the radius of the defect, are created as equilateral triangles. The central axis of the triangles is 45 degrees from the long axis of the wound along the line of greatest skin tension. The skin flaps are made by incising only two sides of the triangles, forming two V-shaped incisions with their points directed towards the long axis of the wound. After the flaps are incised and undermined, they are transposed and the flap tips are tacked into position. When the flap tip is sutured to the side of the circular defect, the original circular defect is converted into smaller, irregular fusiform defects. These defects are closed with simple interrupted sutures, beginning with a suture in the center of the defect to divide its length in half and continuing to divide the defect in half with each subsequent suture; this ensures an even approximation of skin over the unequal sides of the defect.

6. Drains to prevent dead space are generally not needed in wounds sutured under tension, especially if open relaxing incisions have been made.

Postoperative Care

- Bandaging is similar to that for postoperative care of wounds closed without tension. Do not remove "walking" sutures and absorbable intradermal continuous horizontal mattress sutures. Remove vertical mattress tension sutures after 3 to 4 days. Remove "far-near-near-far" and "far-far-near-near" sutures at about 10 days. Remove stent sutures after 7 to 10 days, and remove presutures within 24 hours after their placement. The adjustable horizontal mattress suture (see Fig. 55-8) may be left in place and tightened daily for several days to a week.
- Prevent self-mutilation of wounds with an Elizabethan collar or other device such as a cervical collar (Bite Not Products or Jorgensen Laboratories) or side braces, as necessary.

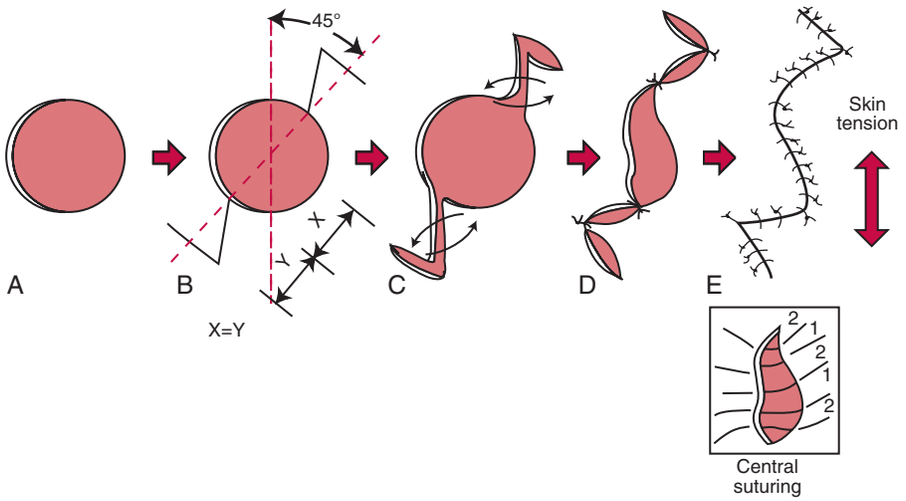

Figure 55-15. Combined-V closure of a circular skin defect. *A,* Circular defect. *B,* V-shaped flaps oriented 45 degrees off and pointing toward the line of greatest tension. Flap width (y) equals radius of the defect (x). *C,* Arrows showing transposition of the flaps. *D,* Flap tips sutured into place, creating a series of irregular fusiform defects. *E,* The completed closure. Skin from each V-shaped flap closes half of the original circular defect. *Inset,* Central suturing technique. A suture is placed at the center of each defect, subdividing it into smaller and smaller defects until it is closed. (First sutures = 1, subsequent sutures = 2.) (After Swaim SF, Henderson RA: Small Animal Wound Management. 2nd Ed. Philadelphia: Williams & Wilkins, 1997, p 266–67.)

Postoperative Complications

- When vertical mattress tension sutures are applied, there may be areas of pressure necrosis of the skin near the wound edge under the Penrose drain segments.
- Simple relaxing incisions may result in a wound equal in size to the closed wound.
- Large and numerous multiple punctate relaxing incisions may result in good tension relief but may jeopardize the blood supply to the skin between incisions with a resultant slough. Utilizing the minimum number of incisions needed for wound closure will reduce the risk of this complication; this is achieved by placing a single row of punctate relaxing incisions at a time and checking wound tension after each row is placed.
- Skin closed too tightly around a limb may result in a "biologic tourniquet," with edema and hypothermia distal to the closure site. Skin closed too tightly around the thorax may result in impaired respiration. Consider suture removal to release the tension in such cases.

Chapter

56 Management of the Open Wound

David W. Knapp

Open wound management is a method of treatment which should be considered when immediate primary wound closure is not possible. Wound healing is a complicated biologic process involving inflammatory, debridement, reparative, and maturation phases. When managing a wound in an open fashion, one or all of these biologic phases may come into play. To employ open wound management techniques successfully requires a thorough understanding of the phases of wound healing. For more comprehensive descriptions of basic wound healing, see other texts. As a large percentage of wounds are associated with traumatic events, the following material is focused on traumatic wounds and skin defects. However, the same principles may be applied to defects created by surgical excision of tumors, restrictive scar tissue, or dysfunctional tissues. The goal of wound management is to restore normal anatomy and function to the patient, when possible. Reconstruction of open wounds using skin flaps or grafts is discussed in Chapter 57.

ETIOLOGY OF OPEN WOUNDS

- Vehicular trauma resulting in lacerations and/or degloving injuries or shear forces creating a devascularized section of skin
- Bite wounds resulting in lacerations, punctures, or shearing/tearing defects
- Gunshot, stab injuries, or other forms of penetrating wounds
- Skin loss due to abscesses or embolic vascular events
- Burns resulting from thermal, electrical, chemical, and radiation injury
- Large defects resulting from surgical excision of lesions, especially tumors
- Defects created by circumferential restrictions such as casts, bandages, or choke collars caught in long haired pets, or full thickness defects (i.e., decubital ulcers)

PREOPERATIVE CONSIDERATIONS

Indications

Consider leaving a wound open as a method of treatment in the following situations:

- Grossly contaminated wounds. Consider the "golden period" of 8 hours from time of injury. Wounds are classified as clean (surgically created), clean contaminated (minimal contamination, which can be effectively removed) and contaminated (gross contamination with obvious foreign material).
- Wounds with established infections.
- Wounds with large skin losses or excessive tissue trauma, particularly wounds with questionable vascular supply and tissue viability or incomplete debridement. These wounds will have impaired host local defense systems and are more susceptible to infection if closed prematurely.
- Wounds with inadequate adjacent tissue available for closure. Wounds on the distal extremities and around the face often fall into this category.
- Wounds that would result in increased tension or excessive dead space if closed primarily.
- Wounds that have failed previous closures.
- Temporary wound management while awaiting results of orthopedic or neurologic diagnostics.
- Temporary wound management before grafting techniques, the use of skin expanders or skin stretchers, or while awaiting microscopic examination of wound margins following tumor excision.

Advantages of Open Wound Management

- Provides ability for continual debridement through surgical, mechanical, or chemical means.
- Provides for optimal wound drainage when compared with primary closure combined with other methods of drainage.

- Provides access for daily wound lavage when indicated.
- Provides for daily wound inspection to evaluate progress and to adjust treatment as indicated.

Disadvantages of Open Wound Management

- Labor-intensive, requiring more time and effort on the part of the veterinarian and owner.
- More expensive due to hospitalization and repeated bandage changes, often requiring anesthesia or sedation and tranquilization.
- The wound must be protected from further injury caused by exposure or self-mutilation.
- Increased risk of nosocomial or ascending infection.
- Protein loss from large wounds with excessive drainage.
- May result in increased healing time and prolonged discomfort for the patient.

INITIAL WOUND MANAGEMENT

Patient Evaluation

- Evaluate and treat as needed for concurrent life-threatening injuries, particularly hypovolemic shock, thoracic and/or abdominal trauma, and cerebral edema or hemorrhage.
- Evaluate for concurrent orthopedic or neurologic trauma (e.g., fractures, ligamentous or tendinous injuries, spinal cord injuries, or peripheral nerve damage). If necessary, obtain radiographs when the patient is stable.
  - Orthopedic. Orthopedic injuries are common and may be located at the wound site or distant from the open defect. Evaluate for fractures and ligamentous injuries in all cases of trauma-related wounds. Carefully palpate the long bones and joints for pain and stability and obtain radiographs when indicated. Stress views may be necessary to evaluate joint stability.
  - Neurologic. Assess neurologic injury through deep and superficial pain perception and motor function. It is uncommon for neurologic limb dysfunction to result from an injury to the lower portions of an extremity since most nerve function originates from higher segments.
- Evaluate wounds involving the extremities for vascular, orthopedic, and neurologic involvement. Any defect that is full circumference will likely create severe vascular compromise.
- Evaluate wounds of the thorax and abdomen for potential involvement of the deeper thoracic, peritoneal, and retroperitoneal cavities. If exploring and/or debriding a thoracic wound, always be prepared to assist in ventilation if pneumothorax is created.

▼ ***Key Point*** Vascular compromise may lead to loss of the limb; therefore, tissues distal to the wound should be carefully assessed. Several days may be required to fully appreciate the extent of vascular injuries. Shear and tearing injuries of the skin and subcutaneous tissues of the trunk may also result in delayed tissue necrosis and eventual loss.

- Patient factors to consider which affect wound healing are age, nourished verses malnourished, concurrent metabolic diseases such as diabetes, hyperadrenocorticism and uremia, hypoproteinemia, anemia, hepatic disease, and obesity. Immunocompromised patients are at greater risk of developing infections.
- Wound factors affecting management and healing include foreign material such as dirt, plant material, suture or surgical implants, wound exudates, bacteria/infection, and vascularity.

Initial Wound Evaluation

- Analgesic or anesthetic drugs (if necessary) aid in the evaluation and treatment of the wound, especially if extensive debridement and lavage are required (see Chapters 2 and 6). In cases where general anesthesia may not be safe and sedation alone is not completely effective, consider administering epidural analgesia to provide for a more comfortable and cooperative patient. Local blocks may also be helpful in certain circumstances. Always consider intravenous postoperative analgesia, during the recovery from surgical procedures, then as needed to facilitate comfort and management of the patient. Consider placing transdermal fentanyl patches for hospitalized patients. Continued wound management may require repeated use of analgesics or anesthesia, usually diminishing in use as the wound progresses through the healing stages.
- Use sterile gloves and instruments to help prevent further bacterial contamination.
- Consider the following during the initial evaluation:
  - The extent of tissue damage to both soft and osseous structures. Closely evaluate the vascular integrity of the wound.
  - The degree of contamination or probability of existing infection. Consider the time lag between the traumatic event and the presentation of the patient to the hospital.
  - The feasibility of successful primary closure.
  - If a limb is involved, the feasibility of the leg becoming functional again.
  - The anticipated time required as well as the expense to the owner.
- Obtain bacterial cultures in advance of wound debridement and lavage. Select antibiotics based on culture and sensitivity results. If necessary, a broad spectrum antibiotic may be used while awaiting culture results.

- If active bleeding is encountered, controlling hemorrhage is best accomplished with direct pressure or isolation and ligation of the vessel. Avoid placing tourniquets, which will result in increased circulatory compromise of an area already suffering decreased vascular perfusion.

Clipping and General Cleaning

Protect the wound from loose debris and hair during the initial preparation and clipping of the adjacent area. Use a sterile water-soluble gel to cover the defect, cover with saline moistened surgical sponges, or sterile towel clamps, sutures, skin staples, or wound clips to provide an economical and efficient temporary closure. Clip a generous margin surrounding a truncal wound or the expected bandaged portion of a limb and scrub with an antiseptic soap or solution.

Cleansing the Wound

Lavage Solution

The ideal lavage solution is sterile, non-irritating, non-cytotoxic, normothermic, and isotonic. Of available solutions, warmed sterile isotonic saline best meets these criteria. Lactated ringers solution may also be used.

- The use of antibiotic or antiseptic solutions for wound lavage is controversial. There is evidence for both beneficial and detrimental effects. Controversy exists between in vitro versus in vivo studies and the antibacterial versus the cytotoxic effects of varying concentrations of chlorhexidine and povidone-iodine solutions. Use a 0.5% to 1.0% chlorhexidine solution due to its broad-spectrum and extended residual activity.
- Tap water is an economical alternative to other commonly used sterile solutions, even though it does not meet all criteria for an ideal lavage solution. When large volumes are anticipated, tap water may be the most practical irrigation solution. Due to the hypotonic nature of distilled or sterile water, their use in lavage is not recommended.
- Effective lavage often depends more on the copious volume of fluid rather than the contents of the solution. The effect of lavage is to loosen and flush away from the wound any foreign material, damaged, necrotic or free tissue, wound exudates, and bacteria.
- Do not scrub the wound, which results in increased tissue damage due to mechanical trauma. Trauma to the tissue will result in increased inflammation, delayed healing, and increased risk of infection.

Lavage Delivery Systems

Delivery systems are categorized based on pressures at which the lavage solution is applied to the wound.

- *High-pressure systems* (e.g., Water Pik) deliver solutions at pressures near 60 psi. Advantages are their ability to dislodge debris and bacteria. A potential disadvantage is the possibility of driving bacteria into tissues near wound margins resulting in microabscessation.
- *Medium-pressure systems* deliver solutions at pressures near 7 to 8 psi, which has been shown to be effective in dislodging foreign material and bacteria without risk of driving bacteria into the wound. Such a system can be developed by using a 35-ml syringe and an 18-gauge needle. Systems which combine the syringe and needle with a three way stop cock and intravenous tubing will speed the process.
- *Low-pressure systems* are ineffective at dislodging bacteria and debris. Such systems include a syringe without a needle, a bulb syringe, and tap water delivered directly from the faucet.
- Removal of lavage solution from the wound by suction, very light pressure on gauze sponges placed over the wound, or gravity avoids dilution of opsonins necessary for phagocytosis.

Debridement

▼ ***Key Point*** Surgical debridement is the most effective method for removal of dead or devitalized tissue.

- Inspect and palpate questionable tissues to determine tissue viability. Signs suggestive of non-viable tissue include the following:
  - Black, bluish-black, or a shiny white discoloration (especially if there is a distinct demarcation between abnormal and normal color)
  - Lack of bleeding at wound margins
  - Texture is leathery to touch or skin is very thin and no pain sensation is detectable.
  - Skin temperature is cool.
  - Hair is easily epilated.
- Other methods of tissue viability determination include transcutaneous oxygen (PO_2), transcutaneous carbon dioxide (PCO_2), and ultrasonic Doppler flow detection. The use of intravenous dyes is not a reliable method of evaluation.
- Reddish discoloration or severe edema is not necessarily indicative of non-viable tissue. Such tissue should be managed conservatively in the initial treatment period.
- During each surgical debridement it is best to maintain a conservative approach, leaving critical tissue of questionable viability while surgically excising only confirmed non-viable tissue. Resect contaminated or devascularized fat to decrease the risk of bacterial propagation. Use a scalpel rather than scissors to decrease additional trauma to the wound. Preserve vessels, nerves, and tendons. Remove any devascular-

ized bone to prevent sequestra formation or delay of granulation tissue bridging the wound.
- Daily mechanical debridement may be accomplished when the primary layer of the bandage is removed. In cases of continued necrosis and tissue loss, repeated surgical debridement may be necessary in addition to the routine bandage changes.
- Chemical debridement is an enzymatic removal of devitalized tissue, while selectively sparing viable structures. Such treatments may be irritating to the healing wound bed.

Bandaging

Open wound management, in most cases, requires the use of some form of bandage.

Functions of the bandage include:

- Coverage of the wound to maintain cleanliness and control wound environment
- Provide support
- Decrease swelling/edema
- Control bleeding
- Reduce potential dead space

These bandages are composed of primary, secondary, and tertiary layers. If immobilization or support is indicated, splints of metal, plastic, or fiberglass may be incorporated between the secondary and tertiary layers. A comfortable bandage will increase the probability that it will be well tolerated by the patient. Use an Elizabethan collar when patients attempt to chew or remove the bandage.

Primary Contact Layer

The primary or contact layer of the bandage is that portion of the bandage applied directly over the wound.

When selecting a dressing consider the following properties:

- Facilitates removal of exudates
- Hinders secondary infection
- Maintains moisture at the wound surface
- Permits gaseous exchange
- Creates minimal wound trauma when removed

Dressings may be adherent or non-adherent. The primary layer is also defined as either semiocclusive or occlusive. A semiocclusive dressing permits oxygen to move across the dressing as well as exudates to move away from the wound surface and into the secondary layer. Occlusive dressings function to maintain moisture at the wound surface. The primary layer should remain in contact with the wound surface, even during movement.

The primary layer may serve to:

- Debride
- Facilitate removal of wound exudates
- Deliver medication
- Provide a protective layer over the wound

Adherent Dressings

- Adherent dressings are defined by their condition on application and removal and can be classified as wet-to-wet, wet-to-dry, and dry-to-dry. Wet dressings aid in the movement of viscous exudates away from the wound and into the secondary layer, while dry dressings adhere to necrotic tissue and debris, producing mechanical debridement when removed.

▼ ***Key Point*** *Wet-to-dry* dressings are the most frequently employed method in the early management of open wounds. These dressings allow for effective removal of exudate and mechanical debridement.

The fluid dilutes the exudates, facilitating its transfer into the secondary layer of the bandage. To apply a wet-to-dry dressing, soak sterile cotton gauze sponges in sterile saline or antiseptic solution, hand squeeze to remove excess solution, and place the sponges in contact with the wound bed, being sure to pack all recesses of the wound. Remove the dressings at 12- to 24-hour intervals, permitting the gauze to dry and adhere to necrotic tissue and debris which then provides mechanical debridement on removal of the gauze sponges. Rewetting the dried sponge with sterile saline may reduce patient discomfort during bandage removal. Continue wet-to-dry dressings only as long as mechanical debridement or excessive viscous exudate removal is necessary.

- *Wet-to-wet* dressings are used for wounds requiring removal of viscous exudates only, with no removal of necrotic tissue or debris necessary. Place sterile cotton gauze sponges soaked in sterile saline or another lavage solution in contact with the wound bed. The secondary layer is a non-absorbent material, which aids in maintaining a wet primary dressing.
- *Dry-to-dry* dressings are used on wounds with no exudate or very serous exudates, but do require mechanical debridement of necrotic tissue and debris. Place dry sterile cotton gauze sponges in contact with the wound bed. An absorbent secondary layer is not necessary with this method.

Nonadherent Dressings

- Use non-adherent dressings in the management of newly formed granulation tissue, where minimal disruption of the wound bed is desirable. They are commonly used following the methods previously described for adherent dressing techniques or for surgically created wounds not amenable to primary closure. These dressings serve to keep wounds moist and to promote epithelialization.
- *Semiocclusive nonadherent* dressings are composed of man-made materials such as polyester films (Telfa pads) or gauze sponges with a layer of a petrolatum-based product (Adaptic, Johnson & Johnson).

- *Occlusive non-adherent dressings* (e.g., Ulcer Dressing, Johnson & Johnson) do not allow for absorption of wound exudate, and therefore are used in non-exudative wounds. Occlusive dressings also prevent gaseous exchange. These dressings are left in place for longer periods of time, often 2 to 4 days. Disadvantages of occlusive dressings include difficulty in accessing wound progress due to their nontransparent nature as well as delaying wound contracture.
- *Occlusive dressings* speed re-epithelialization of partial-thickness defects. Constituents of occlusive dressings include polyethylene, polyurethane, hydrocolloids, and hydrogels.

Wound Medications

- Wound management continues to advance as increasing knowledge of cellular and chemical mediators within the wound environment are more clearly defined. The trend toward the use of natural and synthetic growth factors is increasing. In addition, products used for dressing wounds with additional wound surface interaction and enhancement of healing are available.

▼ ***Key Point*** Sugar can be used in open wounds. Granulated sugar draws macrophages into the wound thereby decreasing the need for surgical debridement; facilitating the formation of a protein layer thereby providing additional surface layer protection; creating a hyperosmotic environment which is bactericidal; providing a local nutritional source for the wound; decreasing edema; and promoting granulation and epithelialization.

- Application of a thin layer of sugar at each bandage change is not painful to the patient and easily accomplished at little expense.
- Honey has also proven successful in the management of open wounds. Principles of its use are similar to those of sugar.
- Maltodextrin N. F. is a polysaccharide soluble powder, which also exhibits many of the same properties of sugar.
- Silver sulfadiazine (Silvadene cream) serves to penetrate into the wound and is effective against gram-negative and gram-positive bacteria and enhances epithelialization. There is some concern about cytotoxicity to fibroblasts and an inhibition to lymphocytes and polymorphonuclear cells.
- Triple antibiotic ointment is a broad-spectrum treatment, which may promote epithelialization due to the zinc component. It has little efficacy for treatment of pseudomonads. Its use may be greater for prevention of infection rather than treatment.
- Gentamicin sulfate is used to inhibit the growth of *Pseudomonas*, *Proteus*, and *E. coli* organisms.
- Nitrofurazone is a broad-spectrum antibacterial in a polyethylene base, which promotes removal of body fluid from the wound to dilute the thicker exudates resulting in easier transfer into the bandage. Some delay in epithelialization may be expected.
- Acemannan acts as a synthetic growth factor, which enhances wound healing through its effects on macrophages and cytokines.
- Bovine collagen has been used to stimulate fibroblast ingrowth and deposition of collagen. When placed in the wound it creates scaffolding for the patient's own fibroblasts and collagen. It is most effective during the late inflammatory and early reparative phases of healing.
- Tripeptide-copper complex acts as an attractant for cells such as macrophages, monocytes, and mast cells. The result is increased wound debridement, release of additional cytokines, and increased collagen synthesis.
- Enzymatic debriding agents (Granulex, Elase, Preparation H) function to chemically debride wounds through the effects of trypsin, deoxyribonuclease, and fibrinolysin and to increase angiogenesis, epithelialization and collagen synthesis.
- Ointments may leave residual material in or on the wound surface. Water-soluble creams leave a decreased amount of foreign material at the wound surface and are preferred.

Secondary Layer

- The secondary layer of the bandage functions as the absorptive constituent, drawing fluid away from the wound and then acting as a reservoir for wound exudate or the absorbed lavage solution.
- This layer is often composed of cotton pads or layers of rolled cotton or cast padding.

Tertiary Layer

- The tertiary layer functions to hold the other layers of the bandage in place and is a layer of rolled gauze covered with adhesive tape or self-adherent tape (e.g., Vetwrap, 3M). The more porous the layer, the more rapid the evaporation of fluids or drying of the deeper layers. Porosity may also allow for translocation of bacteria across the bandage.
- Wounds over areas of increased motion or on limbs with concurrent orthopedic injuries may require splints incorporated into the tertiary layers for support or immobilization. Increased motion will delay wound healing.
- When bandaging thoracic or abdominal wounds, bandages should be snug but not restrictive of normal respiration.

Tie-Over Bandage

- If the area of the wound is not amenable to standard bandaging techniques (e.g., over the shoulder, hip, or axilla), a tie-over bandage may be used to

secure the primary and secondary layers to the wound bed.

- To make a tie-over bandage, place six to eight "eyelet" sutures around the wound (Fig. 56-1). Place primary and secondary bandage layers over the wound, then lace umbilical tape through the sutures to hold the layers of the bandage in place (Figs. 56-2 and 56-3).

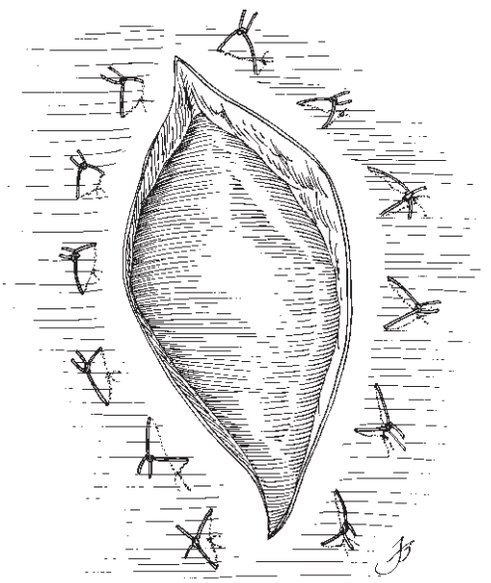

Figure 56-1. Place eyelets for a tie-over dressing around the wound using large suture material (e.g., 2-0 or 0 monofilament polypropylene).

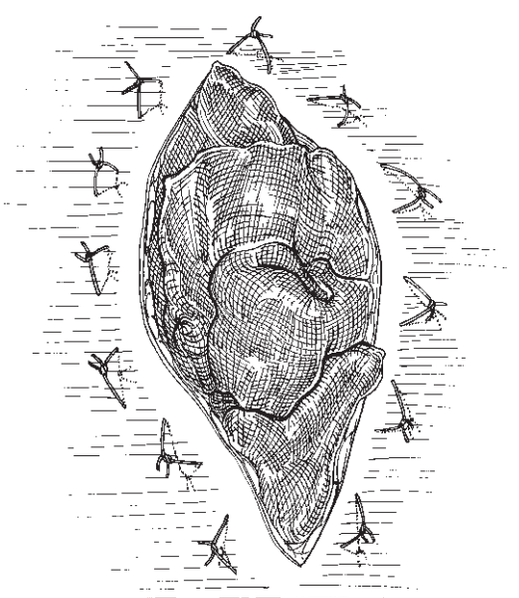

Figure 56-2. Place appropriate primary and secondary bandage layers over the wound.

- In cases where additional skin is recruited with the use of Velcro skin stretchers, the cable portion of the stretcher device can be used in a similar manner as a tie-over bandage.

Antibiotics

- Antibiotic therapy, whether applied topically or given systemically as a prophylactic measure, is controversial. If an established local infection exists, topical therapy is often all that is necessary.

▼ ***Key Point*** Control of infection is most effective through good open wound management, especially copious lavage and frequent bandage changes.

- Whenever possible, select antibiotics based on culture and sensitivity results. Use a broad-spectrum antibiotic while awaiting culture and sensitivity results.
- Use a combination of intravenous beta-lactam (e.g., cephalosporin) and aminoglycoside (e.g., gentamicin) antibiotics if septicemia is suspected.

DAILY WOUND MANAGEMENT

Frequency of Bandage Changes

- The timing of bandage changes is influenced by the need for debridement, the amount of exudate from the wound bed, and manageability of the patient.

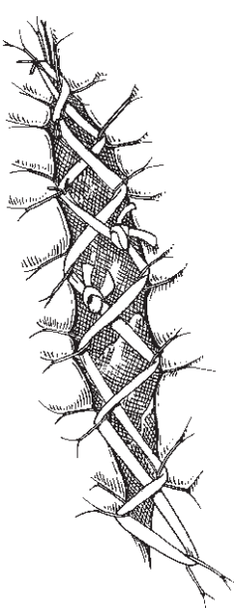

Figure 56-3. Lace sterile gauze or umbilical tape over the layers.

- Early in wound management, change bandages on a daily or twice-daily schedule. Wounds with healthy granulation tissue may be inspected and rebandaged every other or every few days.
- The volume of wound exudate or nature of the exudate in the bandage is often the guide to frequency of bandage changes. If wound drainage increases, consider more frequent bandage changes, and consider changing the primary layer.

Analgesia

- Animals with extensive wounds often require analgesics or, if discomfort is more severe, anesthetics to permit patient comfort at the time of bandage changes. This is particularly true with adherent dressings. Once granulation tissue begins to form, sedation/analgesia can be tapered or discontinued completely. Daily pain management may be provided through the use of nonsteroidal anti-inflammatory drugs (NSAIDs), narcotic injections, or a fentanyl patch (see Chapter 6).

Debridement

- During the early management of wounds, intermittent surgical debridement is the best means of removing necrotic tissue and debris.
- Surgical debridement is complemented by mechanical debridement through regular bandage changes.

Lavage

- Daily wound lavage aids in dislodgement of bacteria, removal of debris, dilution of exudates, and promotion of drainage.
- Whirlpool baths may benefit animals with extensive truncal wounds. If such treatments are instituted, monitor closely for signs of wound infection.

Bacterial Cultures

- With daily bandage changes and wound inspections the nature of the wound bed and exudate may be monitored. If during these inspections a change in the wound is noted and infection is suspected, submit wound swab samples of debrided tissue or punch biopsy samples of granulation tissue for culture and sensitivity.

Rebandaging

- As wound healing progresses to healthy granulation tissue, change the type of dressing from adherent to non-adherent and decrease the frequency of bandage changes.

▼ ***Key Point*** In cases of infection or deterioration of the wound, consider changing from a non-adherent to an adherent dressing.

WOUND CLOSURE

Closure and resolution of open wounds may be accomplished non-surgically by natural second intention healing or surgically by delayed primary closure or secondary closure. Surgical closures will decrease the labor-intensive component of open wound management and is often recommended when possible. Surgical methods of closure are described in Chapter 55. Skin grafts and skin flaps are described in Chapter 57. Consider surgical closure of open wounds once healthy granulation tissue is apparent.

Second Intention Healing

Second intention healing is the body's natural method of wound closure, and healing is the result of progressive formation of granulation tissue followed by wound contraction and epithelialization. Epithelialization often coincides with granulation tissue. In most cases this tissue provides adequate blood supply with little risk of infection. Additional closure is accomplished through wound contracture.

Advantages

- Additional surgery may be avoided.
- May be less expensive than other closure options.
- In wounds with no tension at the skin edges, the wound is covered with full-thickness, normal-appearing skin if contraction is complete.

Disadvantages

- Anatomic dysfunction and disfigurement from excessive contraction and scar tissue formation. If a joint is involved, decreased range of motion may result.
- With incomplete wound contraction, the epithelium may not cover the remaining defect.
- If the wound defect is large, the epithelium covering the defect is often fragile, easily disrupted, and has a poor aesthetic appearance.

Chapter 57

Selected Skin Graft and Reconstructive Techniques

Stephen J. Birchard / Daniel D. Smeak

Large skin wounds can occur (1) from trauma directly to the skin or to its blood supply; (2) secondary to necrotizing skin diseases (see Chapter 49); and (3) after removal of large skin, subcutaneous, or body wall neoplasms. Most open wounds eventually heal by the formation of granulation tissue, wound contraction, and epithelialization. Skin flaps or grafts are indicated when wound healing is either not progressing or will take a very long time for completion. Full-thickness skin is necessary to prevent mechanical problems caused by repeated trauma (e.g., in the dorsum of the leg or paw). Skin reconstruction is also necessary if the open wound is so large it will cause significant patient morbidity or wound contracture is likely to cause a significant problem (e.g., the wound is over a joint and the scar limits full extension and weight-bearing). Skin flaps are usually preferred over skin grafts because they are simpler to perform and have a higher success rate. However, if a skin flap is not feasible due to lack of adjacent skin (such as the distal limb), consider a skin graft.

Consider several factors before performing skin flaps or skin grafts, such as viability of adjacent tissue, systemic illness that may affect wound healing, function of the affected area of the body, tolerance of the wound by the animal, feasibility of long-term bandaging of the affected area, desired cosmetic result, and cost to the owner. Thoroughly discuss these factors with the owner prior to performing any of these procedures.

This chapter describes practical methods of reconstructing skin using skin flaps and grafts. More complicated methods of skin grafting that require specialized skill or equipment, such as using a dermatome for split-thickness skin grafts, microvascular flap transfer, or tube grafts, are not discussed in this chapter. Primary closure of skin wounds is reviewed in Chapter 55, and open wound management in Chapter 56.

SURGICAL ANATOMY

Skin

The skin is composed of the epidermis and dermis.

- Structures that compose the skin adnexa, hair follicles, sweat glands, and sebaceous glands are located in the dermis.
- Besides adnexa, the dermis is composed of fibroblasts, collagen fibers, and various other structures, such as blood vessels, nerves, tissue cells, and fluid.

Subcutaneous Tissue

The subcutaneous tissue is mainly composed of loose connective tissue, including elastic fibers, fat, blood vessels, and nerves.

Cutaneous Muscles

- Thin, superficial muscles, collectively called the panniculus muscle, lie within the subcutis or hypodermis (the most superficial aspect of the subcutaneous layer) in certain body regions in both dogs and cats. Examples are the platysma muscle in the neck and the cutaneus trunci muscle in the trunk.
- Preservation of these muscles during undermining and flap creation is a very important principle in skin reconstruction.

Blood Supply to the Skin

- Deep or subdermal plexus
- This plexus is the major source of blood supply to the skin and of most importance to the surgeon.

▼ ***Key Point*** When creating skin flaps in dogs and cats, preserve the deep vascular plexus.

- In regions where cutaneous musculature is present, this vascular network is present on the superficial and deep layers of the muscle. Dissection beneath this thin muscle layer is critical to flap survival.
- Direct cutaneous arteries are present in several areas of the body. They arise from deep vessels that course superficially and run parallel to the skin. These direct cutaneous arteries communicate with the deep vascular plexus.

- Middle and superficial plexuses complete the layers of vascular network to the skin.

SKIN FLAPS

Skin flaps are a means of reconstructing open wounds by rotating, transposing, or advancing adjacent or regional skin to allow wound closure. Blood vessels supplying these flaps are maintained. Therefore, skin flaps do not rely on a bed of granulation tissue in the defect for their early blood supply and nutrition. Skin flaps can be classified according to their blood supply, such as *random subdermal flaps* versus *axial pattern flaps*, or according to their location with respect to the recipient bed, such as *local flaps* versus *distant flaps*.

Random Subdermal Flaps

Random subdermal skin flaps are those constructed without regard to the presence of a direct cutaneous artery. Viability of these skin flaps is dependent on the availability of local subdermal blood vessels supplied in the flap base, so they rely on a wide skin attachment to insure adequate blood supply. Random subdermal skin flaps can be further classified as *advancement flaps, rotation flaps,* and *transposition flaps,* depending on how the flap is moved to the defect; *single pedicle* and *bipedicle flaps,* depending on how the flap is attached to the body; and *direct distant flaps,* moving an extremity wound to a distant region of redundant host skin for flap coverage.

- Advancement refers to how the flap is moved to the wound. These are usually rectangular flaps. Simple advancement flaps are undermined and pulled (horizontally or vertically) directly to the wound (Fig. 57-1).
- A transposition flap is a tongue-shaped flap, usually constructed immediately adjacent to the wound. It is rotated (clockwise or counterclockwise) to cover the wound (Fig. 57-2).
- A rotation flap is a semicircular flap that pivots into an adjacent recipient bed. Single or paired flaps can be employed to close triangular defects (Fig. 57-3); no secondary defect is created with this flap.
- Direct distant flaps include thoracic or abdominal single pedicle or bipedicle flaps that can be used as a method for transferring skin to the distal extremities.
  - Single pedicle: Attached to the body only at one end (Fig. 57-4*A*, *C*). The pedicle provides the vascular attachment to the flap.
  - Bipedicle: Attached to the body at both ends (Fig. 57-4*B*).
  - These flaps are transferred from a distance to the recipient defect. The lesion is advanced to the flap rather than the flap being transferred to the lesion as in construction of advancement flaps.

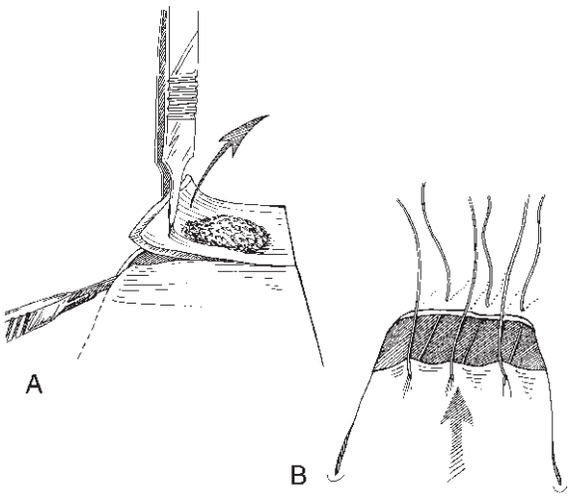

Figure 57-1. Simple advancement flap. Make the initial incisions *(A)*, then deeply undermine the flap and advance to the defect *(B)*.

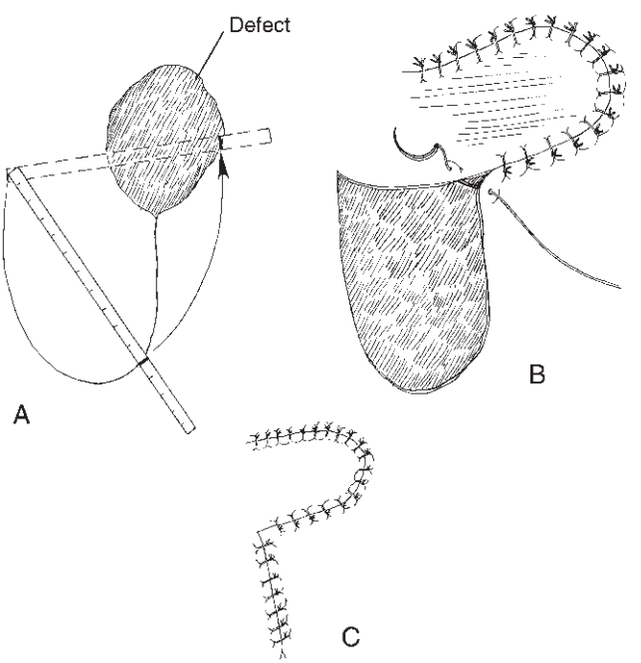

Figure 57-2. Transposition flap. After measuring the length of flap needed (*A*), make the incisions and rotate the flap to the defect (*B*). Suture the flap first and then close the remaining defect (*C*).

  - Forelimb defects are more often reconstructed using this technique than are rear limb defects.

Indications

Advancement, Rotation, and Transposition Flaps

- For large skin wounds that are located in areas with adjacent loose, redundant skin (e.g., neck, flank, dorsal trunk) that allows formation and closure of defects remaining after flap transfer without tension.

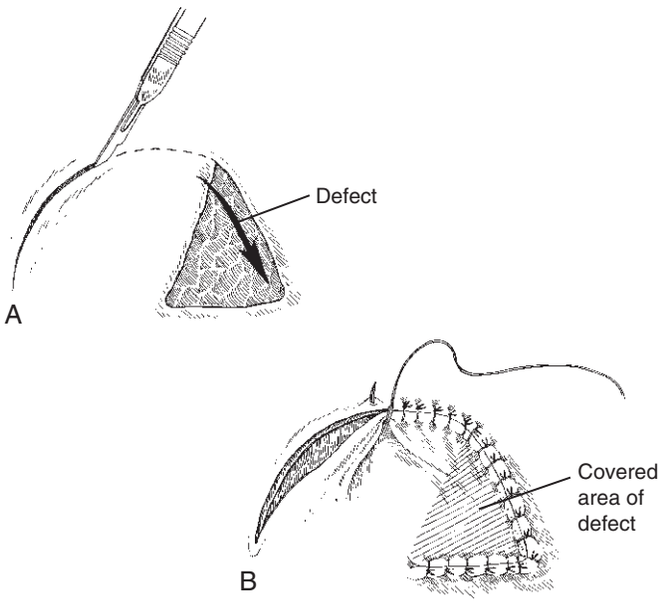

Figure 57-3. Create a curved incision in a stepwise fashion to close a triangular wound.

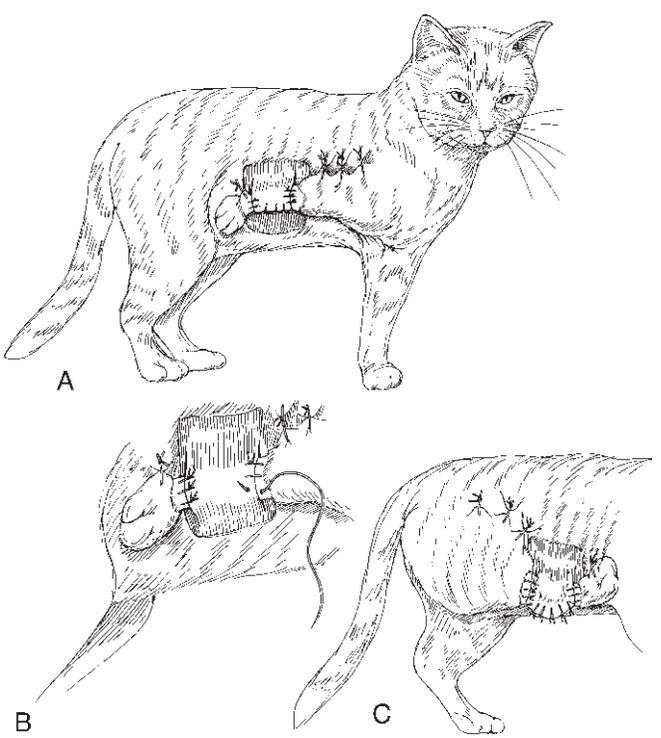

Figure 57-4. Direct distant flap. Make the skin flap using the lateral thoracic or abdominal skin. Suture the flap to the limb defect. This flap can have a single *(A)* or double *(B)* pedicle. Secure the limb to the lateral body wall with skin sutures placed between the leg and the body wall *(C)*. Place a padded bandage around the body to help stabilize the elevated limb.

- As a general rule, do not consider these flaps for wounds distal to the stifle, elbow, or tail head, since there is often not enough skin to close the donor site without excessive tension.

Direct Distant Pedicle Flaps

- For large wounds of the distal extremities in which local skin is not available or would be closed under excessive tension.
- These flaps are usually made from skin over the lateral thoracic or abdominal wall. The leg is attached to the side of the animal's body for a period of time while healing of the pedicle to the extremity wound progresses. The pedicle is then removed from the thorax or abdomen and the leg returned to its normal position.
- These flaps are very successful, but patient tolerance is variable.

Preoperative Considerations

- Carefully plan the surgical procedure. Review vascular anatomy of the region. The size, location, shape, and condition of the wound dictate the type of flap.
- Check the health, looseness, and pliability of the skin adjacent to the lesion or wound to determine feasibility of the intended skin flap.
- Consider administration of prophylactic antibiotics, given intravenously at induction of anesthesia, if significant contamination of the surgical site is possible.
- Prepare the recipient bed preoperatively to ensure that the area is free of infection, foreign material, and necrotic tissue.
- Direct distant flap technique requires two surgical procedures to complete. The owner is made fully aware of the costs involved, the postoperative management, and the problems related to the prolonged immobilization of the leg. Hair direction and cosmetic problems are more common with distant techniques than with local flap techniques.

▼ ***Key Point*** Consider the mobility of the extremity that contains the defect when determining the location and type of direct distant flap. Make sure the leg opposite the host limb is able to accept the extra weight-bearing load. Evaluate the size and temperament of the patient. Smaller animals with calm dispositions seem to tolerate this technique best.

Surgical Procedure

Objectives

- To provide full-thickness reconstruction of a large skin wound.
- To avoid tension along the suture line.
- To create flaps that maintain viability and provide satisfactory cosmesis.

Equipment

- Standard surgical pack and suture.
- Measuring device to plan length and width of flaps.
- Sterile marking pen to draw incisions (optional). Sterile methylene blue and a cotton-tipped applicator can be as effective as a marker.
- A piece of sterile double-knit cloth or section of paper drape can be used as a pattern for designing flaps intraoperatively.
- Penrose ($^1/_4$–$^1/_2$ inch) or closed suction drains (e.g., Jackson-Pratt drain).

Technique

Advancement or Transposition Flaps

1. Carefully position the patient to free up any available skin in the region and to reduce tension while the flap is being sutured.
2. Aseptically prepare a liberal amount of skin in the region of the proposed flap and donor sites.
3. Remove epithelialized portions of the granulation bed by sharp dissection (usually present at the edges of the granulation bed). Undermine attachments of skin at the margin of the granulation bed to free up the bordering skin.
4. Gently manipulate the skin margins surrounding the defect to ascertain the availability of adjacent local skin.
5. Optimally, the donor area has enough skin available to elevate a flap without leaving a secondary defect that cannot be closed primarily.
6. If possible, avoid choosing a donor area that may be subject to excessive motion or tension.
7. Choose the type of flap depending on the availability of skin, shape, and location of the defect and size of the area to be covered.
8. It is better to create two adjacent short flaps rather than one long flap, which have a greater risk of necrosis from inadequate blood supply.
9. Try to design the flap so that the base is slightly wider than the tip to avoid inadvertently devascularizing the flap.
10. Design the flap to fill the defect without tension.
11. Create the flap by sharply incising along the preplanned donor skin margins.
12. Use stay sutures or fine skin hooks when elevating the flap to avoid causing excessive damage.

▼ ***Key Point*** The depth of flap undermining is very important to preserve the deep vascular plexus under the panniculus muscle group. Be especially careful when undermining in the region of the base of the flap to avoid interrupting critical direct cutaneous vessel branches.

13. Transfer the skin flap to the defect (see Figs. 57-1 and 57-2).
14. Consider placing a drain in large dead space areas (under flaps and donor areas) if the condition of the tissues warrants it. If a Penrose drain is used, exit the drain in a ventral-dependent area of the wound away from the primary suture line.
15. Meticulously close subcutaneous tissues with fine (3-0 to 4-0), simple interrupted, absorbable suture material to evenly distribute skin tension.
16. Use fine (4-0) monofilament non-absorbable suture material placed in a simple interrupted pattern to close the skin. Skin staples may also be used. Simple interrupted sutures allow for individual control of suture tension. If fluid accumulation develops in the dead space, simple removal of one or two skin sutures in a gravity-dependent area often allows adequate drainage.

Technique

Direct Distant Flap (Single or Double Pedicle)

1. Aseptically prepare the entire limb and lateral thoracic wall for a forelimb defect or abdominal wall for a rear limb defect. When preparing a bipedicle flap, meticulously clip and clean the medial portion of the paw or limb that will be in contact with the skin of the trunk.
2. Position the affected limb in the most comfortable angle possible to locate the donor area (see Fig. 57-4).
3. Attempt to construct the flap so that any movement of the limb will pull the flap onto the defect rather than away from it.
4. Create a bipedicle flap if the defect is large or nearly circumferential (Fig. 57-4*B*), or a single pedicle flap if the defect is less than 180 degrees circumferential (Fig. 57-4*A, C*), using the principles described previously in the section on advancement flap technique.
5. After creating the pedicle flap, a skin defect remains on the trunk that must be closed. Use advancement or rotation flaps to close this defect.
6. Place the limb through the bipedicle flap or adjacent to the single pedicle flap.
7. Carefully prepare the host wound site for flap transfer. Remove any islands of epithelial tissue in the host wound bed; be sure there is no evidence of necrotic tissue or foreign material in the wound. Excise the margin of the wound to create a clean square skin edge, if necessary.
8. Suture as much of the flap to the defect margins as possible.
9. Drains may be placed to drain fluids that may accumulate under the flap or limb.
10. Use large (2-0 to 0) monofilament non-absorbable suture material to tack the skin of the limb to the thoracic wall skin in several areas to help immobilize the limb.

▼ ***Key Point*** Complete immobilization of the limb is mandatory for at least 14 to 18 days to ensure adequate vascularization of the flap from the wound bed.

11. Design a bandage for immobilization that will remain in place for the full 2 to 2.5 weeks but will still allow the flap area to be monitored and separately rebandaged.
12. If the flap appears healthy, sharply incise the pedicles from the donor area. Suture the remaining free skin margins to the defect to complete the transfer. If in doubt about the flap vascularization, delay the flap transfer. Incise half the length of the pedicle, close the incisions, and complete the flap transfer in 3 to 5 days.

Axial Pattern Flaps

Axial pattern flaps are those skin flaps that are developed using a major direct cutaneous artery as the primary blood supply. Considerably more flexibility in the length and mobility of these flaps is possible compared with random skin flaps. Since only the axial vessel is necessary for nourishment of these skin flaps, they can be made with or without skin attachment to the flap (island axial pattern flaps). These long vascular pedicles allow transfer of skin to more remote areas of the body because of the direct cutaneous artery allowing adequate perfusion of a large area of tissue. Consequently, axial pattern flaps usually allow reconstruction of a defect in a one-step procedure.

Axial pattern flaps can be based on many direct cutaneous arteries, such as the caudal superficial epigastric, the cervical cutaneous branch of the omocervical, the thoracodorsal, the deep circumflex iliac, and the genicular branch of the saphenous artery. More recently, an axial pattern flap based on the lateral thoracic artery holds promise for elbow and proximal forelimb wounds. Caudal auricular and the superficial temporal axial pattern flaps are used for maxillofacial and cervical wounds. The caudal superficial epigastric and thoracodorsal axial pattern flaps are commonly selected for large defects of the proximal thigh, perineum, and flank and thoracic, axilla, and proximal forelimb wounds, respectively. The thoracodorsal axial vessels are less robust than the caudal superficial epigastric vessels; hence, these flaps have higher risk of flap necrosis. Only these two flap techniques are described here. However, other axial pattern flaps as listed previously can be created using similar principles and are described in veterinary surgical textbooks (see Pavletic, 1998).

Indications

- Similar to those for random subdermal flaps except that axial pattern flaps are used when the skin defect is very large or when the donor skin needs to be transferred over a longer distance to the recipient site.
- A major direct cutaneous artery and vein must be in the region of the skin defect for this technique to be indicated.

Preoperative Considerations

- Same as those for random subdermal flaps, plus the following:
  - Carefully plan the design of the flap to include the direct cutaneous vasculature.
  - Consider how the resultant defect of the donor area will be closed.
  - Be sure the skin and the direct cutaneous artery that will be used for the flap are viable.

Surgical Procedure

Objectives

- Same as those for random skin flaps, plus:
  - Preserve viability of the direct cutaneous artery by avoiding excessive surgical trauma to the tissue.
  - Prevent undue tension on the vascular pedicle especially if flap rotation approaches 180 degrees.

Equipment

- Same as that for random skin flaps.

Technique

Caudal Superficial Epigastric Axial Pattern (CSE) Flap

1. Use preparation and tissue handling principles as described for advancement or rotation flaps.
2. Be particularly careful when positioning the patient so that the vascular pedicle will not become distorted before planning the incisions.
3. Incise the skin as shown in Figure 57-5.
4. The entire mammary chain up to the cranial thoracic gland can be included in this flap.
5. Deeply undermine the flap to the level of the abdominal fascia.
6. Dissect very carefully around the origin of the direct cutaneous vessel to avoid inadvertent damage to this vessel, which is vital to the survival of the flap.
7. Avoid creating a kink or excess tension in the base of the flap, which could obstruct blood flow.
8. Drain dead space if needed with a passive (Penrose) or closed suction (Jackson-Pratt) drain.
9. Suture the flap to the defect, as described for the other flap techniques.

Thoracodorsal Axial Pattern Flap

1. Use the same principles as described for the CSE flap.
2. The thoracodorsal vessel originates at the caudal shoulder depression, at a level parallel to the dorsal border of the acromion. Maintain this landmark as

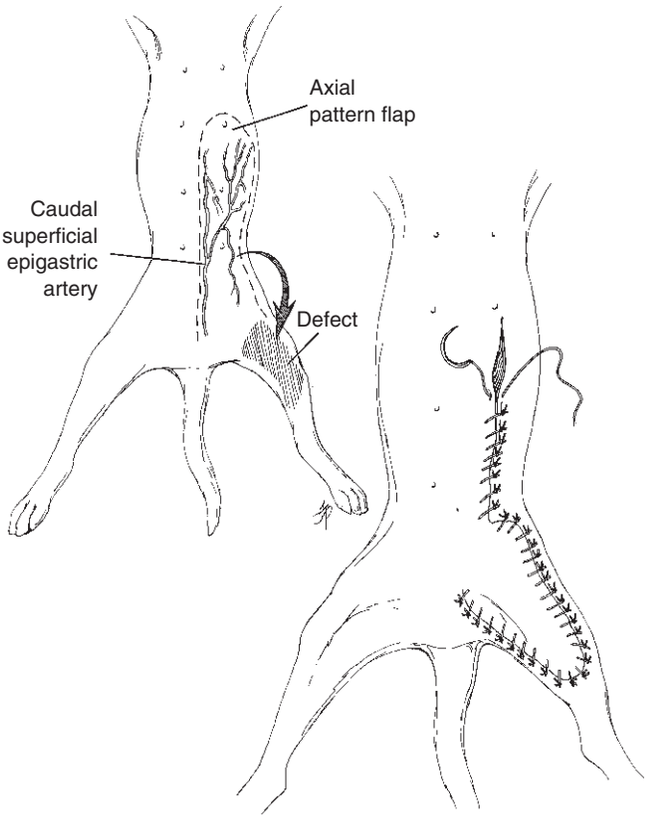

Figure 57-5. Example of an axial pattern flap. This flap is based on a direct cutaneous artery—the caudal superficial epigastric artery. Design the flap around this artery and deeply undermine the skin and mammary tissue. Rotate the flap and suture to the defect.

the flap is planned and undermined to preserve the vascular pedicle.

3. Make incisions to create the flap as shown in Figure 57-6. Direct the cranial incision along the spine of the scapula. Create the caudal incision parallel to the cranial incision. This incision line is made behind the caudal shoulder depression equal to the distance between the scapular spine and the caudal shoulder depression. The flap margins can be extended safely up to the level of the dorsal midline.
4. Elevate the flap just below the level of the cutaneous trunci muscle, beginning at the end of the flap. Be careful to avoid interrupting the thoracodorsal vasculature, which is often hidden from view in the deeper subcutaneous fat.
5. Pivot the flap into the host bed. Use a bridging incision between the host and donor beds if necessary. Alternately, tube the flap base to traverse the skin interposed between the two areas.
6. Prepare the host wound bed as explained for the direct distant flap technique.
7. Avoid kinking or excess tension at the base of the flap, which could obstruct blood flow from the axial vasculature.
8. Use the drainage and closure directions as for the CSE axial pattern flap.

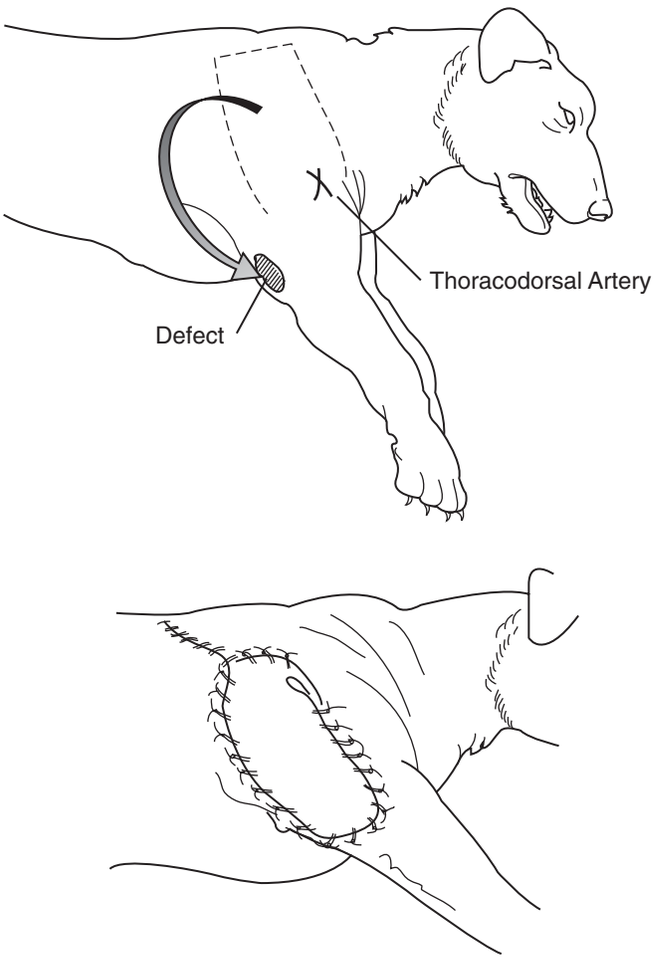

Figure 57-6. Thoracodorsal axial pattern flap reconstruction of a proximal brachial wound. Incisions are created as described in the text. Undermine the flap in a dorsal to ventral direction to the level of the origin of the thoracodorsal pedicle (caudal shoulder depression). Rotate the flap into the wound and suture the flap to the defect edges.

Postoperative Care and Complications

All Flap Types

- Restrict exercise until suture removal.
- If necessary, apply an Elizabethan collar as the patient is recovered from anesthesia and leave on the animal until the flaps are completely healed.
- Change wound dressings as necessary.
- Immobilize the limb for at least 14 days for direct distant flap techniques.
- Major complications resulting from skin flaps include local problems, such as partial or total ischemia of the flap, infection, seroma, and dehiscence of the flap or donor suture line.
- Carefully pad the elbow if the thoracodorsal (TD) flap extends over this area to avoid pressure necrosis over the olecranon.
- Dehiscence of donor site incisions is usually due to excessive skin tension. If dehiscence occurs, allow these areas to heal by second intention. Excise

ischemic areas of flaps when these areas are clearly demarcated. Let the wounds heal by second intention, or reconstruct the skin wound after all wound surfaces are lined with healthy granulation tissue.

FREE SKIN GRAFTS

Free skin grafts involve complete removal of skin from one area of the body and implantation to another. These grafts are completely separated from their blood supply, so they are solely dependent on the wound bed for viability in the early stages of graft healing. For the first 3 to 4 days after grafting, the skin graft obtains its nutrition from the wound bed by diffusion, a process called plasmatic imbibition. During this process, the graft acts like a sponge, soaking up fluid and oxygen from the granulation tissue of the wound. Imbibition is a very delicate process that is easily disrupted by excessive movement of the wound, seroma formation, and infection. During this initial phase of healing, the graft usually looks its worst, appearing congested and sometimes purple. After a few days, this appearance dramatically improves if the graft "takes."

After the first 3 to 4 days, viability of the graft depends on the growth of capillaries from the wound bed into the graft (i.e., inosculation). These invading capillary buds are very fragile structures and are easily damaged by trauma (such as licking of the graft), excessive shear motion, and infection. Once this blood supply becomes well established, viability of the graft is maintained.

Skin grafts vary in their final cosmetic result. The best cosmesis is obtained from a full-thickness skin graft, because there is growth of hair over the area. However, full-thickness grafts are the most difficult to establish because they are thicker than split-thickness grafts. This greater thickness makes the initial process of imbibition and inosculation more difficult, resulting in a higher incidence of graft failure. Some authors recommend harvesting skin from areas where the skin is thin, such as the cranio-ventral aspect of the lateral thorax. Thin skin grafts are preferred because they are more readily incorporated into the granulation tissue.

Pinch (or Punch) Skin Grafts

When rapid epithelization of a wound is needed, pinch grafts can be effective. Pinch skin grafting is performed by simply harvesting small (2–3 mm) sections of full-thickness skin and placing them into the wound granulation bed. They are not difficult to perform and are highly successful. However, the major disadvantage of pinch grafts is the final cosmetic result. Uniform full-thickness skin does not form over the wound with pinch grafts; therefore, very little hair grows over the area.

Preoperative Considerations

- Determine the desired result of the graft. If a high degree of success and rapid epithelial coverage of the wound are desired, consider pinch grafts. If complete regrowth of hair and excellent cosmesis are necessary, employ a different skin graft method, such as mesh graft. If the recipient site is over a joint or area that is frequently traumatized, the more durable full-thickness grafts may be needed and pinch grafts may not be satisfactory.

▼ ***Key Point*** Maximize the chances of graft "take" by properly preparing the wound bed before grafting.

Use standard techniques of wound debridement, lavage, and bandaging (see Chapter 56) for several days prior to grafting to establish a healthy bed of granulation tissue. Postpone the graft procedure if any evidence of infection is present.

Surgical Technique

Objectives

- To establish epithelial coverage of an open wound.
- To atraumatically harvest small plugs of skin from an area of healthy redundant skin.
- To implant these plugs of skin into an area of healthy granulation tissue for rapid epithelial coverage.

Equipment

- Same as for skin flaps, plus:
- Several #15 scalpel blades
- Skin biopsy punch (optional), size 4 and 5 mm.

Technique

1. Aseptically prepare the wound bed and the harvest site.
2. Gently pick up the skin with thumb forceps or stay suture and excise a 1-mm piece of skin, using the #15 scalpel blade. Be careful not to include subcutaneous tissue with the skin pinch.
3. Alternatively, harvest a punch graft using a 5-mm skin biopsy punch. Place the punch at the same angle as the hair follicle during harvesting.
4. Trim any subcutaneous tissue found deep to the dermis of the graft plug.
5. Place the skin pinch or punch in a saline-moistened surgical sponge.
6. Make a "vest pocket" stab incision in the granulation tissue with a #15 scalpel blade (Fig. 57-7).
7. Slide the skin pinch into the incision in the granulation tissue (Fig. 57-7). Be sure the epithelial side of the pinch is facing out.
8. Repeat this process as many times as necessary to have skin pinches (punches) covering the wound at about 1 to 2 cm apart.
9. If using a skin punch, use a 4-mm punch to make the hole in the granulation tissue. The slightly

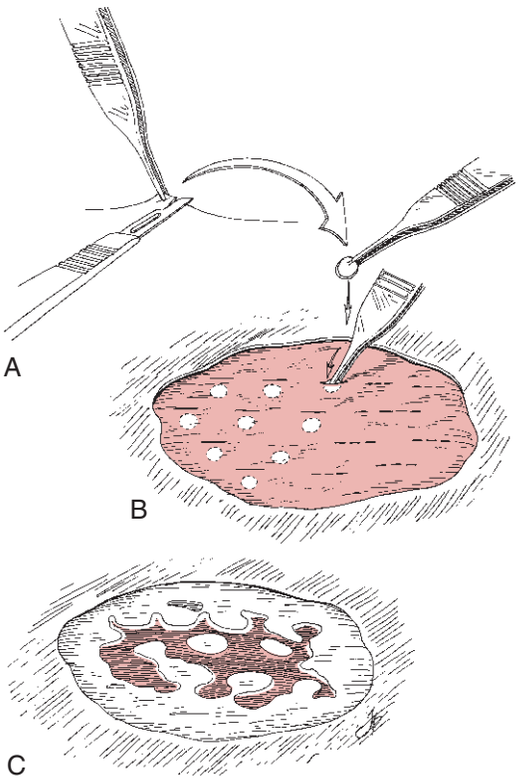

Figure 57-7. Pinch skin graft. *(A),* Obtain small pinches of skin using a scalpel. *(B),* Make small "vest-pocket" incisions in the granulation bed, and slide skin pinches into these incisions with the epidermal side facing out. Pinches can be approximately 1 to 2 cm apart. *(C),* Wound will be filled in by epidermal growth from the pinch grafts.

smaller hole compared to the skin punch will allow a snug fit of the graft in the granulation tissue.

10. Place a non-adherent dressing over the wound. The primary layer of the dressing can be petrolatum-impregnated gauze or Telfa pad with a thin layer of triple antibiotic ointment (Bacitracin-Neomycin-Polymyxin, Pharmaderm).
11. Let the donor sites heal by second intention, or close them with simple interrupted sutures of 4-0 nylon.

Postoperative Care and Complications

- Restrict exercise to leash walking only.
- Change the wound dressing every day for the first 5 to 7 days, then every 2 to 3 days if wound healing is progressing normally.
- Keep the wound dressed until it is completely covered with epithelium.
- If necessary, place an Elizabethan collar on the animal to prevent damage to the bandage or the wound.
- Potential complications include dislodgement of the pinch grafts due to self-trauma or excessive motion and poor cosmetic result due to scarcity of hair formation.

Mesh Skin Grafts

Mesh skin grafts are usually full-thickness skin grafts that are harvested, stripped of subcutaneous tissue, and "meshed" by making multiple scalpel cuts in them. The purposes of making holes in the graft are to increase coverage of the wound by "expanding" the graft and to allow escape of fluid from underneath the graft. Mesh grafts provide better cosmesis than pinch grafts. The healed wound has some hair coverage, although it may not be as much as on the surrounding skin, depending on how much the mesh is expanded.

Mesh grafts are fairly simple to perform and require no special equipment. Results are generally good when the tissues are in good condition and the techniques are performed appropriately.

Preoperative Considerations

- These are the same as those for pinch grafts.
- Consider giving a prophylactic systemic antibiotic (beginning preoperatively) to help prevent infection of the graft.
- Do not perform the procedure if any evidence of infection is present in either the donor or recipient sites.

Surgical Procedure

Objectives

- To establish epithelial and some full-thickness skin coverage of the wound.
- To atraumatically harvest the donor skin from an area of redundant skin.
- To meticulously prepare the graft for implantation by removing all subcutaneous fat and creating a mesh by making multiple small holes in the skin.

Equipment

- Same as for pinch grafts, plus:
  - A sterile board (plastic, wood, or cardboard) for stretching out and preparing the graft
  - #11 scalpel blade

Technique

1. Aseptically prepare the donor and recipient sites.
2. Estimate the size of the wound by measuring or cutting out a template using sterile drape material.
3. Sharply excise the donor skin from an area of thin and redundant skin (e.g., cranial ventral thorax and lateral flank area).
4. Avoid excising the subcutaneous tissue.
5. Note the direction of hair growth in the harvested skin.

6. Place multiple stay sutures at the edge of the harvested skin.
7. Place the skin on a sterile board (epidermal side down), and stretch it out using the stay sutures (Fig. 57-8) or 25-gauge needles.
8. Carefully dissect all remaining subcutaneous fat from the skin using sharp dissection (Fig. 57-8*A*). When this has been done correctly, exposed hair follicles create a stippled appearance on the dermal surface.
9. Lavage the skin frequently with sterile saline.
10. Make multiple full-thickness holes, approximately $\frac{1}{2}$ cm in length and $\frac{1}{2}$ cm to 1 cm apart (Fig. 57-8*B*).
11. Place the mesh graft on the wound, dermal side down.
12. Position the graft so that the hair growth will be in the same direction as that of the adjacent hair.
13. Suture the graft to the surrounding skin (Fig. 57-8*C*).
14. Suture the graft under slight tension so that the mesh expands and the granulation tissue can be seen through the graft (Fig. 57-8*C*).
15. Place additional tacking sutures from the center of the graft to the granulation bed to prevent movement of the graft and prevent separation of the graft from the wound bed.
16. Cover the wound with a nonadherent dressing (see the description under pinch grafts). Change the dressing as needed to prevent desiccation of the primary layer and adherence to the graft.

▼ ***Key Point*** When changing the contact dressing, be very careful to prevent separation of the graft from the underlying granulation tissue.

Postoperative Care and Complications

- Same as for pinch grafts, plus:
  - Prevent desiccation of the graft by applying small amounts of triple antibiotic ointment or sterile petrolatum on the contact layer of the bandage.
  - Immobilize the limb if grafting over a joint (e.g., elbow, carpus, stifle, hock) to prevent excessive movement of the graft.
  - The major complication is failure of the graft to heal due to infection, excessive motion, or lack of adherence of the graft to the underlying granulation tissue.

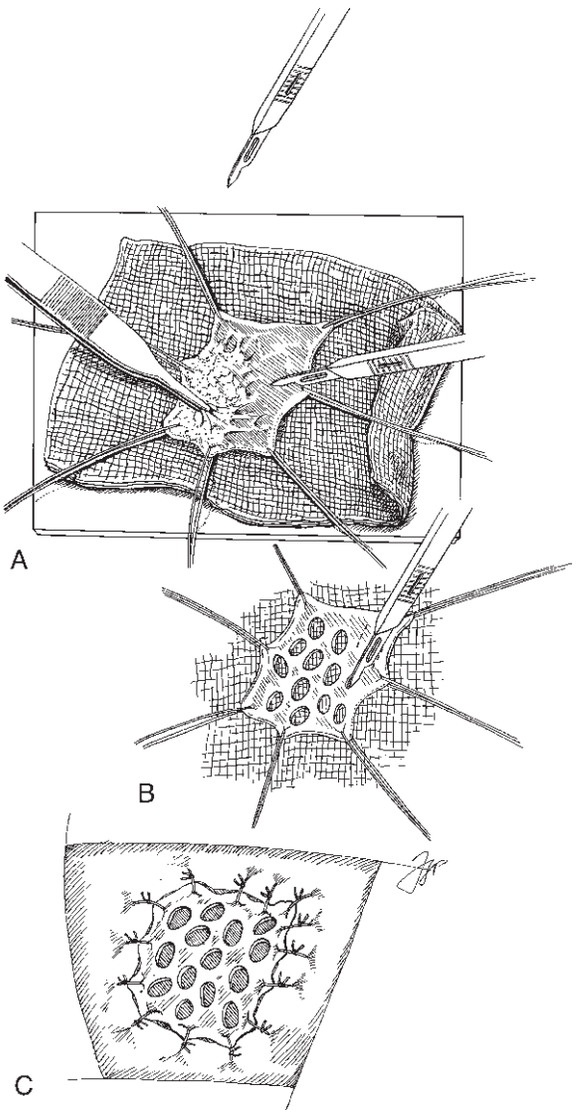

Figure 57-8. Mesh skin graft. Harvest skin and stretch it out on a sterile board using stay sutures and meticulously remove all subcutaneous fat *(A)*. Make multiple slits in the graft using a scalpel *(B)*. Suture the graft, with the epidermal side facing out, to the granulation bed *(C)*.

Chapter 58

Diseases of the Pinna

Lynette K. Cole

The pinna is a mobile structure designed to localize and collect sound waves and transmit them to the tympanic membrane. The pinna has vastly different breed conformations in the dog, while in the cat; there is very little breed variation. The auricular cartilage expands to form the pinna, with the skin of the concave portion of the pinna tightly adherent to this cartilage. The cartilage of the pinna becomes funnel shaped at the opening of the external ear canal.

The pinna is a region of the body prone to numerous skin diseases. In most cases, the pinnal lesions are associated with lesions on other body areas. There are a few diseases where lesions are limited to the pinna (Table 58-1).

The work-up for all animals with pinnal disease should include a complete history, general physical examination, and dermatologic examination. Next, an otoscopic examination is performed, as well as microscopic examinations of skin scrapings for mites and fungi, cytology for bacteria and yeast, and mineral oil swabs for mites (*Otodectes cynotis* and *Demodex* spp.). A bacterial culture is indicated if rod bacteria are seen cytologically. Further testing may be needed such as a complete blood count, serum biochemical profile, urinalysis, allergy testing, food elimination trial, and skin biopsy for histopathology of the ear pinna (see Chapter 59 for diagnosis and treatment of otitis externa).

▼ ***Key Point*** In some cases, the definitive diagnosis of the pinnal disease is made based on the histopathological results from the pinnal biopsy.

The biopsy technique of the ear pinna can be difficult. For lesions on the margin of the pinna, a wedge biopsy is preferred, while for central lesions, a small punch biopsy, size 3.5 to 4 mm, is used to obtain samples. For additional information on the skin biopsy technique, please refer to Chapter 37).

INFECTIOUS DISEASES

Dermatophytosis (also see Chapter 42)

Clinical Signs

- The pinna is often affected in dogs and cats with dermatophytosis.
- In addition to the pinna, lesions may occur anywhere on the body.
- The lesions are quite variable and commonly include erythema, papules, pustules, alopecia, and crusts.

Diagnosis

- Tentative diagnosis: Wood's lamp examination, microscopic examination of the hair (potassium hydroxide [KOH] preparation, chlorphenolac), and histopathology.
- Definitive diagnosis: positive dermatophyte test medium (DTM) culture.

Treatment

- For localized lesions on the ear pinna only, topical therapy, such as miconazole (Conofite Lotion, Schering-Plough Animal Health) or clotrimazole (Clotrimazole Solution, Vet Solutions), may be effective.
- In generalized conditions where the pinna is not the only affected body site, topical rinses with lime sulfur (LymDyp, DVM Pharmaceuticals) along with systemic therapy (ketoconazole [generics; Nizoral, Janssen] or itraconazole [Sporanox, Janssen]) are necessary for resolution.
- Inform owners that this is a zoonotic disease.

Malassezia Dermatitis (also see Chapter 41)

Clinical Signs

- *Malassezia pachydermatis* may cause a pruritic dermatitis and otitis in the dog; cats are less frequently affected.
- In addition, the concave and convex portion of the pinna may be affected.
- Lesions include erythema, alopecia, scale, crusts, hyperpigmentation, and lichenification.

Diagnosis

- Obtain samples for cytology by skin scrapes, acetate tape preparations, swabs, and impression smears.
- The yeast organisms are identified microscopically.

Table 58-1. DERMATOSES OF THE PINNA

Affected Site(s)	Disease	Clinical Lesions Found on Pinna
Pinna only		
	Canine eosinophilic pinnal folliculitis	Erythema, papules, crusts
	Ear margin seborrhea	Scale, fissures
	Fly bite dermatitis	Ulcers, crusts, erythema, alopecia
	Proliferative thrombovascular necrosis of the ear pinnae	Ulcers, scale, hyperpigmentation
Pinna and other body areas		
	Actinic keratoses	Erythema, hyperkeratosis, crusts, hyperpigmented plaques
	Arteriovenous fistula	Edema
	Atopic dermatitis	Erythema
	Canine demodicosis	Erythema, papules, scale, alopecia, crusts
	Canine sarcoptic mange	Erythema, papules, crusts, scale, alopecia, excoriations
	Contact dermatitis	Erythema, macules, papules, erosions, ulcers
	Cutaneous adverse food reaction	Erythema
	Dermatomyositis	Alopecia, erythema, scale, crusts, ulcers, scars
	Dermatophytosis	Erythema, alopecia, papules, pustules, crusts
	Discoid lupus erythematosus	Alopecia, crusts, ulcers
	Feline demodicosis	Erythema, papules, scale, alopecia, crusts
	Feline sarcoptic mange	Erythema, papules, crusts, scale, alopecia, excoriations
	Frostbite	Ulcers, necrosis
	Hereditary lupoid dermatosis of German short-haired pointers	Scale, crusts
	Juvenile cellulitis	Papules, pustules, crusts
	Malassezia pachydermatis	Erythema, alopecia, scale, crusts, hyperpigmentation lichenification
	Melanoderma and alopecia in Yorkshire terriers	Alopecia, hyperpigmentation
	Pattern baldness	Alopecia, hyperpigmentation
	Pemphigus erythematosus	Erythema, scale, papules, pustules, alopecia, crusts
	Pemphigus foliaceus	Erythema, scale, papules, pustules, alopecia, crusts
	Psoriasiform-lichenoid dermatosis of springer spaniels	Erythema, hyperpigmentation, plaques, papules
	Sebaceous adenitis	Papules, alopecia, scale, follicular casts
	Systemic lupus erythematosus	Alopecia, crusts, ulcers
	Vasculitis	Erythema, alopecia, ulcers, crusts, necrosis
	Zinc-responsive dermatosis	Erythema, scale, crust, hyperkeratotic plaques

Treatment

- Topical therapy (miconazole, ketoconazole, chlorhexidine) in the form of lotions, sprays, leave-on conditioners, shampoos, or medicated pads
- Systemic therapy: oral ketoconazole ([generics; Nizoral, Janssen] or itraconazole [Sporanox, Janssen])
- Identification of the underlying dermatologic condition, such as allergic or endocrine diseases, that triggered the secondary infection.

PARASITIC DISEASES

Sarcoptic Mange (also see Chapter 44)

Clinical Signs

- Canine scabies (sarcoptic mange) is caused by the mite *Sarcoptes scabiei* var. *canis*, while feline scabies (notoedric mange) is caused by *Notoedres cati*.
- Both diseases cause intense pruritus and are contagious to other animals and humans.
- The lesions frequently start at the edge of the pinna.
- In dogs, the lesions may then spread to the ventral portions of the abdomen, chest, elbows, and legs.
- In cats, the lesions rapidly spread to the face, eyelids, and neck.
- The lesions consist of erythematous papules, thick crusts, scales, alopecia, and excoriations.

Diagnosis

- Perform superficial skin scrapings in animals suspected of sarcoptic mange.
- The mites may be extremely difficult to find; therefore, a negative skin scraping does not eliminate scabies as the cause of the lesions and pruritus.

▼ ***Key Point*** Pinnal pedal scratch reflex (vigorously rubbing the tip of one ear flap on the base of the ear with a response of a scratching movement of

the ipsilateral hind leg) for the diagnosis of sarcoptic mange in the dog was found to have a sensitivity and specificity of 81.8% and 93.8%, respectively.

- In the absence of identification of the mites, make the diagnosis of scabies based on response to therapy.

Treatment

- In multiple-pet households, treat all other in-contact animals.
- Conventional therapy consists of weekly lime sulfur dips (LymDyp, DVM Pharmaceuticals) for 6 to 8 weeks.
- Selamectin (Revolution, Pfizer Animal Health) is a novel, semi-synthetic avermectin approved for treatment of canine sarcoptic mange.
- Extra-label treatments (see below) for sarcoptic mange have also been used successfully, including amitraz dips (Mitaban, Pfizer Animal Health), ivermectin (Ivomec 1% injection for cattle and swine, Merial) (this form and dosage of ivermectin should not be given to collies, Shetland sheepdogs, Old English sheepdogs, other herding dogs, or their crosses), and milbemycin oxime (Interceptor Flavor Tabs, Novartis) (low incidence of side effects in collies).

Canine Demodectic Mange (also see Chapter 43)

Clinical signs

- Demodectic mange in the dog is caused by *Demodex canis*.
- Both the localized and generalized form may affect the ear pinna, in addition to other areas of the body.
- Lesions of demodicosis in dogs consist of erythema, scale, alopecia, papules, pustules, crusts, and secondary bacterial infections.

Diagnosis

- Make the diagnosis by identifying multiple demodectic mange mites on deep skin scrapings.

Treatment

- The majority of localized demodicosis cases will resolve without treatment; however, topical benzoyl peroxide (Pyoben Gel, Virbac; OxyDex Gel, DVM Pharmaceuticals) may be used on the alopecic areas.
- In cases of generalized demodicosis, the FDA-approved treatment is bi-weekly dips with amitraz (Mitaban, Pfizer Animal Health).
- Extra-label daily high dose ivermectin (Ivomec 1% injection for cattle and swine, Merial) or milbemycin oxime (Interceptor Flavor Tabs, Novartis) is effective in the treatment of generalized demodicosis. As stated previously, this form and dosage of ivermectin should not be given to collies, Shetland sheepdogs, Old English sheepdogs, other herding dogs, or their crosses.

Feline Demodectic Mange (also see Chapter 43)

Clinical Signs

- Demodectic mange in the cat is caused by two mites, *Demodex cati* and *Demodex gatoi*.
- *D. cati* is a rare disease.
- The localized form affects the head and neck while the generalized form affects the head, neck, trunk, and limbs
- Lesions consist of erythema, papules, alopecia, scales, and crusts.
- Generalized demodicosis is usually associated with an underlying disease (diabetes mellitus, feline leukemia virus infection, feline immunosuppressive virus infection).
- Mites have been isolated from skin scrapings of the external ear canal.
- Lesions of *D. gatoi* consist of alopecia, scale, and crusts of the head, neck, and elbows or non-inflammatory alopecia of the ventral abdomen.
- *D. gatoi* is contagious to other cats.

Diagnosis

- Diagnosis is based on identification of the mites on skin scrapings, deep scrapings for *D. cati*, and superficial scrapings for *D. gatoi*.

Treatment

- Treatment consists of weekly lime sulfur dips (LymDyp, DVM Pharmaceuticals).
- For *D. gatoi*, treat all in-contact cats.

Stable Fly Dermatitis (Fly Bite Dermatitis)

Clinical Signs

- Stable flies (*Stomoxys calcitrans*) are the most frequent cause of fly bite dermatitis.
- The rasping mouthparts shred the skin while they feed, which is highly irritating to the dog.
- The flies usually attack the tips of the ears or the folded edge of the ear.
- The flies produce small ulcers, which then may ooze blood and result in hemorrhagic crusts.
- The affected area may also be alopecic and erythematous.
- Ulceration, fibrosis, and scarring with deformation of the pinna may result if the condition is chronic.
- The lesions may become recurrent due to head shaking or scratching by the dog.

Diagnosis

- Diagnosis is based on clinical signs and a history of exposure to stable flies.

Treatment

- House the dog indoors and apply a fly repellent containing a pyrethrin or permethrin.
- Control the flies. Since the stable fly lays eggs in decaying hay and manure, manure clean up and environmental insecticides are indicated.

ALLERGIC DISEASES

Atopic Dermatitis and Cutaneous Adverse Food Reaction (also see Chapters 46 and 47)

Clinical Signs

- Hypersensitivity disorders such as atopic dermatitis and cutaneous adverse food reaction may involve pruritus of the pinna in addition to other areas of the body.
- In a small number of dogs, the ears may be the only affected sites.
- Lesions are characterized by erythema of the concave, convex, or both surfaces of the pinna and may occur in the presence or absence of otitis externa.

Diagnosis

- Diagnosis of atopy is based on history, clinical signs, and the exclusion of other diseases causing pruritus.

Treatment

- Treatment of atopic dermatitis includes allergen avoidance, antihistamines, fatty acids, glucocorticoids, cyclosporine (Atopica, Novartis), treatment of secondary bacterial and yeast infections, and allergen-specific immunotherapy.
- Diagnosis of cutaneous adverse food reaction is based on response to a food elimination trial consisting of a novel protein and carbohydrate source or hydrolyzed protein diet.

Contact Dermatitis

Clinical Signs

- Contact dermatitis is a rare dermatosis in small animals.
- Affected areas include sparsely haired areas of the body, such as the concave surface of the pinna, external ear canal, axillae, and inguinal region.
- It may occur due to topical application of medications or as a result of systemically administered medications.
- Pinnal lesions are usually caused by otic preparations. Some commonly implicated ingredients include neomycin and propylene glycol.
- Erythema, papules, and macules are seen initially, and with continued exposure, erosions and ulcerations may develop.

▼ ***Key Point*** Suspect contact dermatitis when a case of otitis fails to respond or worsens after appropriate topical medication is administered.

- A drug reaction to a systemically administered medication may present with lesions on the pinna as well as other parts of the body.

Treatment

- Discontinue the medication.
- Glucocorticoids may be needed for the inflammation.
- Pentoxifylline (10 mg/kg q12h) has been used for the prevention of clinical symptoms of allergic contact dermatitis in dogs with a confirmed allergy to plants of the *Commelinceae* family (spreading day flower, doveweed, wandering Jew).

IMMUNE-MEDIATED DISEASES

Pemphigus Foliaceus and Pemphigus Erythematosus (also see Chapter 48)

Clinical Signs

- Pemphigus is an autoimmune vesicular to pustular dermatitis.
- Pemphigus foliaceus is the most common autoimmune disease reported in the dog and cat.
- Lesions include papules, pustules, erythema, scale, alopecia, and crusts.
- In the dog, the lesions are most commonly found on the face, nasal planum, ear pinnae, and footpads, while the ear pinnae and face are commonly affected in the cat.
- Pemphigus erythematous is thought to be a benign form of pemphigus foliaceus and may represent a crossover between pemphigus and lupus erythematosus.
- Lesions are common on the face and pinnae and consist of erythema, scale, pustules, papules, alopecia, and crusts.
- The nasal planum may be depigmented.

Diagnosis

- Diagnosis is based on histopathology of skin biopsies.

Treatment

- Treatment for pemphigus foliaceus includes systemic glucocorticoids usually combined with other immunosuppressive medications.
- Pemphigus erythematosus may respond to less aggressive medications such as tetracycline and niacinamide, topical glucocorticoids, or topical tacrolimus (Protopic ointment, Fujusawa).

Systemic Lupus Erythematosus

(also see Chapter 48)

Clinical Signs

- Systemic lupus erythematosus is an autoimmune disease that affects multiple organ systems.
- Cutaneous lesions include alopecia, crusts, ulceration, and depigmentation.
- Skin lesions may be multifocal or generalized and frequently involve the face, ears, and distal limbs.

Diagnosis

- Diagnosis is based on clinicopathologic abnormalities, cutaneous histopathology, and a positive antinuclear antibody test.

Treatment

- Treat with immunosuppressive drugs. Base treatment upon specific organ involvement.

Discoid Lupus Erythematosus

(also see Chapter 48)

Clinical Signs

- Discoid lupus erythematosus usually presents as nasal ulceration and depigmentation.
- Rarely, the ear pinna, scrotum, and limbs may be alopecic with crusts and ulcers.

Diagnosis

- Diagnosis is based on cutaneous histopathology, lack of systemic signs of illness, and negative or normal diagnostic tests.

Treatment

- Treatments may include one or more of the following: topical steroids, oral steroids, sunscreen, tetracycline and niacinamide, tacrolimus (Protopic ointment, Fujusawa), and vitamin E.

Vasculitis

Clinical Signs

- Cutaneous vasculitis is uncommon in the dog and rare in the cat.
- It may be characterized by erythema, alopecia, ulcers, crusts, and necrosis involving the extremities and ear pinnae, which may be idiopathic, immune-mediated, drug induced, or associated with a concurrent infectious or neoplastic disease.

Diagnosis

- The diagnosis is made based on histopathology results.
- Perform other diagnostic tests to look for an underlying cause of the vasculitis.

Treatment

- Treat by removing the inciting cause, controlling the underlying disease, glucocorticoids, pentoxifylline (generics; Trental, Aventis Pharmaceuticals), sulfone (Dapsone, Jacobus Pharmaceutical Co., Inc.) and sulfasalazine (Azulfidine, Pharmacia & Upjohn).

Proliferative Thrombovascular Necrosis

Clinical Signs

- Proliferative thrombovascular necrosis is an uncommon disease in dogs.
- The etiology is unknown and there are no breed, sex, or age predilections.
- The lesions begin at the apical margin of the ears and spread along the concave surface.
- An ulcer may be located in the center of the lesions.
- A scaly, thickened, hyperpigmented zone surrounds the ulcer.
- Prominent vessels can be seen coursing the margins of the lesions.
- Older lesions undergo necrosis and eventually deform the ear pinna.

Diagnosis

- The diagnosis is based on history, physical examination, and histopathology.
- The histopathology reveals arteriolar proliferation, sclerosis, hyalin degeneration, and thrombosis.

Treatment

- The disease is slowly progressive. Treat with partial pinnectomy.
- However, there have been anecdotal reports of treatment with pentoxifylline (generics; Trental, Aventis Pharmaceuticals) or the combination of tetracycline and niacinamide.

ENVIRONMENTAL DISEASES

Frostbite

Clinical Signs

- Frostbite is due to prolonged exposure to freezing temperatures or contact with frozen metal objects.
- Frostbite may affect the tips of the ears, digits, scrotum, and tail tip.
- These areas are poorly insulated by the hair and the blood vessels are not protected.
- Frozen skin appears pale and is cool to the touch.
- In severe cases, the skin ulcerates, becomes necrotic, and sloughs.

Diagnosis

- Base the diagnosis on history and physical examination.

Treatment

- Handle frozen tissues gently and thaw by the application of warm water.
- In severe cases, amputation of the affected part may be necessary.
- Delay surgery until a distinction between viable and necrotic tissue can be made.

Actinic Keratoses

Clinical Signs

- Actinic (solar) keratoses are caused by excessive exposure to ultraviolet light.
- The lesions occur on lightly pigmented animals or on areas of the body that have sparse hair coverage (ear pinnae, face, abdomen).
- Actinic keratoses of the pinna occur rarely in dogs and occasionally in white-eared cats in sunny areas of the world.
- The lesions may be single or multiple.
- Acute lesions consist of poorly defined areas of erythema, hyperkeratosis, and crusting, while chronic lesions are indurated, crusted, hyperpigmented plaques.

Diagnosis

- Base the diagnosis on history, physical examination, and histopathology.

Treatment

- Treatment for early lesions is reduction of ultraviolet exposure.
- Actinic keratoses are premalignant lesions capable of becoming squamous cell carcinomas. Surgery (pinnectomy, cryosurgery, laser surgery) is the treatment of choice for advanced actinic keratoses or neoplastic lesions.

Arteriovenous Fistula

Clinical Signs

- An arteriovenous fistula is a direct communication between an artery and vein that bypasses the capillary circulation.
- They are rarely reported in dogs and cats.
- They may be congenital or acquired, with acquired being the more common of the two.
  - Acquired arteriovenous fistulas may result from penetrating wounds, blunt trauma, infection, neoplasia, and surgical procedures and mainly affect the paws, neck, temporal region, pinna, legs, flank, and tongue.
- Affected areas are edematous and painful.
- Superficial blood vessels proximal to the fistula may be distinct and tortuous.
- The fistula is characterized by pulsating vessels, palpable thrills, and continuous murmurs.

Diagnosis

- Base diagnosis on history, physical examination, and demonstration of the fistula by contrast radiography.

Treatment

- Treatment includes removal of the fistula or amputation of the affected part.

Neoplastic Disease (also see Chapter 28)

Clinical Signs

- Ears are common sites for skin tumors.
- Neoplasms that affect the ear pinnae include squamous cell carcinoma, histiocytomas, mast cell tumors, basal cell tumor, sebaceous adenomas, hemangiomas, hemangiosarcomas, epitheliotropic lymphoma, and fibrosarcomas.
- Refer to Chapter 28 for a complete discussion of cutaneous neoplasia.

HEREDITARY DISEASES

Pattern Baldness

Clinical Signs

- One form of pattern baldness affects the pinna of male and rarely female Dachshunds.
- Hair loss from the pinna occurs at 6 to 9 months of age and slowly progresses to complete pinnal alopecia.
- As the alopecia progresses, the skin hyperpigments.
- Complete baldness may occur by 8 to 9 years of age.

Diagnosis

- Base the diagnosis of pattern baldness on history, physical examination, and histopathology.
- Histologically, there is a decrease in size (miniaturization) of the hair follicles with normal adnexal structures.

Treatment

- Studies evaluating melatonin (5 mg PO q24h and constant-release implants, 1–3 implants containing 12 mg each, SC) as a treatment for pattern baldness have shown it to be effective for hair regrowth.
  - Hair regrowth is apparent in 1.5 months after initiation of therapy, with maximum growth in 3 to 4 months.

Psoriasiform-Lichenoid Dermatosis of English Springer Spaniels

Clinical Signs

- Psoriasiform-lichenoid dermatosis of English Springer spaniels is a rare disease.

- Asymptomatic, symmetric, erythematous, lichenoid plaques and papules are noted on the concave portion of the pinna, in the external ear canal, and in the inguinal region.
- The lesions become hyperkeratotic, and spread to involve the face, ventral trunk, and perineal region.

Diagnosis

- Base diagnosis on history, physical examination, and histopathology.

Treatment

- Four cases treated with cephalexin showed excellent response with complete resolution of the lesions. No other treatment to date has been found effective.

Melanoderma and Alopecia in Yorkshire Terriers

Clinical Signs

- Melanoderma and alopecia in Yorkshire terriers is presumed to be a genetic dermatosis.
- Lesions consist of symmetric alopecia and hyperpigmentation over the bridge of the nose, pinnae, tail, and feet.
- The syndrome usually begins at 6 months to 3 years of age.

Diagnosis

- Base diagnosis on history, physical examination, and histopathology

Treatment

- Mild lesions may resolve spontaneously.
- Most dogs are affected for life.

Hereditary Lupoid Dermatosis of German Shorthaired Pointers

Clinical Signs

- Hereditary lupoid dermatosis of German shorthaired pointers is an uncommon disease.
- Lesions are first seen at 6 months of age and consist of scaling and crusting on the face, ears, and back and then become generalized.
- The hocks and scrotum may be severely affected.

Diagnosis

- Diagnosis is made based on history, physical examination, and histopathology.

Treatment

- Dogs respond poorly to treatment.
- Treatments that have been tried include antiseborrheic shampoos, glucocorticoids, fatty acid supplementation, and retinoids.

Dermatomyositis

Clinical Signs

- Dermatomyositis is a hereditary disease seen most commonly in collies and Shetland sheepdogs. Other breeds have been reported.
- Lesions begin before 6 months of age and consist of alopecia, erythema, scaling, and mild crusting.
- Ulcerations and scarring may be seen in severely affected dogs.
- Lesions are found on the face, tips of ears, carpal and tarsal regions, digits, and tail tip.
- The myositis occurs after the skin lesions are recognized and correlate with the severity of the skin disease.

Diagnosis

- Base diagnosis on history, physical examination, and histopathology of the skin and muscle.

Treatment

- Treatments include sun avoidance, vitamin E, pentoxifylline (generics; Trental, Aventis Pharmaceuticals), fatty acid supplementations, and glucocorticoids.

MISCELLANEOUS DERMATOSES

Zinc-Responsive Dermatosis

Clinical Signs

- In dogs, two syndromes of zinc-responsive dermatosis have been recognized.
  - In Syndrome I, young adult Siberian huskies, Alaskan malamutes, and bull terriers develop erythematous, crusty, scaly lesions affecting the mouth, chin, periocular region, and ears.
  - Syndrome II occurs in rapidly growing puppies fed zinc-deficient diets, high-calcium or high-cereal diets that have high levels of phytate and thus poor zinc absorption, or diets oversupplemented with vitamins and minerals.
- Hyperkeratotic plaques occur over areas of repeated trauma.

Diagnosis

- Base diagnosis on history, physical examination, and histopathology.

Treatment

- Zinc supplementation is necessary for treatment of Syndrome I. Supplementation is life long.
- Treatment for Syndrome II involves changing to an appropriate diet.

Juvenile Cellulitis

Clinical Signs

- Juvenile cellulitis is an uncommon disease that usually affects puppies 6 to 14 weeks of age.
- The etiology is unknown.
- Predisposed breeds include golden retrievers, dachshunds, and pointers.
- Lesions mainly affect the eyelids, pinna, periocular, and muzzle region.
- Initially, the affected areas are swollen. Papules and pustules develop, which then fistulate, drain, and crust.
- They may have concurrent otitis externa.
- Systemic signs of fever, depression, and inappetence are usually present.
- There is severe submandibular lymphadenopathy.

Diagnosis

- Base diagnosis on history, physical examination, and histopathology.

Treatment

- Treatment consists of high doses of oral glucocorticoids.

Ear Margin Seborrhea (also see Chapter 50)

Clinical Signs

- Ear margin seborrhea is a keratinization disorder and is a common condition in the dachshund.
- Cocker spaniels and springer spaniels may be affected.
- Ear margin seborrhea is characterized by numerous small, greasy plugs and scale adhering to the skin and hairs of the medial and lateral margins of the pinna.
- The disease is frequently asymptomatic. In chronic cases, fissuring may occur which is painful.

Diagnosis

- Base diagnosis on history, physical examination, and histopathology. Histopathologically there is marked surface and follicular orthokeratotic or parakeratotic hyperkeratosis.

Treatment

- Remove the accumulated debris using sulfur-salicylic or benzoyl peroxide shampoos.

Canine Eosinophilic Pinnal Folliculitis

Clinical Signs

- Canine sterile eosinophilic pinnal folliculitis is an uncommon, non-seasonal, bilaterally symmetric dermatosis in dogs. The etiology is unknown.
- Lesions consist of erythematous papules and crusts on the concave surface of the pinna.

Diagnosis

- Base diagnosis on history, physical examination, cytology, C/S, and histopathology.
- Cytologic examination of a papule reveals numerous eosinophils, cultures are negative, and histology reveals an eosinophilic folliculitis and furunculosis.

Treatment

- The disease is responsive to topical or oral glucocorticoids but may recur.

Sebaceous Adenitis

Clinical Signs

- Sebaceous adenitis is an uncommon dermatosis of the dog and rare in the cat.
- Many breeds may be affected; however, there are breed predilections for standard poodles, Akitas, Vizslas, and Samoyeds.
- Lesions are commonly found on the face, pinnae, head, and dorsal trunk.
- Lesions consist of papules, alopecia, scales, and follicular casts.

Diagnosis

- Diagnosis is made based on history, physical examination, and histopathology.

Treatment

- Treatment includes topical antiseborrheic shampoos, emollient rinses, fatty acid supplementation, glucocorticoids, cyclosporine (Atopica, Novartis), vitamin A, and retinoids.

Chapter 59

Otitis Externa

James O. Noxon

The external ear canal consists of skin overlying cartilage, which provides the structural support to keep the canal open. The auricular cartilage is the framework for the pinnae and vertical aspect of the ear canal, and the annular cartilage supports the horizontal component of the external ear canal. The cartilage is covered by skin, which contains sebaceous sweat glands, apocrine (ceruminous) glands, and hair follicles. Otitis externa is defined as inflammation of the skin and adnexal structures of the ear canal. This condition is one of the most common and frustrating problems encountered in small animal practice.

▼ ***Key Point*** Otitis externa is often a clinical manifestation of a generalized dermatologic condition.

The cause of otitis externa in a patient is usually multifactorial especially when chronic and requires a systematic diagnostic and therapeutic plan for resolution and to prevent recurrence.

ETIOLOGY AND PATHOGENESIS

Primary Factors

- Primary factors are those conditions or disorders that *initiate* the inflammatory process within the ear canal.
- Examples include parasites *(Otodectes cynotis);* allergies (food, atopic dermatitis, contact); foreign bodies (grass awns, foxtails); keratinization disorders (seborrhea); and, less frequently, trauma, autoimmune disease (pemphigus), sebaceous adenitis, zinc-responsive dermatoses, and endocrinopathies (hypothyroidism)
- Primary factors may initially induce disease outside the external ear canal. Otitis externa may be an extension of a pinnal disorder (see Chapter 58), otitis media, or otitis interna (see Chapter 61).

▼ ***Key Point*** Identification and management of the primary factors is the key to long-term control of otitis externa.

Predisposing Factors

- Predisposing factors facilitate the inflammation by *promoting* an environment conducive to survival of perpetuating factors.
- Examples include conformation of the ear canal (long canal with a deep vertical component), moisture in the canal (dogs that swim, residual cleaning agents in the ear canal), hair in the ears (e.g., in poodles and terriers), breed predisposition (e.g., Chinese Shar-Pei, stenotic canals), immunodeficiency syndromes, endocrine imbalances, iatrogenic ear trauma (e.g., unnecessary hair removal and cleaning with cotton-tipped applicators), and obstructive disease (e.g., cancer, polyps, and hyperplasia).

▼ ***Key Point*** Predisposing factors do not initiate otitis externa.

Perpetuating Factors

- Perpetuating factors *sustain and aggravate* the inflammatory process.
- Mechanisms include occlusion of the canal, which prevents drying or proper application of medication; secretion of irritating factors; alterations in pH of the canal; and formation of a focus of infection (otitis media).
- Examples include bacterial infections *(Staphylococcus intermedius, Proteus mirabilis, Pseudomonas aeruginosa,* and *Escherichia coli),* and yeast infection *(Malassezia pachydermatis).* Otitis media serves as a source of infectious agents, and chronic hyperplastic changes of the ear canal may obstruct the canal.

▼ ***Key Point*** Medication may also act as a perpetuating factor (or a primary factor) of otitis externa, by causing secondary contact irritation or allergy (e.g., neomycin and topical anesthetics), or by leaving residue in the canal (e.g., oil-based preparation).

CLINICAL SIGNS

Signs Directly Related to Ear Involvement

- Head shaking
- Scratching and rubbing of the ears
- Discharge from the ears
- Pain around the ears or head (manifested as crying or whining)
- Malodor
- "Hotspots" around the periauricular skin (cheek, behind the ear)
- Behavioral changes: pets may become irritable and aggressive toward family members as a result of ear pain.
- Licking of ears by *other* pets in the household may indicate malodor and an inflammatory process.
- The pet's loss of hearing, although difficult to document, is a common owner's complaint.

Signs Reflecting an Underlying (Predisposing) Dermatologic Disorder

- Face rubbing, sneezing, foot licking, anal scooting, and generalized scratching suggest underlying allergic disease.
- Severe pruritus may incriminate parasitic (scabies, *Notoedres* mange) or allergic (flea allergy dermatitis) causes.
- Scaling and crusting may indicate seborrheic disease, sebaceous adenitis, or pemphigus foliaceus as a primary disease.
- Recurrent bacterial dermatitis may suggest an allergy, an endocrine imbalance, or immunologic insufficiency.
- Accompanying alopecia may reflect an underlying endocrine imbalance or ectoparasitic infestation.
- Bilaterally symmetrical alopecia with easily epilated hair is a feature of endocrine disease.
- Focal alopecia or alopecia characterized by broken or fragmented hairs may indicate trauma (pruritus) or infectious (bacterial, fungal) disease.

Signs of Associated Otitis Media and Otitis Interna

Typically, the most common clinical sign of otitis media is chronic and recurrent otitis externa. Neurologic signs are more specific for otitis media (sympathetic and facial neuropathy) and otitis interna (peripheral vestibular syndrome) but are not always present in dogs with middle or inner ear disease. Refer to Chapter 61.

DIAGNOSIS

Use diagnostic procedures to identify primary factors (initiating factors), predisposing factors, and perpetuating factors. All etiologic factors must be considered for successful long-term management of the patient.

History

- Use the history to detect evidence of allergies (seasonality), parasites (possible exposure), and environmental factors of concern.
- Determine the frequency of ear problems and the response to previous treatment, which may give important clues about the pathologic processes.

Physical Examination

- Physical evaluation includes palpation of the external ear canals for pain or evidence of calcification of the external canals (firm or hard on palpation), smelling of the ears, and careful examination of the skin over the entire body for evidence of systemic disease.
- Examine the skin surrounding the opening of the ear canal and the ear pinna
- Examine for vestibular and cranial nerve abnormalities that could indicate otitis media and otitis interna (see Chapter 61).

Otoscopic Examination

- For equipment, a standard otoscope with a diagnostic or operating head is generally adequate; however, a video otoscope is strongly recommended for enhanced imaging and its specialty applications.
- Evaluate for the size of the ear canals; the presence of parasites, exudate, hair, or foreign material; the color of the epithelium; the presence of ulcers or masses; and the appearance and integrity of the tympanic membrane (see Chapter 1).
- Sedation of the animal may be necessary.
  - Topical anesthesia with 1% to 2% lidocaine HCl, 0.5% proparacaine, or other similar agents may be sufficient.
  - General anesthesia is indicated for removal of most foreign objects; for biopsy, and for thorough evaluation of the horizontal ear canal.
- Avoid trauma to the ear canal by advancing the otoscope cone only while directly visualizing the canal.

Otoscopic Abnormalities

- **Erythema:** reddened epithelium
- **Exudation:** dark, dry, granular exudate is generally found with ear mite infection; moist, yellow, odoriferous exudate is generally a sign of bacterial infection; brown, waxy exudate is generally consistent with yeast infection and overgrowth; and yellow, waxy-to-dry scale may be found with keratinization disorders. Cytology of otic exudates is always indicated to confirm these clinical clues.
- **Hyperplasia** (lichenification, hyperpigmentation) is a sign associated with chronicity. Surgical management

may be necessary in patients with severe hyperplasia (occlusion) that is unresponsive to therapy.
- **Ulcers** suggest more severe disease and indicate a need for aggressive treatment—seen especially with *Pseudomonas* and yeast infections.

Cytology

- Cytology often provides an indication for the best initial treatment plan and is essential in the assessment of secondary bacterial and yeast infections.
- Use a cotton-tipped applicator to swab the external canal, if possible at the outer end of the horizontal ear canal. Remove and gently roll the applicator onto a clean glass slide.
- Heat fix and stain the slide with a modified Wright-Giemsa preparation (Diff-Quik; American Scientific Products). Examine a separate slide after adding mineral oil (and without heat fixing or staining) to look for external parasites.
- Examine for parasites, cellular components, and infectious agents (bacteria, yeast, fungi). Notice whether infectious agents are present within inflammatory cells or free in the exudate and whether the infectious agents are present as a single population or part of a mixed population.

▼ ***Key Point*** Cytology is a rapid, inexpensive diagnostic procedure that is indicated in all cases of otitis externa. It should be repeated at every recheck examination and the results used to modify and adjust therapy. Document the extent (or severity) of bacteria and/or yeast for comparisons at follow-up visits.

Culture and Susceptibility Testing

- Bacterial culture of the external ear canal is recommended when:
  - Cytologic examination of exudate from the external ear canal shows a uniform population of gram-negative bacteria (or rod-shaped bacteria if Diff Quick is the stain used).
  - Ulcers are present in the external ear canal and bacteria are present on cytologic examination of exudate.
  - A bacterial infection continues to be present (as demonstrated by cytologic examination of smears from the ear canal) despite appropriate empiric antimicrobial treatment.
- Otitis media should also be suspected in animals with chronic (recurrent or persistent) otitis externa even when the tympanic membrane is intact. Bacterial culture of the middle ear (by myringotomy if the tympanic membrane is intact) may be indicated if the tympanic membrane appears at all abnormal (see Chapter 61).

Biopsy

- Biopsy is indicated when abnormal growths are detected.
- Biopsy instruments designed for endoscopic procedures are useful to collect a small tissue sample from the ear canal.
- Excisional biopsy of lesions is preferred whenever possible.

Diagnostic Imaging

- Radiography is occasionally indicated (especially in severe or chronic otitis) to evaluate the patency of the ear canal, to aid in detecting the presence of otitis media and otitis interna, and to determine the extent of involvement of surrounding structures.
- Computerized tomography (CT scans) and magnetic resonance imaging (MRI) are more sensitive diagnostic tests to evaluate the patency of the ear canal (and involvement of the middle ear).
- All imaging techniques are more valuable in evaluating the middle and inner ear than the external ear canal, where their main benefit would be to determine if the ear canals are patent and the extent of any calcification of the canal (considered a poor prognostic indicator if extensive).

Other Tests

- Miscellaneous diagnostic tests are helpful to identify predisposing and primary factors. See respective chapters for details on these tests. Tests frequently recommended include hematology, serum biochemistry profiles, urinalysis, thyroid function tests, adrenal function tests, intradermal allergy tests, serum (in vitro) allergy tests, skin scrapings, fungal cultures, and dietary trials.

TREATMENT

The initial treatment of otitis externa is directed toward control of the active inflammatory process, because this aspect of the disease is of immediate concern to the client and patient. After the perpetuating factors are controlled, treatment is directed toward removing the underlying predisposing factors and managing the primary etiologic factor.

Successful long-term management of otitis externa requires identification and treatment of perpetuating factors, predisposing factors, and primary etiologic factors.

Principles of Medical Treatment

- Most commercial ear preparations contain multiple therapeutic agents. Select otic preparations carefully for the desired active agents (Table 59-1). Do not use products with agents that are not specifically indicated

Table 59-1. ACTIVE INGREDIENTS COMMONLY PRESENT IN OTIC PREPARATIONS

Ceruminolytic/softening agents
- Hexamethyltetracosane
- Docusate sodium (dioctyl sodium sulfosuccinate, DSS)
- Squalane

Keratolytic
- Carbamide peroxide
- Benzoic acid
- Salicylic acid
- Sulfur
- Resorcinol

Antifungal
- Nystatin
- Thiabendazole
- Miconazole
- Clotrimazole
- Cuprimyxin
- Silver sulfadiazine

Antibacterial
- Bacitracin
- Chloramphenicol
- Colistin
- Enrofloxin
- Gentamicin
- Neomycin B sulfate
- Polymyxin B
- Penicillin G
- Silver sulfadiazine
- Sulfacetamide
- Sulfur

Anti-inflammatory

Glucocorticoids
- Hydrocortisone
- Prednisolone
- Isoflupredone acetate
- Triamcinolone acetonide
- Dexamethasone
- Fluocinolone acetonide

Dimethyl sulfoxide

Antiparasitic
- Pyrethrins
- Thiabendazole
- Carbaryl
- Rotenone

Topical Anesthetic
- Tetracaine
- Lidocaine

in the ear being treated (i.e., do not use a product with antibiotics if there is not a bacterial infection).

▼ ***Key Point*** Do not apply cleansing agents, parasiticides, ceruminolytic/keratolytic agents, disinfectants, ototoxic antimicrobials, or oil-based medications into the ear canal of animals in which the tympanic membrane is ruptured.

- Choose the delivery vehicle for medication carefully.
  - Lotions and solutions are more easily applied deep in the external canal.
  - Oil-based medications are useful to treat dry, scaly lesions, such as those of seborrhea sicca. These products penetrate into the skin well, but their penetration deep into the canal is often limited by hair or debris.
  - Creams, pastes, and powders are difficult to apply deep in the external ear canal and may leave a residue. These formulations are rarely indicated in the treatment of otitis externa in dogs and cats.
- Apply topical otic medications liberally to ensure delivery of adequate amounts of medication to the deeper aspects of the canal. An average size dog (around 20 kg) would require 0.5 to 1.0 ml of medication in the ear canal to penetrate to the level of the tympanic membrane.
- Gently massage the external canal for 15 to 30 seconds to help to deliver medications deep into the horizontal canal.

Cleaning the External Canal

▼ ***Key Point*** The initial objective of medical management of otitis externa is to clean and dry the external canal. This process makes the environment less favorable for sustained microbiologic growth and reduces the inflammatory process in most patients.

Cleaning Techniques

- There are several techniques useful to clean ears. In order of increasing effectiveness, they include: hand cleaning by infusion and massage, the use of commercial ear flushing equipment, deep ear flushing, and spot flushing and suction through the otoscope.
- Hand cleaning is generally the easiest and fastest method to clean ears. It is the technique used for rapid cleaning in the hospital and may be taught to pet owners to be done at home (Table 59-2).
- A commercial ear-cleaning unit (AuriFlush, Schering-Plough) is useful and moderately effective for cleaning ears. Limitations include poor cleaning deep in the horizontal canal and loud noise for the patient, which will result in low tolerance by unsedated patients.
- Deep flushing of the ear canal is done under general anesthesia with a pediatric gastric tube, which has dual ports, one for flushing sterile saline and one for constant suction. This is a highly effective technique to clean deep in the ear canal.
- The most thorough ear cleaning can be accomplished using a catheter (Figure 59-1) passed through a hand-held or video otoscope (Table 59-3).

Cleaning Procedures

- Deep flushing and thorough cleansing of the ear canal requires the patient to be placed under a general anesthetic.

Table 59-2. EAR-CLEANSING TECHNIQUE

Several commercial ear cleansing solutions are suitable for this procedure (see Table 59-4). Isotonic (0.9% saline) is recommended for ear cleansing if the integrity of the tympanic membrane is unknown.

1. Supplies needed include ear cleansing solution, clean cotton balls, and cotton-tipped applicators.
2. Fill the entire ear canal with the desired cleansing solution.
   a. Do not force the solution into the ear canal under pressure.
   b. Fill the entire canal, so that the solution is overflowing from the external ear canal.
3. Place a clean, dry cotton ball into the opening of the external ear canal.
4. Gently massage the external canal using an upward, circular motion in an attempt to pull cleansing solution up from the canal into the cotton ball.
5. Replace the cotton ball periodically to absorb the solution and to remove exudate.
6. Repeat the process as many times as needed to ensure cleansing of the canal. The amount of exudate removed during the massaging process should decrease with each rinsing.
7. Remove any excess fluid (not removed by the cotton balls) by using a dry cotton ball without adding cleanser. Cotton-tipped applicators may be used to dry visible portions of the ear. They should *not* be used to clean deep in the vertical or horizontal external ear canal, as this is likely to cause trauma and lead to impaction of debris and exudates deeper into the ear canal.
8. Infuse a drying solution into the ear canal if necessary. Wipe out excess.

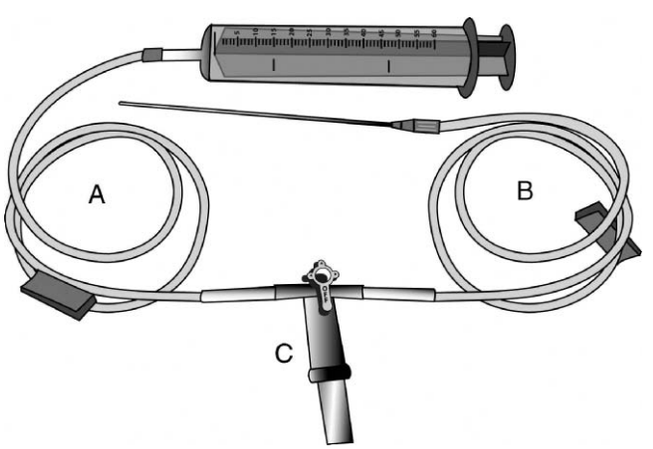

Figure 59-1. Catheter setup for deep ear flushing. *(A),* Intravenous extension set from syringe, *(B),* Intravenous extension set from stopcock to catheter, *(C),* suction attachment to stopcock.

- Several commercially available irrigating solutions are effective for routine cleansing of the external ear canal (Table 59-4).
- Use warm 0.9% saline to flush the ear canal when the integrity of the tympanic membrane is unknown.
- Use an ear loop carefully to remove impacted debris and wax. General anesthesia is strongly recommended.
- Owners of pets with chronic otitis externa, especially ceruminous otitis externa, should be taught the proper ear-cleansing technique that facilitates long-term management of their pet's condition.
- Ceruminolytic agents may be applied in cases of severe, exudative otitis to facilitate removal of the wax; they are most effective when applied to the external canal for 15 minutes before flushing. Ceruminolytic agents act primarily as softening agents and are contraindicated when the tympanic membrane is not intact. One product, (Cerumene, Vetoquinol) has been shown to be safe when it was experimentally deposited and left in the middle ear. If the integrity of the tympanic membrane is not known and ear cleaners are used, a final rinse with sterile saline may remove excess cleaning agents that could be ototoxic if left in the ear.

Table 59-3. DEEP EAR CLEANING TECHNIQUE

1. Supplies needed include a 3-way stopcock, a 60 cc syringe, two intravenous extension sets, a 14-gauge (hand-held otoscope) or 16-gauge (video otoscope) Teflon coated intravenous catheter, and a suction unit with adjustable suction intensity.
2. Suction is attached to one port of the stopcock, the 60 cc syringe with sterile saline is attached via an extension set to the second port, and the catheter is attached to the third port via another extension set.
3. The catheter is passed through the hand-held or video endoscope and the flushing is done by an assistant as the operator guides the catheter to "trouble spots."
4. Suction is used both to clean saline from the field of view and to remove particulate matter.
5. The process is repeated as necessary to thoroughly clean the ear.
6. A dual adaptor (Y-piece) is useful for the video otoscope, to allow constant saline infusion through one port with directed suction through the other port.

▼ ***Key Point*** If inflammation is severe or hyperplasia of the ear canal is moderate to severe, then glucocorticoid therapy is necessary before adequate cleaning can be achieved.

Drying the External Canal

- Several commercial drying solutions are available (see Table 59-4). Active ingredients include acetic acid, sulfur, boric acid, alcohol, benzoic acid, and Burow's solution.
- Infusion of solutions containing alcohol can result in severe discomfort (stinging sensation) to the patient and are avoided when the external ear canal is ulcerated.

Topical Medications

Topical Anti-inflammatory Agents

▼ ***Key Point*** Glucocorticoids applied to the external canal are significantly absorbed and may affect the hypothalamic-pituitary-adrenal axis.

Table 59-4. COMMERCIAL PREPARATIONS USEFUL IN CLEANING AND DRYING THE EXTERNAL EAR CANAL*

Category	Product	Active Ingredients
Cleansing/Flushing Solutions	Oti-Clens (SmithKline)	Propylene glycol Malic acid Benzoic acid
	Epi-Otic (Allerderm)	Lactic acid Salicylic acid Propylene glycol Docusate sodium Chitosanide
	Panotic (Pfizer)	Diazolidinyl urea methylparaben dioctyl sodium sulfosuccinate octoxynol sodium lauryl sulfate, propylene glycol
	OtiCalm Cleansing Solution (DVM Pharmaceuticals)	Propylene glycol Salicylic acid Malic acid Eucalyptus oil
	Zymox Ear Cleanser (Pet King Brands, Inc.)	Glycerin Propylene glycol Benzyl alcohol Zinc gluconate
	Dermapet Malacetic Otic (DermaPet)	Boric acid Acetic acid
	Otifoam Ear Cleanser (DVM Pharmaceuticals)	Cocamidopropyl betaine Salicylic acid Eucalyptus oil
Drying Solutions	ClearX Drying Solution (DVM Pharmaceuticals)	Acetic acid Sulfur Hydrocortisone acetate
	Bur-OticHC Ear Treatment (Virbac)	Burow's solution Acetic acid Propylene glycol
	Panodry (Solvay)	Boric acid Isopropyl alcohol

*Commercial otic cleansers may include both cleansing and drying agents. Products listed are examples—many other effective medications are commercially available.

- Topical glucocorticoids are indicated in most cases of otitis externa to reduce inflammation and swelling, to alleviate pain, and to help minimize fibrosis.
- Otic glucocorticoid administration may interfere with diagnostic procedures, such as intradermal skin tests, adrenal function tests, thyroid function tests, and routine hematologic and biochemical tests (e.g., serum alkaline phosphatase activity); therefore, perform these tests prior to treating with topical glucocorticoids if possible.
- Use the least potent glucocorticoid necessary to accomplish the desired effect.
- Most otic glucocorticoid preparations also contain antiparasitic and/or antimicrobial agents.

Topical Antibacterial Agents

- Base choice on cytologic findings or culture and susceptibility results.
- Medications with antibacterial properties include aminoglycosides, polymyxin B sulfate, chloramphenicol, chlorhexidine, enrofloxacin, iodophors, propylene glycol, and silver sulfadiazine.
- Tris-EDTA alone or added to antimicrobials increases the sensitivity of resistant *Pseudomonas* spp. to several antibiotics.
- Several antibacterial agents, such as ticarcillin (see under "Pseudomonas Infection"), are available in formulations for injection and may be formulated as topical preparations for specific problems.
- Other antibiotic preparations, available as otic or ophthalmic preparations for humans, may be applied to the external ear canal. Examples include colistin sulfate (Coly-mycin Otic, Parke-Davis) and tobramycin (Tobrex Ophthalmic Solution, Alcon).

Topical Antifungal Agents

- Clotrimazole (Lotrimin, Schering) is effective against *Malassezia* spp. yeast.
- Miconazole lotion (Conofite, Pitman-Moore) may be used in the external canal to control yeast or fungal infections (contains alcohol and may be irritating).

- Chlorhexidine
- Povidone-iodine
- Cuprimyxin cream
- Silver sulfadiazine cream (1% Silvadene, Marion) may be diluted with sterile saline or water (1 part cream to 9 parts saline or water) and infused into the ear twice daily as effective treatment against *Malassezia pachydermatis*.

Topical Antiparasitic Agents

- Preparations containing pyrethrins, carbaryl, thiabendazole, milbemycin oxime (MilbeMite, MilbeMite Otic solution, Novartis), ivermectin (Acarexx, Idexx Pharm), and rotenone are effective against ear mites.
- Apply these preparations to the external ear canal regularly (every day or every other day) for 3 weeks or as directed.
- Apply a topical parasiticide (i.e., preparations used for adult fleas) to the skin over the remainder of the animal once weekly during the treatment period.

Acidifiers

- Acidifiers, such as acetic acid and benzoic acid, are somewhat helpful in controlling yeast and bacterial infections.
- Vinegar and water, mixed in a 1:2 ratio, appears to be a safe and effective acidifying agent in the external ear canal of dogs and cats.

Systemic Therapy

Glucocorticoid Therapy

- Systemic glucocorticoids may help alleviate the pain and inflammation of otitis externa.
- Administer a short-acting glucocorticoid (e.g., prednisone [1.1 mg/kg PO q24h]) for 5 to 7 days.
- In a patient with inflammation and hyperplasia of the ear canal and painful ears, use of a short-acting glucocorticoid will help reduce the inflammation and the pain and will facilitate thorough evaluation and cleansing of the ear canal. Administer the glucocorticoid as described previously, and perform the otic examination 24 to 48 hours later.
- Longer term glucocorticoid therapy may be necessary in patients with poorly controlled allergic otitis. Topical glucocorticoids are preferred to systemic.

Antimicrobial Therapy

- Systemic antimicrobial therapy is indicated in a patient with bacterial otitis externa when the tympanic membrane is ruptured (see Chapter 61), the epithelium of the canal is ulcerated, or inflammatory cells containing bacteria are found during cytologic examination.
- Systemic antifungal therapy (see Chapter 20) is rarely necessary but is indicated in patients with severe recurrent yeast infections, in patients that are difficult to medicate topically, or in patients with otitis externa that is caused by a systemic mycotic agent (e.g., *Cryptococcus* spp.). Ketoconazole is effective against *Malassezia pachydermatis* infection in dogs, while itraconazole (5 mg/kg PO q24h) is recommended for use in cats.

Antiparasitic Therapy

- Selamectin (Revolution, Pfizer), milbemycin oxime (MilbeMite, Novartis), and ivermectin (Acarexx, Idexx) are effective topical agents for the treatment of ear mites in dogs and cats.
- Ivermectin (0.3 mg/kg PO) is reported to be effective against ear mite infections in dogs and cats. Treatment may be necessary weekly for 3 to 4 doses to eliminate infection. Do not administer this to collies and collie-mix breed dogs or to heartworm-infected animals because treatment of these breeds or in these circumstances may result in profound adverse reactions. The use of ivermectin in this manner is off-label use; thus, obtain prior owner consent in writing.
- In the case of ear mite infestations, treat all pets in contact with the affected pet with the selected miticidal therapy.

Surgical Management

- Surgical management of otitis externa is indicated to correct conformational defects that predispose an animal to inflammatory disease and to improve ventilation and drainage in affected ears (see Chapter 60).

Treatment of Specific Otic Conditions

All of the following conditions are considered perpetuating factors. Successful long-term management also requires identification and treatment of the primary etiologic factors.

Malassezia Infection

- Instill topical antifungals, such as 1% clotrimazole, once or twice daily (see Table 59-1).
- Give oral ketoconazole (dogs: 5 mg/kg, PO, q12h for 7 days, then q24h) when owners are unable to administer topical medications or when the ears have severe hyperplastic changes that reduce penetration of topical preparations.
- Topical or oral glucocorticoids will help reduce inflammation and edema.
- Some cleansers, such as Epi-Otic (Virbac) and DermaPet Ear Cleanser (DermaPet) have been shown to have some efficacy against yeast infections.
- Acidification of the ear canal with commercial products, such as Advanced pHormula Ear Cleanser

(EVSCO Pharmaceuticals) or with white vinegar and water in a 1:2 ratio will reduce yeast populations.

Pseudomonas Infection

- *Pseudomonas* infections generally cause ulcers and severe pain in the ears and are accompanied by a mucoid to purulent exudate.
- Suspected *Pseudomonas* infections (i.e., if rods are seen on cytology) should be cultured to obtain a sensitivity pattern to allow for the best antibacterial treatment.
- Topical agents with some efficacy include tobramycin, gentamicin, enrofloxacin, silver sulfadiazine, and polymixin B sulfates.
- The effectiveness of topically-applied fluoroquinolones, aminoglycosides, and some other antibiotics may be enhanced by co-treating with Tris-EDTA buffered solution (TRIZ-EDTA, DermaPet; T8 Solution, DVM Pharmaceuticals).
- Ticarcillin may be applied as a 3% solution (Ticar, GlaxoSmithKline) twice daily. Dilute the 3.1 gm vial for injection with 100 ml of sterile water for injection, draw up in 1.0 ml aliquots with an additional 0.5 ml of air added to each syringe, cap each syringe, then freeze. The content of one syringe is applied to each ear, after thawing to room temperature, twice daily for 25 to 30 days. Reevaluate cytology or a bacterial culture after completion of therapy.
- Systemic antibacterial therapy is indicated when otitis media is suspected or when owners are unable to treat ears topically. The fluoroquinolone antibiotics, especially marbofloxacin (Zenequin, Pfizer), are the most likely systemic antibiotics to be effective.
- Give prednisone (1.1 mg/kg, PO, q24h for 5–10 days) to reduce pain and inflammation.

Hyperplastic Changes

- Hyperplastic changes are seen clinically as lichenification and proliferative changes within the external canal and on the pinnae. They are perpetuating factors.
- Manage bacterial and yeast infections with appropriate medications. Orally administered or parenteral medications may be necessary due to the obstructive nature of hyperplastic changes.
- Give prednisone (1.1–2.2 mg/kg, q24h for 14 days) then reevaluate the ears:
  - If there has been no reduction in the degree of hyperplasia, surgery (e.g., total ear canal ablation) is indicated as the best therapeutic option (see Chapter 60).
  - If there has been a partial reduction of the hyperplasia, continued prednisone therapy (either at the same dose or at a reduced q48hr dose) may be necessary.
  - Perform cytology to monitor the type and extent of secondary infection.
- Apply a topical glucocorticoid, such as fluocinolone acetonide (Synotic Otic Solution, Fort Dodge) once or twice daily to each ear canal. Instill medication as deeply into the canal as possible.

PREVENTION

- Use behavioral modification directed toward decreasing activities that predispose the animal to otitis, such as swimming and running through the woods and fields.
- Use regular medical care to decrease the recurrence of otitis externa in predisposed patients.
- Thoroughly clean and dry ears after swimming. Infuse a topical medication containing an astringent, such as boric acid or Burow's solution, into the ears of patients who swim to help keep the ears dry and make the local environment less favorable for bacterial and yeast infections.
- Regularly clean ears of pets with seborrheic disorders.

▼ ***Key Point*** Remove hair only when indicated by the patient's history. Hair clipping or plucking is not recommended as part of routine ear care in most animals because the irritation associated with these procedures may predispose them to otitis externa.

Chapter 60

Surgery of the External Ear Canal and Pinna

Daniel D. Smeak

External ear canal surgery is performed to provide exposure and drainage for the vertical and horizontal ear canal or to remove irreversibly infected tissue or neoplasia. Procedures for the external ear canal include lateral ear canal resection, vertical ear canal ablation, and total ear canal ablation. Drainage of auricular hematoma is the most common surgical procedure of the pinna; this is discussed later in this chapter.

Success of ear surgery relies on the following:

- An accurate diagnosis
- An appreciation of the severity and extent of the disease
- Correct choice and technical execution of the procedure
- Appropriate postoperative medical treatment of the local disease and any underlying primary skin disorder (see Chapter 59)

▼ ***Key Point*** As a general rule, surgical intervention is considered when appropriate medical treatment for otitis externa fails, or when medical treatment is not expected to be successful.

As ear disease progresses, more extensive surgery is often required to relieve clinical signs. Risk of complications, however, also increases as the surgery becomes more extensive.

GENERAL SURGICAL INDICATIONS

- For ear disease that fails to respond to appropriate medical treatment
- For relapse of clinical signs after initial response to medical therapy
- For extensive irreversible changes of cartilage and/or epithelium
- For certain predisposing factors causing the ear condition (congenital or acquired malformation, stenosis or atresia of the ear canal, or neoplasia)

▼ ***Key Point*** External ear surgery rarely is indicated in the cat except for traumatic or neoplastic conditions. Inflammatory polyps extending into the external ear canal from the tympanic cavity usually do not require external ear surgery for removal. See middle ear surgery (see Chapter 62) for further information.

ANATOMY

A clear understanding of ear anatomy and related structures is critical to uncomplicated ear surgery. The surgeon must identify and preserve several key structures, especially during horizontal canal dissection.

External Ear Canal

- The normal external ear canal (Figs. 60-1 and 60-2) is a 5- to 10-cm–long pliable cartilaginous tube lined by glandular epithelium, extending from the base of the pinna to the tympanic membrane.

Vertical Ear Canal

- From the external opening (aditus), the vertical canal (auricular cartilage) runs ventrally and slightly rostrally, before bending toward the skull to form the shorter horizontal canal.

Horizontal Ear Canal

- The horizontal canal consists of a circular (annular) cartilage extending from the ligamentous attachment to the auricular cartilage medially to the short osseous ear canal (projection of the petrous temporal bone). The canal ends at the tympanic membrane.

Important Local Structures

Salivary Glands (Fig. 60-2*B*)

- The V-shaped parotid salivary gland overlays the ventrolateral aspect of the vertical ear canal and extends ventral to the distal aspect of the horizontal ear canal.

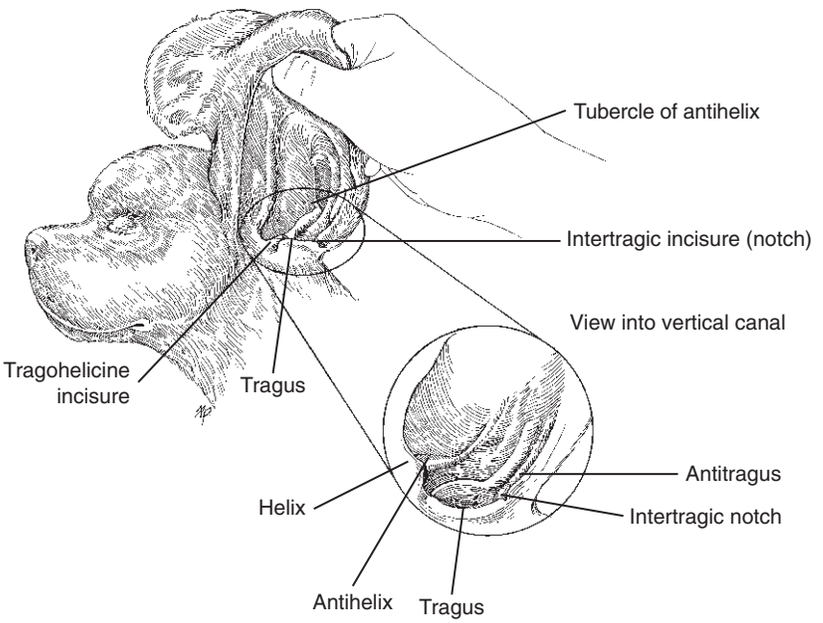

Figure 60-1. Anatomy of the external aditus of the ear.

Blood Vessels (Fig. 60-2*B*)

- Blood supply to the ear is via the great auricular artery, arising from the external carotid artery located medial to the parotid gland and ventral to the osseous bulla.
- Small branches of the great auricular and maxillary arteries run dorsally, parallel to the long axis of the pinna, and medial to the pinna cartilage.

Nerves (Fig. 60-2*B*)

- The facial nerve arises from the stylomastoid foramen located just caudodorsal to the osseous ear canal.
- The nerve is closely associated with the caudal aspect of the horizontal ear canal shortly after it exits the foramen, and courses directly under the horizontal ear canal.
- Terminal branches of the facial and auriculotemporal branch of the mandibular portion of the trigeminal nerve are located just rostral to the ear canal.

PREOPERATIVE CONSIDERATIONS

An accurate preoperative diagnosis along with determination of the extent and severity of disease is important when choosing the surgical procedure. Attempt to identify and control any systemic skin condition before surgery. Changes in the ear canal that usually represent *irreversible* disease include neoplasia, thickening and calcification of cartilage, and firm hyperplastic or proliferative epithelium. Determine if middle ear disease is present concurrently since exploration and drainage of the middle ear is recommended in addition to surgical treatment of the external ear disease (see Chapter 62).

The ear canal is difficult to prepare aseptically, and contamination is inevitable during surgery; so antibiotics should be given during the procedure. Administer a broad-spectrum, bactericidal, intravenous (IV) antibiotic (optimally based on preoperative culture and susceptibility) before and during surgery so that adequate levels are maintained in tissues during dissection.

Ear Palpation

Carefully palpate the ear canal and surrounding structures and determine the degree of pain elicited and if there is evidence of end-stage disease.

- Sharp pain elicited on deep palpation of the external ear canal usually indicates concurrent middle ear infection.
- Palpation of severely thickened and firm ear canal tissue indicates that irreversible changes have occurred.

Dermatologic Examination

Most chronic bilateral ear conditions in dogs are manifestations of a generalized skin condition. Failure to identify and control the primary skin condition may cause failure of the surgical procedure since the disease will likely progress in any remaining ear tissue after surgery.

- Perform a complete dermatologic examination and obtain appropriate tests to determine whether primary systemic skin disease (e.g., hypothyroidism, atopy) is present.

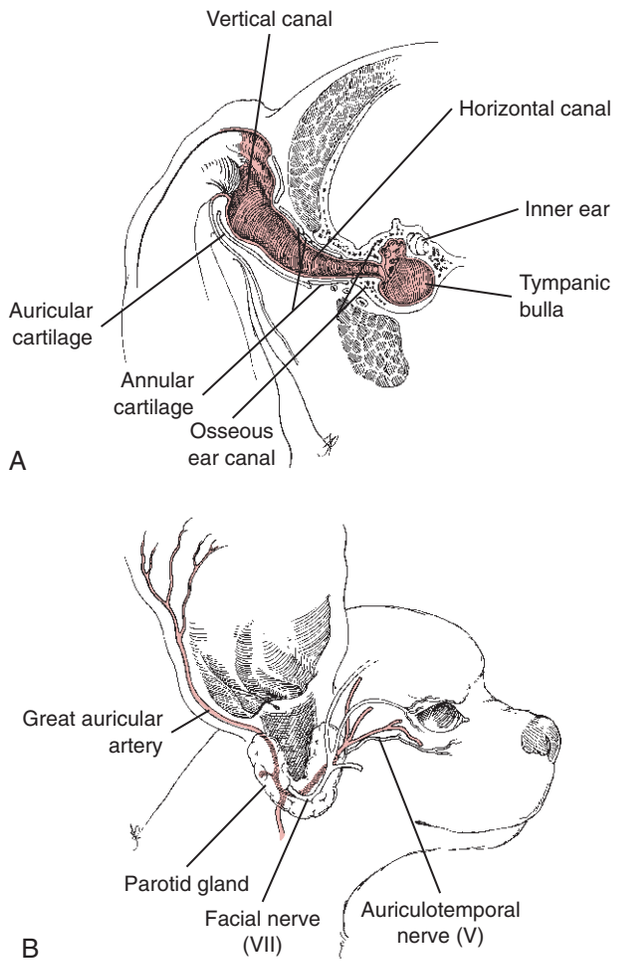

Figure 60-2. Important anatomic structures of the external ear canal. *A*, Transverse section of the head showing ear canal regions and middle ear and inner ear structures. *B*, Location of branches of the external carotid artery in relation to the ear canal and middle ear, and important neural structures in the external ear canal region.

Neurologic Examination

- Perform a neurologic examination, especially in chronic cases of otitis externa, to evaluate for facial nerve involvement (e.g., hemifacial spasm and slow or absent palpebral reflex) and involvement of inner ear structures (e.g., nystagmus and circling).
- Evaluate the patient's ability to hear and alert the owner to any problems before contemplating bilateral ear canal ablation.

Radiographic Examination

Perform any imaging tests before otoscopic examination because irrigation fluid entering the bulla through a damaged tympanic membrane could be misinterpreted as middle ear disease.

- Ventrodorsal skull radiograph is the view of choice to evaluate horizontal canal diameter and to help determine whether the walls of the canal have undergone irreversible calcification.

▼ ***Key Point*** Evaluate for middle ear involvement (Chapter 61) before deciding on the surgical procedure.

- Open-mouth radiography of the bulla is the view of choice to evaluate for middle ear involvement (see Chapter 4).

▼ ***Key Point*** Lack of osseous changes on bulla radiographs does not rule out otitis media.

- Bulla osteitis takes months to form after deep-seated infection. Changes are often very subtle, and evaluation of fluid density within the bulla on plain radiographs also is not an accurate method of diagnosis.
- Computed tomography (CAT scan) is a more sensitive imaging modality to detect subtle changes in the tympanic bulla and cavity.

Otoscopic Examination

- Perform a thorough ear cleansing after obtaining the appropriate diagnostic specimens for culture and susceptibility, cytology, and biopsy (see Chapter 59).
- Otoscopic examination is the most important diagnostic modality to evaluate the severity and extent of disease and tympanic membrane rupture.

▼ ***Key Point*** Otoscopic examination usually requires general anesthesia to completely assess the entire ear canal and tympanum.

Staging of Neoplastic Disease

- Perform regional lymph node aspiration, cytology, biopsy, and thoracic radiography if neoplasia is suspected in the underlying ear disease.

LATERAL EAR CANAL RESECTION—ZEPPS MODIFICATION (LECR)

Surgical Procedure

Objectives

- To expose the medial portion of the vertical canal and horizontal ear canal. Exposure enhances medical treatment of otitis externa and changes local ear conditions favoring drainage. Ventilation of the area improves the local environment by decreasing moisture, humidity, and temperature in the ear canal.
- To resect the lateral portion of the vertical ear canal to remove tumors or to relieve congenital or acquired non-proliferative vertical canal stenosis that is restricting ear drainage and interfering with medical treatment.

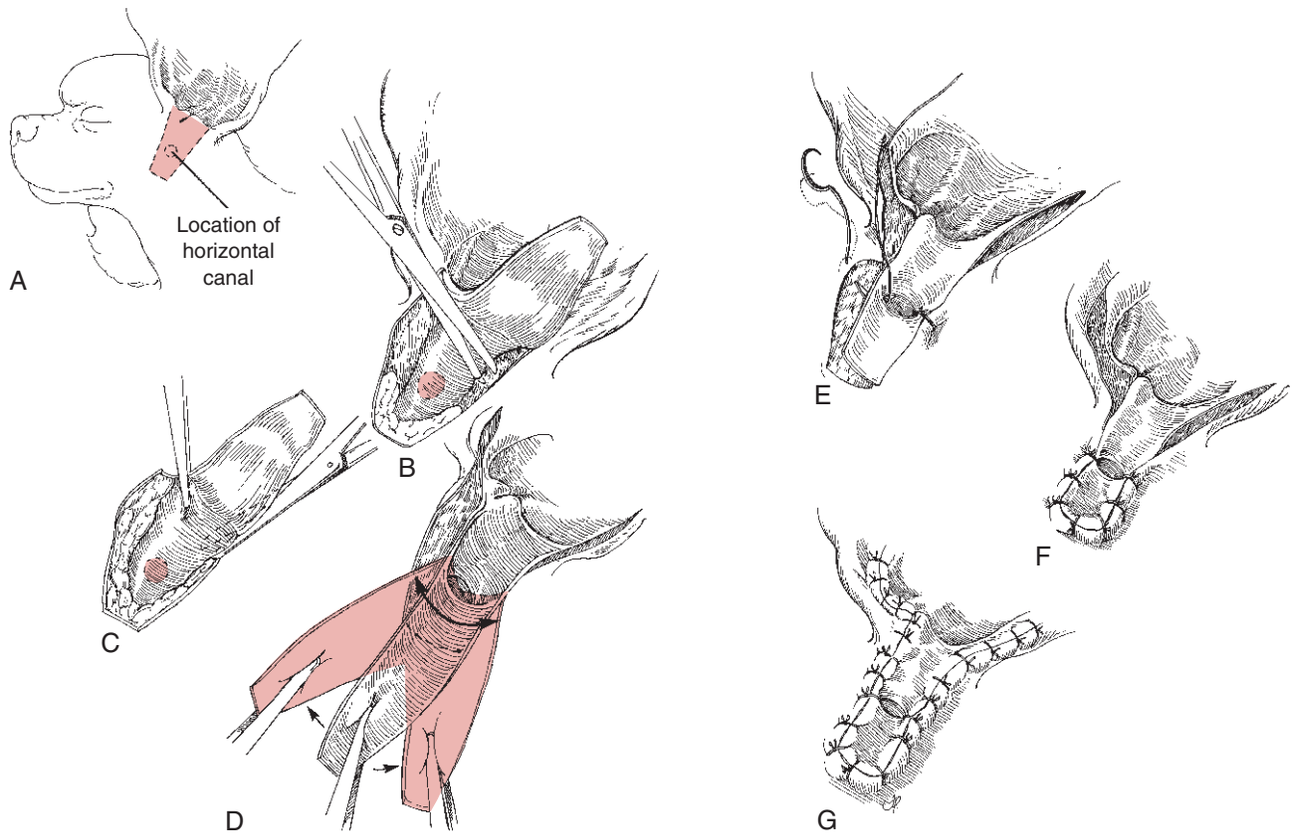

Figure 60-3. Lateral ear canal resection technique. *A,* Two skin incisions are extended parallel to each other from the intertragic notch and tragohelicine notch, tapering down to a distance of 1.5 to 2 cm between the incisions, about 1.5 to 2.5 cm (depending on the size of the animal) ventral to the horizontal ear canal. A transverse incision joins the two vertical incisions. Undermine the skin flap dorsally up to the margin of the aditus. *B,* Incise through the subcutaneous tissue to the level of the vertical ear cartilage. Expose the entire lateral aspect of the vertical ear canal by blunt and sharp dissection of the subcutaneous tissue in a rostral and caudal direction and parotid gland ventrally. *C,* Place an Allis tissue forceps on the tragus, and apply dorsal traction so that the vertical ear canal can be seen from the dorsal aspect of the head. With serrated scissors, make two incisions through the vertical ear canal on the rostrolateral and caudolateral margins while maintaining dorsal traction. Extend the rostral and caudal incisions ventrally in an alternating fashion until the floor of the horizontal canal is reached. The vertical canal essentially is divided into lateral and medial halves. *D,* Extend incisions medially toward the head until the horizontal canal is fully exposed after the lateral wall is reflected ventrally. The base of the lateral wall flap should approximate the width of the horizontal canal. More cartilage can be removed from the remaining ear canal as necessary to fully expose the remaining vertical canal. Manipulate the flap rostrally and caudally until the horizontal canal is held open as wide as possible. *E,* Remove the skin flap and all but the proximal portion of the lateral wall. The 1.5- to 2-cm cartilage (drain board) flap remaining is modified to lie flat and fit the skin defect ventral to the horizontal ear canal. *F,* Begin closure by placing simple interrupted 3-0 to 4-0 monofilament nonabsorbable sutures from the caudal and rostral margins of the most proximal aspect of the drain board to the skin. Throughout closure, place sutures through ear canal epithelium and cartilage first and then to skin to aid in skin coverage of cartilage. *G,* Appose the remaining portion of the flap to the skin with simple interrupted sutures so that the flap is flat against the head. Place additional sutures so that the skin and ear canal epithelium edges are apposed but not crushed.

▼ ***Key Point*** Do not perform LECR if the horizontal or vertical ear canal is hyperplastic and lined with proliferative tissue. In one study, LECR failed in 85% of Cocker spaniels, most likely due to their propensity to develop early hyperplastic disease. Likewise, LECR is contraindicated if medically uncontrolled primary skin disease (e.g., seborrhea) is present because progressive ear disease would be expected in the remaining section of the ear canal.

▼ ***Key Point*** Assess whether there is evidence of concurrent otitis media in the patient; if so, surgical drainage of the middle ear is recommended along with LECR. Left untreated, clinical signs of otitis externa will persist due to persistent otic discharge originating from the middle ear.

Equipment

- Standard general surgical pack and suture
- Heavy serrated straight Mayo scissors

Technique (Fig. 60-3)

1. Place the animal in lateral recumbency with the head positioned, aseptically prepared, and draped so that

the ear region, including the pinna, is exposed and all anatomic relationships are identifiable.
2. Use forceps to determine vertical canal depth and position of the horizontal canal.
3. Incise the lateral portion of the vertical ear canal and reflect ventrally.
4. Preserve the proximal portion of the lateral canal flap for a "drain board."
5. Begin closure at the base of the flap; then appose the distal flap to the skin. Appose the remaining ear epithelium and skin so that no cartilage is exposed.

Postoperative Care and Complications

- Administer appropriate analgesics after surgery (see Chapter 6).
- Continue systemic antibiotics until the incisions are healed and the ear discharge has stopped.
- Continue appropriate topical medical treatment and ear cleansing (see Chapter 59) until no signs of ear infection are present.
- Place an Elizabethan collar to prevent self-inflicted trauma to the wound until suture removal.
- Bandages are rarely necessary unless violent head shaking is noticed in the early postoperative period.
- If wound dehiscence occurs, let it heal by secondary intention closure.
- Remove sutures in 14 days.
- Continue treatment of primary skin disorders as required.

Prognosis

- Prognosis for control of ear disease is good provided that
  - Surgery is performed correctly and for the right indication.
  - No middle ear disease is present.
  - Postoperative medical management of otitis externa is appropriate.
- Up to 35% of LECRs fail because the aforementioned considerations are not met.

VERTICAL EAR CANAL ABLATION (VECA)

This technique combines some of the advantages of the LECR (maintenance of horizontal canal drainage) and total ear canal ablation (removal of chronically infected vertical canal tissue). VECA is a less complicated procedure than total ear canal ablation (TECA); however, surgical treatment of concurrent chronic middle ear disease must be made through a separate ventral bulla approach (see Chapter 62).

▼ ***Key Point*** VECA is contraindicated if irreversible hyperplastic thickening or neoplasia is present in the horizontal canal.

If chronic hyperplastic tissue is present in the vertical canal, it usually extends into the horizontal canal. Therefore this procedure is not commonly indicated, but VECA may be an alternative method for those patients requiring LECR. As with LECR, hearing is preserved, but more diseased ear canal tissue is removed, reducing the need for extensive ear cleaning except at the opening of the horizontal ear canal. Some clinicians believe that VECA may be performed in dogs with end-stage inflammatory ear disease. Owners need to be aware that clinical signs may improve, but continued ear cleaning and antimicrobial therapy may be necessary long after surgery.

Surgical Procedure

Objectives

- To remove the vertical ear canal and preserve the horizontal canal.
- To provide drainage for the horizontal canal.

Equipment

- Same as that for LECR.

Technique (Fig. 60-4)

1. Patient positioning, skin preparation, and vertical ear canal exposure are the same as those described for LECR.
2. Isolate the entire vertical ear canal and resect lateral to the annular cartilage.
3. Incise the remaining section of the ear canal to create a dorsal and ventral flap.
4. Appose the skin to ear epithelium without tension.
5. The closure forms a T shape.

Postoperative Care and Complications

- Similar to those of lateral ear canal resection.
- This procedure affects ear carriage; LECR rarely does.

Prognosis

Prognosis is good provided the procedure is performed for the correct indications. In a large retrospective study of 75 dogs undergoing VECA, 72 were asymptomatic within 12 weeks postoperatively.

TOTAL EAR CANAL ABLATION (TECA)

Total ear canal ablation is a salvage procedure that involves removal of the entire vertical and horizontal ear canal cartilage and epithelium. If severe horizontal canal disease is present, only TECA is successful in eliminating the associated clinical signs.

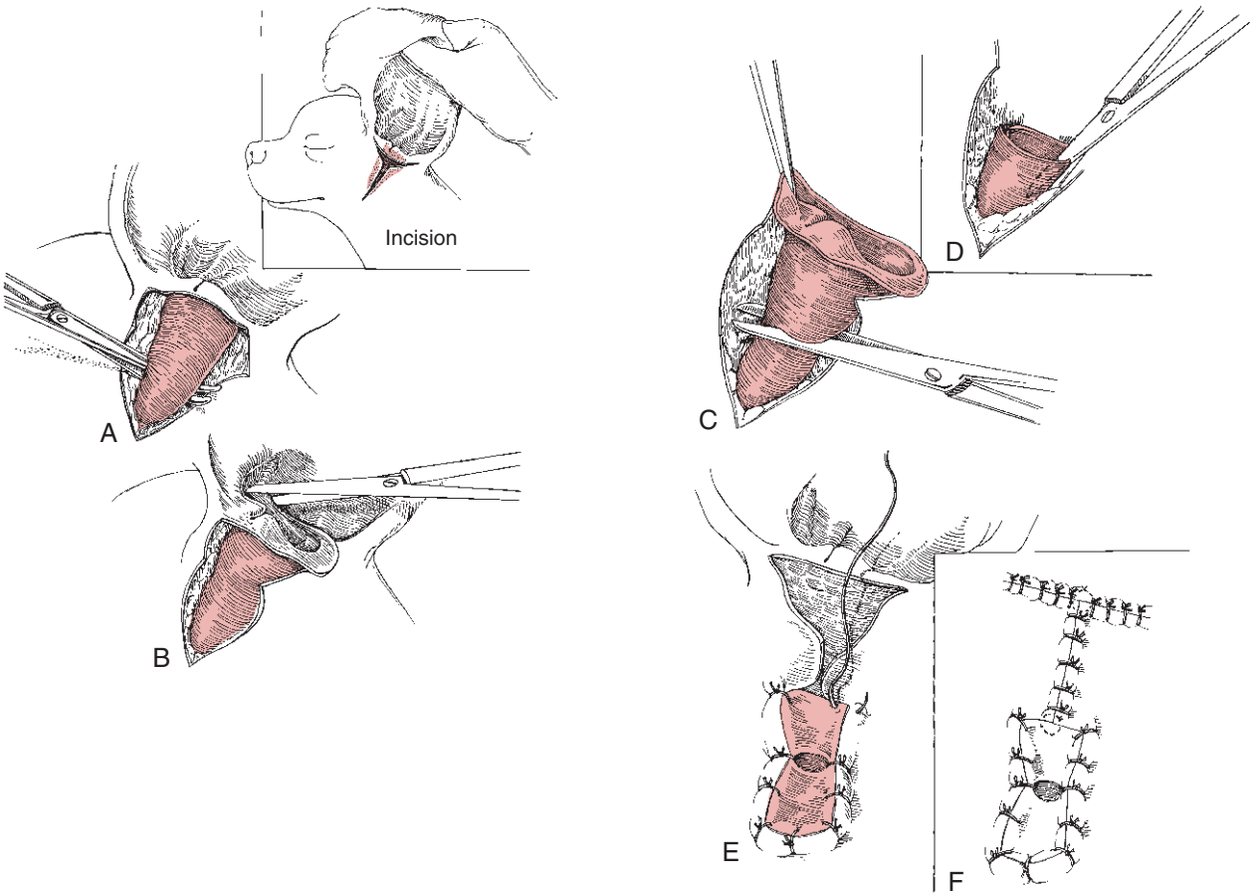

Figure 60-4. Vertical ear canal ablation technique. Begin with T-shaped skin incision over the ear canal. *A,* Continue blunt dissection medially until the entire vertical canal is isolated and freed up. Dissect just underneath the cartilage to avoid damaging vascular supply to the pinna. *B,* Cut the auricular cartilage with heavy straight Mayo scissors, removing all affected tissue on the dorsal aspect of the medial vertical canal and pinna. This step allows complete mobilization of the vertical canal, which remains attached only at its proximal aspect. *C,* Remove the vertical canal approximately 1 to 2 cm distal to the annular cartilage junction. *D,* Incise remaining vertical canal rostrally and caudally, if necessary, to fully expose the horizontal ear canal. *E,* Suture the ventral flap to the skin in a fashion similar to that in lateral ear resection. *F,* Suture the dorsal flap to appose the cut edges of the canal and skin with simple interrupted 3-0 to 4-0 monofilament nonabsorbable material. Remaining skin is apposed to form a T-shaped closure.

▼ ***Key Point*** Neglected chronic otitis externa results in extensive chronic inflammatory changes in periannular tissue. These greatly increase the risk of iatrogenic complications associated with difficult ear canal dissection.

Preoperative Considerations

TECA is most often performed in dogs to treat end-stage otitis externa or global ear disease unresponsive to medical therapy. In cats, about half are performed to treat neoplastic disease such as ceruminous gland adenocarcinoma.

- Severe ear trauma that cannot be managed adequately with reconstruction.
- Congenital or acquired deformity affecting the horizontal ear canal.
- Irreversible hyperplastic and proliferative ear disease or neoplasia extending into the horizontal canal.
- Persistent otitis externa after LECR or VECA. If signs stem from middle ear infection, drainage of the middle ear is all that may be required, provided the horizontal ear canal is not affected irreversibly.

▼ ***Key Point*** TECA alone is contraindicated when middle ear infection is present because it eliminates a major drainage exit for the tympanic cavity. The auditory tube cannot be relied on to drain thickened exudates within the middle ear. In these common instances, TECA can be performed successfully if a means of tympanic bulla drainage also is provided.

- TECA is an aggressive surgical procedure, and appropriate analgesia must be provided. Application of a

fentanyl patch (Duragesic, Janssen, Titusville, New Jersey) 12 hours before the procedure ensures that serum levels of the analgesic will be at therapeutic levels *before* the procedure. Local nerve blocks or constant local anesthetic infusion devices can be used successfully through the early postoperative period. Supplemental systemic narcotics are also commonly used to treat breakthrough pain postoperatively (see Chapter 6).

Surgical Procedure

Objectives

- To remove the entire external ear canal without trauma to the facial nerve.
- To provide access to the tympanic bulla to observe and treat infection or other disease.

Equipment

- Standard general surgical pack and suture
- Gelpi or Weitlaner self-retaining retractors
- Senn retractors
- Heavy serrated Mayo scissors
- Suction apparatus and Frazier suction tip
- Electrocoagulation unit and sterile electrode
- Lempert and Cleveland bone rongeurs
- Straight Simon and Daubenspeck curettes
- $\frac{1}{4}$-inch Penrose drains (surgeon preference)

Technique (Fig. 60-5)

1. Use the same positioning, skin preparation, and draping as for LECR.
2. Lavage the ear canal repeatedly with iodinated antiseptic solution to remove as much debris and contamination as possible.
3. Administer appropriate prophylactic IV antibiotics (preferably based on culture and susceptibility results) and maintain appropriate blood levels during the surgery. Fluoroquinolone and ampicillin + sulbactam (Unisyn) are appropriate antibiotics if no culture is available. Continue antibiotic administration until intraoperative culture results are available; revise the regimen if necessary.
4. Make a T-shaped skin incision to expose the ear canal.
5. Reflect loose connective tissue from the vertical ear canal.
6. Isolate the vertical and horizontal canal by blunt and sharp dissection. Maintain dissection immediately adjacent to the ear canal cartilage. Occasionally, the facial nerve is found embedded in the annular cartilage.
7. Careful dissection along the caudal aspect of the proximal horizontal ear canal isolates the origin of the nerve.
8. Carefully dissect the nerve out along its course adjacent to the horizontal canal.
9. In some patients with chronic proliferative otitis externa, a greenish-brown epithelial pouch forms between the tympanic bulla and the annular cartilage. This epithelium extends lateral and ventral to the tympanic bulla. Removal of this tissue is critical to the success of the surgery because chronic fistulation occurs if it is not removed fully. Use hemostatic forceps to grasp the edges of the pouch and, with traction, bluntly dissect the pouch out without injuring major local vessels and nerves.
10. Sharply amputate the annular cartilage from the petrous temporal bone, excise the ear canal, and submit it for biopsy.
11. Carefully remove the secretory epithelial lining of the short osseous external auditory canal by curettage. Submit this lining for culture and susceptibility.
12. Examine the middle ear for exudates and chronic thickened epithelium.
13. Routinely remove the ventral and lateral aspect of the bulla with rongeurs (see Chapter 62).
14. Remove all epithelium and debris in the tympanic cavity with irrigation and curettage.
15. Avoid inner ear structures on the craniodorsal aspect of the tympanic cavity during curettage.
16. If massive contamination has occurred during surgery, or signs of periauricular inflammation are present after the ear canal is removed, place a Penrose drain within the dead space remaining where the ear canal was removed, exiting ventral to the T-shaped incision. Place a percutaneous suture through the dorsal end of the Penrose tube to prevent premature dislodgement.
17. Place subcutaneous and skin sutures to form a T-shaped wound.

Postoperative Care

- Examine the wound for evidence of fluid accumulation or ensuing infection.
- If a Penrose drain is used, rebandage daily until drainage ceases.
- Place an Elizabethan collar to prevent self-inflicted trauma to the wound until suture removal.
- If acute postoperative infection occurs, open the wound for drainage. Flush and bandage the open wound daily.
- Administer systemic antibiotics based on susceptibility testing for a minimum of 3 to 4 weeks, if otitis media is present (see Chapter 61).
- If facial nerve injury has occurred, place eye lubricants (e.g., Hypotears, Cibavision) in the affected eye q6h, especially if the dog has decreased tear production or has an exophthalmic conformation.
- Remove skin sutures in 14 days.
- Remove Penrose tubes when drainage has decreased significantly. Generally, this is in 2 to 3 days.

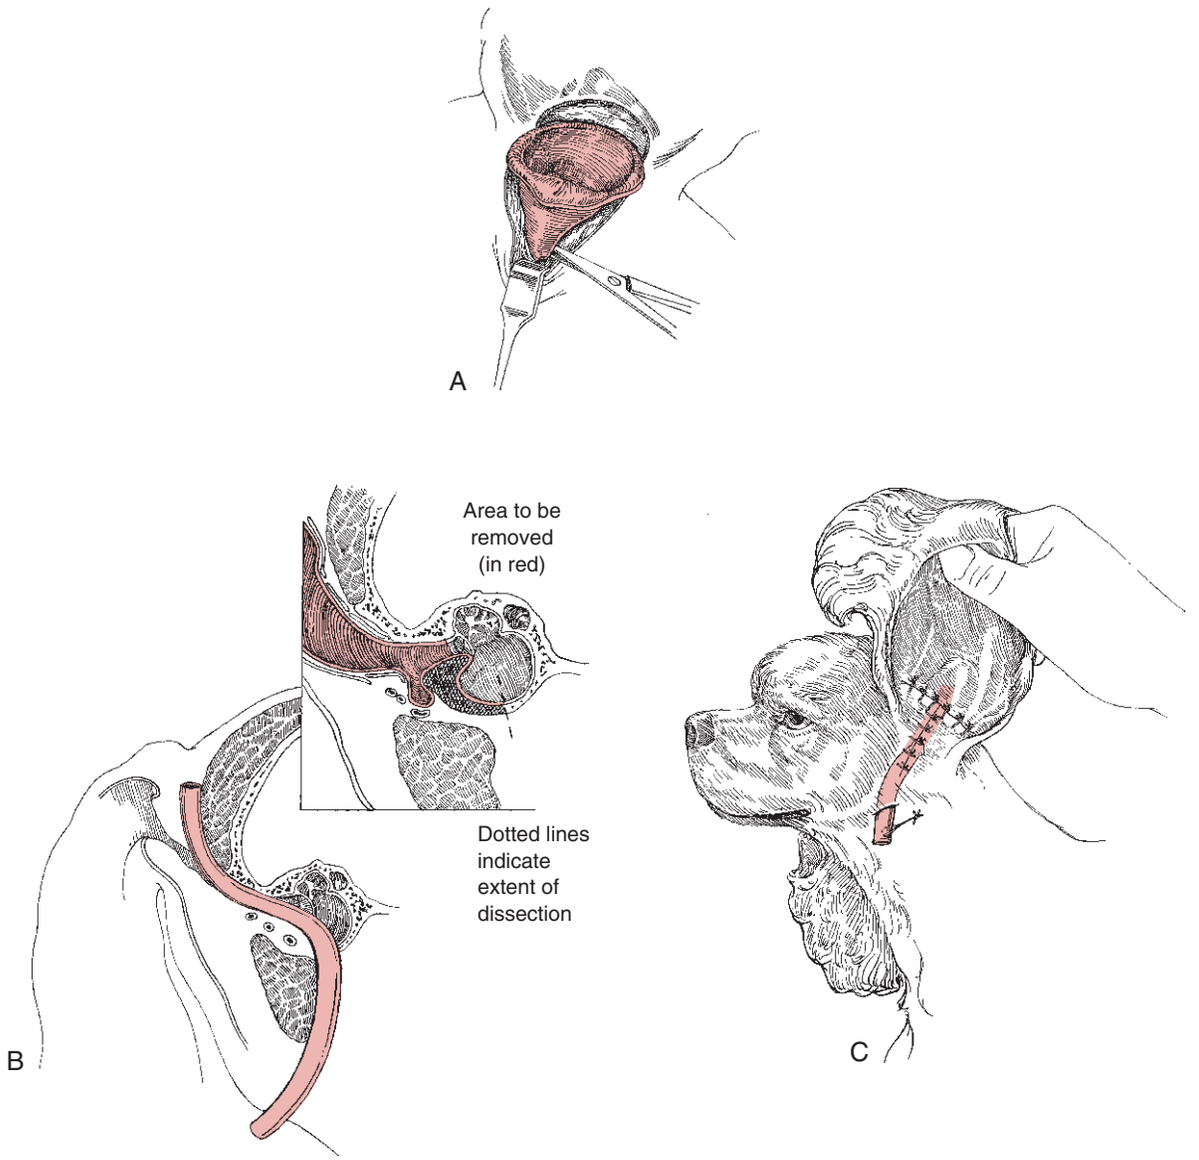

Figure 60-5. Total ear canal ablation technique. Make a horizontal incision parallel and just below the upper edge of the tragus between the tragohelicine and intertragic notches (also see Fig. 60-4*B* inset). Make a vertical incision perpendicular from the midpoint of the horizontal incision to a point just ventral to the horizontal canal, forming a T-shaped incision. The two triangular skin flaps are undermined and retracted, exposing the lateral aspect of the ear canal. After hemostasis is achieved, bluntly dissect the proximal aspect of the vertical canal free from the surrounding tissues, avoiding the auricular vessels located medial to the canal *(A)*. Use heavy serrated Mayo scissors to cut the medial aspect of the proximal vertical ear canal connecting the ends of the original horizontal incision. Retention of as much of the normal medial vertical canal as possible encourages ear support in cats and dogs with erect ears (see Fig. 60-4*B*). The parotid gland is retracted ventrally. By a combination of blunt and sharp dissection, isolate the horizontal canal to the level of the tympanic bulla. While maintaining meticulous hemostasis, dissection continues as close to the cartilage as possible, carefully exposing and retracting the facial nerve away from the line of dissection. Excise the ear canal and remove epithelium from osseous ear canal. *B,* Transverse section of head shows common location of epithelial pouch between annular cartilage and petrous temporal bone. All epithelium must be removed to avoid chronic fistulation after surgery. If otitis media is present, an aggressive lateral bulla osteotomy is performed to expose the bulla for curettage and to improve ventral drainage. Crosshatching indicates area of resection of the lateral and ventral osseous bulla. Be sure all exudate and abnormal tissue are moved from the tympanic cavity. A Penrose drain is shown exiting ventral to the skin incision. *C,* Completed ear ablation showing placement of drain and skin closure.

- Patients with established severe otitis media may require extensive postoperative wound management.
- If the surgical wound is left open, irrigate it once or twice daily with 25 ml of lukewarm (1:100) diluted povidone-iodine (Betadine) solution and saline (or TRIS-EDTA if *Pseudomonas* sp. is isolated) for 5 to 10 days.
- Administer nonsteroidal anti-inflammatory drugs for 5 to 7 days after surgery to reduce post-surgical pain and inflammation (see Chapter 6).

Complications

▼ ***Key Point*** Owner education is critical before attempting TECA because the following serious and long-standing complications are possible:

- Acute pharyngeal edema and upper airway obstruction.
- Acute postoperative wound infection (up to 40% of patients).
- Facial nerve damage (usually temporary; but permanent paralysis occurs in <10% of patients).
- Transient hypoglossal nerve dysfunction (rare and usually temporary).
- Chronic fistulation from unresolved middle ear infection or retained ear canal epithelium may occur up to 1 to 2 years after surgery (<10% of patients). Perform middle ear exploration and complete removal of epithelial remnants, and administer systemic antibiotic therapy for 4 to 6 weeks.
- If inner ear signs are present before surgery, their exacerbation is common after surgery. Neurologic signs usually improve over time if otitis media is controlled, but minor signs usually persist indefinitely.
- Horner's syndrome (rare and usually temporary) if middle ear surgery also is performed, especially in cats.
- Pinna necrosis from damage to the vasculature during dissection is rarely seen. It usually occurs at the proximal aspect of the caudal pinna margin. Debride the necrotic area and let it heal by secondary intention closure.
- Dogs undergoing bilateral TECA generally hear about as well as they did before surgery.
- Like VECA, this procedure affects ear carriage.

Prognosis

Long-term follow-up for dogs undergoing TECA shows improvement in clinical signs in up to 90% of patients and shows the same or worse in 10%. Poor results usually are caused by persistent infection from unresolved middle ear infection or retained infected epithelial tissue. A total of 25 of 26 owners of dogs undergoing TECA with long-term follow-up indicated satisfaction with the procedure and improvement in their dogs' demeanor.

AURICULAR HEMATOMA

Auricular or aural hematoma is an accumulation of blood within the cartilage of the pinna, usually caused by violent head shaking or scratching. The blood collection usually is confined to the concave surface of the pinna. This injury is seen most often in pendulous-eared dogs but occasionally is seen in erect-eared dogs and, less frequently, in cats.

▼ ***Key Point*** Auricular hematomas occur secondary to inflammatory conditions of the pinna or external ear canal, such as foreign bodies, atopy, food allergy, bacterial infection, yeast infection, and ear mites. Identify the underlying cause of the irritation, if possible, to avoid further injury and recurrence. Recent findings do not support an autoimmune pathogenesis but suggest that an early immunologic event may cause early cartilage erosion. Weakened cartilage is more readily damaged, leading to hematoma formation from minor trauma.

Anatomy

The major blood supply to the pinna is derived from branches of the external carotid artery and internal maxillary vein. The great auricular arteries and veins arborize and course longitudinally along the long axis on the convex side of the pinna. Mattress pattern sutures placed through the ear are oriented parallel to these vessels to avoid interrupting the blood supply to the pinna.

Preoperative Considerations

- The first objective for management of auricular hematoma is to identify the source of the ear irritation.
- Perform a thorough otoscopic examination to identify abnormalities within the ear canal.
- Obtain a complete history and perform a dermatologic examination, particularly when no obvious cause of the irritation is uncovered during otoscopic examination.
- Rule out the diagnosis of atopy or other systemic manifestation of skin disease.

▼ ***Key Point*** Drain auricular hematomas as soon as possible because delay often leads to enlargement and extension throughout the pinna. With time, fibrous organization of the hematomas eventually leads to a permanently thickened, cauliflower-like ear.

- If the cosmetic appearance of the pinna is of secondary importance to the owner, the incision and drainage technique is the most consistently successful. I prefer this technique for more chronic

hematomas because it allows for thorough debridement of organized clots.
- A more cosmetic and less time-consuming technique is the drainage-only procedure. Use this technique only in hematomas with fluid consistency (acute cases) and, preferably, those located toward the distal aspect of the pinna. Owners must understand that recurrence develops more often with drainage only compared with incision and suture.
- Simple aspiration alone is not the best option because of a high rate of hematoma recurrence.
- A CO_2 laser has been used successfully to create multiple small incisions into the hematoma for drainage and to allow for evacuation of blood, similar to the punch technique.

Surgical Procedure

Objectives

- To treat the source of irritation.
- To drain the hematoma.
- To maintain apposition of cartilage surfaces for an adequate time to prevent recurrence.

Equipment

- Standard general instrument pack
- Penrose drain, $^1/_4$ inch (if drain-only technique is planned)
- Skin biopsy punch (3.5 or 5 mm) for alternative punch technique

Technique

Incision, Drainage, and Bandage

1. Clip both sides of the pinna and prepare the ear for aseptic surgery. Place sterile 4 × 4 sponges in the ear canal to soak up blood from the hematoma.
2. Incise the hematoma with a #10 blade in a linear fashion on the concave side no closer than 1 cm from the margin of the pinna.
3. Make this incision along the long axis of the pinna extending the length of the hematoma. Removal of a strip of skin to widen the incision and permit drainage is not usually necessary.
4. Explore the hematoma and remove any fibrin tags or blood clots.
5. Place 1-cm–wide mattress sutures (3-0 or 4-0 monofilament nonabsorbable material) parallel to and no closer than 0.5 cm from the incision.
6. Hold the incised edges of the skin 2 to 3 mm apart when placing the first row of sutures. Sutures need not penetrate both skin surfaces because this creates another source of irritation and entry way for contamination.
7. Pass the needle carefully from the concave surface of the pinna, catching both cartilage planes.
8. Place the remaining mattress sutures in a staggered fashion 1 cm apart until the entire dead space area is obliterated.
9. Tie sutures with just enough tension to appose cartilage surfaces. Do not crush skin.

Alternative Technique Using Biopsy Punch and Suture (Fig. 60-6)

1. For acute hematomas, this technique creates a cosmetic result with minimal recurrence problems.
2. Prepare pinna for surgery as described for incision and drainage technique.
3. Punch staggered holes over hematoma on concave pinna surface. Avoid creating holes any closer than 1 cm from the ear margin.
4. Tack skin adjacent to punch holes to underlying cartilage.
5. Bandaging after the first postoperative day usually is not necessary.

Drainage Only

1. Aseptically prepare the skin on the concave surface of the pinna only. It is not necessary to clip the convex, haired surface (unless the patient is long-haired) because this creates more inflammation, which could lead to continual head shaking or scratching. Place 4 × 4 sponges in the ear canal to soak up blood from the hematoma.
2. Make a small (0.5–1-cm) incision extending into the hematoma at its most proximal and distal extent on the pinna.
3. Remove all fluid and fibrin tags with mosquito hemostats and digital expression.
4. Place a drain ($^1/_4$-inch Penrose or sterilized IV extension tubing) through the dead space and exiting both stab wounds.
5. Suture the drain to the skin near the stab incisions with a loose nonabsorbable suture.

Postoperative Care and Complications

- After treatment of the hematoma by the incision method, bandage the affected ear over the top of the head in pendulous-eared dogs. Bandage erect ears in an upright position.
- Leave the ear canal exposed in each method to permit cleansing and medication as needed.
- Leave the bandages on for at least 10 days and change as needed.
- Remove sutures in 3 weeks (incision or punch method).
- If aspiration of the hematoma is elected, remove reaccumulating fluid daily with a 20-gauge needle, and a tapering anti-inflammatory dose of prednisone is given for 7 to 14 days to reduce head shaking from otic irritation.

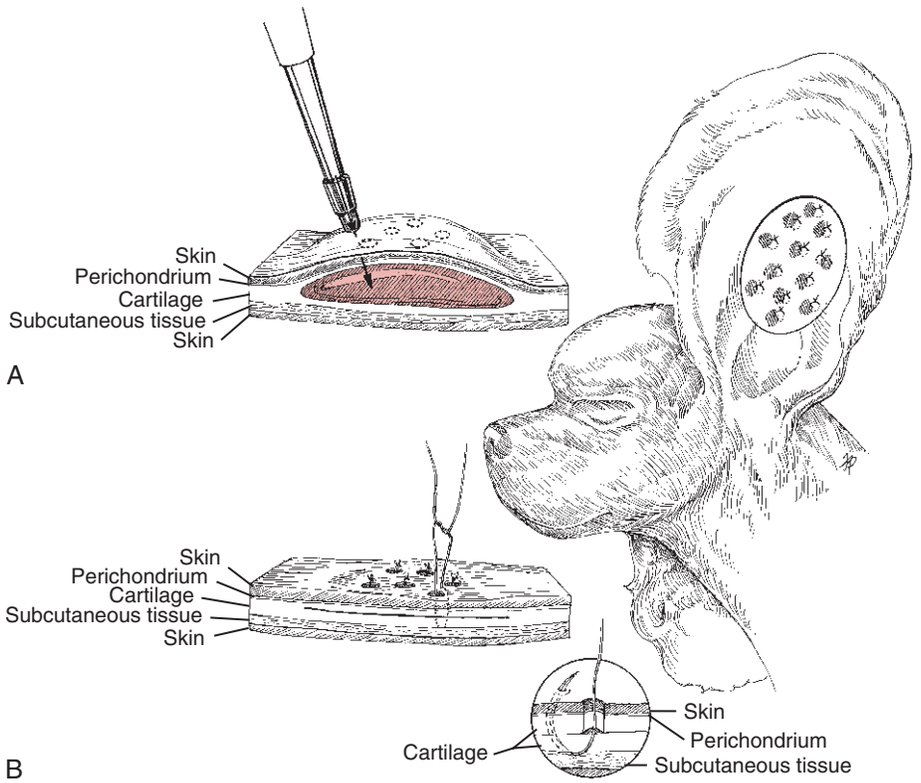

Figure 60-6. Concave surface of the pinna. Shaded area indicates hematoma location. Create staggered (3.5- or 5-mm) punch biopsies approximately 1 to 1.5 cm apart over the hematoma. Use 4-0 filament nonabsorbable sutures to tack through each punch into underlying cartilage to adjacent skin edge for dead space obliteration.

- No bandages are used after the first day for the drainage-only method or punch method unless the patient continues violent or persistent head shaking.
- Use an Elizabethan collar to reduce the incidence of self-trauma in all cases.
- Leave drains in place for 3 weeks.
- Instruct the owners to watch for signs of infection and to milk out any fluid (drain technique only) that may accumulate within the hematoma during this time.
- Instruct the owners about the proper treatment of the primary source of the ear irritation.
- The appearance of the ear after surgery is related to the drainage technique and to the chronicity of the hematoma. Inadequate drainage or continued inflammation results in a permanently thickened pinna.
- Make no guarantees to the owners regarding the final cosmetic appearance of the ear and the impossibility of recurrence, because these are often unpredictable.
- Reevaluate the patient weekly after drainage to determine the response to primary treatment and any problem related to wound management.

Chapter

61 Otitis Media and Otitis Interna

Lynette K. Cole

Otitis media: *Otitis media* is defined as inflammation of the middle ear and is an important perpetuating cause of recurrent otitis externa.

- Otitis media occurs as a direct extension from an existing otitis externa through a ruptured tympanic membrane.

▼ ***Key Point*** The presence of an intact tympanic membrane does not rule out otitis media since the defect in the membrane may have healed.

- In a recent study, 72.5% of the ears in dogs with otitis media diagnosed by a myringotomy had an intact tympanic membrane.
- Less common routes include extension through the eustachian tube or hematogenous dissemination.

Otitis interna: *Otitis interna* is defined as inflammation of the inner ear structures, which include the cochlea, vestibule, and semicircular canal. Otitis interna usually occurs as a direct extension from an existing otitis media.

ETIOLOGY

- *Bacteria:* The most common etiology of otitis media is a bacterial infection. The two most common bacterial isolates are *Staphylococcus intermedius* and *Pseudomonas* spp.
- *Yeast* may be a significant pathogen, and in one study was the sole isolate in 23.7% of the middle ears of dogs with otitis media.
- *Congenital palatine defects* (secondary cleft palate) have been associated with radiographic signs of middle ear disease.
- *Primary secretory otitis media* has been reported in the Cavalier King Charles spaniel. Clinical signs include moderate to severe pain in the head or cervical region; neurologic signs such as ataxia, facial paralysis, nystagmus, head tilt, or seizure; otic pruritus; otitis externa; and fatigue. In most cases in the study, a bulging but intact tympanic membrane was observed. A highly viscous mucous plug was removed with ear forceps or a suction catheter. Removal of the mucous plug and flushing the middle ear had to be repeated up to five times for resolution.
- *Neoplasia* and *polyps* can cause otitis media. Tumors present in both the ear canal and tympanic bulla can be malignant. Inflammatory polyps are common in the cat, whereas they are relatively uncommon in the dog.
- *Otoliths* (mineral opacities) of the middle ear have been reported in three dogs; however, their significance is unknown, since only one dog had clinical signs of vestibular disease.
- *Cholesteatomas* are abnormal growths of the epithelium within the middle ear consisting of keratinizing stratified squamous epithelium, inflammatory cells, and ceruminous debris. These may occur congenitally or secondary to chronic otitis media and require surgical removal.
- Other causes of otitis media include trauma and foreign bodies.
- Otitis media may lead to otitis interna.
- Otitis media is uncommon in cats.

CLINICAL SIGNS

Otitis Media

▼ ***Key Point*** Recurrent otitis externa may be the only clinical sign associated with otitis media.

- Signs of recurrent otitis externa include discharge from the external ear canal, pawing or rubbing of the affected ear, head shaking, and pain.
- Specific clinical signs indicative of otitis media are facial nerve paralysis and Horner's syndrome. Injury to the facial nerve, as it courses near the middle ear, produces clinical signs such as drooping of or inability to move the ear or lip, drooling of saliva, or decreased/absent palpebral reflex. Horner's syndrome is due to injury to the sympathetic nerve fibers, which course near the middle ear, and is characterized by ptosis, miosis, enophthalmus, and protrusion of the nictitating membrane.

- Keratoconjunctivitis sicca (KCS) may occur if the parasympathetic nerves that innervate the tear gland are injured. The parasympathetic nerve fibers course with the facial nerve. Tear production can be evaluated with the Schirmer tear test.

▼ ***Key Point*** Otitis media is uncommon in dogs with acute otitis externa; however, it is quite common in dogs with chronic, recurrent otitis externa, with an incidence of 50% to 88.9%.

Otitis Interna

- Signs of otitis interna are those typically associated with peripheral vestibular syndrome and include a head tilt, circling, falling, or rolling toward the affected side; horizontal or rotary nystagmus with the fast phase away from the affected side; and asymmetric ataxia with strength preserved (Table 61-1).

DIAGNOSIS

History

- Obtain a thorough history in order to establish the age of onset, duration of clinical signs, and the extent of the involvement of the skin (such as pruritus), to be able to identify the primary underlying dermatologic disease. See Chapter 59 for details on the primary underlying diseases causing otitis externa.
- Identify past treatment protocols and response to therapy to help guide decisions for future treatments.

Physical Examination

- Perform a *dermatologic examination* to identify an underlying disease, such as parasitic disease, allergic disease, keratinization disorder, endocrine disease, or autoimmune disease.
- Perform a thorough *physical examination* and include the lymph nodes, oral cavity, and nasopharyngeal region.
- Perform a *neurologic examination* to evaluate for signs of facial nerve paralysis or Horner's syndrome, which would be consistent with otitis media, as well as nystagmus and vestibular disease, which would support otitis interna.

▼ ***Key Point*** Peripheral vestibular signs, which occur in otitis interna, must be differentiated from central vestibular signs, which occur with diseases of the brain stem.

▼ ***Key Point*** The absence of neurologic signs does not rule out the possibility of otitis media and otitis interna.

- Perform an *otoscopic examination* to evaluate the external ear canal and tympanic membrane. The examination is performed with a hand-held otoscope or video otoscope (see under Video Otoscopy, following). Palpate the external ear canals to determine if there is any calcification indicating chronic disease.

▼ ***Key Point*** In cases of chronic otitis externa, an otoscopic examination on initial presentation may not be possible, due to ulcerations, hyperplasia, or stenosis. Two to three weeks of topical and systemic glucocorticoids are often necessary in order to be able to perform an otoscopic examination.

- In addition, an otic examination may not be possible without sedation or general anesthesia, due to pain.
- The normal tympanic membrane is translucent and concave. Suspect otitis media if the tympanic membrane is ruptured, bulging, opaque, or cloudy.

Table 61-1. VESTIBULAR SIGNS ASSOCIATED WITH INNER EAR VS. BRAIN STEM LOCATIONS

Sign	Inner Ear	Brain Stem
Head tilt	Present	Present
Circling	Present	Present
Falling, rolling	Present	Present
Positional strabismus	Present	Present
Nystagmus	Usually spontaneous and type (horizontal, rotary) does not vary with head position	Usually not spontaneous but found with changes in head position; type (horizontal, rotary, vertical) varies with head position
Conscious proprioception	Normal	Delayed or absent
Horner's syndrome	May be present	Usually absent
Gait changes	Mild to severe ataxia	Ataxia and weakness
Postural reactions (e.g., hopping, hemiwalking, wheelbarrowing)	Normal if examined slowly	Weak or absent
Cerebellar signs (hypermetria, head intention tremors)	Absent	May be present

Video Otoscopy

- Perform video otoscopy using an otoendoscope, camera, light source, and monitor.
- The vertical and horizontal ear canal and tympanic membrane are brightly illuminated and magnified, allowing better evaluation of these structures than with the hand-held otoscope.
- While the patient is sedated or anesthetized, utilizing the opening on the otoendoscope, the ears can be flushed; foreign objects, debris, or parasites may be retrieved with the grasping forceps; biopsies can be obtained with biopsy forceps; and myringotomy may be performed with a catheter.
- With an attachable dual-port adapter, suction and saline may be used simultaneously to completely clean the ear. See Deep Otic Flush and Myringotomy later in this chapter for further details.

Cytology and Bacterial Culture and Susceptibility Testing (C/S)

Cytology and C/S are diagnostic tests used to aid in the choice of systemic and topical antimicrobial agents. Cytology is a rapid and inexpensive procedure indicated in all cases of otitis (also see Chapter 59). It is the best method for detection of yeast organisms.

- After collecting the sample, roll the swab onto a glass slide, heat fix, and stain with a modified Wright's stain (Diff-Quik) or gram stain. Under scanning power (100×), locate keratinocytes or inflammatory cells. Once those are found, apply immersion oil to the slide and examine under oil immersion power (1000×). Count and record the number and type of bacteria, yeast, and inflammatory cells.
- Obtain samples for cytology and C/S from the horizontal ear canal prior to a deep otic flush.
- After the deep flush, obtain samples directly from the middle ear cavity if the tympanic membrane is ruptured, or via a myringtomy if the tympanic membrane is abnormal (bulging, discolored, opaque). See below for specifics on the deep otic flush and myringotomy procedure.

Radiography

- Radiography is indicated in suspected cases of otitis media to evaluate the soft tissue structures of the external ear along with the bony structures of the middle ear. Radiography is also used as a prognostic indicator for the success of medical management of otitis media. With significant radiographic changes, such as sclerosis or osteolysis, surgical intervention may be required for resolution. Animals must be anesthetized to allow for proper positioning for the procedure.
- The most commonly utilized radiographic projections of conventional radiography of the bulla include the dorsoventral, right and left lateral obliques, and rostroventral-caudodorsal open mouth.

Computed Tomography Scan

- Computed tomography (CT) allows cross-sectional imaging of the external, middle, and internal parts of the ear. The overall accuracy of CT and conventional radiography for the diagnosis of otitis media are similar; however, CT is a more sensitive indicator of otitis media. CT can be used to better define changes in bony structures, while magnetic resonance imaging (MRI) is superior to CT for detecting soft tissue changes. MRI is also helpful in investigation into the pathology of the inner ear.

▼ ***Key Point*** For conventional radiography and CT, the absence of evidence of otitis media does not rule out the disease.

Positive Contrast Canalography

- Positive contrast canalography evaluates the patency of the tympanic membrane by infusing positive contrast medium (iohexol) into the ear canals of anesthetized dogs. Pre- and post-bullae radiographs are performed.
- This procedure may aid in the identification of tympanic membrane rupture; however, lack of contrast medium in the tympanic bulla does not rule out a ruptured tympanic membrane.

Pneumotoscopy

- The purpose of pneumotoscopy is to assess the mobility of the tympanic membrane (compliance) and to determine the presence or absence of fluid in the middle ear.
- Pneumotoscopy is performed using a hand-held otoscope and a pneumatic bulb. In order to perform this procedure, the animal may need to be sedated or under general anesthesia.

Technique

- Attach the pneumatic bulb to the side of the otoscope.
- Insert the otoscopic cone into the horizontal ear canal and make a seal with the cone and the ear canal.
- Identify the tympanic membrane. Air is gently "puffed" with the bulb while observing for motion of the tympanic membrane.
- A noncompliant tympanic membrane may occur if there is a tear in the membrane or fluid in the middle ear. One must be able to identify the tympanic membrane in order to perform the procedure.
- A noncompliant tympanic membrane is suggestive of otitis media; however, a compliant tympanic membrane does not rule it out.

Ultrasonography

- An ultrasonographic technique has been described to differentiate between gas and fluid in the bulla of dog cadavers. Studies to determine the usefulness of this technique in the clinical situation have not been performed as yet.

Biopsy

- Biopsy any mass found in the vertical ear canal, horizontal ear canal, and middle ear. Submit the biopsy specimens in formalin for histopathologic evaluation.

TREATMENT

▼ ***Key Point*** The goals of treatment are to clean the external and middle ear; remove infected, inflammatory, or foreign debris; and allow drainage of the middle ear.

Deep Otic Flush and Myringotomy

Deep Otic Flush

- Perform under general anesthesia.
- Soak the ear canal for 10 minutes with a ceruminolytic ear cleaner, then flush using warm saline: first with a bulb syringe, then using an 8-French polypropylene urinary catheter attached to a 12-ml syringe passed through an otoscopic cone.
- Other flushing options include a red rubber feeding tube, water-propulsion dental device, or the Auriflush system (Shering-Plough Animal Health).
- Once the exudate and debris are removed from the ear canal, evaluate the tympanic membrane with an otoscope or video otoscope.
- If the tympanic membrane is not intact, perform cytology and bacterial C/S from the middle ear cavity using the hand-held otoscope or the video otoscope. Using a hand-held otoscope, insert a sterile otoscopic cone into the horizontal ear canal and a pass sterile swab (Calgiswab, Hardwood Products Company LLC) into the middle ear cavity. Use the first swab for C/S. Pass a second swab into the middle ear cavity for cytologic analysis.
- If the video otoscope is used, place an open-end $3^1/_2$-Fr tomcat catheter attached to a 12-ml syringe through the port of the otoendoscope. Flush 1 ml of warm sterile saline into the middle ear cavity and aspirate back for culture.

▼ ***Key Point*** Some ceruminolytic agents may be ototoxic. If the tympanic membrane is not intact, remove the ear cleaner by repeatedly flushing the middle ear with warm saline after collection of samples.

Myringotomy

- If the tympanic membrane is intact, appears abnormal, and otitis media is suspected, perform a myringotomy to obtain samples for cytology and bacterial C/S and to flush the middle ear cavity.
- Using a hand-held otoscope, insert a sterile otoscopic cone into the horizontal ear canal, and identify the tympanic membrane. Use a sterile Calgiswab to make an incision into the caudoventral quadrant of the tympanic membrane. Submit the swab used for the myringotomy incision for bacterial C/S. Insert a second swab into the original incision and submit the sample obtained for cytologic analysis.
- If the video otoscope is used to perform the myringotomy, place an open-end, sterile $3^1/_2$-Fr tomcat catheter through the port of the otoendoscope. Use the tomcat catheter to make the incision, and flush 1 ml of warm sterile saline into the middle ear cavity for culture.
- A spinal needle may also be used to make the myringotomy incision.
- After the myringotomy procedure, flush the middle ear with warm sterile saline until all of the exudate is removed from the middle ear.
- The normal tympanum has been shown experimentally to heal in 21 to 35 days.

▼ ***Key Point*** Possible complications of a deep otic flush and myringotomy are Horner's syndrome, facial nerve paralysis, vestibular disturbances, and deafness. Although the occurrence of these complications is uncommon to rare when the procedures are performed with care, owners should understand these complications and sign a consent form prior to the procedure. These complications occur more commonly in the cat than in the dog.

Systemic and Topical Antimicrobial/Antifungal Agents

Systemic

- Once the ear has been cleaned and flushed, begin systemic and topical antimicrobial/antifungal treatment based on cytologic results from the external and middle ear.
- The most common coccoid bacteria isolated from the middle ear of dogs with otitis media is *S. intermedius;* appropriate antibiotic choices include cephalexin, 22 mg/kg PO q12h (generics), and amoxicillin and clavulanate, 13.75 to 22 mg/kg PO q12h (Clavamox, Pfizer Animal Health).
- The most common rod bacteria is *Pseudomonas aeruginosa.* A fluoroquinolone such as enrofloxacin, 5 to 20 mg/kg PO q24h (canine only) (Baytril, Bayer

Animal Health), or marbofloxacin, 2.75 to 5.5 mg/kg q24h PO (Zeniquin, Pfizer Animal Health), would be appropriate. Once the C/S results are known, modification of the treatments may be needed.
- Certain systemic antibiotics (primarily aminoglycosides) are ototoxic and should be used cautiously.
- Use ketoconazole (generics; Nizoral, Janssen) or itraconazole (Sporanox, Janssen) at 5 mg/kg PO q24h for yeast otitis media.
- Administer antibiotics and/or antifungal agents until the infection resolves, clinically, cytologically, and on bacterial C/S, and then for an additional 2 to 4 weeks, or until resistance to the antibiotic is found on subsequent bacterial C/S.

Topical

▼ ***Key Point*** With topical medications, one is able to achieve concentrations in the ear 100 to 1000 times higher than if the drug were given systemically. An antibiotic that is resistant on bacterial C/S may thus be efficacious when administered topically.

- Numerous otic medications are available (e.g., neomycin sulfate, polymyxin B sulfate, and hydrocortisone [Neo-Poly-W/HC Otic Solution, generics], enrofloxacin and silver sulfadiazine [Baytril Otic, Bayer Animal Health], gentamicin sulfate and betamethasone valerate [generics; Gentocin Otic Solution, Schering-Plough Animal Health]; thiabendazole, dexamethasone, and neomycin sulfate solution [Tresaderm, Merial]).
- However, none of these otic medications is labeled for use with a non-intact tympanic membrane. Do not use otic preparations in an ointment base with a non-intact tympanic membrane.
- In addition, ophthalmic solutions (e.g., tobramycin [Tobramycin Ophthalmic Solution 0.3%, generics]), as well as extra-label solutions (e.g., silver sulfadiazine [Silvadene Cream 1%, Monarch Laboratories], enrofloxacin [Baytril Antibacterial Injectable Solution 2.27%, Bayer Animal Health]), are also used topically for otitis, but again, their ototoxic potential has not been established.

▼ ***Key Point*** Always warn the owner of the possibility of neurologic signs of ototoxicity while administering topical medications when the tympanic membrane is not intact.

- Use enough topical medication to fill the ear canal, and repeat the application q12h.
- Topical otic and/or systemic treatment in animals with chronic otitis may need to be continued for weeks to many months to achieve complete resolution of the infection, especially in animals with chronic otitis.

Systemic and Topical Glucocorticoids

- Anti-inflammatory doses (1 mg/kg PO q24h, then taper) of oral glucocorticoids (e.g., prednisone [generics]) reduce hyperplasia and stenosis of the ear canal to facilitate therapy.
- Topical glucocorticoids may be used solely or in combination with oral glucocortocoids to reduce hyperplasia and stenosis of the ear canal.
- Glucocorticoids are available in topical combination products, with antibacterial and antifungal agents, or in combination with acetic acid (ClearX Ear Drying Solution, DVM Pharmaceuticals), acetic acid and Burow's solution (Bur-Otic-HC, Virbac), Burow's solution (CortAstrin, Vedco), and dimethyl sulfoxide (DMSO) (Synotic Otic Solution, Fort Dodge).

Topical Cleaning and Drying Agents

- These are used to aid in keeping the external ear clean by removing exudate. Most products contain an acid to dry the ear. Some examples include lactic acid and salicylic acid (Epi-Otic, Virbac); salicylic acid, benzoic acid, and malic acid (OtiCalm Cleansing Solution, DVM Pharmaceuticals); alcohol, salicylic acid, lactic acid, and benzoic acid (OtiRinse Cleansing/Drying Ear Solution, DVM Pharmaceuticals); and olefin and citric acid (Advanced pHormula Ear Cleanser, EVSCO).

Prevention of Recurrent Otitis Externa

- Prevention of recurrence of otitis is dependent on diagnosing and controlling the primary underlying disease.
- While the primary disease is being diagnosed or if the primary disease has been diagnosed but has not controlled the recurrence of the otitis, maintenance ear cleaning (i.e., ear cleaning and drying agents) and topical therapy (i.e., glucocorticoids) may be helpful in preventing a recurrence.

Surgical Management

- Consider surgical intervention in unresponsive or recurrent cases of otitis media (see Chapter 62).
- Perform surgery if middle ear polyps, neoplasia, foreign bodies, or osteomyelitis of the tympanic bulla is present.
- The surgical technique depends on the specific condition.

Other Treatments

- Treat exposure keratitis due to facial nerve paralysis or KCS with artificial tears, lubricating eyedrops, or topical cyclosporine (Optimmune, Schering–Plough Animal Health).

PATIENT MONITORING

- Reevaluate the animal every 2 weeks until the infection has resolved.
- Perform otoscopic examination with a hand-held otoscope or video otoscope.
- Perform otic cytology at each reevaluation to monitor the response to therapy. If there is no response or the infection has worsened, obtain samples for a bacterial C/S.
- Monitor healing of the tympanic membrane.
- Repeat ear flushing under general anesthesia may be required to keep the ear canal clean of otic exudate.

Neurologic Signs

- Horner's syndrome and facial nerve paralysis/paresis may persist even when infection has resolved.

Chapter 62

Surgery for Otitis Media and Otitis Interna

Harry W. Boothe

Selection of a surgical procedure to treat otitis media and otitis interna is based on duration of clinical signs, response to previous treatment, status of the external ear canal, and the surgeon's familiarity with related anatomy and technique. Surgical options for treating otitis media and otitis interna include myringotomy (see Chapter 61), lateral bulla osteotomy, and ventral bulla osteotomy. Nasopharyngeal polyps are most appropriately excised using a bulla osteotomy in combination with other excision techniques. Potential complications of bulla osteotomy surgery include facial nerve injury, Horner's syndrome (ptosis, miosis, enophthalmos, nictitating membrane protrusion), and vestibular signs. See Chapter 61 for diagnosis and medical treatment of otitis media and otitis interna.

ANATOMY

- The tympanic membrane slopes downward, forward, and inward—toward the middle ear cavity. The membrane is composed of a larger, more peripherally located pars tensa and a smaller, triangular-shaped pars flaccida.
- The air-filled tympanic cavity constitutes the major portion of the middle ear and is connected to the nasopharynx by the auditory (eustachian) tube.
- Structures located within the dorsal aspect of the tympanic cavity include the three auditory ossicles, associated muscles and ligaments, and tympanic nerve.

▼ ***Key Point*** The feline tympanic cavity is divided into a larger ventromedial and a smaller dorsolateral compartment by a nearly complete thin bony septum.

- Surgically important structures near the tympanic bulla are the facial nerve (ventrolaterally), the carotid artery (medially), and the hypoglossal nerve (ventrally).

LATERAL BULLA OSTEOTOMY

Preoperative Considerations

- Thoroughly examine the external ear canal.
- Evaluate the radiographic appearance of the tympanic bulla and the microbiologic status of the middle ear before lateral bulla osteotomy. Computed tomography, or CAT scan, (see Chapter 4) is particularly helpful in assessing disorders of the tympanic bulla.
- Lateral bulla osteotomy is simplest when performed in conjunction with a total ear canal ablation. If the external ear canal is normal or only mildly affected by infection, bulla osteotomy can be performed via a lateral (without ear canal ablation) or ventral approach. The ventral approach is preferred by most surgeons.
- Assess the integrity of the facial nerve preoperatively.

Surgical Procedure

Objectives

- Provide access to the tympanic cavity to obtain samples for diagnosis.
- Provide drainage and access to the middle ear cavity for therapeutic intervention (e.g., flush, curettage, and resection of abnormal tissue).

Equipment

- Standard general surgery pack and suture
- Periosteal elevator, Steinmann pin, hand chuck, and rongeurs
- Warm saline solution and tubing for flushing the tympanic cavity

Technique for Lateral Bulla Osteotomy without Total Ear Canal Ablation

1. Position the patient in lateral recumbency, and prepare the lateral aspect of the head and neck.
2. Incise the skin over the vertical ear canal to a point ventral to the horizontal ear canal (Fig. 62-1).

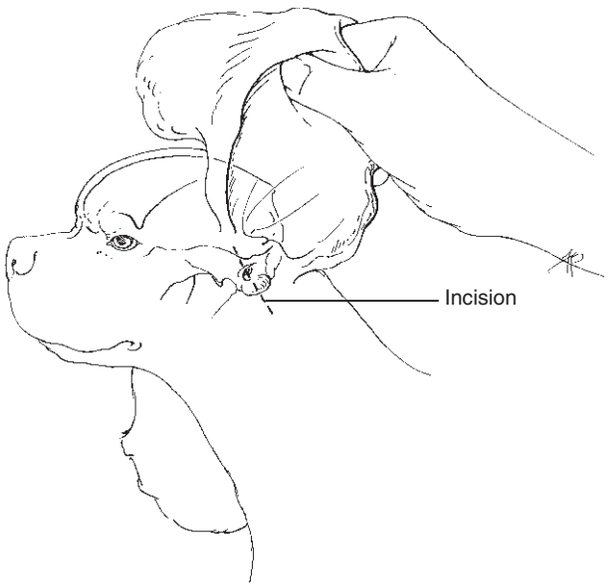

Figure 62-1. Skin incision for performing a lateral bulla osteotomy without total ear canal ablation.

3. Bluntly dissect between the parotid salivary gland and the ventral aspect of the horizontal ear canal to reveal the facial nerve.
4. Retract the facial nerve ventrocaudally near its exit from the stylomastoid foramen.
5. Elevate the soft tissue overlying the lateral aspect of the osseous bulla using a periosteal elevator.
6. Enter the tympanic cavity ventral to the horizontal ear canal with the Steinmann pin and hand chuck.
7. Enlarge the osteotomy site ventrally with rongeurs.
8. Obtain microbiologic samples, and flush the middle ear cavity using warm saline solution. If curettage is performed, avoid traumatizing the inner ear structures on the dorsomedial aspect of the bulla.
9. Place and secure a drain tube (e.g., Penrose drain) into the tympanic cavity by suturing it to the adjacent soft tissue with fine absorbable suture material.
10. Routinely close the subcutaneous tissue (simple interrupted, absorbable suture) and the skin (simple interrupted, nonabsorbable suture).
11. Position the drain tube so that it exits the skin adjacent to the primary incision.

Technique for Lateral Bulla Osteotomy with Total Ear Canal Ablation

1. Position the patient in lateral recumbency, and prepare the lateral aspect of the head and neck, including the external ear canal.
2. Incise the skin over the vertical ear canal, and perform a total ear canal ablation (see Chapter 60).
3. Reflect the soft tissue from the lateral aspect of the tympanic bulla, insert the rongeur tips into the external auditory meatus, and remove the ventral aspect of the bony auditory meatus.
4. Extend the osteotomy site as far ventrally into the middle ear cavity as possible. Obtain samples of tissue and fluid for culture and sensitivity. Flush the cavity with warm saline solution.
5. Use a bone curette to carefully remove epithelium and debris from the bulla. Avoid curretting the dorsal aspect of the bulla to prevent injury to structures of the inner ear.
6. Place a drain tube to exit the ventral aspect of the bulla osteotomy site and skin adjacent to the primary incision.

Postoperative Care and Complications

Short-Term

- Prevent self-inflicted trauma to the drain tube by using an Elizabethan collar or similar device.
- Facial nerve damage, manifested by inability to close the eye and by drooping of the upper lip on the ipsilateral side, may be observed.

▼ ***Key Point*** Administer eye lubricant (artificial tears) to animals with facial nerve damage to prevent corneal ulceration.

- Remove the drain tube when drainage has decreased significantly, generally within 3 to 4 days.
- Continue an appropriate systemic antibiotic for at least 3 weeks.

Long-Term

▼ ***Key Point*** Incomplete removal of secretory epithelium from the tympanic bulla can result in recurrent deep tissue infections. Clinical signs include pain on opening the mouth and on palpation of the area over the tympanic bulla, and nonspecific signs such as anorexia, lethargy, and fever.

Prognosis

- Response to bulla osteotomy tends to be incomplete in long-standing cases of otitis media and otitis interna.
- Immediate response following bulla osteotomy indicates a more favorable prognosis.

VENTRAL BULLA OSTEOTOMY

Preoperative Considerations

- See Preoperative Considerations under Lateral Bulla Osteotomy.
- Radiographically assess the density of the tympanic bulla to assist in the initial osteotomy procedure.

Surgical Procedure

Objectives

- See Objectives under Lateral Bulla Osteotomy.
- To establish ventral drainage of the middle ear cavity.

Equipment

- See Equipment for Lateral Bulla Osteotomy without Total Ear Canal Ablation.

Technique

1. Position the patient in dorsal recumbency with the neck slightly hyperextended over a pad or rolled towel, and prepare the ventral cervical region from the mid-mandibular area to the wings of the atlas.
2. Incise the skin just off the midline between the level of the angular process of the mandible and the wings of the atlas (Fig. 62-2).
3. Bluntly dissect between the digastricus muscle and the hyoglossal and styloglossal muscles. The hypoglossal nerve on the lateral aspect of the hyoglossal muscle helps verify the proper dissection plane.
4. Carefully retract the adjacent musculature to reveal the rounded tympanic bulla between the more angular jugular process of the skull (caudal) and the angular process of the mandible (rostrolateral).
5. Reflect the thin jugulohyoideus muscle that covers the osseous bulla in the dog.
6. Accurately locate the bulla before proceeding with the osteotomy. Carefully penetrate the ventral aspect of the tympanic bulla with a Steinmann pin in a hand chuck, and enlarge the osteotomy site using rongeurs (Fig. 62-3). In cats, remove the septum to fully expose the tympanic cavity.
7. Carefully remove abnormal tissue and fluid from the tympanic bulla. Obtain samples of tissue and fluid for histopathology and culture. Avoid trauma to the inner ear structures and auditory ossicles. Do not curette the dorsal aspect of the bulla.
8. Flush the middle ear cavity with warm saline solution, and place a drain to exit the ventral cervical skin through a separate skin incision.
9. Routinely close the subcutaneous tissue (simple interrupted, absorbable suture) and the skin (simple interrupted, nonabsorbable suture).

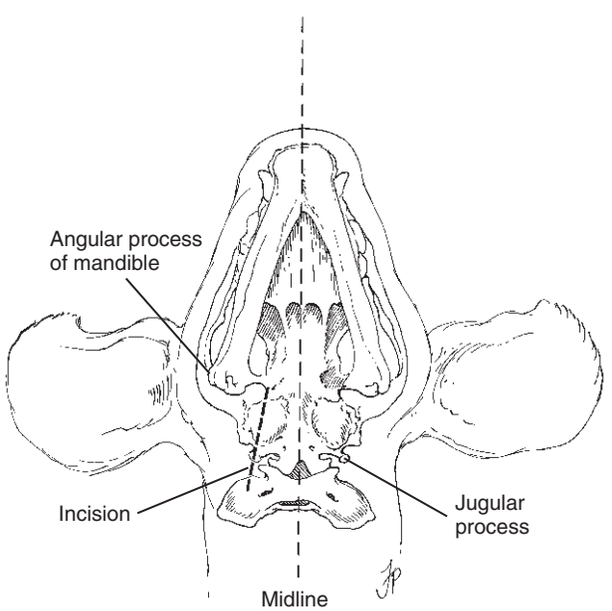

Figure 62-2. Skin incision for ventral bulla osteotomy.

Postoperative Care and Complications

- See Postoperative Care and Complications under Lateral Bulla Osteotomy.

SURGICAL MANAGEMENT OF NASOPHARYNGEAL POLYPS

Preoperative Considerations

- Carefully inspect the nasopharynx by rostrally displacing the soft palate to assess the size of the nasopharyngeal mass.
- Radiographically assess the tympanic bulla to determine the potential involvement of the middle ear cavity. Computed tomography is helpful in identifying changes in the affected tympanic bulla.
- See Chapter 161 for additional information on nasopharyngeal polyps.

Surgical Procedure

Objectives

- Excision of the mass using both an oral approach and a ventral bulla osteotomy.

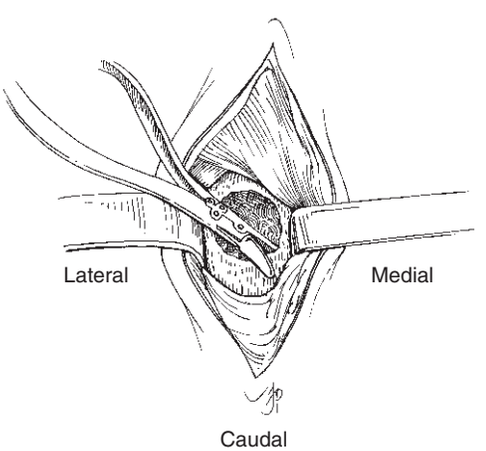

Figure 62-3. Use bone rongeurs to enlarge the opening in the ventral tympanic bulla.

- Removal of the mass from the nasopharynx or ear canal using a simple traction technique, while carefully excising polypoid tissue from the tympanic cavity via a ventral bulla osteotomy.

Equipment

- See Equipment for Lateral Bulla Osteotomy without Total Ear Canal Ablation.

Technique

1. Position the cat in dorsal recumbency and prepare the ventral cervical region from the mid-mandibular area to the wings of the atlas. Perform the procedure with the cat's mouth held open.
2. Displace the soft palate rostrally using a soft tissue retractor or stay suture to provide adequate exposure of the mass.
3. Apply traction to the mass to remove the pharyngeal component of the polyp.
4. Perform a ventral bulla osteotomy, as previously described, and excise tissue proliferations within the tympanic cavity using careful curettage. Perform a bilateral bulla osteotomy if it is unclear which middle ear is involved.
5. Examine the ipsilateral ear canal, and excise any polypoid tissue.

Postoperative Care and Complications

Short-Term

- Temporary Horner's syndrome of 1 to 2 weeks' duration is common following curettage of the middle ear cavity.
- See short-term complications following lateral bulla osteotomy.

Long-Term

- Recurrence of the polyp is possible, although less likely, following both excision by traction and ventral bulla osteotomy than following excision by traction alone.
- Disruption of the otic ossicles from trauma to the dorsal aspect of the tympanic cavity results in hearing loss.

Prognosis

- The long-term prognosis following removal of nasopharyngeal polyps using both the traction excision and ventral bulla osteotomy techniques is good. Recurrence is uncommon.

Chapter 63

Disorders of the Claw

Ralf S. Mueller

INTRODUCTION

Onychology (the study of nails) is an area of veterinary dermatology that has only recently become the focus of more detailed study. In the past decade, several studies have shed light on the etiology, diagnosis, and treatment of claw disease in the dog. Some relevant terms are explained in Table 63-1. A thorough diagnostic approach is essential, as treatment is successful only when the cause of the disease is known. In this chapter, a review of claw anatomy is followed by the diagnostic approach to claw disease, and finally a discussion of the treatment options for the most common disorders affecting the claw is presented.

ANATOMY

- The anatomy of the claw is shown in Figure 63-1. The superficial layers of the epidermis are modified to form the claw horn. The claw is curved and consists of a sole (the most distal portion), two laterally compressed walls (forming the axial and abaxial surfaces of the claw), and a central dorsal ridge. This ridge is thicker than the walls and sole, which maintains the pointed appearance of the claw. The coronary border (vallum) of the claw fits into the space under the ungual crest, a crescent-shaped dorsal process of the distal third phalanx. Most of the claw is formed from the coronary band, which is surrounded and hidden by the claw fold.
- The claw fold is a fold of skin at the proximal border of the claw that is continuous with the horn of the claw. Dorsally, it is a modification of haired skin. The periosteum of the distal phalanx is continuous with the dermis of the claw; these two tissues occupy the space between the bone of the distal phalanx and the claw itself.
- The corium or dermis underneath the claw epidermis and horn is often referred to as the quick. This tissue is highly vascularized, which is readily demonstrated by hemorrhage after excessive trimming of the claws.
- Any inflammation of the dermis, which is present between these two rigid structures, leads to swelling and explains why pronounced pain occurs rapidly with any disease of the canine claw matrix.
- The keratogenous zone (the basal cell layer and lower spinous cell layers) at the very proximal end of the claw is the proliferative claw matrix thought to be actively involved in producing the claw plate. Damage to the claw matrix typically results in malformation of the plate.
- The normal canine claw epithelium lacks a granular layer. The epithelium produces keratinocytes that flatten, cornify, and fuse to form the claw horn. The claw wall is curved, laterally converging and enclosing the sole distally.

Table 63-1. Definition of Terms Used to Describe Claw Disease

Paronychia	Inflammation involving the folds of tissue surrounding the claw
Onychodystrophy	Malformation of the claw
Onychomadesis	Separation of the claw from its bed
Onychomalacia	Softening of the claw
Onychomycosis	Fungal disease of the claw
Onychorrhexis	Brittleness, spontaneous splitting, or breaking of the claws
Onychoschizia	Separation of the claw from its bed
Onychia	Inflammation of the claw or claw bed, resulting in loss of the claw
Onychogryposis	Abnormal hypertrophy and curving of the claws
Onycholysis	Complete loss of the claws

ETIOLOGY

- *Trauma* is the most common cause of claw disease, particularly if only a single claw or a single paw is affected. Animals typically present with lameness and pain, particularly if the claw plate is loose.
- *Neoplasia* is a common cause of claw disease affecting single digits. A variety of tumors such as melanoma, mast cell tumors, keratoacanthoma, inverted papil-

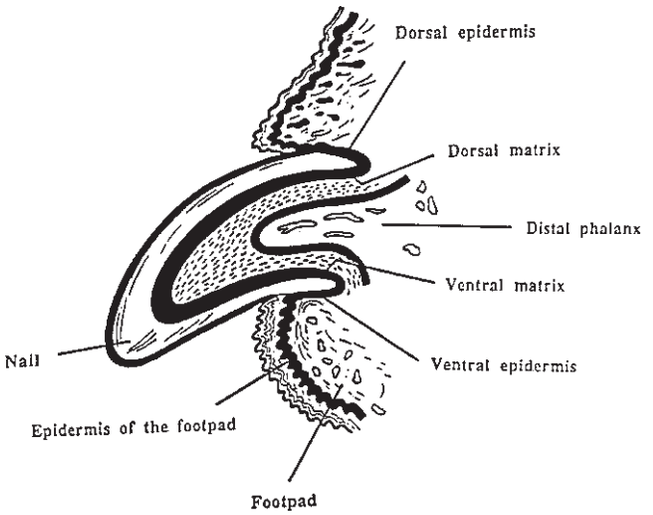

Figure 63-1. Schematic anatomy of the canine claw. (From Mueller RS, Sterner-Kock A, Stannard AA: Microanatomy of the canine claw. Vet Derm 4:5, 1993, with permission.)

loma, lymphosarcoma, fibrosarcoma, osteosarcoma, and others have been reported to affect the canine claw and claw bed. However, squamous cell carcinoma is the most common neoplasm of the distal digit and seems to be particularly frequent in large-breed dogs with black hair coats. Squamous cell carcinoma often invades the bone of the distal phalanx.

- *Systemic disease* is likely if multiple digits on several paws are affected. Consider drug reactions, immune-mediated diseases such as lupus erythematosus or the pemphigus complex, or allergies such as food adverse reactions. Involvement of dew claws with other claws also is indicative of systemic disease. Paronychia or inflammation of the claw fold is most commonly caused by infection with bacteria and/or yeast organisms. However, immune-mediated diseases such as pemphigus foliaceus and pemphigus vulgaris may also cause paronychia.
  - Immune-mediated diseases such as lupus erythematosus, pemphigus vulgaris, pemphigus foliaceus, bullous pemphigoid, drug eruption, and cold agglutinin disease have all been reported to cause claw disorders. In the majority of cases other cutaneous or non-cutaneous signs will provide clinical clues for the diagnosis. See Chapter 48 for discussion of the clinical signs, diagnosis, and treatment of immune-mediated diseases.
- *Bacterial infection* is commonly seen secondary to an underlying disease such as trauma, hyperadrenocorticism, hypothyroidism, pemphigus foliceus, or systemic lupus erythematosus.
- *Onychorrhexis* (brittle claws) may be due to chronic infection in some dogs. In old dogs, it may involve all claws including the dew claws and is most likely a degenerative change. Onychorrhexis can also be seen in dogs with nutritional deficiencies.
- *Idiopathic onychomadesis* or *lupoid onychodystrophy* is the most common cause of symmetrical claw disease in my experience. The condition is characterized by histopathology resembling lupus erythematosus typically with no other abnormal clinicopathological findings. The disease has an acute onset with loss of one or several claw plates, followed rapidly in the ensuing weeks with shedding of most or all other claw plates. The pathogenesis has not been completely elucidated, but allergic, infectious, or immune-mediated diseases may all be able to cause this disease. Thus, the lupoid reaction histopathologically and onychomadesis clinically may be a reaction pattern of the claw rather than an individual disease. Perform an extensive diagnostic work-up for allergies and infections before an immune-mediated pathogenesis is assumed.
- *Onychomycosis*, although a common disease in human medicine and thus familiar to most owners, is a rare cause of claw disease in small animals. Transient contamination of distal extremities with fungal organisms is possible and may result in positive fungal cultures. Biopsies or cytology should confirm the disease and document invasion of the tissue.
- *Demodex* infection of the claw has been reported in some dogs.

CLINICAL SIGNS

- Pain and resultant lameness is a very common sign of a claw disorder.
- Onychomadesis or claw shedding is another common clinical sign in patients with claw disease. The dermis of the claw is situated between the claw horn itself and the bone of the distal digit; there is no subcutis present in this structure. Thus, inflammation of the claw matrix and/or the dermis and the associated swelling between the bone and horn quickly leads to pain and onychomadesis. This can be seen with trauma, infection, immune-mediated diseases, and most other causes of claw disorders affecting single or multiple digits.

DIAGNOSIS

History

- As many diseases of the canine claw present very similarly, the history is essential in providing clinical clues to the underlying disease. Age of onset and breed may be helpful. The American cocker spaniel is predisposed to keratinization defects that may affect the claws. German shepherd dogs are predisposed to onychomadesis of unclear etiology associ-

ated with abnormal mineral composition. Young dogs tend to be affected more by contagious disease, whereas neoplastic diseases are more commonly seen in old dogs.

- An acute onset may be seen with trauma or immune-mediated disease. A slow progression is to be expected with dermatophytosis or keratinization defects. Commonly, trauma affects only single claws or is restricted to one foot, while multiple paws are affected more often by systemic disease. Other systemic signs such as polyuria and polydipsia or recurrent lameness point to a systemic disease such as lupus erythematosus. Investigate the possibility of other animals in the household or humans in contact having skin disease. Pay special attention to fungal infections such as athlete's foot in the owner, which may serve as a source of infection for the dog.

Physical Examination

- Perform a thorough overall physical examination to look for evidence of generalized diseases.
- Carefully examine the claws. Twisted, curled, or malformed claws are usually due to disturbed growth of the claw horn frequently associated with a damaged claw matrix, trauma, or congenital defects. This malformation can lead to shedding of the claw.

Diagnostic Tests

Cytology

- Many patients with claw disease have inflammation of the tissue surrounding the claw. In these animals, material (pus, debris, keratinaceous material) may be squeezed out and applied to a glass slide with a small, soft paint brush. Alternatively, use a swab to remove material deep inside the claw fold and roll it onto a slide. Impression smears may be useful, if the skin adjacent to the claw fold is abnormal.
- If the claws and claw folds are dry, moisten swabs with saline prior to sampling the claw fold. Alternatively, in patients with changes of the claw horn, use a #10 scalpel blade and scrape material from the most proximal portion of avulsed or affected claws. Apply the material to the slides and use the staining techniques and methods of microscopic evaluation of specimens discussed in Chapter 37.
- *Interpretation* of results of cytology may be difficult at times. The presence of bacteria alone is not diagnostic of bacterial infection. However, if bacteria are present in large numbers, suspect infection and initiate trial therapy with antibiotics. Numerous yeast organisms or inflammatory cells with intracellular bacteria confirm clinically relevant infection and the need for appropriate therapy. If these bacterial or yeast infections are secondary to trauma, treatment with antimicrobial agents alone may be successful without a relapse of the claw disease. However, if another disease is responsible for the infection, identify and treat to prevent recurrence of claw disease.

Bacterial Culture

- Bacterial culture is not performed routinely, since most bacterial infections (due to cocci) of the claw respond well to empirical therapy.
- Indications for a bacterial culture and sensitivity are (1) bacterial infections not responding to appropriate antimicrobial therapy and (2) infections where a significant number of rod-shaped organisms have been identified on cytology. Obtain material for bacterial cultures as for cytological specimens. Prior clipping of the claw may decrease the risk of contamination. Interpret results of culture in light of cytology results.

Fungal Culture

- If the history and clinical examination indicate a possible fungal infection or spores/hyphae are identified on cytology or histopathology, perform a fungal culture to confirm the diagnosis and to allow determination of the fungal species involved. Different fungal organisms have different zoonotic potential.
- Obtain scales from the claw fold and/or proximal part of avulsed or intact claws and hair from the area directly adjacent to the claw fold for culture agars. Use Sabouraud's agar and dermatophyte test medium. Apply shaved thin slices of the claw to the culture medium to improve the probability of fungal growth. Cleaning of the claw and surrounding skin with alcohol may reduce bacterial contamination.
- Transient contamination of claws with *Trichophyton* spp. and *Microsporum gypseum* is possible. Identify organisms not only on culture, but also directly on hairs, in hair follicles, or in claw material cytologically and/or histopathologically to confirm the diagnosis.

Skin Scrapings

- Deep skin scrapings for *Demodex canis* may be useful since they may cause claw disease in some dogs. After gently clipping the skin adjacent to an affected claw, perform scrapings with a #15 scalpel blade until capillary bleeding is observed. Typically, heavy sedation or general anesthesia is required to achieve proper skin scrapings in dogs with claw disease.
- An alternative to the scraping may be a trichogram, where numerous hairs adjacent to the claw fold are plucked and examined under the microscope. If mites are identified, the diagnosis is confirmed. If no mites are present, perform a skin scraping.

Biopsy

▼ ***Key Point*** Claw biopsy is the diagnostic tool of choice for neoplastic disease, but may also confirm immune-mediated diseases such as the various

forms of pemphigus and bullous pemphigoid and may give important clues to diseases such as drug reactions.

- Claw biopsy may identify fungal or bacterial organisms in the tissue, thus complementing culture results. Histopathologic features similar to lupus erythematosus such as interface onychia, basal cell vacuolization, a band-like or perivascular to diffuse lymphocytic and plasmacytic infiltrate, and pigmentary incontinence are not always associated with immune-mediated diseases but can be found in other disorders as well. These "lupoid" changes may be a reaction pattern of canine claw epithelium rather than a diagnostic change.

Biopsy Technique

- To obtain appropriate specimens of claw matrix, surgically remove the distal phalanx (see Chapter 114) to allow the pathologist to evaluate the changes most thoroughly. However, amputation of the digit is often met with owner resistance.
- Recently, a biopsy technique was developed that allows evaluation of the claw matrix while avoiding onychectomy. To minimize postsurgical discomfort, take specimens from claws bearing no or little weight. If dew claws are not present or not affected, obtain samples from P2 and/or P5 of one hind paw.
- Place the animal under general anesthesia, and clip the affected paw. Apply a tourniquet to reduce hemorrhage during the procedure.
- Obtain the biopsy specimen by rotating a biopsy punch slowly in one direction deep into the tissue, initially cutting medially through the horn of the claw and then through the bone of the distal phalanx and laterally through normal skin on the lateral aspect of the claw fold (Figs. 63-2 and 63-3). Cut the base of the sample with iris scissors or scalpel blades.
- Place the specimen in 10% buffered formalin. Close the incision with two monofilament nonabsorbable sutures. Bandage the paw for 2 to 3 days postoperatively. Analgesic therapy may be used postoperatively for the first 8 to 10 hours. Remove the sutures after 2 weeks.

Blood Tests

- Blood samples have been reported to be rarely useful in patients with exclusive claw disease. However, complete blood counts, serum biochemistry, and urinalysis may be helpful in individual patients (particularly in older pets). They are essential when systemic diseases such as lupus erythematosus are suspected. Antinuclear antibody titers or determination of cold agglutinins may also be useful in individual patients.

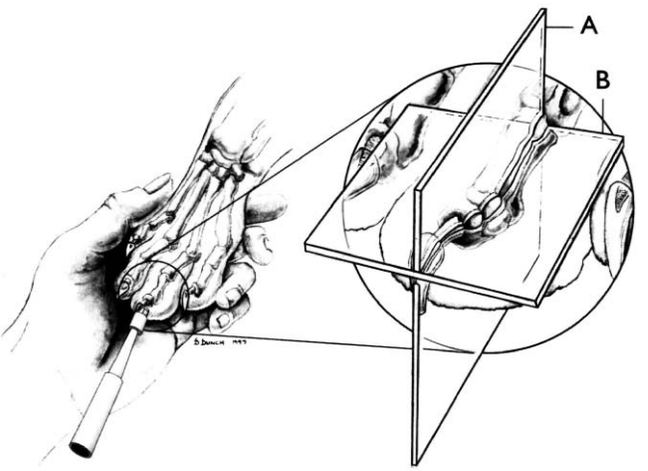

Figure 63-2. Positioning of the biopsy punch for onychobiopsy. Place the punch horizontally such that the direction of the cutting edge is perpendicular to planes A and B. The medial edge of the punch needs to cut through the lateral edge of the claw. (From Mueller RS, Olivry T: Onychobiopsy without onychectomy: description of a new biopsy technique for canine claws. Vet Derm 10:55, 1999, with permission.)

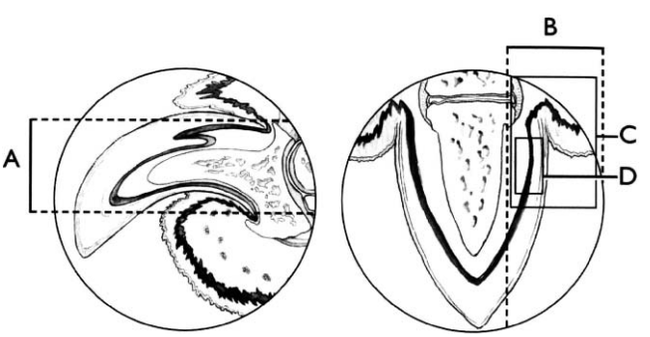

Figure 63-3. Localization of the excised biopsy specimen. Areas A and B depict the incision direction of the punch throughout the procedure, and area C delineates the area evaluated histopathologically. (From Mueller RS, Olivry T: Onychobiopsy without onychectomy: description of a new biopsy technique for canine claws. Vet Derm 10:55, 1999, with permission.)

Radiography

- Radiographs can identify lysis of bone, soft tissue swelling, and periosteal elevation and thus may be helpful in diagnosing secondary osteomyelitis and invasive neoplastic lesions in dogs with severe pain and swelling of the affected digit.

TREATMENT

General Therapy of the Claw

- To decrease pressure and associated pain, keep the claws very short so that the foot pads absorb most of

the weight. Distorted or brittle claws also benefit greatly from frequent clipping. In addition, clipped claws are less likely to catch on material. However, take care not to cause significant hemorrhage by clipping beyond the cornified part of the claw.

- Remove the claw plate if it is partially separated from the claw bed and causes constant pain or discomfort. Sedation or even general anesthesia may be necessary. Removal will typically diminish clinical signs of discomfort quickly. Apply antimicrobial ointments and a bandage for 1 to 3 days to minimize pain and bleeding. The prognosis for regrowth is good as long as the claw matrix is not significantly damaged.
- Topical antimicrobial solutions such as chlorhexidine at 0.05% to 0.1% (or available in 1–2% concentration in some products such as Malaseb [DVM Pharmaceuticals], Resichlor [Virbac]) may be beneficial with bacterial or fungal paronychia and can be used as a spray or shampoo daily to weekly.
- When an underlying etiology cannot be identified or treated successfully, and multiple claws are affected, amputation of all affected distal digits can be performed. However, long-term lameness may be seen following exercise.

Therapy for Bacterial Infection

- Perform antibacterial soaks or shampoos two to three times daily. Alternatively use 2% mupirocin ointment twice daily. Apply the ointment before walking or feeding the dog or before play time to prevent foot licking for the first 10 minutes after application. However, any topical therapy of the feet is cumbersome and often not tolerated easily by the patient, and systemic therapy may be preferred.
- If cytology has revealed an infection with cocci, cephalexin (20–30 mg/kg PO q12h), enrofloxacin (for dogs, 5–10 mg/kg PO q24h), or clavulanic acid/amoxycillin combination (12.5–25 mg/kg PO q8h) are all reasonable choices. If rod-shaped organisms predominate on cytology, perform culture and sensitivity to determine the choice of antibiotics. Continue treatment for 3 to 8 weeks depending on the underlying disease and the severity of the infection. If radiographs have indicated the presence of bacterial osteomyelitis, long-term systemic antibiotic therapy will be necessary (see Chapter 120).
- Consider amputation of the distal phalanx in conjunction with antibiotic therapy to avoid the risk of treatment failure and financial obligation associated with long-term antimicrobial therapy.

Therapy for Fungal Infection

- Onychomycosis is a refractory or recurrent disease that needs to be treated aggressively. Administer antifungal agents for extended time periods. Clinical improvement is an indicator of effective therapy, but continue treatment for several months beyond a negative fungal culture in conjunction with clinical remission.
- Griseofulvin at 50 mg/kg PO daily has been used successfully. Administer with a fatty meal to maximize absorption. Griseofulvin is teratogenic; do not give to breeding bitches.
- Other options include ketoconazole at 10 mg/kg PO q12h or itraconazole at 10 mg/kg PO q12h. Both of these drugs are occasionally hepatotoxic and may lead to vomiting and nausea, although these side effects are much more common with ketoconazole than with itraconazole.
- Terbinafine (25–30 mg/kg q24h) may also be used for onychomycosis in dogs. Pulse therapy may be useful with itraconazole or terbinafine; the drugs are given at their normal dose every other week.
- Consider amputation of the distal phalanx for clients with financial constraints. If the disease recurs after discontinuing extended therapy, onychectomy is recommended. Another reported alternative is long-term, low-dose daily therapy with systemic antifungal agents.

Therapy for Neoplasia

▼ ***Key Point*** In all patients with neoplasia of the claw, amputation of the digit is the therapy of choice.

Obtain lymph node aspirates or biopsies and radiographs to evaluate the extent of tumor invasion and the possibility of metastases. If the local lymph nodes show evidence of neoplastic cells, consider excision of the affected lymph node and limb amputation, or adjunctive therapy, depending on tumor type (see Chapter 115).

Idiopathic Onychomadesis (Lupoid Onychodystrophy)

- I have had reasonable success with a combination of tetracycline and niacinamide at 250 to 500 mg/animal PO q8h. If a good response is seen within 8 to 12 weeks, treatment may be changed to doxycycline hydrochloride or preferably doxycycline monohydrate at 5 to 10 mg/kg PO once daily. Many patients will stay in remission with this once-daily therapy, which is less cumbersome than administration of tetracycline/niacinamide and thus preferred by many owners.
- In a recent study, some patients also responded to pentoxifylline at 200 to 800 mg/dog PO once daily. However, the condition in some dogs may wax and wane, and spontaneous remission has been seen.
- Supplementation with essential fatty acids (omega-6 and omega-3 fatty acids (DermCaps, DVM Pharmaceuticals) or vitamin E (at 400 IU twice daily) has been reported to be very effective. However, in my

experience, response to supplements has been less reliable.

Chapter

64 Dentistry and Diseases of the Oropharynx

Sandra Manfra Marretta

Dental disease and diseases of the oropharynx are common in dogs and cats. These diseases can be divided into categories including oral surgical disease, periodontal disease, endodontic disease, orthodontic disease, stomatitis/gingivitis, neoplastic disease, and salivary gland disease. Neoplastic disease of the maxilla and mandible is discussed in Chapter 99.

ORAL SURGICAL DISEASE

The two major categories of oral surgical (non-neoplastic) disease are:

- Diseases requiring dental extraction
- Oronasal fistulas and palatal defects that can be surgically corrected

Anatomy

Proper performance of dental extractions requires a thorough knowledge of dental formulas, dental root structure, and pericoronal and periradicular anatomy.

▼ ***Key Point*** Determine the number of roots in any tooth to be extracted to ensure that all roots are removed during extraction.

- Deciduous and permanent dental formulas for dogs and cats are listed in Table 64-1.
- The dentition, including root structure, of dogs and cats is illustrated in Figures 64-1 and 64-2, respectively. Tooth roots for both species are listed in Table 64-2.
- Basic anatomic structures of the teeth and related areas are illustrated in Figure 64-3 and defined in Table 64-3.

Diseases Requiring Dental Extraction

Etiology

Dental diseases in which extraction is a treatment option include retained deciduous and supernumerary teeth, malocclusion teeth, advanced periodontal disease, fractured teeth, gross decay/erosions, diseased teeth in the fracture site of the mandible or maxilla, periapical abscess, impacted and deformed teeth, and teeth causing ophthalmic problems.

Clinical Signs

Common historical findings and signs of dental disease include changes in eating habits, halitosis, pawing at the mouth, abnormal salivation, oral hypersensitivity, facial swelling, oral hemorrhage, sneezing, nasal discharge, ophthalmic changes, and abnormal behavior.

Diagnosis and Indications for Extraction

The decision to perform dental extraction depends not only on the dental disease present but also on the

Table 64-1. DECIDUOUS AND PERMANENT DENTAL FORMULAS FOR DOGS AND CATS

Deciduous Dentition
Dog: 2(I3/3 C1/1 P3/3) = 28
Cat: 2(I3/3 C1/1 P3/2) = 26

Permanent Dentition
Dog: 2(I3/3 C1/1 P4/4 M2/3) = 42
Cat: 2(I3/3 C1/1 P3/2 M1/1) = 30

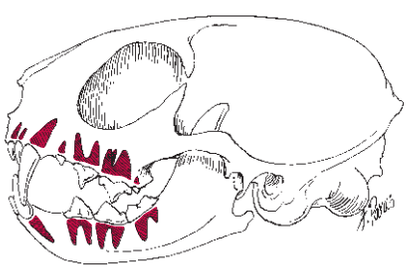

Figure 64-2. Dental root structure in the cat.

client's ability and desire to pursue alternatives to extraction, such as periodontal, endodontic, and orthodontic therapy.

▼ ***Key Point*** If a client is unwilling to pursue alternatives for treatment of a painful tooth, then the tooth should be extracted.

Overly Retained Deciduous and Supernumerary Teeth

Deciduous teeth are considered overly retained if they are firmly attached following the initial stage of eruption of the permanent tooth. Failure to extract deciduous teeth during this initial stage may result in malocclusion of the permanent teeth. Retained deciduous teeth and supernumerary teeth can be diagnosed as extra teeth present in the dental arcade. Deciduous teeth may be differentiated from supernumerary permanent teeth by their smaller crown size grossly and smaller root structure radiographically.

Table 64-2. TOOTH ROOTS IN DOGS AND CATS

Type of Tooth	No. of Roots
In Dogs	
Incisor	1
Canine	1
Maxillary (upper) cheek teeth:	
1st (1st P)	1
2nd and 3rd (2nd and 3rd P)	2
4th–6th (4th P; 1st and 2nd M)	3
Mandibular (lower) cheek teeth:	
1st and last (1st P; 3rd M)	1
2nd–6th (2nd–4th P; 1st and 2nd M)	2
In Cats	
Incisor	1
Canine	1
Maxillary (upper) cheek teeth:	
1st (2nd P)	1
3rd (4th P)	3
All others	2
Mandibular (lower) cheek teeth:	
All	2

M, molar; P, premolar.

Table 64-3. BASIC ANATOMIC STRUCTURES OF THE DENTITION

Crown:	Portion of the tooth located in the oral cavity. It is covered by enamel.
Root:	Portion of the tooth that lies within the alveolar bone. It is covered by cementum.
Furcation:	The space between the roots of a multirooted tooth.
Periodontal ligament:	Ligament that attaches the root of the tooth to the alveolar bone.
Interradicular bone:	Bone located between the roots.
Buccal bone:	Bone located on the buccal, or cheek, side of the tooth root.
Attached gingiva:	Keratinized gingiva firmly attached to the underlying alveolar bone.
Alveolar mucosa:	Mucosa that is loosely attached to the underlying bone.
Mucogingival line:	Anatomic landmark that separates the attached gingiva from the alveolar mucosa.

Maloccluded Teeth

Extraction may be required for maloccluded teeth that cause traumatic soft tissue occlusion or interfere with proper closing of the mouth. Orthodontic therapy is a viable alternative in these cases.

Advanced Periodontal Disease

Extremely mobile teeth caused by severe periodontal disease should be extracted. Other indications for extraction of teeth affected by periodontal disease include periodontal pockets extending to the apex of the tooth, pockets that reach the nasal cavity or maxillary sinus, and periapical abscess (discussed later).

Fractured Teeth

Extract fractured teeth with exposed pulp tissue if endodontic therapy is not an option. To diagnose pulpal exposure, place a dental explorer over the suspected exposure site. If the explorer penetrates into the tooth, the pulp is exposed.

Gross Decay/Dental Erosion

Gross decay, characterized by soft areas of demineralized enamel or dentin, is rare in dogs and cats. Dental erosive lesions or odontoclastic resorptive lesions are very common in cats.

- In dogs, gross decay, which usually occurs on the occlusal or biting surface of the maxillary first molar, and less frequently on the distal cusp of the mandibular first molar, can be identified with a dental explorer placed into the soft carious lesion. Penetration of the explorer into the soft demineralized enamel/dentin confirms gross decay. Radiographs of the affected tooth will show the extent of the lesion.
- Odontoclastic resorptive lesions are very common in cats. These defects are referred to as feline odontoclastic resorptive lesions (FORLs).
- FORLs often are extensive and painful and usually are covered by granulation tissue. Removal of the granulation tissue reveals the underlying erosive lesion.
  - Determine the extent of the resorptive lesion in the region of the cementoenamel junction and crown of the tooth with a dental explorer.
  - Radiographs are imperative to determine the severity of root resorption, because minor resorptive lesions in the crown may be associated with major root resorptive lesions.
- Treat dental caries and odontoclastic root resorptive lesions that extend into the pulp with extraction. Minor lesions can be restored with various dental restorative materials.

Diseased Teeth in a Mandible or Maxilla Fracture Site

Extract teeth in a fracture site that are severely affected with periodontal disease or that have fractured roots. If the fracture line in the jaw is located along the periodontal ligament and communicates with the apex of the tooth, extraction may also be necessary; however, temporary retention of the teeth that are not severely affected with periodontal disease may assist in anatomic reduction of the fracture site. Careful gross assessment and radiographic examination of the fracture site can determine if an extraction is necessary.

Periapical Inflammation

In small animals, a periapical inflammatory reaction (inflammation around the apex of a tooth) usually is secondary to periodontal or endodontic disease and is often characterized by acute, severely painful swelling in the area of the affected tooth. Periapical inflammation may be associated with a tooth that appears grossly normal. Concussive trauma without overt trauma to the tooth surface can cause pulpal necrosis with a secondary periapical inflammatory reaction.

- Carefully examine teeth in the area of acute facial swelling for deep periodontal pockets with a periodontal probe and for pulpal exposure with a dental explorer.
- Periapical lysis will be present around the apex of the affected root. Radiographs can confirm the diagnosis.
- Extraction of the affected tooth is recommended.

Impacted Teeth

Impacted (unerupted) teeth may cause nasal discharge, orthodontic problems, and bone loss.

- Dentigerous cysts may occur and can cause expansion of bone with subsequent facial asymmetry, extreme

displacement of teeth, severe root resorption of adjacent teeth, and bone loss.
  - Dentigerous cysts may give rise to ameloblastomas.
- Radiography can diagnose impacted teeth. Perform extraction if they are causing problems and when associated with a dentigerous cyst. Remove the entire cyst lining to prevent recurrence of the cyst and submit cyst lining for histopathology to confirm diagnosis.

Deformed Teeth

Diagnose deformed teeth based on gross and radiographic appearance. Usually they result from trauma or fever that occurred during tooth development. Abnormalities in development of teeth occur rarely and include dens-in-dente and gemination of teeth, which results when a single tooth bud attempts to divide into two teeth. Dens-in-dente results when there is invagination of enamel and dentin into the pulp space often resulting in secondary endodontic disease.

- Diagnose minor dental deformities such as enamel hypoplasia based on the observation of symmetric defects and staining of enamel combined with a history of illness during tooth development. No treatment is required in most cases.
- Extract severely deformed teeth that are causing pain.
- Gemination of the teeth usually requires no treatment. When a tooth has this developmental defect and extraction is necessary, perform dental radiography before extraction to determine the location of abnormal roots.

Ophthalmic Manifestations of Dental Disease

Tooth roots of the maxillary fourth premolar and first and second molars in dogs are in close proximity to the orbital floor and globe. Periodontal and endodontic disease of these teeth can result in ophthalmic signs, including orbital, periorbital, conjunctival, nasolacrimal, and neuro-ophthalmologic abnormalities.

- When signs of ophthalmic disease are suggestive of a primary dental disorder, do a complete oral examination under general anesthesia or sedation.
- Examine the maxillary teeth for fractures or deep periodontal pockets.
- Take dental radiographs of the maxillary teeth to check for periapical lysis.
- Extract teeth that are causing secondary ophthalmic disease.

Preoperative Considerations

- Before performing dental extractions, perform a thorough physical examination, standard laboratory tests including a complete blood count (CBC), serum biochemistry, and urinalysis.
- Perform appropriate radiographic procedures, based on the animal's clinical signs, physical examination findings, and age.
- Correct any underlying metabolic abnormalities such as dehydration, azotemia, electrolyte imbalances, hyperglycemia, and hypoglycemia.

Surgical Procedure

There are three basic types of extractions: simple, multirooted, and complicated surgical. An alternative to routine extraction techniques, feline crown amputation with intentional root retention can be utilized in feline teeth with advanced odontoclastic resorptive lesions following proper screening.

Equipment

- See Tables 64-4, 64-5, and 64-6.

Simple Extraction

Simple extraction refers to the extraction of a small single-rooted tooth such as an incisor.

Technique

1. Place an appropriate-size dental elevator in the periodontal ligament to sever the attachments of the gingiva around the tooth.
2. Advance the elevator apically (toward the apex or tip of the root) between the alveolar bone and root.
3. Rotate the elevator and hold for 15-second intervals to tear the periodontal ligament (Fig. 64-4*A*).

Table 64-4. DENTAL EQUIPMENT APPLICATIONS

Equipment	Applications
Portable electric dental drill with low-speed hand piece and prophy angle (Vetroson Millennium Motor Pack, Henry Schein, Inc.; Port Washington, NY)	Sectioning teeth, removal of alveolar bone, polishing teeth
Mobile delivery system with high-speed handpiece, low-speed handpiece, water and air syringe (Vet-Base, Henry Schein, Inc.)	Sectioning teeth, removal of alveolar bone, polishing teeth, cavity and crown preparations
Piezoelectric scaler, electric or air driven (Spartan USA, Inc.; Fenton, MO)	Permits rapid, easy removal of dental calculus
Dental radiography unit (AFP Imaging, Elmsford, NY)	Permits rapid, easy exposure of dental radiographs

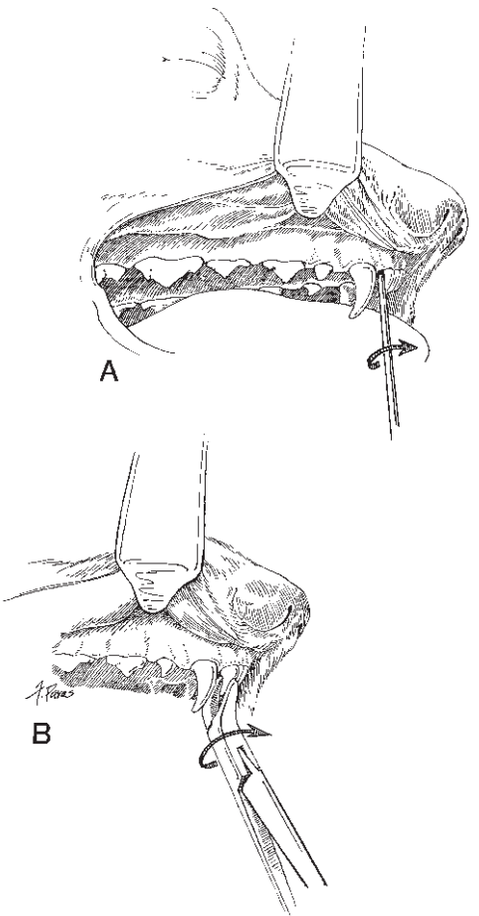

Figure 64-4. *A,* Dental elevator in periodontal ligament space is rotated 90 degrees. Tooth is rotated with extraction forceps.

4. Advance the elevator again apically, rotate it 90 degrees, and hold for 15 seconds.
5. When the tooth is loose, place an appropriate-size dental extraction forcep on the crown near the gingival margin and rotate and remove the tooth from the alveolus (Fig. 64-4*B*).
6. Examine the tooth to confirm that the root has been removed completely.

Multirooted Extraction

Multirooted teeth such as premolars and molars are more difficult to extract than incisors. Often only one root is affected and the other root(s) are firmly attached to the alveolar bone. Furthermore, most roots are embedded in the alveolar bone at divergent angles, making removal of the intact tooth difficult.

▼ ***Key Point*** Sectioning of a multirooted tooth into two or three sections converts the procedure into multiple simple extractions. A high-speed handpiece or a low-speed electric handpiece with adequate irrigation can be used for sectioning teeth.

Technique

1. Locate the furcation with a dental elevator.
2. Place a tapered fissure bur (#701 in small animals and #702 in larger animals) at the furcation and direct it through the crown (Fig. 64-5*A*).
3. Advance the elevator apically between two roots.
4. Gently rotate the elevator and hold for 15 seconds to gently force the roots apart (Fig. 64-5*B*).
5. Advance the elevator further apically, rotate it 90 degrees, and hold for 15 seconds.

Table 64-5. DENTAL INSTRUMENTATION

Instrumentation*	Applications
Oral Surgery	
Dental elevator	Tears periodontal ligament during extraction
Dental luxators	Has a thinner, sharper blade than traditional elevators
Extraction forceps	Completes breakdown of periodontal ligament and removal of tooth from alveolus during extraction
Root tip pick	Removal of small-breed deciduous teeth or broken root tips
Bone curette	Debridement of alveolus following extraction
Periosteal elevator	Elevation of mucoperiosteum during oronasal fistula repair and palatal surgery
Periodontic	
Periodontal probe/explorer	Measurement of depth of periodontal pocket (probe); detection of pulpal exposures and carious lesions (explorer)
Hand scalers	Subgingival scaling
Curette (Columbia #13/14)	Removal of accretions on the root surface and removal of granulation tissue from the pocket wall
Prophylaxis paste	Polishing teeth following scaling
Endodontic	
Endodontic files (Hedstrom/K-Files)	Debridement of necrotic pulpal tissue from canal
Root canal plugger	Compression of gutta percha into the apex
Light-Speed and SimpliFil System†	

*Available from Henry Schein, Inc.; Port Washington, NY and from Cislak Manufacturing Inc, Niles, IL.
†Available from Light Speed Endodontics, San Antonio, TX.

Table 64-6. DENTAL MATERIALS

Material	Applications
Composite resins (Prodigy, sdsKerr, Orange, CA)	Aesthetic restorations following endodontic therapy or cavity preparation
Glass ionomers (Vitrebond, 3M EPSE, St. Paul, MN)	Restoration of feline external root resorptive lesions
Endodontic sealers (AH Plus, Dentsply, Konstanz, Germany)	Endodontic filling material
Mineral trioxide aggregate (ProRoot MTA, Dentsply Tulsa Dental, Tulsa, OK)	Stimulates closure of an apex and reparative dentin formation following spulpotomies
Gutta percha (Successfil, Hygenic)	Fills the pulp canal following debridement during root canal therapy

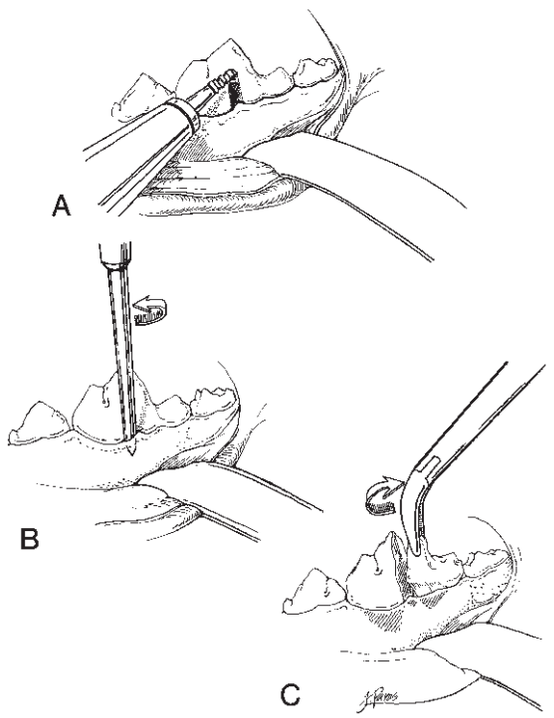

Figure 64-5. *A,* Tooth is sectioned with a tapered fissure bur. *B,* Elevator is rotated 90 degrees. *C,* Extraction forceps is used to extract each root separately.

6. Place a dental extraction forceps on each crown segment and rotate to extract each root independently (Fig. 64-5*C*).

Complicated Surgical Extraction

This procedure involves the removal of teeth with large roots, such as the canine teeth in dogs, or large multirooted teeth, such as the maxillary fourth premolars and the mandibular first molars.

Technique

1. Reflect a mucoperiosteal flap to expose buccal alveolar bone overlying the root (Fig. 64-6*A*).
2. Remove the buccal alveolar bone overlying the root with a large round bur (Fig. 64-6*B*).
3. If the tooth is multirooted, section it with a #702 bur.
4. Elevate and extract the tooth.

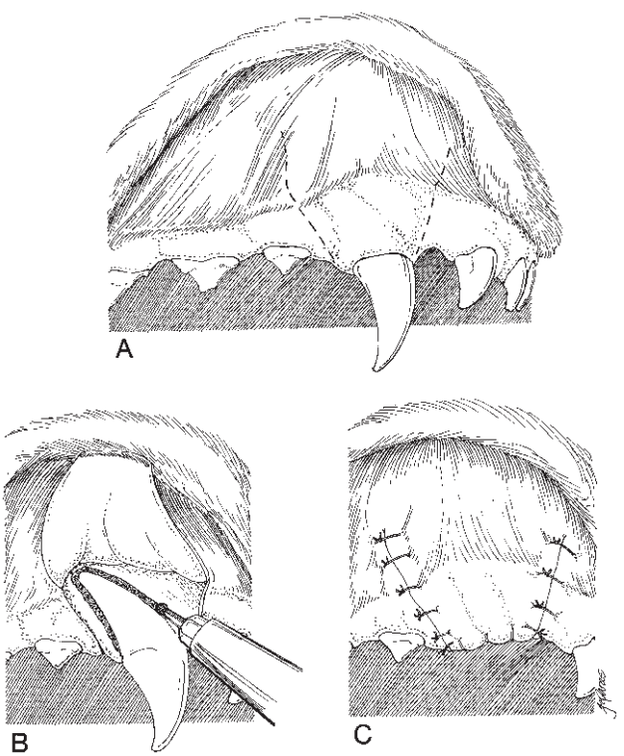

Figure 64-6. *A,* Proposed mucoperiosteal flap incision site for extraction of a maxillary canine tooth. *B,* Buccal alveolar bone is removed. *C,* Mucoperiosteal flap is replaced and sutured.

5. Perform an alveoloplasty to remove the rough edges of the alveolus, using a large, round bur.
6. Curette and flush the alveolus.
7. Incise the deepest layer of the flap, the periosteal layer, over the entire width of the apical aspect of the flap to prevent tension on the flap closure.
8. Replace and suture the mucoperiosteal flap to the adjacent mucosa and gingiva with a simple interrupted pattern (Fig. 64-6*C*).

Crown Amputation with Intentional Root Retention (DuPont Technique)

This procedure involves the removal of the crown with intentional retention of the roots in appropriately screened feline teeth with severe odontoclastic resorptive lesions.

Technique

1. Reflect a small flap to expose the marginal alveolar bone of affected tooth (Fig. 64-7A).
2. Retract the gingival and protect it with the end of a small flat feline periosteal elevator while the crown is amputated with a #3 round bur on a high-speed handpiece at or slightly apical to the level of the alveolar crest (Fig. 64-7B).
3. Check the crown amputation with a dental explorer and remove any residual crown or sharp bony projection with the bur (Fig. 64-7C).
4. Flush the site with sterile saline, replace the flap, and close with simple interrupted absorbable sutures (Fig 64-7D).

Postoperative Care and Complications

- Offer a soft diet for 3 to 10 days, depending on the number and complexity of dental extractions.
- Administer a broad-spectrum antibiotic (e.g., amoxicillin clavulanate) for 3 to 7 days when infection is present.

Hemorrhage

Hemorrhage is a common complication of dental extractions and usually is minor and can be easily controlled with a gauze sponge and digital pressure. Control persistent alveolar hemorrhage by suturing the gingiva over the alveolus, thereby permitting clot formation.

Broken Root Tips

Broken root tips are common when inappropriate dental extraction techniques are used. Various types of dental pathology such as odontoclastic resorptive lesions, dental caries, and ankylosis of the root to the alveolar bone may predispose to broken root tips.

▼ ***Key Point*** Always remove any tooth roots that break during extraction.

- Differentiate broken root tips from surrounding alveolar bone by the following features:
  - The tooth is whiter than the surrounding off-white bone.
  - The tooth is harder than the surrounding bone, as detected by a dental explorer.
  - The hard tissues of the tooth do not bleed.
  - Remove root tips with a root tip pick or obliterate with an appropriate-size round bur (Fig. 64-8). Removal with a root tip pick is preferred because obliteration of roots with a bur may cause damage to underlying structures.

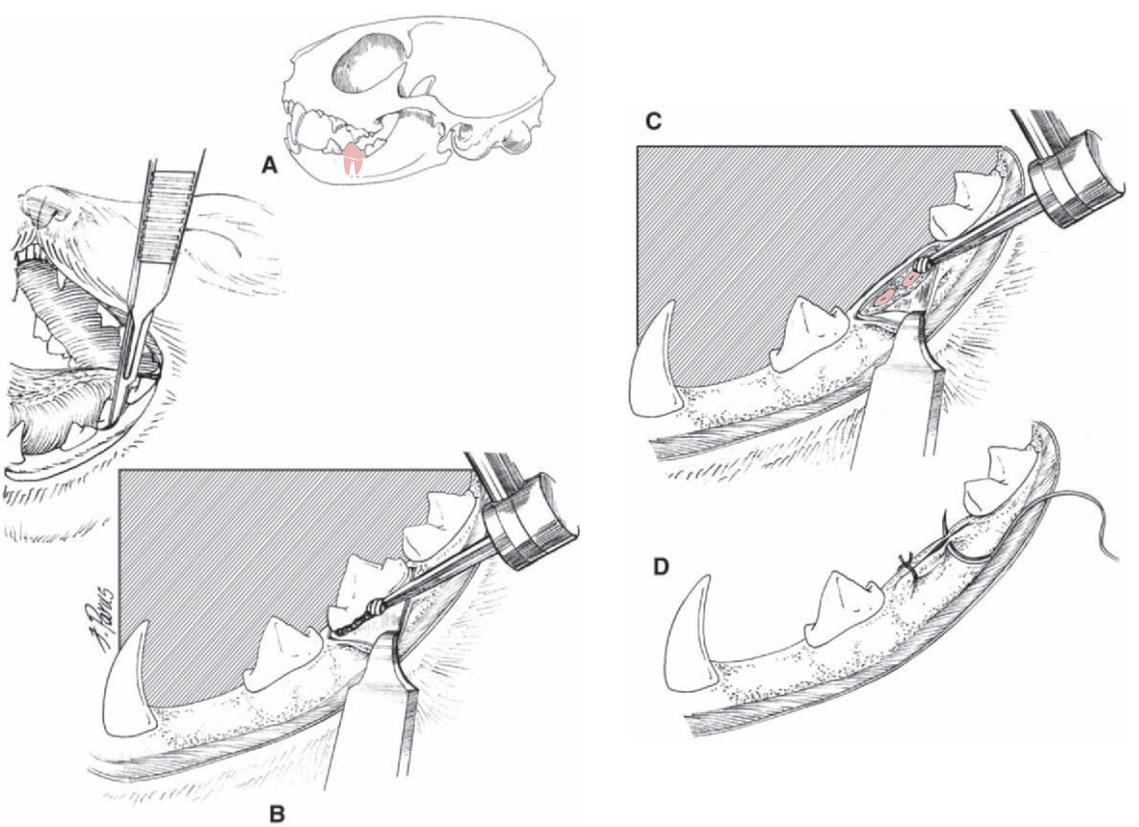

Figure 64-7.

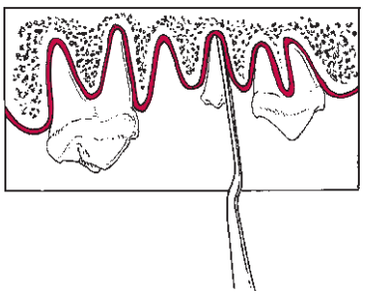

Figure 64-8. Elevation of root tip with root tip pick.

Damage to Permanent Teeth

▼ ***Key Point*** Permanent teeth may be damaged during the extraction of deciduous teeth.

Careful extraction of deciduous teeth can help minimize this complication. However, extraction of deciduous teeth before complete formation of the permanent crowns (especially at 8–12 weeks of age) can result in enamel hypocalcification, enamel hypoplasia, crown deformity, and eruption failure.

Misplaced Tooth or Root Tip

A tooth or root tip infrequently may be misplaced in the nasal cavity or mandibular canal during an extraction. Advanced periodontal disease in combination with aggressive extraction techniques can force a tooth or root tip into the nasal cavity or mandibular canal.

- Enlarge the defect in the floor of the extraction site to remove a misplaced tooth or root tip.

Iatrogenic Fractures

Severe periodontal disease, inappropriate extraction techniques, and metabolic bone disease in geriatric animals may be predisposing factors in iatrogenic mandibular fractures.

- Careful elevation of the tooth, digital support of the mandible during extraction, and a rotational movement with the dental extractor can help prevent iatrogenic mandibular fractures.

Osteomyelitis and Bony Sequestra

Osteomyelitis following extraction of teeth may be caused by retained tooth roots, exposed alveolar bone, and osseous necrosis. A bone sequestrum may develop when a segment of alveolar bone is fractured off during a dental extraction and left in the extraction site.

- Treat osteomyelitis and bony sequestra by removing retained tooth roots and bony sequestra and by curettage of necrotic bone to the level of healthy, bleeding bone and closing extraction site with a mucoperiosteal flap.

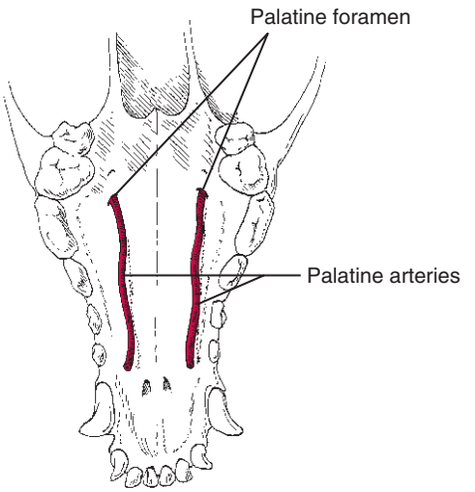

Figure 64-9. Palatine arteries.

Ophthalmic Complications of Dental Extractions

Inappropriate techniques during extraction of the maxillary fourth premolar and the first and second molars in dogs may result in severe ophthalmic complications caused by penetration of the elevator into the orbit or globe, causing orbital cellulitis, orbital abscess, or endophthalmitis.

- Prevent ophthalmic complications of dental extractions by using a finger stop near the tip of the elevator during extraction of the maxillary fourth premolar and the first and second molars to prevent deep penetration of the elevator into orbital tissues or the globe.

Oronasal Fistulas and Palatal Defects

Oronasal fistulas are abnormal communications between the oral and nasal cavity. Palatal defects may occur anywhere in the palate and result in a communication between the oral and nasal cavities.

Anatomy

▼ ***Key Point*** Oronasal fistulas are associated most frequently with defects in the area of the maxillary canine tooth.

The surgical anatomy varies with the location of the defect. The mucoperiosteal flap used in the repair of oronasal fistulas extends from the margins of the defect across the mucogingival line (the anatomic landmark separating the attached gingiva from the alveolar mucosa). Surgical techniques used to repair defects in the hard palate often require preservation of the palatine arteries, which arise approximately 1 cm palatal to the maxillary fourth premolar and course rostrally along the hard palate (Fig. 64-9).

Etiology

Palatal defects may be congenital or acquired.

Congenital Defects

Congenital palatal defects occur primarily in brachiocephalic breeds, miniature schnauzers, cocker spaniels, beagles, and cats. Congenital abnormalities of the primary palate (incisive bone) are referred to as a hare lip. These defects may occur concomitantly or independent of secondary palate (hard and soft palate) abnormalities.

Acquired Defects

- Acquired palatal defects are most frequently caused by a deep maxillary periodontal pocket that has progressed toward the apex of the tooth, resulting in lysis of the thin layer of bone that separates the palatal aspect of the root of the maxillary tooth and the nasal cavity.
- Acquired palatal defects that have etiologies other than dental disease usually are located in the hard palate and may be caused by various types of trauma including dog bites, blunt head trauma, electrical shock, gunshot wounds, foreign body penetration, and pressure necrosis. They also may occur as a complication of maxillectomy for oral neoplasia.

Clinical Signs

- Clinical signs associated with oronasal fistulas and palatal defects include unilateral or bilateral mucopurulent and occasionally hemorrhagic nasal discharge.
- Animals often are presented because of recurrent episodes of sneezing, especially after eating.

Diagnosis

- Identify defects in the hard palate by an oral examination.
- Perform a thorough periodontal examination to identify oronasal and oroantral fistulas secondary to periodontal disease. This requires tranquilization or general anesthesia.
- Insert a periodontal probe into the suspected periodontal pocket, which often is located on the palatal aspect of the maxillary canine tooth but may be located anywhere along the periodontal ligament of the maxillary cheek teeth.
- If the probe penetrates easily into the nasal cavity the presence of an oronasal fistula is confirmed.

Preoperative Considerations

▼ ***Key Point*** Tube- or bottle-feed animals with congenital hard palatal defects until they are 3 to 4 months of age to decrease the incidence of inhalation pneumonia.

- Perform surgery when the animal is 3 to 4 months of age following thoracic radiography to check for pneumonia.
- Give animals with severe, purulent rhinitis or pneumonia antibiotics before surgery.

Surgical Procedure

Two techniques used frequently for the repair of oronasal fistulas are the single-layer and the double-layer mucoperiosteal flap. The overlapping flap technique is used frequently for the repair of hard palatal defects.

Objectives

- Maintain blood supply to the tissue.
- Provide a tension-free closure of the defect.

Equipment

- Standard general surgical instruments and suture
- Periosteal elevator

Single-Layer Mucoperiosteal Flap

Technique

1. Place the animal in lateral recumbency.
2. Remove the epithelial margin of the fistula with a #15 scalpel blade.
3. Make two divergent incisions in the mucosa, beginning at the mesial and distal aspects of the fistula and extending across the mucogingival line (Fig. 64-10*A*).
4. Using a periosteal elevator, gently raise the flap (Fig. 64-10*B*).
5. Reflect the flap apically and incise the deepest layer of the flap (the periosteal layer) the entire width of the flap at its most dorsal aspect (Fig. 64-10*C*).
6. If necessary, remove excess buccal bony plate and sharp edges of bone with a rongeur or dental bur to permit tensionless apposition of tissues (Fig. 64-10*D*).
7. Before closure, remove all debris and granulomatous tissue with a bone curette, and irrigate the surgical site with sterile saline.
8. Suture the flap to the palatal and gingival mucosa with 3-0 or 4-0 poliglecaprone (Monocryl) in a simple interrupted pattern (Fig. 64-10*E*).

Double-Layer Mucoperiosteal Flap

- Use to repair large chronic or recurrent oronasal fistulas.

Technique

1. Remove the mesial, distal, and buccal epithelial margins of the fistula with a #15 blade. Do not remove the palatal epithelial margin.
2. Elevate an elliptical palatal mucoperiosteal flap with a periosteal elevator, preserving the lateral attachment of the base of the flap (Fig. 64-11*A*).

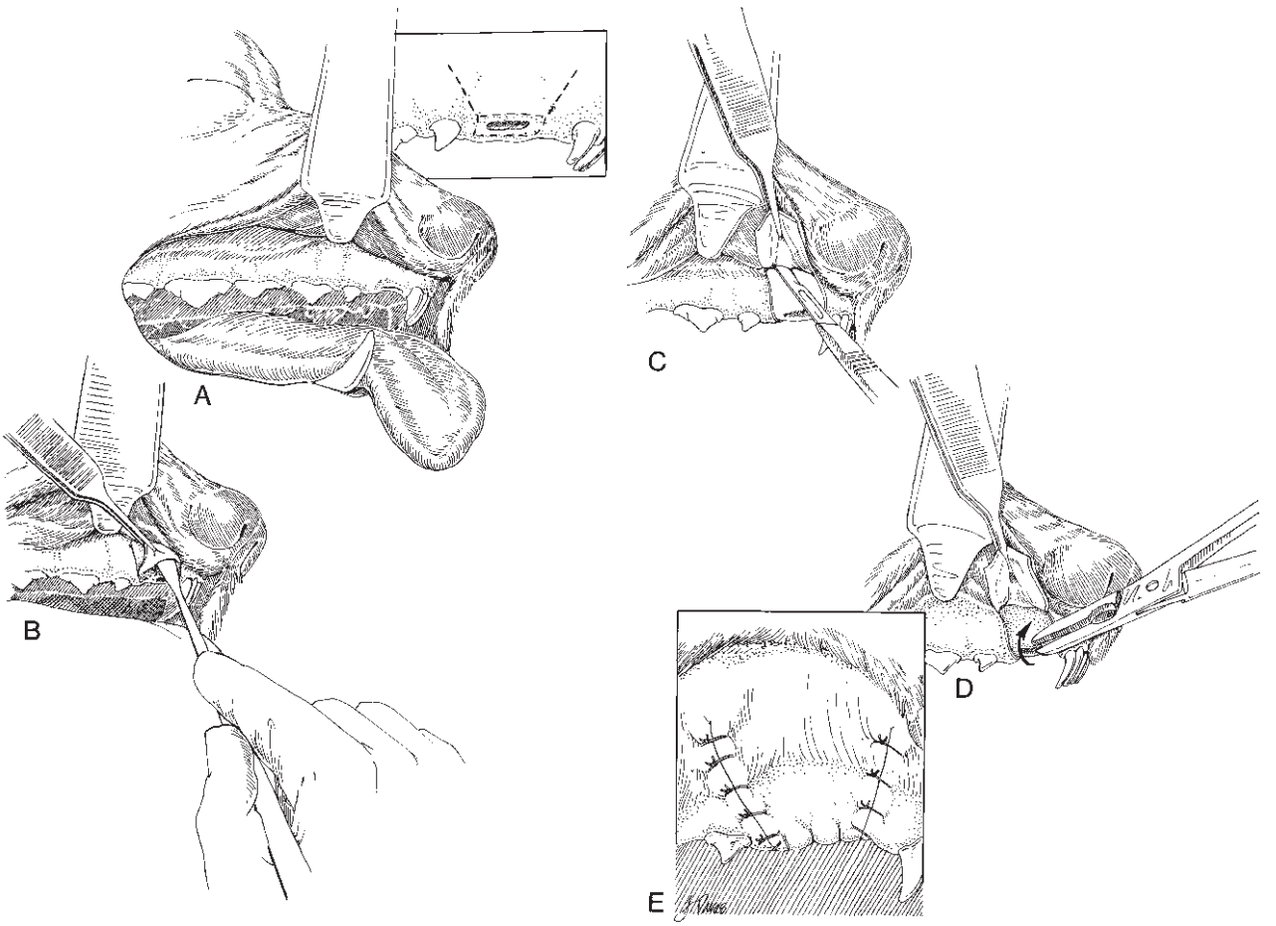

Figure 64-10. *A,* Proposed incision sites in mucosa for oronasal fistula repair. *B,* Elevation of mucoperiosteal flap. *C,* Incision of periosteal layer of flap. *D,* Removal of rough edges of buccal alveolar bone with rongeurs or round bur. *E,* Mucoperiosteal flap is replaced and sutured.

3. Fold over and suture the flap to the periosteum of the edge of the defect with 3-0 or 4-0 poliglecaprone (Monocryl) in a simple interrupted pattern (Fig. 64-11*B*).
4. Elevate a buccal mucoperiosteal flap from the lateral aspect of the oronasal fistula (see Fig. 64-10*C*).
5. Advance the buccal mucoperiosteal flap palatally to cover the inverted flap and the denuded palatine bone (Fig. 64-11*C*).
6. Suture the flap to the palatal and gingival mucosa with 3-0 or 4-0 poliglecaprone (Monocryl) in a simple interrupted pattern (Fig. 64-11*D*).

Overlapping Flap Technique

- Use for repair of hard palatal defects, especially on the midline.

Technique

1. Make an incision the length of the palatal defect in the palatal mucosa just palatal to the maxillary dental arcade. The rostral and caudal aspects of these incisions are connected to the rostral and caudal aspects of the hard palatal defect (Fig. 64-12*A*).
2. Incise the opposite side of the palatal defect along the entire length of the defect and gently elevate with a periosteal elevator to create a recipient site for the mucoperiosteal flap. Carefully elevate the mucoperiosteal flap with a periosteal elevator, preserving the palatine artery (see Fig. 64-9) that arises approximately 1 cm palatal to the upper fourth premolar (Fig. 64-12*B*).
3. Hinge the mucoperiosteal flap at the end of the palatal defect and place beneath the mucosa on the other side of the defect.
4. Preplace 3-0 PDS (polydioxanone) sutures in an interrupted vest-over-pants suture pattern through the recipient site and the flap.
5. Tie the sutures from caudal to rostral to complete the procedure (Fig. 64-12*C*).
6. Make an incision along the edges of the soft palatal defect and close in two layers by apposing nasal

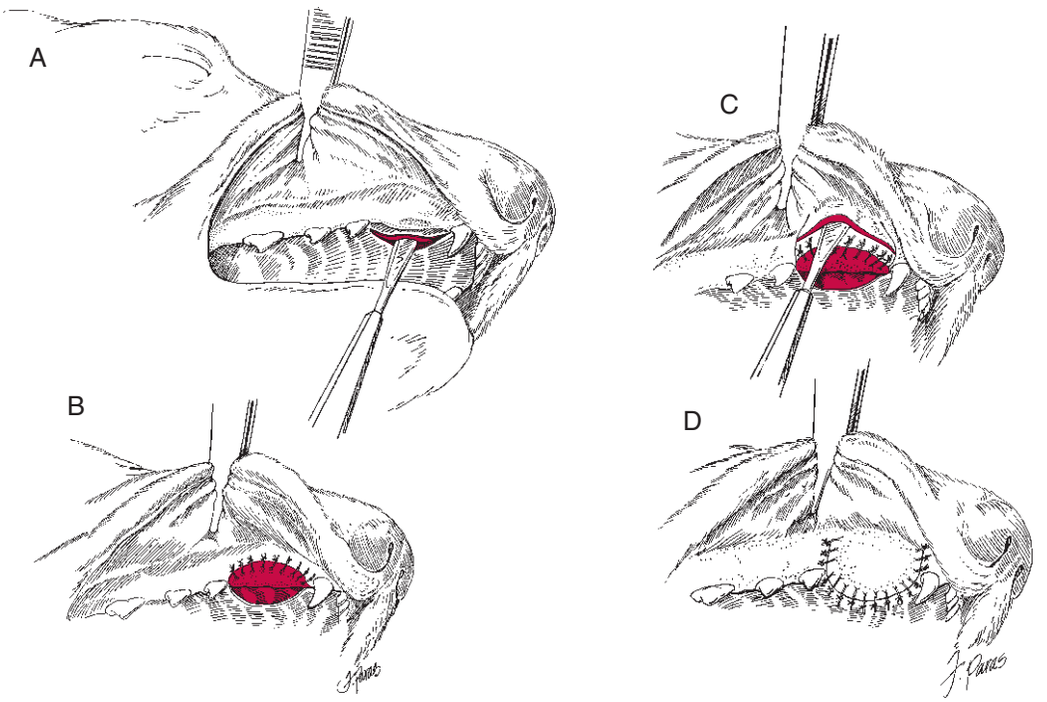

Figure 64-11. *A,* Periosteal elevation of palatal flap. *B,* Palatal flap is sutured to debrided edges of defect. *C,* Buccal mucoperiosteal flap is elevated and advanced palatally. *D,* Flap is sutured to palatal and gingival mucosa.

mucosa to nasal mucosa with the knots in the nasopharynx and oral mucosa to oral mucosa with the knots in the oral cavity.

Postoperative Care and Complications

- Feed a soft diet (gruel or liquid) for 2 to 3 weeks. For animals requiring complicated repair, consider using esophagostomy or gastrostomy tube feeding (see Chapter 3). Place Elizabethan collars on patients that paw at the oral cavity.
- In 3 weeks, reexamine the patient to assess the integrity of the repair.
  - If the repair is intact, gradually return to a normal diet over the next 2 to 3 weeks.
  - If the repair was unsuccessful, schedule a second operation in approximately 4 weeks.

PERIODONTAL DISEASE

▼ ***Key Point*** Periodontal disease is the most common cause of oral infection and tooth loss in dogs.

- Periodontal disease occurs in two forms: gingivitis and periodontitis. Gingivitis is a reversible inflammation of the gingiva. Periodontitis involves deeper inflammation with loss of tooth support and permanent damage.
- The purpose of periodontal therapy is to prevent gingivitis from progressing to periodontitis and to delay the progression of periodontitis once it is established.

Anatomy

The periodontal tissues are composed of the gingiva, cementum, periodontal ligament, and alveolar bone. An accurate estimate of the amount of support that has been lost around a tooth depends on the appropriate

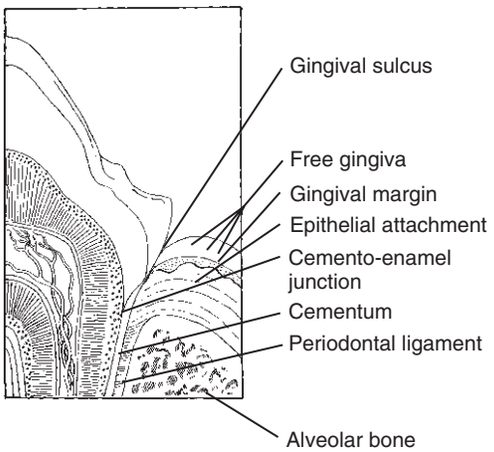

Figure 64-13. Normal periodontal anatomy.

use of a periodontal probe and the recognition of a few anatomic landmarks.

- Locate the cemento-enamel junction that separates the anatomic crown from the anatomic root, 1 to 2 mm below the normal gingival margin (Fig. 64-13).
- The free gingival margin, an important anatomic landmark when assessing periodontal disease, is the highest point of gingival tissue that lies on the tooth. In normal tissues, the free gingival margin is just above the CEJ (see Fig. 64-13).
  - When gingival recession is present, the free gingival margin is below the CEJ.
  - In cases of gingival hyperplasia, it is >2 mm above the CEJ.
- Measure and record the depth of the pocket in millimeters. Also note the relationship of the free gingival margin to the CEJ. These values will adequately assess the level of attachment and thereby dictate the appropriate therapy.

Etiology

- Periodontal disease is initiated by an accumulation of large amounts of bacteria at the junction of the tooth and the gingiva. Prolonged retention of these bacteria results in a change of the predominant flora from gram-positive aerobic coccoid bacteria to more motile gram-negative anaerobic rod-shaped bacteria.
- Tissue destruction occurs secondary to inflammation, resulting in a loss of periodontal support. Over a period of time (usually years), the presence of plaque, calculus, and gingivitis results in loss of periodontal support.

Clinical Signs

- Common signs include mobile teeth, periodontal and periapical inflammation, facial swelling, periodontal pockets, nasal discharge, and oronasal fistulas.
- Severe gingival sulcus hemorrhage, pathologic mandibular fractures, intranasal tooth migration, painful contact buccal mucosal ulcers, osteomyelitis, and ophthalmic manifestations of periodontal disease develop infrequently.

Diagnosis

The diagnosis of periodontal disease is based on a thorough oral and periodontal examination and dental radiography.

Gingivitis

- Animals with gingivitis have swollen gingival margins that bleed after the application of light pressure. Serous or purulent exudate may be produced from the gingival sulcus. Halitosis commonly is present.
- Examination with a periodontal probe demonstrates no attachment loss and there is no radiographic evidence of bone loss around the teeth.

Periodontitis

- Hyperplasia and gingival recession are seen, as well as severe gingival inflammation with various amounts of calculus and debris.
- Periodontal probing reveals periodontal pockets that can progress to tooth loss if untreated.
- Dental radiographs can identify bone loss, which most frequently is horizontal or parallel to the cemento-enamel junction (CEJ), which separates the crown from the root. The bone loss may also be vertical or parallel to the long axis of the root.

Preoperative Considerations

- Prior to treatment, a thorough physical examination and clinical laboratory testing are recommended to rule out concurrent disease.
- In severe cases, administer perioperative broad-spectrum antibiotics (amoxicillin clavulanate). Initiate antibiotic therapy before the dental procedure so that adequate blood levels are present during the dental procedure.

Surgical Procedures

Several procedures are used to treat periodontal disease. These include scaling, root planing, subgingival curettage, polishing, gingivectomy, and open-flap curettage.

Dental Scaling

Dental scaling can be divided into two main categories: supragingival and subgingival.

Supragingival Scaling

This involves the removal of calculus located above the gingival margin. It is most easily performed with a power scaler.

Technique

1. A universal tip is most appropriate for use in small animals.
2. Place the side of the tip below the edge of the calculus and gently lift to remove calculus.
3. Move the tip gently across the surface of the tooth with a paint brush–type movement.
4. Continuously move the tip across the dentition during scaling; never hold it on one tooth continuously for more than 10 to 15 seconds.
5. Spray copiously with water to prevent overheating of the tooth and to wash away dislodged calculus.

Subgingival Scaling

Following supragingival scaling, perform subgingival scaling, root planing, and curettage with a power scaler designed for subgingival scaling, hand scalers, and curettes.

Technique

1. Use a power scaler such as a piezoelectric scaler subgingivally with a light touch, copious water spray, and constant motion to remove the major portion of subgingival calculus. Alternatively, hand scalers may be used.
2. With a hand instrument such as the Columbia 13/14 curette, complete the root cleaning. Place the curette at the bottom of the pocket, then engage the root with the edge of the curette and pull the curette coronally along the surface of the root (Fig. 64-14).
3. Continue subgingival scaling and root planing (scaling of the root) until the root is smooth and clean.
4. Following removal of subgingival calculus, record areas of pathologic deepening (>3 mm) on a dental chart.
5. Perform subgingival curettage by gently scraping the soft tissue lining of the pocket with a sharp curette until all epithelial and granulation tissue is removed.

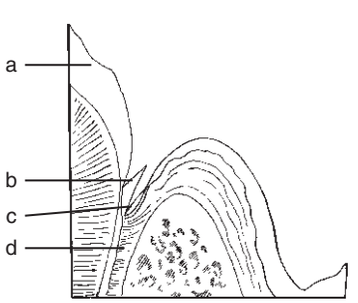

Figure 64-14. Cross section of curette placed beneath calculus for subgingival scaling: (a) enamel, (b) calculus, (c) curette in cross section, (d) periodontal ligament.

Polishing Technique

1. Place a prophylaxis angle on a slow-speed handpiece. Fill the cup with medium-grit prophylaxis paste.
2. Rotate the cup over the entire exposed surface of the teeth, smoothing the surface of the enamel.
3. Rinse the teeth with forced air and water spray to remove any residual debris.

Gingivectomy

Gingivectomy is the resection of unsupported gingival tissue. This technique is used to eliminate periodontal pockets greater than 5 mm deep that are caused by horizontal bone loss. Gingivectomy is also used to remove hyperplastic gingival tissue and for harvesting gingival biopsies.

▼ ***Key Point*** Do not perform gingivectomy unless sufficient attached gingiva (>3 mm) can be retained following the procedure, because removal of tissue below this point may result in dehiscence of the gingiva.

Technique

1. With a periodontal probe, mark the depth of the periodontal pocket on the gingiva opposite the affected tooth (Fig. 64-15*A*).

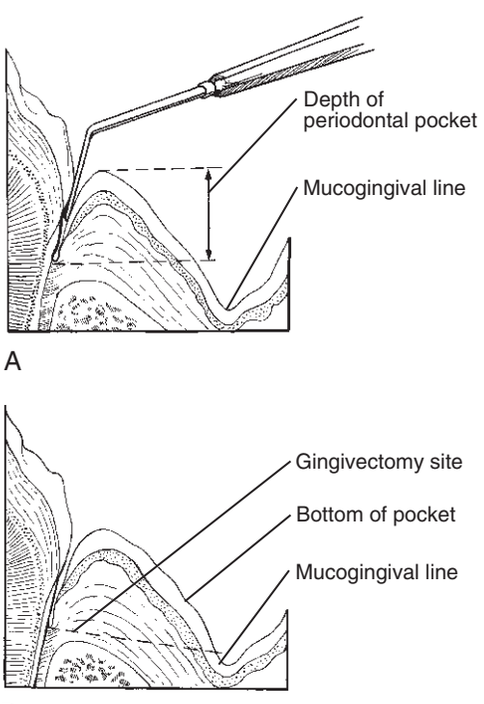

Figure 64-15. *A*, Periodontal probe measures pocket depth. *B*, Proposed gingivectomy site.

2. Make a beveled incision in the gingiva, slightly apical to the pocket mark, to create a natural gingival contour to the gingiva following the gingivectomy (Fig. 64-15*B*). The incision can be made with a gingivectomy knife, scalpel blade, or electrosurgery tip. If electrosurgery is used, surgical cutting modes are recommended.
3. Following removal of excessive hyperplastic tissue and pocket elimination, scale and polish the exposed tooth surface.

Open-Flap Curettage

This technique is used to treat periodontal pockets that extend beneath the level of the alveolar crest. Open-flap curettage permits access to intrabony defects without loss of attached gingiva.

Technique

1. Make an incision with a #11 or #15 scalpel blade 1 to 2 mm from the tooth and directed toward the alveolar crest (Fig. 64-16*A*).
2. Make a scalloped incision on the buccal and lingual or palatal surfaces of the affected tooth, dipping interproximally (between the teeth) to preserve most of the gingival tissue.
3. Elevate the mucoperiosteal flaps 3 to 5 mm from the edge of the incision, using a sharp periosteal elevator (Fig. 64-16*B*).
4. Remove the collar of gingival tissue around the tooth with curettes.
5. Perform scaling and root planing on the exposed tooth surface.
6. Polish the tooth and liberally irrigate the area with sterile saline.
7. Reposition the flaps and hold in place with 4-0 chromic catgut sutures in a simple interrupted pattern, placed interdentally (Fig. 64-16*C*).

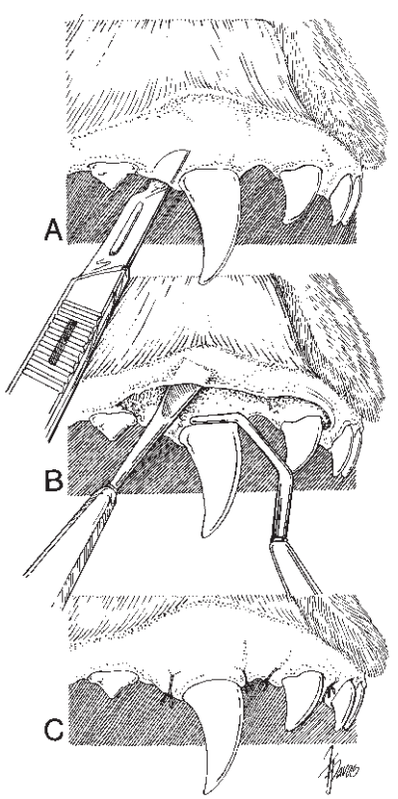

Figure 64-16. *A,* Open-flap curettage is initiated with an incision directed toward the alveolar crest. *B,* Mucoperiosteal flaps are elevated 3–5 mm to permit open curettage. *C,* The flaps are repositioned with 4-0 chromic sutures.

Postoperative Care and Complications

- To retard the recurrence of plaque and calculus accumulation, instruct the owner to irrigate the animal's mouth with a 0.2% chlorhexidine solution (CET chlorhexidine solution; Virbac, Fort Worth, TX) for 2 weeks. Additionally, recommend daily toothbrushing with CET toothpaste (Virbac, Fort Worth, TX).
- If significant stomatitis (discussed later in this chapter) or abscess secondary to periodontal disease occurs, give broad-spectrum antibiotics such as amoxicillin clavulanate (Clavamox, Pfizer, 14 mg/kg PO q12h).
- Reevaluate the animal in 2 weeks. Annual or semiannual scaling is recommended.
- Complications are minimal when procedures are properly performed.

▼ ***Key Point*** Prolonged application of an ultrasonic tip to a tooth without adequate water spraying can result in pulpal necrosis.

- Failure to remove subgingival calculus adequately can result in progressive periodontal disease.
- Inadequate irrigation of the gingival sulcus following therapy can result in entrapment of debris subgingivally and subsequent periodontal abscess.

ENDODONTIC DISEASE

Endodontic disease refers to disease of the pulp (the inner aspect of the tooth). It occurs frequently in small animals and may cause significant pain. Pulp cap, pulpotomy, apexogenesis, apexification, and nonsurgical and surgical endodontic therapy can result in the resolution of endodontic disease and retention of a functional, painless tooth.

Anatomy

Surgical anatomy varies with each tooth. The endodontic system is divided into two parts: the pulp chamber and the pulp canal.

- The endodontic system generally follows the external anatomic contours of the tooth, including its root structure.
- The size of the endodontic system also varies with the age of the patient. Young animals have immature teeth with open apices. As the tooth develops, the apex is formed and, as the tooth matures, the dentinal layer thickens, resulting in a thinner endodontic system.

Etiology

- The most common cause of endodontic disease in small animals is a fractured tooth with pulpal exposure.
- Less common causes include rapid dental attrition (tooth wear), deep odontoclastic resorptive lesions in cats, deep dental caries, severe periodontal disease with secondary endodontic disease, and dental trauma with secondary internal pulpal hemorrhage or damage to the apical vessels.

Clinical Signs

Pulpal exposure can result in the progressive development of the following conditions:

- Bacterial pulpitis
- Pulp necrosis
- Periapical granuloma
- Periapical inflammation
- Acute alveolar periodontitis
- Osteomyelitis
- Sepsis

The time required for this progression varies from months to years. When a tooth is fractured and the pulp is exposed, the pulp will bleed.

▼ ***Key Point*** Pulpal exposure is extremely painful, and animals with a fractured tooth with pulpal exposure may hypersalivate, may be reluctant to eat, and may exhibit other abnormal behaviors.

Over a period of several months, the pulp becomes necrotic and the animal no longer has signs of pain until an inflammatory reaction occurs around the apex of the tooth, at which time the pain recurs.

Diagnosis

The diagnosis is based on a thorough oral examination and dental radiography.

Physical Examination

- Differentiate teeth suspected of being diseased secondary to fractures from worn teeth. Worn teeth, or dental attrition, rarely result in pulpal exposure.
  - A dental explorer will penetrate into the pulp canal when the pulp is exposed.
  - When dental attrition is the cause of a shortened crown, the explorer will not penetrate the tooth but will be stopped by the reparative dentin, or "brown spot," that fills in the area of receded pulp.
- Evaluate the color of the tooth. A discolored tooth (red, purple, or gray) may be diseased.
- Percussion of a tooth with endodontic disease may be painful because of periapical inflammation.
- Soft tissue fistulas may occur secondary to endodontic disease. Usually they are located apical to the mucogingival line. When probed, they will be found to originate from the apex of an endodontically diseased tooth.
- Severe maxillary or mandibular swelling may be present with endodontic disease when the disease process has progressed to severe periapical inflammation and/or osteomyelitis.

Radiography

Perform dental radiography to delineate the endodontic system and confirm endodontic disease. Radiography reveals the stage of apical development.

- Chronic endodontically diseased teeth have an area of periapical lysis around one or more roots.
- When soft tissue fistulas are present, radiopaque material such as a gutta percha point may be placed into the fistula before radiography to confirm that the fistula arises from the apex of the affected tooth.

Preoperative Considerations

- Examine the teeth for concurrent periodontal disease with a periodontal probe.

▼ ***Key Point*** Teeth with combined periodontal and endodontic lesions have a poorer prognosis than teeth with only endodontic lesions.

Surgical Procedures

Numerous endodontic procedures are available (Table 64-7). The type selected depends on the status of the endodontic system and the following factors:

- Vital pulp versus non-vital pulp
- Mature versus immature tooth
- Closed versus opened apex
- Exposure time

Partial Coronal Pulpectomy (Pulpotomy) with Direct Pulp Capping

This procedure is used when the pulp of a vital tooth is exposed during a dental procedure or when the pulp of an immature tooth has been recently exposed.

Table 64-7. ENDODONTIC PROCEDURES RECOMMENDED FOR COMMON ENDODONTIC PROBLEMS PROCEDURE INDICATION

Pulp cap	Vital tooth with iatrogenic pulpal exposure
Pulpotomy and apexogenesis	Vital immature tooth with open apex and traumatic pulpal exposure <5 days
Apexification	Immature nonvital tooth with open apex
Nonsurgical root canal	Nonvital mature tooth with closed apex
	Vital mature tooth with prolonged pulpal exposure
Surgical root canal	Nonvital mature tooth with apical lysis
	Unsuccessful nonsurgical root canal

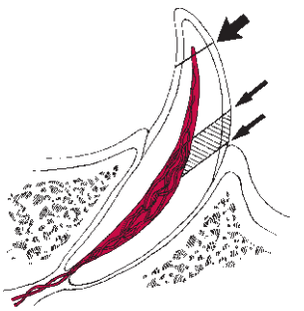

Figure 64-17. *Large arrow* points to fracture site; *small arrows* show straight access site to apex.

Technique

1. Flush the tooth with 0.2% cholorhexidine solution.
2. Remove approximately 6 to 8 mm of the most coronal aspect of the pulp with a diamond pear-shaped bur.
3. Flush the remaining pulp with sterile saline.
4. Control pulpal hemorrhage with the blunt end of point points moistened with saline.
5. Apply a layer of mineral trioxide aggregate (ProRoot, Dentsply Tulsa Dental, Tulsa, OK) to the exposed pulp with a sterile amalgam carrier.
6. Apply an intermediate layer of flowable glass-ionomer (Vitrebond, 3M EPSE, St. Paul, MN).
7. Apply a final layer of compactible composite material (Prodigy, sdsKerr, Orange, CA).

Apexogenesis

This endodontic procedure allows the root to continue to grow. Apexogenesis is useful in cases in which apical development and closure are not complete and the pulp is not irreversibly compromised. Maintenance of vitality of an immature tooth is desirable so that the tooth will continue to develop, resulting in a thicker dentinal layer and a formed apex.

Technique

Remove the involved or injured portion of the pulp and treat as described for pulpotomy.

Apexification

This procedure is used in the treatment of immature teeth in which there is an absence of vital tissue. Teeth in which early pulp death has occurred have large open apices, making root canal filling by non-surgical techniques difficult. Apexification permits closure of the apex by cementum formation, which is stimulated by the application of mineral trioxide aggregate.

Technique

1. Remove the necrotic contents of the immature root canal just short of the radiographic apex with endodontic files. During debridement, do not disrupt the root-forming tissues beyond the apex.
2. Irrigate the canal with 2.5% sodium hypochlorite solution and then rinse with sterile saline.
3. Carefully dry the canal with pre-measured paper points to prevent penetration beyond the apex, which can result in additional hemorrhage.
4. Apply mineral trioxide aggregate into the apical aspect of the root canal with a sterile carrier, and condense gently with a sterile plugger.
5. Mix calcium hydroxide powder and sterile saline to a thick consistency and fill remainder of canal.
6. Restore the access site with a temporary filling material and take a dental x-ray.
7. In 4 weeks remove the temporary filling and the calcium hydroxide and complete treatment by performing a non-surgical root canal procedure.

Non-surgical (Conventional) Root Canal

This procedure is used to treat non-vital mature teeth with closed apices and vital mature teeth with pulpal exposure of greater than 8 hours.

▼ ***Key Point*** Non-surgical root canal therapy is preferable to partial coronal pulpectomy (pulpotomy) with direct pulp capping in mature teeth because of a higher success rate associated with non-surgical root canal therapy. Non-surgical root canal therapy is preferable to surgical treatment in most cases of endodontic disease because of its relative ease and speed of completion, non-invasive nature, and relative decreased cost.

Technique

1. Using a #1 or #2 round bur, obtain access to the pulp at a point that will permit straight delivery of the files to the apex of the tooth (Fig. 64-17).
2. Enlarge the access site with orifice shapers.
3. Begin debridement of the canal with a #15 file inserted to the apex of the tooth. Use a rubber stop to mark the length of the file, and insert all subsequent files to that depth.

4. Introduce progressively larger files into the canal. Flush the canal with 2.5% sodium hypochlorite solution before changing files.
5. Debridement is complete when white dentinal shavings are present on the file and there is no further bleeding from the canal. An alternative technique to hand filing canals is an engine-driven rotary file system (Light Speed Endodontics, San Antonio, TX).
6. Flush canal with sterile saline.
7. Dry the canal with paper points.
8. Apply a sealer (AH Plus, Dentsply, Konstanz, Germany) into the canal with a paper point or endodontic file rotated in a counter-clockwise direction.
9. Obturate (fill) the root canal with gutta percha.
   a. Gutta percha may be applied using a vertical condensation using hot gutta percha. In this technique small amounts of hot gutta percha (Successfil, Hygenic) are placed on the end of a sterile file and rotated counterclockwise into the canal and then vertically condensed with a plugger. This process is repeated until the canal is adequately filled.
   b. An alternative technique for preparing and filling canals is the Light Speed and SimpliFil technique (Light Speed Endodontics, San Antonio, TX) in which a 5 mm gutta percha plug is placed in the apex followed by a solitary gutta percha master cone.
10. Remove any excess gutta percha and sealer from the access site.
11. Apply a restorative material such as a compactible composite (Prodigy, sdsKerr, Orange, CA) to the access site to complete the procedure.

Surgical (Non-conventional) Endodontic Therapy

This is the treatment of endodontic problems with an approach through oral soft tissue and bone rather than through the crown of the tooth. In a non-surgical root canal procedure, the pulp canal is accessed by the crown only.

Indications for surgical endodontic therapy include

- Apical root resorption
- Incomplete root development
- Complications during conventional root canal therapy (broken files)
- Recurrent apical abscessation following non-surgical root canal therapy (recurrent swelling over the apex of the tooth root or periapical draining fistulous tracts)
- Size, length, or curvature of the canal that makes instrumentation impossible

Technique

1. Perform a conventional root canal procedure before surgical endodontic therapy. Do not flush or fill the canal, if the apex is open, until the periapical tissues around the apex are packed off with cotton pellets.
2. An apical approach for most teeth is through a mucoperiosteal incision just apical to the mucogingival line. However, access to the apex of the mandibular canine is most easily gained through a cutaneous incision overlying the ventral border of the mandible.
3. Access to the apex is achieved by removing the alveolar bone overlying the apex with a #4 or #6 round bur.
4. Perform apical curettage to remove necrotic and fibrotic granulation tissue surrounding the periapical region.
5. Perform an apicoectomy (amputation of the apex of the tooth) using a #701 bur. The exposed face of the cut root tip is beveled at a 45° angle to increase exposure of the canal access site.
6. Flush the periapical region with sterile saline solution.
7. Pack the periapical region with #0 cotton pellets or a hemostatic agent to control hemorrhage.
8. Create an undercut in the root canal of the apex with a #33 inverted cone bur.
9. Place at least a 4-mm layer of mineral trioxide aggregate (ProRootMTA, Dentsply Tulsa Dental, Tulsa, OK) in the apical end of the canal, using a retrograde carrier, and condense the MTA with a small plugger.
10. Before closure, remove all cotton pellets and flush the periapical region with sterile saline solution.
11. Reposition the mucoperiosteal flap and suture with 3-0 chromic catgut in a simple interrupted pattern. Procedures involving the mandibular canine teeth are closed with non-absorbable suture material in the skin.

Postoperative Care and Complications

- Immediately following endodontic therapy, take a radiograph to document and assess the procedure.
- Administer a broad-spectrum antibiotic, such as amoxicillin clavulanate, for 1 week.
- Reexamine and radiograph the treated tooth 6 months postoperatively, and then annually, to evaluate the success of the endodontic therapy.

Intraoperative Complications

Intraoperative complications usually are associated with improper use of instrumentation or inappropriate technique. Examples are:

- Broken endodontic files lodged in the root canal
- Perforation of the root canal or pulpal floor

Postoperative Complications

Postoperative complications usually are associated with improper technique, inadequate apical seal, or inadequate follow-up.

- Vital endodontic procedures such as partial coronal pulpectomy (pulpotomy) with direct pulp capping and apexogenesis require oral and radiographic reevaluations 3 to 6 months postoperatively and then annually. If there are persistent signs such as periapical swelling, periapical fistulas, painful tooth percussion, and progressive radiographic periapical lysis in teeth previously treated with vital endodontic techniques, repeat treatment with non-vital techniques.
- Non-vital techniques include apexification and nonsurgical and surgical root canal therapy.
  - Perform surgical root canal therapy on teeth unsuccessfully treated with apexification and nonsurgical root canal techniques.
  - If there is persistent endodontic pathology following surgical root canal therapy, retreatment or extraction is recommended.

ORTHODONTIC DISEASE

Orthodontic disease refers to malocclusions. Veterinary orthodontics involves the movement and repositioning of teeth to a more normal position.

▼ ***Key Point*** Veterinary orthodontic therapy is indicated to alleviate traumatic malocclusions that result in pain or in an inability to function or eat; it should not be used to correct cosmetic or genetic dental alignment defects.

Etiology

The majority of malocclusions are genetic in origin. Previous trauma or an eruption pattern discrepancy resulting from retained deciduous teeth may also result in a malocclusion of the permanent dentition.

Clinical Signs

Clinical signs depend on the severity of the malocclusion.

- Animals with pronounced prognathic occlusion (mandibular teeth are rostral to their normal position in relation to the maxillary dentition) may be presented because of difficulty in prehending food. This condition is not severe enough to cause nutritional problems.
- Animals with brachygnathic occlusion (maxillary teeth are rostral to their normal position in relation to the mandibular dentition) may be presented because of drooling, but this is usually not severe.
- The majority of dental malocclusions are cosmetic and cause no clinically significant problems. However, animals with lingually displaced mandibular canines may have painful palatal defects caused by traumatic occlusion.
- A dental malocclusion in which one tooth traumatically occludes against another tooth can result in dental attrition of the affected teeth.

Diagnosis

The diagnosis is based on a thorough oral examination. Assess the following factors:

- Incisor relationship: The maxillary incisors should overlap the labial surface of the mandibular incisors.
- Canine tooth relationship: The lower canines should be centered between and not touching either the maxillary canine or the maxillary lateral incisor.
- Mandibular fourth premolar: The large cusp of the lower fourth premolar should be centered between the upper third and fourth premolar.
- Interdigitation of other premolars: The cusp tips of the maxillary premolars should interdigitate with the cusp tips of the mandibular premolars.
- Premolar horizontal alignment: The space between the maxillary and mandibular premolars should have good horizontal alignment.
- Head symmetry: The midlines of the maxillary and mandibular dental arches are centered over each other, and these must also be in alignment with the midplane of the head.

Deviations from these criteria for normal occlusion result in malocclusions of varying severities.

Orthodontic Principles

Tipping is the most common type of corrective movement used in veterinary orthodontics. A single force is applied to the crown of a tooth, resulting in a tipping action. During orthodontic movement, alveolar bone is *resorbed* (osteoclastic activity) on the side of the tooth with less tension on the periodontal ligament. Conversely, alveolar bone is *deposited* (osteoblastic activity) on the side of the tooth with more tension on the periodontal ligament.

Preoperative Considerations

Prior to correction of orthodontic defects, attempt to determine the etiology of the problem. Correction of genetically induced, cosmetic orthodontic defects is contraindicated. Attempt to correct orthodontic defects resulting in a traumatic occlusion. The timing of orthodontic movement is important.

▼ ***Key Point*** Delay orthodontic movement until the animal is 1 to 2 years of age unless simple, quick interceptive movements of the tooth can be achieved.

Surgical Procedures

▼ ***Key Point*** Extraction of overly retained deciduous teeth can prevent malocclusions of the permanent dentition.

Extraction of overly retained deciduous teeth is referred to as *interceptive orthodontics*. Extract a deciduous tooth that is still firmly attached when the permanent tooth starts to erupt to allow the permanent tooth to erupt in its normal position. Perform extraction carefully to avoid disruption of the permanent tooth.

Correction of Lingually Displaced Mandibular Canines

A technique that can be easily applied in one visit is the intraorally fabricated acrylic inclined plane.

Technique

1. Clean and polish the teeth with pumice.
2. Fabricate an inclined plane with a self-curing composite material (Pro-temp 3 Garant, 3MESPE, St. Paul, MN) until the splint is approximately 1 cm thick.
3. When the composite material becomes hard, create the appropriate inclined plane with an acrylic bur, so that when the lingually displaced mandibular canine hits the side of the inclined plane it will be deflected labially and mesially into a normal position. The incline path for the affected tooth should be formed so that the sloping angle is approximately 60° toward its target site.
4. Add additional composite to create a band around the canine teeth to provide retention for the splint.

Postoperative Care and Complications

- Instruct the client to:
  - Restrict the animal's chewing activities and to feed a soft diet.
  - Observe the orthodontic device daily, making sure that it is not displaced or causing excessive soft tissue trauma.
  - Gently clean the device daily with a stream of water from a curved-tip syringe.
  - Leave the orthodontic appliance in place until the appropriate movement has been achieved. This usually takes about 6 weeks.
- Complications usually are caused by inappropriate techniques or inadequate postoperative care.
  - Misapplication of orthodontic forces can result in resorbed roots, devitalized teeth (necrotic pulp), avulsed teeth, periodontal pockets, gingivitis, and failure to achieve the desired orthodontic movement.

STOMATITIS/GINGIVITIS

Stomatitis/gingivitis is a common clinical problem. Always attempt to identify a specific underlying cause, because this can determine the therapeutic approach and prognosis. When a specific cause cannot be identified or specific therapy is not available, treatment is symptomatic and supportive. Chronic relapsing stomatitis can be particularly frustrating to manage.

Etiology

Causes of stomatitis/gingivitis are listed in Table 64-8. Many systemic diseases that cause stomatitis/gingivitis are discussed in detail elsewhere in this book, including viral upper respiratory infections of cats (see Chapter 11), feline leukemia virus (FeLV) (see Chapter 8), feline immunodeficiency virus (FIV) (see Chapter 9), renal failure (see Chapter 77), autoimmune diseases such as systemic lupus erythematosus (SLE) (see Chapter 24) and pemphigus (see Chapter 48), and eosinophilic granuloma complex (see Chapter 53).

Periodontal Disease

Periodontal disease is a common predisposing cause of stomatitis/gingivitis in dogs and cats (see previous discussion).

▼ ***Key Point*** In any animal with stomatitis/gingivitis, perform a complete periodontal examination and dental prophylaxis, including tooth extractions if necessary, to eliminate periodontal disease as a contributing factor.

Physical Injury

Foreign bodies (plant awns, sticks, bones), oral trauma, and thermal, electrical, and radiation burns can cause stomatitis/gingivitis. A history of exposure combined with the oral examination may be diagnostic.

- Plant awn stomatitis (bur tongue, vegetative stomatitis) occurs in outdoor dogs that groom burs from their coat or eat horse feces containing burs. The awns become embedded in the tongue and gingiva, causing glossitis, gingivitis, and gingival hyperplasia.
  - On oral examination, close inspection will reveal tiny plant spicules embedded in tissue, and plant material may be seen on biopsy.

Chemical Injury

Strong alkalis (lye solutions) and acids, petroleum distillates, and phenols can damage the oral cavity. In many cases, the specific agent is not identified and the diagnosis is based on circumstantial evidence. Concurrent esophageal and gastrointestinal mucosal injury supports the diagnosis of ingestion of a caustic substance.

Nocardia Infection

Nocardia spp. have been associated with severe halitosis, gingivitis, and oral ulcerations in dogs. In severe cases,

Table 64-8. DIAGNOSIS AND TREATMENT OF STOMATITIS

Disorders	Diagnosis	Treatment*
Periodontal Disease	Oral exam, dental radiography	Dental prophylaxis, antibiotics
Physical Injury		
Foreign bodies (e.g., plant awns, for plant sticks, bones, fiberglass); trauma; thermal, electrical, radiation burns	Exposure history, oral exam, tissue biopsy for microscopic agents	Remove foreign bodies; awns, scrape with dry 4 inch × 4 inch sponge or scalpel blade Debride necrotic tissue
Chemical Injury		
Strong alkalis (lye solutions); acids; petroleum distillates; phenol	Exposure history, oral exam (lesions may extend into esophagus and GI tract)	Immediate therapy; rinse mouth with water Alkaline chemicals: flush with vinegar solution or citrus juice Acid chemicals: flush with bicarbonate solution
Drug- or Toxin-Induced		
Drug reaction; toxic epidermal necrolysis; heavy metal poisoning (thallium); *Dieffenbachia* (house plant) ingestion	Exposure history	Symptomatic therapy only
Infection		
Feline herpesvirus/calicivirus	History, physical exam (naso-ocular discharges, fever)	Symptomatic therapy only
Ulcerative necrotizing stomatitis	Oral exam, bacterial culture, impression smears for spirochetes	Treat with antibiotics for at least 3 wk
Candidiasis	Oral exam, fungal culture	Ketoconazole (Nizoral) 5 to 10 mg/kg PO q12h Nystatin 2% in Orabase applied topically
Nocardiosis	Oral exam, bacterial culture	Sulfadiazine, 80 mg/kg PO q8h
Bartonella	Bartonella titer	Azithromycin, 5–10 mg/kg PO q24h for 5 days
Immunodeficiency or Immunosuppression		
Feline leukemia virus (FeLV)	FeLV antigen test	Symptomatic therapy only
Feline immunodeficiency virus (FIV)	FIV antibody test	Same as above
Metabolic Disorders		
Renal failure	Creatinine, BUN, urinalysis	Correct or control underlying disorder
Diabetes mellitus	Blood and urine glucose	Same as above
Hypothyroidism	T_4, TSH stimulation tests	Same as above
Autoimmune Disorders		
Systemic LE; pemphigus complex; bullous pemphigoid	Physical exam (other mucocutaneous areas affected); biopsy (including IFA test); ANA and LE tests	Immunosuppressant therapy (e.g., glucocorticoids, azathioprine, cyclophosphamide, gold salts)
Neutropenia		
Cyclic neutropenia; agranulocytosis; leukemia	CBC, bone marrow aspiration	Symptomatic therapy only
Nutritional Deficiencies†		
Niacin deficiency (black tongue)	Diet history	Vitamin supplementation
Idiopathic		
Feline plasma cell stomatitis	Biopsy, total serum protein; protein electrophoresis; dental radiography	Symptomatic therapy including antibiotics and dental prophylaxis initially; other therapies include prednisolone, megestrol aetate, gold therapy and low-dose azathioprine: results are inconsistent Dental extractions in refractory cases
Eosinophilic granuloma	Physical exam (may have other dermatologic involvement); biopsy	Cats: methylprednisolone acetate (Depo-Medrol), 20 mg/cat SC q2wk for at least 30 days; alternate therapy for refractory cases includes megestrol acetate, surgery, cryosurgery, CO_2 laser, radiation therapy, levamisole, gold salts; correct underlying problem (flea control, hypoallergenic diet, hyposensitization) Dogs: Prednisolone, 0.5 to 1.0 mg/kg PO q12h for 7 days; then taper dose over 2 to 3 wk
Underlying Oral Neoplasia		
	Physical exam (enlarged regional lymph node with metastases); biopsy and needle aspirate of lesion and lymph nodes; thoracic and skull radiography	Treat underlying neoplasia (see text)

*Symptomatic therapy appropriate for all causes of stomatitis may include systemic, oral antibiotics, especially for severe gingivitis or necrotic oral ulcerations, such as amoxicillin (10 to 20 mg/kg q12h), metronidazole (25 mg/kg q12h), clindamycin (10 mg/kg q12h), and tetracycline (20 mg/kg q8h); oral rinses with 0.1% to 0.2% chlorhexidine or 1% hydrogen peroxide, three to four times daily; dental prophylaxis as needed; and soft food (canned or gruel).

†Rare in clinical practice.

ANA, antinuclear antibody; BUN, blood urea nitrogen; CBC, complete blood count; GI, gastrointestinal; IFA, indirect fluorescent antibody; LE, lupus erythematosus; T_4, thyroxine; TSH, thyroid-stimulating hormone.

necrosis and pseudomembranes are present. Lesions are most severe in periodontal areas. Rarely, mandibular lymph nodes and adjacent skin may be involved.

Oral Candidiasis

This uncommon cause of stomatitis is characterized by white plaques or pseudomembranes on the oral mucosa. Conditions that may predispose to candidal stomatitis include immunosuppression (including chemotherapy), systemic diseases, and long-term antibiotic therapy.

Necrotizing Ulcerative Stomatitis

This form of stomatitis is characterized by gingivitis, oral ulcerations, tissue necrosis, severe halitosis, and pain on eating. Numerous bacteria have been incriminated as contributing to this disorder, including spirochetes and fusiform bacilli.

Immunosuppression

Immunosuppression secondary to FeLV and FIV infection is an important predisposing cause of chronic stomatitis/gingivitis in cats.

▼ ***Key Point*** Always test for FeLV and FIV in cats with chronic stomatitis/gingivitis.

Uremia

Uremia is a common cause of stomatitis and oral ulcerations. Urease-containing bacteria metabolize urea to ammonia, which is irritating to the oral mucosa. Dehydration and drying of the oral mucous membranes may contribute to the problem. In uremic animals, the rostral portion of the tongue may slough, possibly owing to uremic vasculitis and thrombosis.

Plasma Cell Stomatitis

Plasma cell stomatitis in cats is a disease of unknown etiology characterized by proliferative, often symmetric, hyperemic friable lesions at the glossopalatine arches or angles of the mouth, also called *fauces*. The condition is also called *faucitis*.

- Concurrent pharyngitis is common.
- Ulcerative gingivitis may occur. This condition is extremely painful and can cause difficulty on eating.
- Some cats have concurrent plasma cell pododermatitis.
- An association with chronic calicivirus infection has been found in some cases and supported by experimental and epidemiologic evidence.
- On biopsy, lesions are characterized by plasma cells infiltrated with lesser numbers of lymphocytes, neutrophils, and histiocytes.
- Hyperglobulinemia, characterized as a polyclonal gammopathy, is often present and probably indicates chronic immune stimulation. An immune-mediated basis for the disease is suspected.

▼ ***Key Point*** Underlying dental disease, including periodontal and/or odontoclastic resorptive lesions, may occur concurrently.

- Perform dental radiography to identify odontoclastic resorptive lesions, bone loss secondary to periodontal disease, broken teeth, and retained roots. Cases with severe inflammation around the teeth often respond well to extraction of the teeth.
- FeLV, FIV, and *Bartonella* infection may be contributing factors; however, most cases are FeLV, FIV, and *Bartonella* negative. Calicivirus infection has been identified in many cats by virus isolation.
- The disease is often refractory to medical treatment, and relapse is common after treatment is discontinued.
- Treatment of inflamed mucosa with a CO_2 laser may be beneficial.

Feline Eosinophilic Granuloma Complex

This disorder is an important cause of oral lesions in cats.

- Any of three forms (indolent ulcer, collagenolytic [linear] granuloma, and eosinophilic plaque) may occur in the oral cavity. The indolent ulcer involving the upper lips is most common.
- Differentiate lesions from squamous cell carcinoma.
- Oral lesions may coexist with dermatologic involvement. The disorder may be a hypersensitivity reaction associated with underlying atopy, food allergy, or flea bite hypersensitivity. Diagnosis and treatment are discussed in Chapter 45.

Canine Oral Eosinophilic Granuloma

This disorder occurs in all breeds of dogs, but especially in young Siberian huskies.

- The cause is unknown but a hypersensitivity reaction to an as yet unidentified antigen is suspected, based on the dramatic response that occurs with corticosteroid therapy. Spontaneous regression also may occur. Hereditary factors may play a role.
- Lesions are characterized by proliferative tissue with superficial ulcerations that occur primarily on the lateral and ventral surfaces of the tongue. Soft palate involvement may also occur.
- Peripheral eosinophilia is common. Histologically, the lesion appears identical to collagenolytic (linear) granuloma in cats. Degenerating collagen is surrounded by granulomatous inflammation with an eosinophilic component.

- Differentiate lesions from neoplasia (especially mast cell tumor), mycotic infections, and foreign body reaction.

Clinical Signs

Clinical signs of stomatitis/gingivitis include hypersalivation, drooling, halitosis, oral bleeding, reluctance to eat dry food, dysphagia, anorexia, and weight loss.

▼ ***Key Point*** Chronic stomatitis/gingivitis can be extremely painful and can cause behavioral changes such as reclusive behavior, dropping food while eating, and running away from the food dish because of pain on eating.

Diagnosis

Base the overall strategy for diagnosis of stomatitis/gingivitis without an obvious underlying cause (e.g., foreign body) on the following measures:

- Rule out underlying systemic disorders with appropriate laboratory testing.
- Pursue specific diagnostics such as dental evaluation and oral biopsies and cultures.
- Perform dental prophylaxis (as needed) and initiate symptomatic therapy while awaiting test results (see Table 64-8).

History

- Obtain a complete history, with special emphasis on potential exposure to foreign bodies, chemicals, drugs, and toxins.
- Look for signs suggesting underlying systemic disease (see Table 64-8).

Physical and Oral Examinations

- Perform a general physical examination. In particular, evaluate for concurrent dermatologic lesions, especially at mucocutaneous junctions (e.g., nail beds, anus, vulva, prepuce) that suggest an underlying autoimmune disorder.
- Oculonasal discharges and fever in a cat supports the diagnosis of an underlying viral upper respiratory infection (see Chapter 11).
- Perform a complete oral examination, including periodontal evaluation, to identify and characterize the nature and extent of the lesions. This usually requires sedation or general anesthesia. A specific diagnosis can sometimes be made on oral examination (e.g., foreign body, periodontal disease).

Laboratory Evaluation

- Perform routine laboratory tests including a CBC, biochemical profile, and urinalysis to identify underlying systemic diseases such as renal failure (see Chapter 77) and diabetes mellitus (see Chapter 34).
- If general anesthesia is required for complete oral examination, obtain results of laboratory tests before anesthesia.
- Perform ancillary tests as suggested by specific historical and physical examination findings, such as FeLV, FIV, and *Bartonella* tests in cats with chronic stomatitis/gingivitis; fine-needle aspiration of enlarged mandibular lymph nodes for suspected neoplasia; and antinuclear antibody (ANA) and lupus erythematosus (LE) tests for suspected SLE.
- Bacterial and fungal cultures of the oral cavity can be performed on scrapings, swabs, or pieces of tissue. Unfortunately, cultures are not usually helpful, owing to the large number of potentially pathogenic organisms present as normal flora. Exceptions include isolation of *Candida* and *Nocardia* organisms.
- If bacterial cultures yield a large growth of a single organism, antibiotic therapy based on sensitivity patterns may be warranted.
- Specialized laboratories can use virus isolation techniques to detect calicivirus infection, but the clinical significance of a positive result in cats with chronic stomatitis is poorly understood.

Radiography

- In animals with periodontal disease, radiograph involved areas to identify periodontal defects, retained root tips, and odontoclastic root resorptive lesions, as discussed elsewhere in this chapter.
- Skull radiographs may show lysis of bone secondary to neoplastic disease.

Biopsy and Histopathologic Evaluation

Tissue biopsy is essential when evaluating chronic stomatitis, especially when proliferative lesions are present. Histopathology is useful to characterize the cellular response, identify specific causes, and differentiate neoplastic from non-neoplastic lesions.

- If autoimmune disease is suspected, evaluate oral and skin biopsies as described in Chapter 37.
- Cytology can be performed on impression smears of exudates or biopsied tissue and may be useful to diagnose underlying neoplasia (e.g., melanoma) and infection (e.g., *Nocardia* and *Candida* spp.).

Treatment

Treatment is based on the initiating cause. Whenever possible, institute specific therapy, such as removal of foreign bodies, immunosuppressive therapy for autoimmune diseases, corticosteroids for eosinophilic granuloma complex, sulfadiazine for nocardiosis, and ketoconazole for candidiasis (see Table 64-8). Symptomatic treatment of stomatitis usually is warranted, regardless of whether specific therapy is available.

- Because periodontal disease may be the underlying cause of stomatitis or, at the very least, an important contributing factor, perform thorough dental prophylaxis in all animals.
- Apply a 0.1% to 0.2% chlorhexidine solution topically at the gingival margin once a day to retard plaque formation and provide local antibacterial activity.
- Cleanse the oral cavity in animals with stomatitis with cotton-wrapped applicators soaked in saline or an oral rinse such as 0.1% to 0.2% chlorhexidine solution three to four times daily.
- Administer systemic antibiotics such as amoxicillin, metronidazole, clindamycin, amoxicillin clavulanate, and tetracycline to control secondary bacterial infections, particularly in cases of severe gingivitis or oral ulcerations (see Table 64-8).
- Initiate fluid therapy (see Chapter 5) and tube feeding (nasogastric, esophagostomy, or gastrostomy tube) as needed in animals with severe stomatitis/gingivitis that refuse food and water.
- Consider extraction of the teeth (at least of the premolars and molars) in animals with severe stomatitis/gingivitis that is refractory to medical management and for which extensive diagnostic tests do not reveal an underlying cause.
- Cats with plasma cell stomatitis/gingivitis/pharyngitis, in particular, may have an excellent response following extraction of all teeth or all teeth except the canine teeth when the inflammation is limited to areas around the teeth. Cats with severe pharyngeal or glossopalatine arch inflammation should be given a more guarded prognosis and may require continued medical management with antibiotics and corticosteroids or CO_2 laser treatment.

▼ ***Key Point*** Advise owners of animals with chronic non-responsive stomatitis/gingivitis that long-term therapy may be necessary to control the problem.

- Reexamine animals with chronic stomatitis/gingivitis 2 weeks after initial therapy, and then every 1 to 3 months to assess and reevaluate response to treatment.
- In animals with chronic non-responsive stomatitis/gingivitis treated with tooth extraction, thoroughly examine the oral cavity 1 month postoperatively to assess proper gingival healing. Take radiographs of regional areas of gingival hyperemia to reveal retained roots. Extraction of these roots permits normal gingival healing.

TONSILLITIS

Tonsillitis is seen occasionally in dogs and less frequently in cats.

▼ ***Key Point*** Tonsillitis usually occurs secondary to other diseases associated with chronic irritation or contamination of the pharynx.

Etiology

Disorders that predispose to tonsillitis (and pharyngitis) include chronic vomiting or regurgitation, chronic productive cough, and chronic contamination of the nasopharynx (e.g., severe periodontal disease, cleft palate, nasal disease with discharge). Primary tonsillitis is rare but may occur in young, small-breed dogs.

- The spectrum of bacteria cultured from dogs with pharyngitis/tonsillitis is similar to that cultured from the pharynx of healthy dogs, including *Escherichia coli,* and *Streptococcus, Staphylococcus, Pasteurella, Proteus, Pseudomonas,* and *Diplococcus* organisms.
- Group A *Streptococcus pyogenes,* the cause of "strep throat" in humans, does not cause signs of pharyngitis/tonsillitis in dogs and cats, and the prevalence of infection appears to be low. Dogs and cats can acquire a transient infection from close contact with infected humans; thus, they may serve as a reservoir for human reinfection. When recurrent group A *S. pyogenes* infection in humans in the household is a problem, treatment of pets as well as humans is warranted to prevent reinfection. In dogs and cats, effective antibiotics include penicillin, erythromycin, and chloramphenicol.

Clinical Signs

- Signs of tonsillitis include retching, cough, fever, anorexia, and lethargy.
- When tonsillitis is secondary to other disorders, signs of the primary disease overshadow those of the tonsillitis.

Diagnosis

- Base the diagnosis of tonsillitis on the gross appearance of the tonsils, which may be swollen and bright red with small hemorrhages or punctate white foci (abscesses). Concurrent pharyngitis is common.
- Attempt to identify important predisposing disorders (see Etiology) with a complete history, physical examination, and appropriate laboratory tests.
- Perform bacterial cultures in cases of primary tonsillitis refractory to routine antibiotic therapy.
- Differentiate chronic enlargement of the tonsils from underlying neoplasia (e.g., lymphoma, squamous cell carcinoma), which can be diagnosed by tonsillar biopsy.

Treatment

Secondary tonsillitis is usually resolved with identification and treatment of the predisposing disorder. When a predisposing disorder cannot be identified, adminis-

ter a course of broad-spectrum antibiotics such as ampicillin or amoxicillin (10–20 mg/kg PO q8–12h) for 2 weeks. Tonsillectomy rarely is necessary.

TONSILLAR NEOPLASIA

Etiology

Squamous cell carcinoma and lymphoma are the most common tumors of the tonsil.

Clinical Signs

- Retching and coughing may occur owing to pharyngeal irritation by the mass.
- A cervical mass may be present as a result of metastasis to regional lymph nodes.

▼ ***Key Point*** Carefully examine the tonsils in all dogs with a cranial cervical mass.

Diagnosis

- Diagnosis is based on oral examination and biopsy (tonsillectomy) findings. The tonsils appear enlarged and inflamed, and may have an obvious irregular mass.
- Perform partial or complete tonsillectomy to obtain tissue for histopathology.

Technique

Tonsillectomy (Biopsy)

1. Place the animal in ventral recumbency. Place an oral speculum.
2. Grasp the tonsil with an Allis tissue forceps.
3. Cut the base of the tonsil with a CO_2 laser and remove the tonsil.
4. Control any residual hemorrhage with the CO_2 laser.
5. Submit the tissue for histopathology.

Treatment

- For the management of tonsillar lymphoma, see Chapter 27.
- In animals with tonsillar squamous cell carcinoma, combination chemotherapy (doxorubicin and cisplatin) and radiation therapy have been reported to give the best results.

Prognosis

The prognosis is poor.

SALIVARY GLAND DISEASES

Diseases of the salivary glands that may be encountered include

- Mucoceles
- Fistulas
- Sialoadenitis
- Neoplasia

Anatomy

There are four pairs of major salivary glands in the dog and cat: parotid, mandibular, sublingual, and zygomatic (Fig. 64-18).

- The *parotid salivary gland* is located at the base of the auricular cartilage. The parotid duct is formed by two or three short radicles and passes lateral to the masseter muscle. It enters the oral cavity opposite the maxillary fourth premolar.
- The *mandibular salivary gland* is located at the junction of the maxillary and linguofacial veins. It is covered by a dense capsule. The mandibular duct leaves the medial surface of the gland and courses between the masseter muscle and mandible laterally and the digastricus muscle medially and then passes over the digastricus muscle and between the styloglossus muscle medially and the mylohyoides muscle laterally. The mandibular duct enters the mouth on a papilla lateral to the rostral end of the frenulum.
- The *sublingual salivary glands* consist of a caudal portion (monostomatic) located at the rostral pole of the mandibular gland and a rostral portion (polystomatic) that lies directly below the oral mucosa lateral to the tongue. The sublingual salivary duct originates at the caudal portion of the gland and accompanies the mandibular duct to a common or separate opening on the papilla at the rostral end of the frenulum.
- The *zygomatic salivary glands* are located ventral to the zygomatic arch. The major zygomatic duct opens about 1 cm caudal to the parotid papilla on a ridge of mucosa.

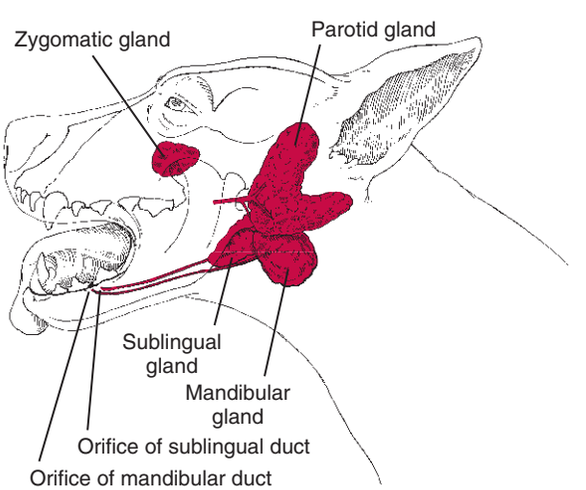

Figure 64-18. Salivary glands in the dog.

Etiology

Mucoceles

Salivary mucoceles, or sialoceles, result from damage to the duct or gland, with subsequent leakage of saliva into the tissues. Salivary mucoceles are lined with granulation tissue rather than epithelium. The sublingual and mandibular salivary glands are most commonly involved. The sites for mucoceles include cervical mucoceles, sublingual mucoceles (ranulas), and, less commonly, mucoceles of the pharyngeal and orbital region.

Fistulas

Salivary gland fistulas occur infrequently in small animals, and they are usually the result of trauma to the parotid salivary gland or duct.

Sialoadenitis

Sialoadenitis (an inflammatory reaction in the salivary glands) occurs infrequently in small animals. The zygomatic salivary gland is most commonly involved.

Sialadenosis

Poorly characterized syndrome of mandibular salivary gland enlargement, associated with hypersalivation, retching, gulping, regurgitation, and vomiting in dogs. Cytologic and histologic evaluations of the salivary glands are unremarkable. Removal of the salivary glands does not result in improvement, suggesting that signs are not related to the physical effect of salivary gland enlargement. Response to oral phenobarbital is rapid and dramatic. Altered parasympathetic or sympathetic innervation or an unusual form of limbic epilepsy has been proposed.

Neoplasia

Tumors of the salivary glands (e.g., adenocarcinoma) are rare. The parotid and submandibular salivary glands are most susceptible to tumor formation.

Clinical Signs

Clinical signs depend on the salivary gland affected and the type of disease present.

Mucoceles

Clinical signs depend on the location of the mucocele.

- Animals with cervical mucoceles usually are presented because of a soft, fluctuant non-painful mass in the cervical area.
- Animals with a ranula often are presented because of abnormal tongue movements, reluctance to eat, dysphagia, and blood-tinged saliva.
- Animals with a pharyngeal mucocele usually are presented because of difficulty breathing or swallowing.
- Animals with zygomatic mucoceles usually have exophthalmos, divergent strabismus, and a fluctuant non-painful swelling in the orbital area.

Fistulas

- Clinical signs include a small skin opening in an area overlying a salivary gland that drains serous fluid. The amount of drainage increases when the animal is eating.

Sialoadenitis

- Zygomatic sialoadenitis—exophthalmos, tearing, divergent strabismus, reluctance to eat, extreme pain on opening the mouth, inflammation of the oral mucosa near the papilla, and mucopurulent discharge from the duct
- Parotid sialoadenitis—a painful, warm, firm parotid salivary gland with mucopurulent discharge from the duct

Sialadenosis

- Clinical signs include hypersalivation, retching and gulping (especially after mild excitement), lip smacking, drooling, reduced food consumption, weight loss, regurgitation, and vomiting. Signs are usually chronic (2- to 18-month duration).

Neoplasia

- Most dogs and cats with salivary gland tumors are usually presented because of an asymptomatic non-painful palpable mass in the region of a salivary gland.
- Associated clinical signs from enlargement, impingement on adjacent structures, and local infiltration can occur.

Diagnosis

The diagnosis of salivary gland disease is based on history, clinical signs, clinical pathologic findings, radiography, and histopathology.

- The diagnosis of mucoceles usually is based on palpation and aspiration of a clear or blood-tinged, viscid, mucinous fluid that is consistent with saliva.

▼ ***Key Point*** Perform aspiration of mucoceles under aseptic conditions to prevent infection of a mucocele.

- Sialography also can be used; however, it is somewhat difficult to perform and is usually not necessary.
- Base the diagnosis of sialoadenitis on clinical signs, an elevated white blood cell count, and histopathology.
- Histopathology is necessary to diagnose salivary gland neoplasia. Thoracic radiography can evaluate for metastatic disease.

- With sialadenosis, the mandibular salivary glands are firm and enlarged to almost twice normal size. Exophthalmos is less common and may occur due to enlargement of zygomatic salivary glands. Dogs are sensitive to external palpation of the throat, which elicits signs of retching and gulping, but not pain.
- Sialadenosis is a diagnosis of exclusion when other causes of salivary gland enlargement, hypersalivation, retching, gulping, regurgitation, and vomiting have been ruled out and a dramatic response to oral phenobarbital is noted within 24 to 36 hours. Long-term therapy (phenobarbital or potassium bromide) is usually required, although in some dogs, anticonvulsant medication can be tapered and discontinued after 6 months.

Preoperative Considerations

- Prior to salivary gland surgery, perform a thorough physical examination and appropriate laboratory tests and radiographic procedures, based on the animal's clinical signs, physical examination findings, and age.
- Diagnosis of the type of salivary disease is necessary before surgical intervention.

▼ ***Key Point*** Surgery is not recommended for animals with sialoadenitis. Treat with systemic antibiotics, drainage of the abscess, and application of warm compresses.

Surgical Procedure

Several surgical procedures have been described in the treatment of salivary gland diseases, including

- Excision of the mandibular and sublingual salivary glands
- Marsupialization of ranulas
- Drainage and excision of the zygomatic salivary gland
- Management of pharyngeal mucoceles

Excision of the Mandibular and Sublingual Salivary Glands (Fig. 64-19)

Technique

1. Determine the affected side by placing the animal in dorsal recumbency. The mucocele will gravitate to the affected side.
2. Place the animal in dorsolateral recumbency and routinely prepare the surgical site.
3. Make a skin incision from the junction of the maxillary and linguofacial veins to the angle of the mandible.
4. Locate the mandibular salivary gland and make an incision in the capsule.
5. Bluntly dissect the mandibular salivary gland from the capsule, ligating and severing the arteries and veins that enter the dorsomedial aspect of the gland.

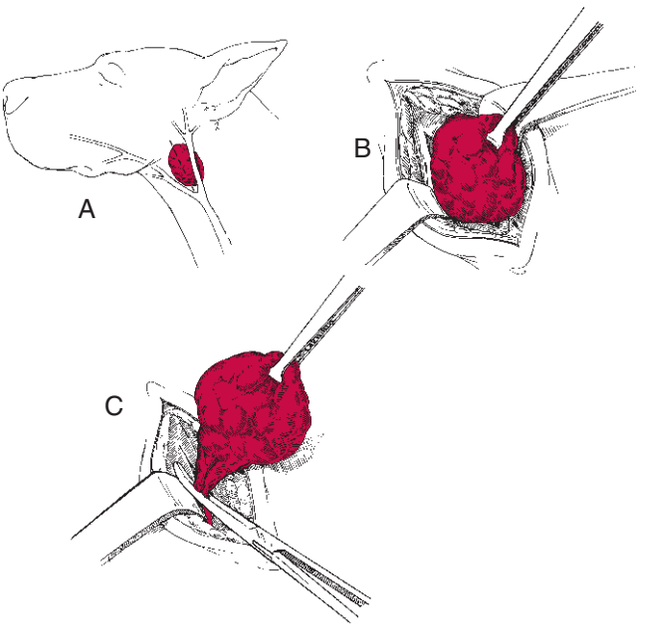

Figure 64-19. Surgical excision of the mandibular and sublingual salivary glands. See text for details.

6. Continue dissecting the sublingual gland rostrally between the masseter and digastricus muscles.
7. Clamp and ligate the glands and ducts as far rostrally as possible with a monofilament non-absorbable suture or a hemoclip. Transect the duct and remove the tissue.
8. Using a simple interrupted pattern, close the dead space with a few sutures in the capsule and deep tissue.

▼ ***Key Point*** To prevent the formation of seroma and provide drainage of the mucocele, place a Penrose drain from the site of the excised gland to the most ventral aspect of the mucocele.

9. Close the skin routinely.

Marsupialization (Surgical Management of Ranula)

Technique

1. Place the animal in lateral recumbency and routinely prepare the surgical site.
2. Incise the ranula longitudinally and remove the redundant portion of the mucosa.
3. Join the mucosal edges of the ranula to the adjacent oral mucosa with a few 4-0 absorbable, monofilament sutures.

If the ranula recurs, remove the mandibular-sublingual salivary gland complex.

Drainage of Zygomatic Salivary Gland (Treatment of Sialoadenitis)

Technique

1. Place the animal in lateral recumbency and swab the mucosa caudal to the maxillary second molar with dilute povidone-iodine (Betadine) solution.
2. Gently advance a small mosquito forceps through a small stab incision in the inflamed oral mucosa caudal to the last maxillary molar.
3. Use caution to prevent damage to the maxillary artery and nerve that course ventromedial to the orbit.

Surgical Excision of Zygomatic Salivary Gland (Treatment of Mucocele)

Technique

1. Place the animal in lateral recumbency and routinely prepare the surgical site.
2. Protect the animal's eyes from irritants with ophthalmic ointment.
3. Make an incision along the dorsal aspect of the zygomatic arch.
4. Reflect the periosteum of the zygomatic arch ventrally and retract the palpebral fascia dorsally.
5. Remove the dorsal aspect of the zygomatic arch, using rongeurs.
6. Retract the globe dorsally to expose the zygomatic salivary gland beneath the periorbital fat.
7. Retract the gland dorsally, ligate the vessels supplying the gland, and remove the gland.
8. Suture the palpebral fascia to the periosteum of the zygomatic arch, using absorbable sutures.
9. Close the subcutaneous tissues and skin routinely.

Management of Pharyngeal Mucoceles

- Treat by marsupialization or by excision of the entire mucocele.
- Remove the ipsilateral mandibular and sublingual salivary glands to prevent recurrence of the mucocele (see previous section in this chapter).

Postoperative Care and Complications

- Administer broad-spectrum antibiotics perioperatively.
- Feed a soft diet for 1 week postoperatively.

Complications

Complications vary according to the initial problem.

- *Salivary mucocele recurrence*—re-explore for residual salivary tissue. Ligation of the mandibular and sublingual salivary ducts with a non-absorbable suture during the initial surgery will aid in the localization of residual salivary tissue. Removal of residual tissue is curative.
- *Sialoadenitis*—clinical response is good if drainage is adequate and appropriate antibiotics, based on bacterial culture and sensitivity testing, are given.
- *Neoplasia*—recurrence is possible. Postoperative adjuvant chemotherapy and/or radiation therapy may be beneficial in animals with salivary gland adenocarcinomas.

Chapter 65

Diseases of the Esophagus and Disorders of Swallowing

Susan E. Johnson / Robert G. Sherding

OVERVIEW

Etiology

Esophageal diseases in dogs and cats can be categorized as structural disorders (e.g., foreign body, stricture, and vascular ring anomaly) and motility disorders (e.g., oropharyngeal dysphagia, and megaesophagus). Motility disorders may be caused by primary neuromuscular disease of the esophagus or may be secondary to systemic neuromuscular disorders.

Clinical Signs

Clinical signs of esophageal disease include regurgitation, dysphagia, odynophagia (painful swallowing), ptyalism, and exaggerated swallowing. Weight loss, polyphagia, anorexia, cough, dyspnea, and fever also may be seen.

Regurgitation

Regurgitation is the passive expulsion of food or fluid from the esophagus and is influenced by mechanical events in the esophagus. The timing of regurgitation in relation to eating is determined by the location of esophageal dysfunction, degree of obstruction, and presence or absence of esophageal dilatation.

- Regurgitation immediately after eating is most likely with proximal esophageal lesions or esophageal obstruction.
- Regurgitation may be unassociated with eating when the esophagus is dilated, because this provides a reservoir for food and fluid.
- Selective retention of fluids over solid food is more likely with partial obstruction.

▼ ***Key Point*** Distinguish regurgitation, which is the passive expulsion of esophageal contents, from vomiting, which is the centrally mediated reflex expulsion of contents from the stomach and duodenum.

- In contrast to regurgitation, vomiting is preceded by hypersalivation, retching, and abdominal contractions.

Dysphagia, Odynophagia, Ptyalism, and Exaggerated Swallowing

These signs are most likely to occur with oropharyngeal and proximal esophageal disorders.

Weight Loss

Weight loss occurs secondary to inadequate food intake and is related to the severity of esophageal dysfunction.

Polyphagia

Polyphagia occurs when an animal is otherwise healthy but is unable to retain ingested food because of partial or complete esophageal obstruction (e.g., esophageal stricture).

Anorexia, Cough, Dyspnea, and Fever

These signs may be seen with complicating aspiration pneumonia, esophageal perforation, or bronchoesophageal fistula.

Diagnosis

The diagnosis of esophageal disease requires an accurate history, radiographic evaluation of the esophagus, and in many cases, esophagoscopy.

▼ ***Key Point*** Aspiration pneumonia is a frequent and serious complication of esophageal disease that must be identified and treated appropriately.

Signalment

The signalment may suggest certain breed predispositions for esophageal disease (Table 65-1). The age at onset is also important because regurgitation caused by a vascular ring anomaly or congenital idiopathic megaesophagus usually begins at the time of weaning.

Table 65-1. PROFILES FOR ESOPHAGEAL DISEASE BASED ON SIGNALMENT

Parameter	Clinical Association
Age	
Young	Vascular ring anomaly; idiopathic megaesophagus; foreign body
Mature	Esophageal neoplasia
Breed	
Abyssinian	Acquired myasthenia gravis
Akita	Acquired myasthenia gravis
Boston terrier	Vascular ring anomaly (PRAA)
Bouvier	Dysphagia due to hereditary muscular dystrophy (oropharyngeal dysphagia and megaesophagus)
Cocker spaniel	Cricopharyngeal achalasia
Collie	Familial canine dermatomyositis (oropharyngeal dysphagia and megaesophagus)
English bulldog	Vascular ring anomaly (esophageal compression by left subclavian artery and brachiocephalic artery)
	Esophageal deviation cranial to the heart (normal variant)
German shepherd	Idiopathic megaesophagus
	Vascular ring anomaly (PRAA)
	Acquired myasthenia gravis
	Giant axonal neuropathy
Golden retriever	Idiopathic megaesophagus
	Acquired myasthenia gravis
	Cricopharyngeal dysphagia
Great Dane	Idiopathic megaesophagus
	Vascular ring anomaly (PRAA)
Greyhound	Idiopathic megaesophagus
Irish setter	Idiopathic megaesophagus
	Vascular ring anomaly (PRAA)
Jack Russell terrier	Congenital myasthenia gravis
Labrador retriever	Idiopathic megaesophagus
	Hereditary myopathy (megaesophagus)
Miniature schnauzer	Idiopathic megaesophagus
Newfoundland	Idiopathic megaesophagus
	Acquired myasthenia gravis
Rottweiler	Spinal muscular atrophy (megaesophagus)
Shar-Pei	Idiopathic megaesophagus
	Hiatal hernia
	Esophageal deviation cranial to the heart (mild regurgitation)
Smooth fox terrier	Congenital myasthenia gravis
Springer spaniel	Cricopharyngeal achalasia
	Polymyopathy (megaesophagus)
	Congenital myasthenia gravis
Wire-haired fox terrier	Idiopathic megaesophagus
Terriers	Acquired myasthenia gravis
Siamese cat	Idiopathic megaesophagus

PRAA, persistent right aortic arch.

History

Obtain a complete history with emphasis on exposure to foreign bodies, chemicals, or drugs such as doxycycline in cats (esophageal stricture), recent anesthesia (reflux esophagitis, esophageal stricture), and systemic signs such as neurologic dysfunction or muscle weakness, atrophy, or pain (central nervous system [CNS] disease, generalized peripheral neuromuscular disorders). The onset and duration of clinical signs may provide important clues to the underlying disorder.

- When the onset of regurgitation is acute, consider an esophageal foreign body or caustic esophagitis.
- A long-standing history of regurgitation is consistent with disorders such as idiopathic megaesophagus, vascular ring anomaly, and esophageal neoplasia.
- Intermittent signs often are seen with hiatal hernia and secondary reflux esophagitis.
- If regurgitation and vomiting occur together, consider hiatal hernia, gastroesophageal intussusception, or reflux esophagitis secondary to disorders causing chronic vomiting.
- In the southern United States, consider *Spirocerca lupi*–associated granuloma and neoplasia of the esophagus.

Physical Examination

Perform a complete physical examination. Observe how the animal eats (using both dry and canned food) to detect abnormalities of prehension and swallowing (suggesting oropharyngeal dysphagia) and to confirm that regurgitation rather than vomiting is occurring.

- Palpate the cervical esophagus to detect masses and foreign bodies.
- Distention of the cervical esophagus may occur with mechanical obstruction or diffuse hypomotility, and it frequently can be induced in animals with megaesophagus by compressing the thorax while the nostrils are occluded.
- A mucopurulent nasal discharge, pulmonary crackles, and fever are indicative of aspiration pneumonia.
- A rigid stance, in conjunction with fever and depression, may indicate mediastinitis secondary to esophageal perforation.
- Weight loss and emaciation can be seen with severe, long-standing esophageal disease.
- Horner syndrome and non-compressible cranial thorax may indicate a mediastinal mass.
- Muscle weakness, atrophy, or pain may indicate a generalized muscle disorder.
- Neurologic deficits may indicate primary CNS disease and esophageal denervation.
- Enlargement of the mandibular salivary glands is indicative of sialadenosis (see Chapter 64).

Radiography

Radiography is the most important tool available for diagnosis of esophageal disease. Survey and contrast radiography provide adequate information to diagnose structural disorders. Esophageal motility disorders are best identified with fluoroscopy.

- Perform survey thoracic and cervical radiography to evaluate the entire esophagus. The esophagus is not normally visible unless it contains air, fluid, food, or

foreign material. Evaluate thoracic radiographs for complications of esophageal disease such as aspiration pneumonia and esophageal perforation.

- Many esophageal diseases can be diagnosed by a contrast esophagram using barium sulfate paste or an aqueous organic iodine (see Chapter 4).

▼ ***Key Point*** For contrast radiography of the esophagus when perforation is suspected, use a water-soluble, non-ionic iodinated contrast agent such as iohexol (Omnipaque, Amersham Health) instead of barium, because it is readily absorbed and less irritating to periesophageal tissues.

- Esophageal motility disorders, especially those causing oropharyngeal dysphagia, are best evaluated with image-intensified fluoroscopy and rapid-sequence filming. Availability of fluoroscopy is limited to universities and referral hospitals because of the cost of equipment.

Endoscopy

Endoscopic evaluation of the esophagus is a unique, noninvasive method for diagnosis of esophageal disorders. The gross appearance of the mucosa can be assessed and tissue can be obtained for biopsy, cytology, and culture. In addition, esophageal foreign body removal or dilatation of esophageal strictures with endoscopy can be therapeutic. Either rigid or flexible endoscopes can be used for esophagoscopy.

- The normal esophagus of the fasted animal is usually empty or contains a minimal amount of clear fluid or foam.
- Under anesthesia, the normal esophagus becomes flaccid and dilated, which makes the lumen appear large when distended by air insufflation.
- The canine esophagus has longitudinal folds throughout. The feline esophagus has less prominent longitudinal folds in the proximal two-thirds and a ring-like pattern of circular annular ridges in the distal one-third.
- Normal esophageal mucosa is smooth, glistening, and pale pink. Superficial submucosal vessels are more visible in the cat. Heavily pigmented dog breeds (e.g., chow chow, Shar-Pei) may have patchy pigmentation of the esophageal mucosa.
- The gastroesophageal sphincter is normally closed, forming a slit-like opening that is eccentrically located at the confluence of a rosette pattern of mucosal folds.

Esophageal Manometry

Manometry evaluates intraluminal esophageal pressures and is useful for evaluation of esophageal motility disorders. Unfortunately, this procedure is infrequently performed in veterinary patients because of lack of availability of equipment and lack of patient cooperation.

Treatment

Treatment of esophageal disease is discussed under each specific disorder. General management of esophageal disease involves fluid therapy as needed (see Chapter 5), management of complications such as secondary aspiration pneumonia (see Chapter 163), and in severe cases, nutritional support by tube gastrostomy (see Chapter 3).

OROPHARYNGEAL DYSPHAGIA

Oropharyngeal dysphagia is defined as difficulty in moving a bolus of food or water from the oral cavity to the cervical esophagus. This disorder can be subclassified as oral dysphagia or pharyngeal dysphagia based on the clinical findings (Table 65-2).

- Oral dysphagia involves difficulty with prehension or aboral transport of ingesta to the hypopharynx during bolus formation.
- Pharyngeal dysphagia is defined as interrupted transport of a bolus from the oropharynx through the cranial esophageal sphincter into the cervical esophagus. It includes disorders of the cranial esophageal sphincter (cricopharyngeus muscle) referred to as cricopharyngeal dysphagia. Cricopharyngeal dysphagia may consist of failure of the sphincter to open (cricopharyngeal achalasia) or lack of coordination between pharyngeal contraction and cranial esophageal sphincter relaxation during swallowing (cricopharyngeal asynchrony).

Etiology

Oropharyngeal dysphagia usually is caused by morphologic disease that interferes with normal prehension and swallowing (see Table 65-2). Functional oropharyngeal dysphagia is associated with neuromuscular disorders that affect the tongue, muscles of mastication, or cranial nerves involved in voluntary and involuntary swallowing.

Clinical Signs

- Oral dysphagia is characterized by abnormalities of prehension and mastication. Weight loss is not a problem because animals compensate for their deficits and maintain food intake. Secondary aspiration pneumonia is uncommon because pharyngeal function is unaffected.
- Pharyngeal dysphagia is characterized by repeated unsuccessful attempts to swallow, with gagging, retching, and spitting out of saliva-covered food. Aspiration pneumonia is a common and serious complication. Weight loss is also common.
- Regurgitation may be a prominent clinical sign since many of the systemic neuromuscular disorders that cause oropharyngeal dysfunction can also cause esophageal hypomotility (megaesophagus).

Table 65-2. DIAGNOSIS OF OROPHARYNGEAL DYSPHAGIA*

	Anatomic Association	Clinical Findings	Etiology	Diagnosis	Treatment
Oral Dysphagia					
			Morphologic Disorders		
(Abnormalities of prehension and mastication)	Teeth, tongue, hard palate, bony structures, and TMJ	Difficulty prehending food or lapping water Excessive chewing and chomping Exaggerated head movements when eating Submerging muzzle to drink Dropping food from mouth Pawing at face Excessive salivation No weight loss or aspiration pneumonia	Dental disease	Oral exam, radiography	See Chapter 64 for treatment of morphologic disorders.
			Oral foreign body	Oral exam, radiography	
			Oral neoplasia	Oral exam, radiography, biopsy	
			Severe stomatitis	Oral exam, biopsy	
			Cleft palate	Oral exam	
			Persistent frenulum	Oral exam	
			Skeletal disorders (e.g., TMJ, craniomandibular osteopathy)	Oral exam, skull radiography	
			Functional Disorders		
			CNS disease or peripheral neuropathy (cranial nerves V, VII, XII)	Oral exam (atrophy or deviation of tongue secondary to denervation), neurologic exam, EMG, nerve biopsy, CSF tap, CT scan (see Chapter 125)	See Chapters 126 and 129.
			Neuromuscular disease (e.g., myasthenia gravis, botulism)	Neurologic exam, EMG with repetitive nerve stimulation, Tensilon test, ARA titer (see Chapter 130)	See Chapter 130.
			Myopathy or myositis (e.g., masticatory myositis, immune polymyositis, hypothyroidism)	EMG, muscle biopsy, CK, AST, ANA, LE, T_4 and TSH assay (see Chapter 130)	See Chapter 130.
Pharyngeal Dysphagia					
			Morphologic Disorders		
(Abnormalities of bolus transport from the oropharynx through the cranial esophageal sphincter)	Pharyngeal constrictor muscles, soft palate, cranial esophageal sphincter	Normal food and water uptake but repeated unsuccessful attempts to swallow Spitting out saliva-covered food Eating with head and neck tucked ventrally	Inflammatory or neoplastic diseases of the pharynx, tonsils, or retropharyngeal lymph nodes	Oral exam, skull and pharyngeal radiography, biopsy of inflammatory or mass lesions, fine-needle aspiration of lymph nodes, endoscopy	See Chapter 64 for treatment of morphologic disorders.
			Retropharyngeal foreign body or abscess	Oral exam, pharyngeal radiography, fine-needle aspiration, endoscopy	
		Pharyngeal food retention and pharyngitis Gagging, retching Regurgitation Nasal discharge Cough, fever (pneumonia)	Soft palate disorders (e.g., cleft soft palate or iatrogenic shortening)	Oral exam	

Table continued on following page

Table 65-2. DIAGNOSIS OF OROPHARYNGEAL DYSPHAGIA*—cont'd

	Anatomic Association	Clinical Findings	Etiology	Diagnosis	Treatment
Pharyngeal Dysphagia (cont'd)					
			Functional Disorders		
			CNS disease or peripheral neuropathy (cranial nerves V, VII, IX, X)	Neurologic exam, EMG, nerve biopsy, CSF tap, CT scan (see Chapter 125)	See Chapters 126 and 129
		Weight loss	Myopathy or myositis (e.g., immune polymyositis, hypothyroidism)	EMG, muscle biopsy, CK, AST, ANA, LE, T_4 and TSH assay (see Chapter 130)	See Chapter 130
			Neuromuscular disease (e.g., myasthenia gravis, botulism)	Neurologic exam, EMG with repetitive nerve stimulation, Tensilon test, ARA titer (see Chapter 130)	See Chapter 130
			Congenital cricopharyngeal achalasia	Barium swallow with fluoroscopy, response to myotomy	Cricopharyngeal myotomy (see Chapter 66)
			Cricopharyngeal asynchrony†	Barium swallow with fluoroscopy	Cricopharyngeal myotomy is contraindicated
			Sialadenosis	Diagnosis of exclusion	Phenobarbitol (see Chapter 64)

*The type of dysphagia is first characterized as oral dysphagia versus pharyngeal dysphagia based on observing the animal eat (e.g., prehension of food and water, swallowing). Barium swallow with fluoroscopy is useful to characterize functional oropharyngeal dysphagia but is not indicated for evaluation of morphologic disorders.
†Lack of coordination between cranial esophageal sphincter opening and pharyngeal contraction.
ANA, antinuclear antibody; ARA, acetylcholine receptor antibody; AST, aspartate aminotransferase; CK, creatine kinase; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EMG, electromyography; LE, lupus erythematosus; T_4, thyroxine; TMJ, temporomandibular joint; TSH, thyroid-stimulating hormone.

- When a neuromuscular disorder is the underlying cause of oropharyngeal dysphagia, generalized signs of muscle weakness, atrophy, and neurologic deficits are often present.

Diagnosis

The strategy for diagnosis of oropharyngeal dysphagia is as follows:

- Identify underlying morphologic disorders with a complete oropharyngeal and radiographic evaluation.
- Characterize functional dysphagia by the affected stage of swallowing.
- Pursue ancillary testing to identify underlying neuromuscular disorders that may be associated with functional dysphagia (see Table 65-2).

Signalment and History

The signalment may suggest certain breed predispositions for congenital neuromuscular disorders associated with oropharyngeal dysphagia (see Table 65-1). Obtain a complete history, including a description of eating and drinking. Evaluate for signs suggestive of aspiration pneumonia (cough, dyspnea, anorexia, depression) or a systemic neuromuscular disorder (weakness, muscle pain, gait abnormalities).

Physical Examination

Many of the morphologic diseases that cause dysphagia are detected initially by visual examination of the oropharynx. Tranquilization or general anesthesia may be required for a thorough oropharyngeal evaluation. A general physical and neurologic examination (see Chapter 125) are particularly important to identify focal and generalized neuromuscular abnormalities that may be associated with functional oropharyngeal dysphagia.

▼ ***Key Point*** Observation of the animal eating and drinking is an important extension of the physical examination to confirm that dysphagia is present and to characterize it as an oral or pharyngeal problem (see Table 65-2).

Radiography

- Perform survey radiographs of the skull and pharyngeal area to identify morphologic disorders such as a pharyngeal foreign body or retropharyngeal abscess that can cause oropharyngeal dysphagia.
- Perform thoracic radiographs to detect aspiration pneumonia and associated megaesophagus.
- A barium swallow with fluoroscopic examination is required for definitive characterization of functional swallowing abnormalities, and it is essential for the diagnosis of cricopharyngeal achalasia. Unfortunately, fluoroscopy is available only at large referral centers.

Ancillary Testing

Ancillary tests are frequently necessary to determine the cause of functional oropharyngeal dysphagia.

- Use a Tensilon response test (edrophonium chloride) (Tensilon, ICN Pharmaceuticals), acetylcholine receptor antibody titer, and electromyography (EMG) for myasthenia gravis (MG) (see Chapter 130).
- Use an EMG and muscle biopsy for polymyositis and polymyopathy (see Chapter 130).
- Use a cerebrospinal fluid (CSF) tap, computed tomography (CT) scan, or magnetic resonance imaging (MRI) for primary CNS diseases (see Chapter 125).

Treatment

- The treatment and prognosis for oropharyngeal dysphagia depend on the underlying disorder (see Table 65-2).
- Supportive care is especially important with pharyngeal dysphagia. Identify and treat aspiration pneumonia (see Chapter 163) and provide appropriate nutritional support, including a gastrostomy tube in severely emaciated animals (see Chapter 3).

ESOPHAGEAL HYPOMOTILITY (MEGAESOPHAGUS)

Esophageal hypomotility refers to a decrease in esophageal tone or peristalsis that may be segmental or diffuse. The term *megaesophagus* commonly is used when a diffuse, severe motility disorder results in a large, flaccid esophagus. In most cases, the primary disturbance is an abnormality of the body of the esophagus rather than a failure of the gastroesophageal sphincter to relax (achalasia), as occurs in humans. Clinical findings associated with megaesophagus reflect impaired esophageal transport with secondary complications such as weight loss and aspiration pneumonia.

Etiology

- Esophageal hypomotility disorders may be congenital or acquired. A familial predisposition for congenital idiopathic megaesophagus has been suggested for many breeds of dogs and Siamese cats (see Table 65-1).

▼ ***Key Point*** Breeding of animals with congenital megaesophagus is not recommended because of potential hereditability of the trait.

- Acquired megaesophagus may occur secondary to many disorders, especially diseases causing diffuse neuromuscular dysfunction (Table 65-3). However, in most dogs, a cause is not identified and the diagnosis is *idiopathic megaesophagus*.
- Megaesophagus is less likely to be idiopathic in cats. Esophagitis associated with hiatal hernia and gastroesophageal reflux is an important cause of feline esophageal hypomotility.
- The underlying pathophysiologic mechanism for idiopathic megaesophagus is unknown. Efferent neuromuscular pathways appear to be intact, and a defective afferent component of the neural reflex is suspected. Mechanisms may be similar for both congenital and acquired idiopathic megaesophagus.

Clinical Signs

- Regurgitation, which may or may not be related to eating, is the primary clinical sign of megaesophagus. In most cases, the more liquid the food, the less likely it is to be regurgitated. Weight loss and emaciation occur secondary to inadequate retention of food.
- Dyspnea, cough, and fever are indicative of secondary aspiration pneumonia, a common complication of megaesophagus.
- Cats with esophageal hypomotility typically present for either upper gastrointestinal signs (regurgitation, vomiting) or chronic or recurrent respiratory tract disease (acute or chronic cough, dyspnea, noisy breathing, nasal discharge) due to secondary aspiration pneumonia.
- In cases in which megaesophagus is associated with an underlying disorder (see Table 65-3), additional clinical signs may be detected, including the following:
  - Generalized muscle weakness with MG, polymyositis, polymyopathy, or hypoadrenocorticism
  - Neurologic deficits with CNS disease or polyneuropathy
  - Generalized muscle atrophy or pain with polymyositis
  - Obesity and alopecia with hypothyroidism
  - Oropharyngeal dysphagia with generalized neuromuscular dysfunction

Table 65-3. CAUSES OF ESOPHAGEAL HYPOMOTILITY (MEGAESOPHAGUS)

Idiopathic
Congenital
Acquired
Central and Peripheral Neuropathies
CNS (caudal brain stem) disorders (e.g., distemper, trauma, neoplasia)
Immune polyneuritis
Polyradiculoneuritis (coonhound paralysis)
Bilateral vagal nerve damage (e.g., surgery, trauma, neoplasia)
Giant axonal neuropathy
Hereditary spinal muscular atrophy
Dysautonomia
Ganglioradiculitis
Neuromuscular Junctionopathies
Myasthenia gravis (congenital or acquired)
Botulism
Tick paralysis
Anticholinesterase toxicity
Myopathy or Myositis
Polymyositis (e.g., SLE, idiopathic, infectious)
Muscular dystrophy
Hereditary myopathy
Familial canine dermatomyositis
Glycogen storage disease type II
Tiger snake envenomation
Miscellaneous
Hypothyroidism
Hypoadrenocorticism (typical and atypical forms)
Lead toxicity
Thallium toxicity
Acrylamide toxicity
Thymoma
Pituitary dwarfism
Esophagitis
Hiatal hernia
Esophageal fistula
Tetanus
Gastric dilatation volvulus
Dystrophin deficiency

CNS, central nervous system; SLE, systemic lupus erythematosus.

Diagnosis

Idiopathic megaesophagus is a diagnosis of exclusion. Strategies for diagnosis of megaesophagus should include the following:

- Confirmation of a persistently dilated esophagus
- Evaluation for underlying obstructive esophageal disease
- Evaluation for underlying causes of esophageal hypomotility (see Table 65-3)

Signalment and History

The signalment is important since idiopathic megaesophagus is a common disorder in young animals with regurgitation and certain breeds are predisposed (see Table 65-1).

- In young animals with congenital idiopathic megaesophagus, regurgitation is often noted at weaning when solid food is first introduced. Multiple animals in a litter may be affected.
- Historical findings that indicate the need for a more complete evaluation for predisposing causes include systemic lethargy or weakness, concurrent oropharyngeal dysphagia, and neurologic abnormalities.
- A history of chronic or recurrent respiratory infections (aspiration pneumonia) may overshadow the gastrointestinal signs when a subtle esophageal motility disorder is present.

Physical Examination

The physical examination is often unremarkable except for weight loss.

- Distention of the cervical esophagus can be accentuated by compressing the thorax while the nostrils are occluded.
- A mucopurulent nasal discharge, pulmonary crackles, and fever suggest secondary aspiration pneumonia.
- Perform a complete neurologic examination with emphasis on cranial nerves IX (glossopharyngeal) and X (vagus).
- Evaluate all skeletal muscles (especially temporal and limb muscles) for weakness, atrophy, or pain.
- Additional physical examination findings are determined by the underlying cause (see Table 65-3).

Radiography

- Survey thoracic radiography usually shows distention of the entire intrathoracic esophagus with gas, fluid, or food. If hypomotility is mild, radiographs may be unremarkable. Evaluate for evidence of aspiration pneumonia.
- A barium contrast esophagram is useful for confirming persistent dilatation of the esophagus and for identifying possible mechanical obstruction at the gastroesophageal junction.
- Esophageal motility disorders are best evaluated with barium swallow fluoroscopy, which provides a means of subjectively assessing the intensity and coordination of esophageal peristalsis and is the only modality that can detect subtle esophageal motility disorders.
- Most cats with esophageal hypomotility do not have overt megaesophagus on survey thoracic radiographs. A barium esophagram with fluoroscopy is required to identify esophageal hypomotility.

Routine Laboratory Tests

Perform a minimum database of tests, including the following:

- *Biochemical profile* to screen for changes associated with underlying systemic disorders that cause megaesophagus (e.g., hyponatremia and hyperkalemia in hypoadrenocorticism; hypercholesterolemia in hypothyroidism; and increased creatine kinase [CK] and aspartate aminotransferase [AST] levels in polymyositis)
- *Complete blood count* (CBC) to detect a neutrophilia and left shift consistent with aspiration pneumonia
- *Acetylcholine receptor antibody titer* to evaluate for acquired MG, even in the absence of generalized muscle weakness, because acquired focal MG may mimic idiopathic megaesophagus (see Chapter 130)

Ancillary Tests

Perform other tests as indicated by clinical and laboratory findings to identify underlying causes of megaesophagus.

- Adrenocorticotropic hormone (ACTH) stimulation test for hypoadrenocorticism
- Thyroid-stimulating hormone (TSH) assay and thyroxine level for hypothyroidism
- Antinuclear antibody (ANA) and lupus erythematosus (LE) tests for systemic LE
- Blood lead assay for lead poisoning
- Tensilon test for MG
- EMG for polymyopathy, polymyositis, polyneuropathy, and MG
- Muscle biopsy for polymyopathy and polymyositis
- CSF tap for CNS disease
- Transtracheal wash for cytology, and culture and sensitivity testing if aspiration pneumonia is suspected

Esophagoscopy

Esophagoscopy is not routinely indicated for evaluation of megaesophagus unless obstructive disease of the gastroesophageal sphincter or reflux esophagitis is suspected. With idiopathic megaesophagus, the esophagus appears flaccid and dilated throughout its entire length and contains variable amounts of froth, fluid, or food. The esophageal mucosa is usually normal.

Esophageal Manometry

This is an extremely useful diagnostic tool to detect and characterize esophageal motility disorders in humans, but it is not widely used in veterinary medicine because of the expense and the lack of patient cooperation.

Treatment

▼ ***Key Point*** Treatment of megaesophagus is primarily supportive and symptomatic, unless a reversible underlying disorder can be identified.

- Offer frequent small meals with the animal in an upright position. Maintain the upright position for 10 to 15 minutes after eating so that gravity can assist entry of food into the stomach. In most cases, the more liquid the diet, the easier it is for it to reach the stomach. However, different types of food should be given on a trial basis to identify those best tolerated.
- Place a gastrostomy tube for temporary nutritional support of animals with severe malnutrition (see Chapter 3).
- Give antibiotics for treatment of aspiration pneumonia based on results of culture and sensitivity testing (see Chapter 163). Caution the owner that recurrent pneumonia is a common problem and that early detection and treatment are essential for long-term success.
- Treat the underlying disorder whenever possible (see Table 65-3). Institute treatment for esophagitis (as discussed later in this chapter) when esophagitis is confirmed endoscopically or when esophageal hypomotility is associated with risk factors for reflux esophagitis (post-anesthesia, hiatal hernia).
- Smooth muscle prokinetic drugs such as metoclopramide (Reglan, Robins) or cisapride (Propulsid, Janssen) do not appear to be useful in the management of idiopathic megaesophagus in dogs, because the dog's esophagus consists entirely of skeletal muscle. These prokinetic agents (cisapride more so than metoclopramide) may be useful in cats with motility disorders involving the distal esophagus because of the smooth muscle composition of this segment of the feline esophagus.
- A therapeutic trial with the cholinergic drug bethanechol may be warranted, since it has been shown to increase the amplitude of esophageal contractions determined manometrically in some dogs with idiopathic megaesophagus. Potential systemic side effects of bethanechol include salivation, lacrimation, urination, and defecation.
- Surgical myotomy of the gastroesophageal sphincter is not recommended because "achalasia" of the sphincter is not usually present.

Prognosis

- Some animals with congenital idiopathic megaesophagus may improve in time with diligent supportive care.
- Idiopathic acquired megaesophagus is usually irreversible. The animal may do well for months to years if the owner is dedicated to performing appropriate feeding procedures and if pneumonia is detected and treated early.
- Aspiration pneumonia and euthanasia are the most common causes of death in animals with megaesophagus.

ESOPHAGEAL FOREIGN BODY

Esophageal foreign bodies are common. They usually lodge at narrowed areas of the esophagus including the thoracic inlet, base of the heart, or hiatus of the diaphragm. The extent of secondary esophageal damage depends on the type of object, its size and shape, and the duration of time in contact with the mucosa. Complications of esophageal foreign bodies include esophagitis, esophageal perforation and mediastinitis, aortic perforation, esophageal stricture, and bronchoesophageal fistula.

Etiology

The most commonly encountered esophageal foreign bodies are bones. Other objects include needles, fishhooks, string, toys, and in cats, vomited hairballs.

Clinical Signs

- Most dogs and cats with esophageal foreign bodies are presented for evaluation of acute onset of gagging, salivation, dysphagia, and regurgitation.
- If esophageal foreign bodies go undiagnosed initially, they may cause chronic regurgitation and dysphagia.

Diagnosis

Consider esophageal foreign body based on clinical signs, especially when ingestion of foreign body is observed by the owner.

Physical Examination

- The physical examination often is normal except for dysphagia, ptyalism, or gagging and retching.
- Cervical esophageal foreign bodies may be palpable.
- Findings of depression, anorexia, fever, cough, and dyspnea may suggest secondary aspiration pneumonia or esophageal perforation. Cervical swelling may be palpated with foreign body-induced perforation of the cervical esophagus.

Radiography

- Thoracic and cervical radiographs usually are diagnostic for metal or bone foreign bodies. Evaluate thoracic radiographs for aspiration pneumonia. Findings of pneumomediastinum, pneumothorax, and mediastinal or pleural effusion suggest esophageal perforation.
- Barium contrast esophageal radiography may be necessary to identify radiolucent objects. Use iohexol (Omnipaque, Amersham Health), a water-soluble, non-ionic iodinated contrast agent, rather than barium sulfate if perforation is a possibility (see Chapter 4).

Routine Laboratory Tests

A CBC, serum biochemical profile, and urinalysis may be indicated.

- Perform routine blood work before general anesthesia for foreign body removal, especially in older animals with possible concurrent systemic diseases (e.g., renal failure) that might warrant special anesthetic considerations.
- With secondary aspiration pneumonia or esophageal perforation, the CBC may indicate a neutrophilia and left shift.

Esophagoscopy

Esophagoscopy is indicated to confirm the diagnosis, remove the object, and assess secondary mucosal damage (see under "Technique for Foreign Body Removal").

Treatment

Esophageal foreign bodies should be considered an emergency situation. Do not delay foreign body removal, as the likelihood of complications increases with time. Institute fluid therapy as needed to correct secondary fluid and electrolyte imbalances before general anesthesia.

▼ ***Key Point*** Endoscopic removal of esophageal foreign bodies is usually successful and should be attempted before surgery.

Surgical exploration is preferred over endoscopy when retrieving penetrating esophageal foreign bodies located at the heart base because of the risk of lacerating the aorta or pulmonary vessels.

Technique for Foreign Body Removal

1. Perform esophagoscopy with the animal under general anesthesia.
2. Use a rigid or flexible endoscope with foreign body retrieval (grasping) instruments.
3. Grasp the object and attempt to dislodge it by gentle rotation. Perform all manipulations cautiously to prevent further mucosal damage or perforation.
4. If the object cannot be extracted orally without causing additional esophageal trauma, advance it into the stomach and remove it by gastrotomy. Gastrotomy is not required for bone foreign bodies, as they dissolve rapidly once reaching the stomach. In this situation, perform serial abdominal radiographs to confirm that the bone has dissolved and does not cause obstruction.
5. If a fishhook is embedded in the esophageal wall, use a rigid endoscope and pass rigid alligator forceps through the lumen of the endoscope to grasp the fishhook. Apply torque to the fishhook with the forceps to dislodge it from the wall. If the hook

cannot be dislodged, perform surgery to expose the esophagus so that the barbs can be cut off the hook. Retrieve the remainder of the hook endoscopically.
6. Once the object is removed, assess the mucosa for hemorrhage, erosions, lacerations, and perforations.
7. Following an uncomplicated foreign body retrieval, withhold oral food and water for 24 hours and give parenteral fluids and parenteral broad-spectrum antibiotics such as ampicillin (22 mg/kg q8h SC, IM, or IV) if mild esophagitis is detected. (See elsewhere in this chapter for diagnosis and management of complications of esophageal foreign bodies such as esophagitis, esophageal perforation, and esophageal stricture.)
8. If the foreign body cannot be removed endoscopically and cannot be advanced into the stomach, an esophagotomy is indicated (see Chapter 66).

Prognosis

The prognosis for recovery after endoscopic foreign body removal is excellent unless secondary complications occur. With perforation and mediastinitis, the prognosis is guarded.

ESOPHAGEAL PERFORATION

Perforation of the intrathoracic esophagus is more likely to be associated with significant morbidity than is perforation of the cervical esophagus.

Etiology

- Esophageal foreign bodies are the most common cause of esophageal perforation, especially objects with irregular or sharp edges, such as bones, and chronically lodged foreign bodies that cause secondary pressure necrosis.
- Iatrogenic perforation can occur during endoscopic removal for esophageal foreign bodies and during therapeutic dilatation of esophageal strictures. Perforation may also be a sequela of esophageal surgery or laser treatment.
- Penetrating injuries of the cervical esophagus can be caused by bite wounds and gunshot injuries.

Clinical Signs

- Anorexia, depression, odynophagia, fever, and a rigid stance are seen with esophageal perforation.
- Cough and dyspnea may occur when perforation of the thoracic esophagus leads to mediastinitis and pleuritis.

Diagnosis

Exposure to potential foreign bodies or trauma to the cervical esophagus may be determined from the history.

Physical Examination

Findings suggesting perforation include depression, fever, and pain. With cervical perforations, there may be cervical swelling, cellulitis, or a draining fistula.

Routine Laboratory Tests

CBC usually reveals neutrophilia and a left shift.

Radiography

- Thoracic radiography shows pneumomediastinum, pneumothorax, and mediastinal or pleural effusion.
- Perform a contrast esophagram using Omnipaque, a water-soluble, non-ionic iodinated contrast agent, to confirm perforation (see Chapter 4).

Esophagoscopy

Esophageal perforation may be detected by esophagoscopy as a deep laceration in the esophagus or a defect in the thoracic esophagus that bubbles bloody fluid.

▼ ***Key Point*** If perforation is present or occurs during endoscopy, life-threatening tension pneumothorax may require immediate thoracentesis and chest tube placement (see Chapter 3).

Treatment

- If a small tear occurs secondary to a sharp foreign body or during endoscopic manipulations, conservative medical management may be sufficient.
- Give broad-spectrum parenteral antibiotics, fluid therapy, and nothing per os for 5 to 7 days; monitor closely for clinical deterioration.
- Consider nutritional support by tube gastrostomy or parenteral alimentation (see Chapter 3).
- Repeat thoracic radiographs on a daily basis to monitor response to therapy and to detect evidence of mediastinitis and pleuritis.
- If perforation is accompanied by fever, and mediastinitis or pleuritis, surgical exploration for primary repair is indicated (see Chapter 66).

ESOPHAGITIS

Etiology

- *Foreign bodies* are a common cause of esophagitis (see "Esophageal Foreign Body"). This includes vomited hairballs that become lodged in the esophagus.
- *Chemical irritants* or caustic substances may cause esophagitis. Concurrent stomatitis and gastritis may occur.
- *Oral medications* (especially doxycycline tablets given to cats) can result in esophagitis and esophageal stricture secondary to prolonged esophageal retention and local tissue irritation (see later). Many other

oral medications, including nonsteroidal anti-inflammatory drugs and bisphosphonates, are reported to cause esophageal irritation in humans and have the potential to cause mucosal injury in dogs and cats.
- *Thermal injury* may occur with ingestion of food that has been heated to high temperature (e.g., in a microwave).
- *Gastroesophageal reflux* of gastric or duodenal contents is a common cause of esophagitis. Esophageal damage is attributed to mucosal contact with gastric acid, pepsin, bile acids, and trypsin. Predisposing factors that may contribute to reflux esophagitis include general anesthesia, use of a head-down tilt table for surgery, an indwelling nasogastric tube or pharyngostomy tube, hiatal hernia, chronic vomiting, and delayed gastric emptying.
- *Pythium insidiosum* as a cause of severe necrotizing pyogranulomatous esophagitis has been described in two dogs from the southern United States. Infection is believed to occur from the ingestion of zoospores in stagnant fresh water. Diagnosis is confirmed by demonstrating characteristic hyphae with Grocott's methenamine silver stain on an esophageal biopsy. Medical therapy of pythiosis is usually unsuccessful; however, the combination of itraconazole (10 mg/kg PO q24h) and terbinafine (5–10 mg/kg PO q24h) has been effective in some dogs with pythiosis (see Chapter 40).

Clinical Signs

- Signs of esophagitis are nonspecific for esophageal disease in general and include dysphagia, regurgitation, repeated swallowing, and excess salivation.
- Anorexia, depression, and fever suggest secondary aspiration pneumonia or perforation.
- Weight loss and dehydration may occur with chronic or severe esophagitis.
- With mild esophagitis, signs may be absent.

Diagnosis

Consider potential predisposing factors in the patient's history, such as recent general anesthesia or exposure to foreign bodies, doxycycline (cats), or caustic materials.

Physical Examination

Oral ulcerations or stomatitis may be present if caustic injury occurred. Weight loss and dehydration may be detected when esophagitis is severe.

Radiography

- Survey radiographs usually are unremarkable. Occasionally, small amounts of gas may be seen in the esophagus and mild to moderate focal esophageal dilatation may occur secondary to delayed motility.
- Contrast radiography is often normal. When esophagitis is severe, the mucosa may appear irregular. Segmental luminal narrowing can occur with involvement of the submucosa and tunica muscularis. This radiographic appearance can be difficult to distinguish from a fibrous stricture.

Endoscopy

Endoscopic evaluation of the esophageal mucosa is the most sensitive method for detecting esophagitis.

- Findings include mucosal erythema, hemorrhage, increased friability, erosions or ulcers, and in severe cases, pseudomembranes, indistensibility, and strictures.
- If gastroesophageal reflux is the cause of esophagitis, lesions are most severe in the distal esophagus, especially linear erythematous streaks and erosions, and the gastroesophageal junction may appear dilated.
- Reflux of gastric contents into the esophagus may be noted during endoscopy.

Treatment

Mild esophagitis frequently resolves without treatment and may not require additional therapy, especially when the cause (e.g., foreign body) can be easily resolved.

General Therapy

- Administer antibiotics (e.g., ampicillin, amoxicillin, or cephalosporins) routinely to prevent or control infection of the altered mucosa by oral bacteria.
- Maintain adequate nutrition in mild cases with frequent oral feeding of small portions of a nonabrasive, soft food. Place a gastrostomy tube in animals with severe esophagitis, prolonged anorexia, or inability to retain food.

Therapy for Reflux Esophagitis

See Chapter 67 (Table 67-3) for pharmacology, adverse effects, and prescribing information concerning each of the following medications.

- Give a promotility agent, such as metoclopramide (Reglan, Robins) (0.2–0.4 mg/kg PO or SC q8h) or cisapride (Propulsid, Janssen) (0.25–0.5 mg/kg PO q8–12h in dogs or 2.5–5.0 mg total dose per cat PO q8–12h), to decrease gastroesophageal reflux (by increasing gastroesophageal sphincter pressure) and promote gastric emptying.
- Decrease acidity of refluxed gastric juice by giving an H_2-receptor blocker such as famotidine (Pepcid, Merck) (0.5–1.0 mg/kg PO or IV q12–24h) or ranitidine (Zantac, GlaxoSmithKline) (2 mg/kg PO or IV q8–12h in dogs or 3.5 mg/kg PO q12h in cats). H_2-receptor blockers are preferable to antacids for control of acid secretion because of their potency and ease of administration.

- Consider a proton pump inhibitor, such as omeprazole (Prilosec, AstraZeneca) (0.75–1.0 mg/kg PO q12–24h), for treatment of severe reflux esophagitis in dogs and cats that is unresponsive to the previously described treatments. Use pantoprazole (Protonix, Wyeth-Ayerst) (0.7–1.0 mg/kg IV q24h) if an injectable proton pump inhibitor is required.
- Sucralfate suspension is beneficial in the treatment of reflux esophagitis. Sucralfate (Carafate, Axcan Scandipharm) (0.5–1.0 g total dose for dogs or 0.25 g total dose for cats PO q8–12h) is an aluminum salt that binds selectively to injured gastroesophageal mucosa and acts as an effective barrier against the damaging actions of acid, pepsin, and bile acids associated with reflux esophagitis.
- Prednisolone (0.5 mg/kg PO q12h) is frequently recommended (but has unproven effectiveness) for animals with severe circumferential esophagitis to prevent healing by fibrosis and stricture formation. Be sure to control any infection (e.g., aspiration pneumonia) before starting corticosteroid therapy.

Prognosis

The prognosis is good for mild to moderate esophagitis and guarded or poor for severe esophagitis, especially when accompanied by perforation. Strictures may occur secondary to severe esophagitis (see the next section).

ESOPHAGEAL STRICTURE

An intramural esophageal stricture results when severe esophagitis involving the submucosa and tunica muscularis heals by fibrosis. Multiple strictures can result from diffuse esophagitis.

ETIOLOGY

Esophageal stricture may occur secondary to severe esophagitis of any etiology (see the previous section).

- Reflux esophagitis associated with gastroesophageal reflux of gastric acid and enzymes during general anesthesia and esophageal foreign bodies are the most commonly recognized causes.
- Administration of oral doxycycline tablets to cats has been associated with esophagitis and esophageal stricture formation secondary to prolonged esophageal retention of the tablet and local tissue irritation. This complication can be prevented by following tablet administration with a 6-ml bolus of water, by placing a small amount of butter or Nutrical on the nose following dry tablet administration to stimulate licking, or by giving doxycycline as a suspension.
- Esophageal surgery may be complicated by healing with stricture formation.

Clinical Signs

- Clinical signs of regurgitation and dysphagia are attributable to esophageal obstruction.
- Regurgitation usually occurs immediately after eating. If the stricture is chronic, regurgitation may not be related to eating because esophageal distention cranial to the stricture acts as a food reservoir.
- A ravenous appetite is common because of inability to get food past the strictured area.

Diagnosis

Suspect esophageal stricture from the history. Progressive dysphagia for solid foods with preferential retention of liquids is common. Clinical signs from a stricture usually occur 3 to 14 days after the onset of esophageal injury and esophagitis.

Physical Examination

The physical examination is often unremarkable unless the stricture has been present for a long time, resulting in weight loss. Animals are often otherwise bright and alert.

Radiography

- Survey radiographs usually are normal unless the esophagus is distended with food or fluid proximal to the stricture. Evaluate for aspiration pneumonia.
- A contrast study of the esophagus using barium paste or barium mixed with food demonstrates the stricture (see Chapter 4). Contrast radiography is useful to assess the number, location, and length of strictures.

Endoscopy

Endoscopy can diagnose an esophageal stricture and, at the same time, allow treatment of the stricture by bougienage or balloon dilatation.

- At endoscopy, a stricture appears as a ring or ridge of white fibrous tissue that circumferentially narrows the esophageal lumen and fails to distend with insufflation. Multiple strictures are sometimes present, causing the tubular shape of the esophagus to be distorted and angulated. Esophagitis, erosions, and ulcers may also be observed.

Procedure

- If possible, pass the endoscope through the stricture to assess its length and to evaluate the esophagus distal to the strictured area.
- Perform a complete endoscopic examination of the esophagus and stomach to evaluate for severity of esophagitis and to identify potential underlying causes of esophagitis and stricture formation (e.g., foreign bodies and hiatal hernia/intussusception).
- If the endoscope cannot be passed through the stricture, contrast studies may be necessary (if not previ-

ously performed) for complete evaluation of number and length of strictures. Balloon dilatation of the stricture to 10 mm should allow subsequent passage of the endoscope.
- Mucosal biopsies of the strictured area may be warranted in some cases to rule out underlying neoplasia, especially when the stricture is associated with a mass effect or mucosal proliferations or fails to respond to therapy.

Complications

Gastric overdistention can be a significant complication of endoscopy in animals with esophageal stricture; thus, use insufflation sparingly. If the stricture precludes passage of the endoscope into the stomach, air introduced during insufflation will pass through the stricture and accumulate in the stomach, and it cannot be suctioned off through the endoscope.

Treatment

Esophageal strictures can be managed surgically or endoscopically. Surgery may be indicated if the stricture is too small to pass a dilator or if inadequate dilatation is achieved after multiple attempts (see Chapter 66). Mechanical dilatation of the stricture is performed under general anesthesia with endoscopic visualization.

▼ ***Key Point*** Conservative management of esophageal strictures with endoscopically guided balloon catheter dilatation or bougienage is preferable to surgery.

Bougienage

- A well-lubricated dilator, such as a bougie or tapered probe (or the endoscope itself), is passed through the stricture. Avoid excessive force because esophageal perforation is a life-threatening complication.
- Passage of progressively larger bougies results in stretching and dilatation of the stricture.
- The procedure is repeated at intervals of 4 to 7 days as needed to maintain clinical improvement.
- The total number of dilatations (3–10) is determined by the severity of the stricture and the clinical response.

Balloon Catheter Dilatation

This technique provides radial stretching of the stricture and is currently considered preferable to bougienage. Balloon catheters (Rigiflex dilator, Microvasive, Milford, MA) used in dogs and cats have 10-mm, 15-mm, and 20-mm diameters and a 8-cm length when inflated. These catheters can be passed through a 2.8-mm endoscopic biopsy channel, or they can be carefully passed adjacent to the endoscope using endoscopic or fluoroscopic guidance.

Procedure

With the patient under anesthesia and using endoscopic guidance, insert the catheter with deflated balloon into the lumen of the stricture and center the balloon in the stricture. Distend the balloon with distilled water (or contrast material for fluoroscopy) to the pressure recommended by the manufacturer (usually 45–50 psi). Use a pressure gauge to avoid overdistention and inadvertent balloon rupture. Distend the balloon for 1 to 2 minutes, and then deflate it to evaluate the size of the stricture and the extent of secondary mucosal hemorrhage. The procedure can be repeated immediately using the next larger balloon.

- Balloon dilatations are usually performed 2 to 5 times at intervals of 4 to 7 days. Refractory strictures may require more than five dilatation procedures initially. Some patients have recurrence of signs weeks to months after initial treatment, requiring periodic balloon dilatation to maintain a functional lumen.
- Give prednisolone, 0.5 mg/kg PO q12h for 10 to 14 days, to prevent further healing by fibrosis and stricture recurrence; taper the dosage over the remaining period of time that the stricture requires dilatation. An alternative consideration is to perform endoscopic-guided intralesional corticosteroid injections (triamcinolone, 10 mg/ml; 0.2 ml per injection site, given in four circumferential sites), at the time of balloon dilation.
- During the series of dilatation procedures and for at least 2 to 3 weeks after the final one, institute medical therapy as described for esophagitis.
- For refractory fibrotic strictures, endoscopically guided four-quadrant electrocautery or laser incisions through the fibrous stricture, followed by balloon dilation, have been recommended.
- An esophageal diameter of 1 cm is usually adequate for a cat or small dog to be maintained on canned food. Larger dogs may require an opening 1.5 to 2 cm in diameter.

ESOPHAGEAL DIVERTICULA

Etiology

- Esophageal diverticula are large pouch-like sacculations of the esophageal wall that may be congenital or acquired. They are rare in veterinary medicine. Diverticula most commonly affect the esophagus at the thoracic inlet or just cranial to the diaphragm.
- Acquired diverticula are classified as *pulsion* or *traction* diverticula. Pulsion diverticula are believed to occur because of increased intraluminal pressure secondary to obstruction or altered motility. They have been associated with foreign bodies, stricture, vascular ring anomalies, esophagitis, idiopathic megaesophagus, and hiatal hernia.

- Traction diverticula occur secondary to periesophageal inflammation that results in fibrosis and contraction, which pulls out the wall of the esophagus into a pouch.

Clinical Signs

- Large diverticula interfere with orderly movement of ingesta through the esophagus and cause clinical signs because they predispose to impaction with foreign bodies or food, which may lead to esophagitis and even perforation.
- Signs include regurgitation, distress after eating, anorexia, weight loss, intermittent thoracic or abdominal pain, and respiratory signs.
- Clinical signs may not occur with small diverticula.

Diagnosis

Radiography

- Thoracic radiography frequently reveals a gas- or food-filled mass in the area of the esophagus.
- A barium esophagram confirms that a pouch communicates with the esophageal lumen.

Endoscopy

- Esophagoscopy reveals a sac-like outpouching with variable esophagitis and accumulation of ingesta and fluid in the sac.
- Use caution to avoid perforation of diverticula.

Treatment

- Large diverticula require surgical resection (see Chapter 66).
- Small diverticula can be managed medically with upright feeding of frequent small meals of a soft-food diet.
- Identify predisposing causes and treat when possible.

ESOPHAGEAL FISTULA

Esophagotracheal, esophagobronchial, and *esophagopulmonary fistulas* are patent communications between the esophagus and the respective airways. They occur rarely in dogs and cats. Of these, esophagobronchial (bronchoesophageal) fistulas are most commonly described. Clinical signs are related to contamination of the airways with esophageal secretions and food.

Etiology

Esophageal fistulas may be congenital or acquired. Acquired fistulas are most likely and are usually associated with esophageal foreign bodies, especially bones. In most cases, a lodged esophageal foreign body is suspected to cause esophageal wall necrosis with subsequent development of a fistula. Other causes include trauma, malignancy, and severe infection.

- Most esophagobronchial fistulas occur in the caudal esophagus, probably due to the close anatomic proximity of the caudal esophagus and bronchi in this region.
- Esophagobronchial fistulas commonly are accompanied by an esophageal diverticulum.
- A traction diverticulum may develop secondary to periesophageal inflammation and fibrosis in the region of the fistula.
- A pulsion diverticulum may develop secondary to lodging of a foreign body.
- The diverticulum may occur first and predispose to lodging of a foreign body and subsequent fistula formation.

Clinical Signs

- Clinical signs are primarily associated with the respiratory tract. Coughing, especially after drinking liquids, is a common presenting sign. Anorexia, fever, dyspnea, and weight loss are attributed to aspiration pneumonia.
- Signs of esophageal disease such as regurgitation, gagging, and retching may be seen but are not consistently described.
- Contamination of the airways can lead to recurrent localized bacterial pneumonia, pulmonary abscesses, and pleuritis.

Diagnosis

Suspect an esophageal fistula when there is a history of chronic cough, recurrent localized pneumonia, and signs of esophageal disease.

Physical Examination

Findings reflect the secondary pulmonary involvement and may include fever, pulmonary crackles, muffled heart sounds (pleural effusion), and weight loss.

Radiography

- Thoracic radiographic abnormalities are primarily indicative of pulmonary complications and include localized alveolar, bronchial, or interstitial infiltrative patterns; lobar consolidation; or pleural effusion. Radiopaque esophageal foreign bodies may be identified. The caudal lung lobes are most commonly affected.
- A barium esophagram is required for definitive diagnosis. Contrast material will outline the communicating airway. Use a thin mixture of barium sulfate (20–30% wt/vol) to enhance filling of small fistulas.

▼ ***Key Point*** Do not use oral iodinated contrast material (e.g., Gastrografin, Squibb) because it is hypertonic and may cause pulmonary edema.

- Esophagoscopy and bronchoscopy can be performed, but a contrast esophagram is more reliable for detecting fistulas.

Treatment

- Treatment of esophageal fistulas requires surgery for esophagotomy, foreign body removal, fistula resection, and lobectomy.
- Perform culture and sensitivity testing of involved tissues for appropriate antibiotic therapy.

Prognosis

If severe complications such as pneumonia, pulmonary abscesses, and pleuritis are present, the prognosis is poor.

VASCULAR RING ANOMALIES

Etiology

Vascular ring anomalies are congenital malformations of the great vessels and their branches that entrap the intrathoracic esophagus and cause clinical signs of esophageal obstruction.

Persistent Right Aortic Arch

This malformation accounts for 95% of vascular ring anomalies in dogs and cats. Persistent right aortic arch (PRAA) occurs when the embryonic right rather than the left fourth aortic arch becomes the functional adult aorta. The ductus arteriosus continues to develop from the left side, forming a band that crosses over the esophagus to connect the main pulmonary artery and the anomalous aorta (Fig. 65-1). Esophageal compression occurs by the aorta on the right, the ligamentum arteriosum (remnant of the ductus arteriosus) dorsolaterally on the left, the pulmonary trunk on the left, and the base of the heart ventrally.

PRAA appears to have a familial tendency, because certain breeds (see Table 65-1), especially German shepherds and Irish setters, appear to be predisposed and multiple animals in a litter may be affected. The mechanism of inheritance may involve single or multiple recessive genes. Breeding of affected animals is not recommended.

Other Anomalies

Other anomalies that have been described include double aortic arch, persistent right ductus arteriosus (with normal left aortic arch), aberrant left or right subclavian arteries, and (in English bulldogs) esophageal compression by the left subclavian and brachiocephalic arteries.

Clinical Signs

- Affected animals are usually presented for regurgitation of solid food that began at the time of weaning. Regurgitation of undigested food commonly occurs immediately after eating but is sometimes delayed, as ingesta is retained in a large esophageal pouch that develops cranial to the obstruction. Liquids and semisolid food are preferentially retained because they can pass through the constricted area.
- Weight loss or failure to gain weight despite a good appetite is common.
- Cough and dyspnea suggest aspiration pneumonia.

Diagnosis

Regurgitation since weaning is very suggestive of a vascular ring anomaly. Most animals are presented by 6 months of age, although occasionally signs are mild and a diagnosis is not made until later in life. Differentiate vascular ring anomalies from other causes of regurgitation in young animals such as congenital megaesophagus and, less frequently, esophageal foreign bodies. Diffuse esophageal hypomotility (megaesophagus) occasionally complicates vascular ring anomalies in dogs.

Physical Examination

The cervical esophagus may be distended secondary to partial obstruction and development of a pouch. Cough, dyspnea, pulmonary crackles, and fever indicate aspiration pneumonia.

Radiography

- Survey thoracic radiographs often suggest a vascular ring anomaly. The dilated esophagus appears as a food- or fluid-filled density cranial to the heart, which tapers to normal at the base of the heart. In the ventrodorsal (VD) view of PRAA, the normal bulge of the aortic arch to the left is absent. Tracheal deviation consisting of a leftward curvature near the cranial border of the heart on the dorsoventral (DV) (or VD) radiographs is a consistent feature. Moderate to marked focal tracheal narrowing may also be seen on the DV (or VD) and lateral thoracic views.
- Perform a barium esophagram (see Chapter 4) to confirm the location of esophageal obstruction and severity of esophageal distention. Differential diagnoses for this radiographic appearance include an intramural stricture, segmental motility disorder, or congenital diverticulum.
- Fluoroscopy is useful to evaluate generalized esophageal hypomotility.
- Angiography is seldom necessary but in selected cases can be used for definitive confirmation of the type and location of vascular ring anomaly prior to surgery.

Endoscopy

- Endoscopy can distinguish a mural lesion from extraluminal compression. In animals with PRAA, the indentation in the esophagus caused by external

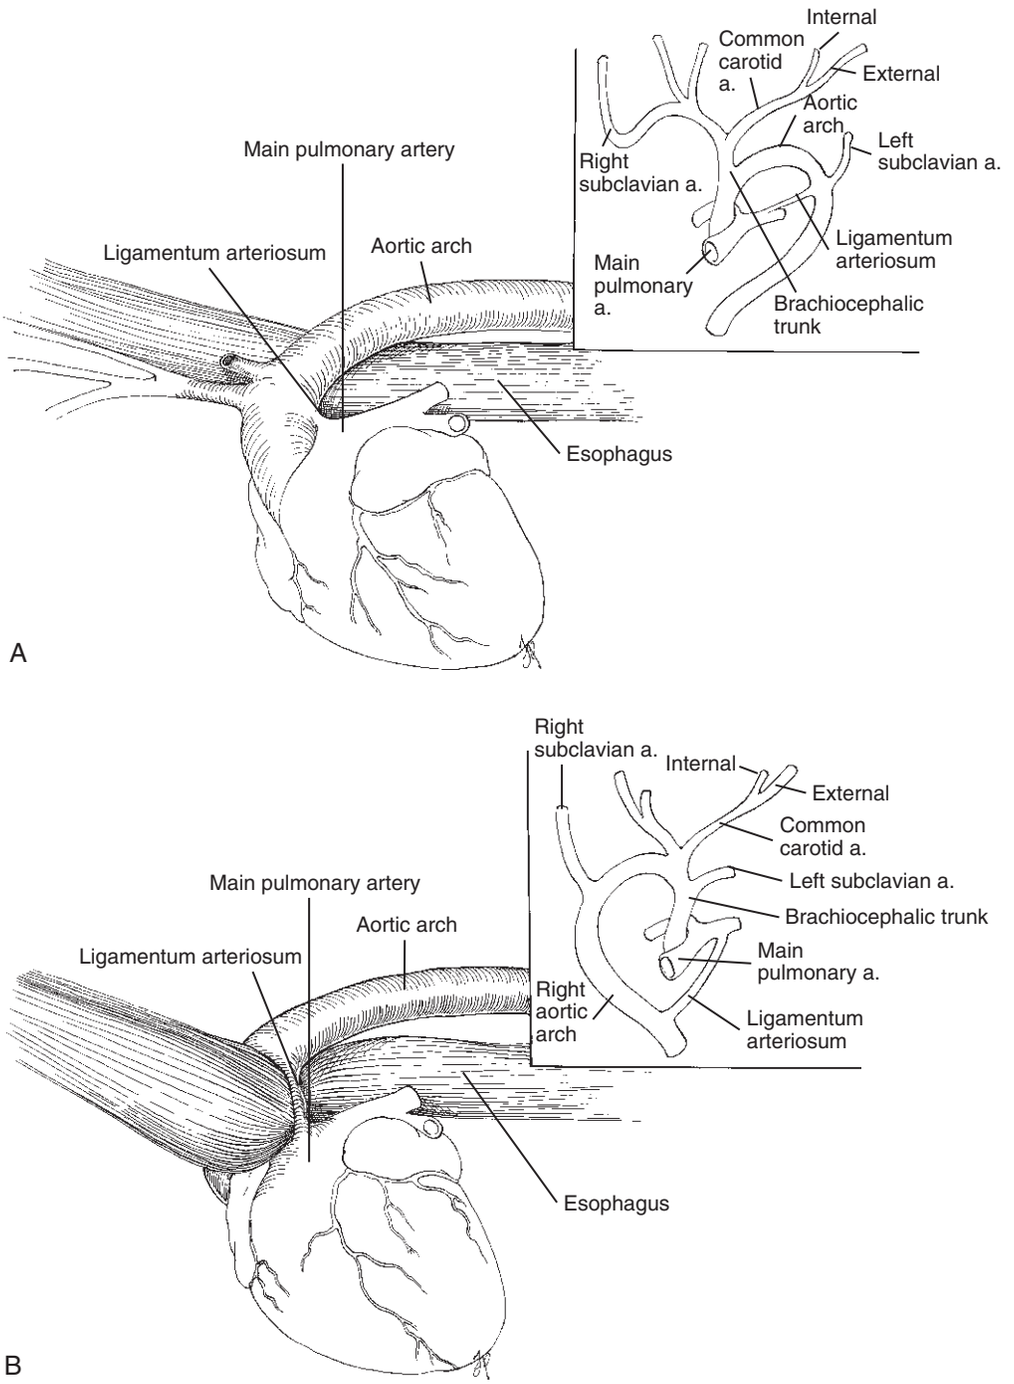

Figure 65-1. Persistent right aortic arch. *A,* Normal development of the aortic arch viewed from the animal's left side. Inset shows normal embryonic development of the great vessels from a dorsoventral view. *B,* When the embryonic right fourth aortic arch becomes the adult aorta, esophageal constriction occurs. Inset shows dorsoventral view of the vascular malformation.

compression from the ligamentum arteriosum is visible. The cranial thoracic esophagus is usually dilated.

- Endoscopy is also helpful to rule out cranial esophageal foreign bodies or hairballs (especially) that become lodged secondary to the PRAA.

Treatment

Definitive therapy for PRAA is surgical ligation and transection of the ligamentum arteriosum (see Chapter 66).

- If the animal is debilitated and malnourished, improve nutritional status before surgery. Give fre-

quent elevated feedings of small amounts of a semimoist or liquid diet. If this diet is poorly tolerated, consider feeding through a gastrostomy tube (see Chapter 3).
- Control aspiration pneumonia with antibiotics before surgery (see Chapter 163).
- Significant clinical improvement usually occurs after surgery, although mild esophageal distention often persists, especially if a large cranial diverticulum was present.
- Manage as described for megaesophagus if regurgitation persists.
- Recovery of normal esophageal function is more likely if surgery is performed at an early age and esophageal dilatation is not severe.

HIATAL DISORDERS

Anatomic abnormalities of the hiatus include hiatal hernia and gastroesophageal intussusception (GEI).

- A *sliding* hiatal hernia is a protrusion of any structure (usually the distal esophagus and stomach) through the esophageal hiatus of the diaphragm into the thorax.
- A *paraesophageal* hiatal hernia involves displacement of a portion of the stomach through a diaphragmatic defect adjacent to the esophageal hiatus and is rare in veterinary medicine.
- Differentiate hiatal hernia from GEI, in which the stomach (and occasionally other structures such as the spleen, proximal duodenum, pancreas, and omentum) invaginates or prolapses into the distal lumen of the esophagus. Hiatal hernias and GEI may be intermittent or persistent.

Etiology

Congenital or acquired enlargement of the esophageal hiatus or laxity of the surrounding ligaments may predispose to hiatal hernias and GEI.

Congenital Hiatal Disorders

- Most hiatal hernias are congenital and occur as a developmental defect of the diaphragmatic esophageal hiatus.
- Sliding hiatal hernia has been described in young Shar-Pei dogs. Concurrent megaesophagus or esophageal hypomotility, which resolved after surgical correction of the hernia, suggests that reflux esophagitis rather than a primary motility disorder was the underlying cause of these complications.

Acquired Hiatal Disorders

- Acquired hiatal hernias may occur secondary to high positive intra-abdominal pressure (e.g., blunt abdominal trauma or vomiting).
- Chronic upper airway obstruction (e.g., laryngeal disease or brachycephalic syndrome) can predispose to hiatal hernia since severe inspiratory dyspnea results in negative intrathoracic pressure, which may pull the stomach into the thorax. Bulldogs with severe manifestations of brachycephalic syndrome appear to be at increased risk for hiatal hernia.
- Reversible hiatal hernia and megaesophagus may be seen as a complication of tetanus in dogs.
- Congenital idiopathic megaesophagus predisposes to GEI, presumably due to decreased esophageal motility and decreased gastroesophageal sphincter pressure.

Clinical Signs

Small hiatal hernias or intussusceptions may not be associated with clinical signs unless complicated by reflux esophagitis. If the hernia or intussusception occurs intermittently, clinical signs also may be intermittent. Common signs include vomiting, regurgitation, hypersalivation, and weight loss. Dyspnea also is common and may be due to aspiration pneumonia or compression of the lungs secondary to large hernias.

Hiatal Hernia

Signs are due primarily to impaired gastroesophageal sphincter function, which predisposes to gastroesophageal reflux, reflux esophagitis, and segmental or diffuse esophageal hypomotility. Dogs and cats with asymptomatic hiatal hernia may become symptomatic after general anesthesia, when impaired gastroesophageal sphincter function predisposes to reflux esophagitis and esophageal stricture formation. If large portions of the stomach are displaced through the diaphragm, signs occur because of esophageal and gastric obstruction.

Gastroesophageal Intussusception

GEI can cause both esophagitis and esophageal obstruction. When a large portion of the stomach is intussusceipted, rapid clinical deterioration is evidenced by signs of dyspnea, hematemesis, profound depression, collapse, and sudden death.

Diagnosis

Shar-Pei dogs and brachycephalic breeds are predisposed to hiatal hernia, and GEI occurs most frequently in young male dogs. Regurgitation prior to the onset of GEI suggests that megaesophagus may be a predisposing factor. When GEI causes esophageal obstruction, the acuteness of onset and rapid progression to death often preclude an antemortem diagnosis.

Physical Examination

Findings often are unremarkable unless a large hernia or intussusception is causing esophageal obstruction. In this situation, dyspnea, collapse, and shock predominate. Evaluate for evidence of concurrent upper airway obstruction, which may worsen the hiatal hernia.

Radiography

Survey thoracic radiography can usually identify both hiatal hernia and GEI if they are large and persistently present. A soft tissue and gas density mass (the stomach) can be seen in the caudal dorsal mediastinum. The normal gastric gas bubble usually seen in the cranial abdomen may be diminished in size.

- Perform a barium esophagram to confirm a hernia or GEI and to distinguish masses arising from other mediastinal structures or the esophagus. With a hiatal hernia, the gastroesophageal junction and gastric rugae are visible cranial to the diaphragm but the linear relationship between the esophagus and the stomach is preserved. Gastroesophageal reflux also may be demonstrated. With GEI, gastric rugae are seen within the esophageal lumen and esophageal obstruction is present.
- Hiatal hernias and GEI that are small and reduce spontaneously are a diagnostic challenge. Because of their intermittent nature, they may not be identified routinely on either survey or contrast radiographs. Fluoroscopy is helpful to detect intermittent hiatal hernias and gastroesophageal reflux.

Endoscopy

Endoscopy can assess secondary reflux esophagitis and may confirm hiatal hernia or GEI.

- In hiatal hernia, findings include enlargement of the hiatal opening, cranial displacement and dilatation of the gastroesophageal sphincter, rugal folds of the stomach extending through the hiatus into the thoracic esophageal region as viewed from the esophageal and gastric retroflex positions, and evidence of reflux esophagitis.
- In GEI, the rugal folds of the invaginated stomach form a bulging mass in the lumen of the caudal thoracic esophagus.

Treatment

- Surgery is indicated for treatment of large hiatal hernias and intussusceptions (see Chapter 66). Emergency surgery is required for reduction of a large GEI, along with intensive fluid therapy for treatment of shock (see Chapter 3).
- Small intermittent hiatal hernias do not usually require surgery. Medical management of reflux esophagitis (see earlier in this chapter) and a low-fat canned or liquid diet fed 3 to 5 times per day (to minimize gastric volume and incidence of gastroesophageal reflux) usually controls clinical signs. In refractory cases, consider other causes of regurgitation and vomiting before surgical intervention.
- Surgical correction of upper airway obstruction (laryngeal disease, brachycephalic syndrome) may resolve clinical signs and radiographic detection of hiatal hernia in some patients, and it should be considered before performing surgical hernia repair.

PERIESOPHAGEAL OBSTRUCTION

Etiology

- Mass lesions arising from the periesophageal tissues may cause signs of esophageal disease, because esophageal compression leads to partial or complete obstruction.
- Examples include thyroid tumors (cervical esophagus), mediastinal tumors (e.g., lymph node, thymus, and heart base), lung tumors, and intrathoracic abscesses.

Clinical Signs

- Clinical signs associated with external compression of the esophagus by mass lesions (especially neoplasia) include chronic progressive regurgitation, dysphagia, and hypersalivation.
- Signs of esophageal disease may be overshadowed by signs reflecting involvement of other systems (e.g., pulmonary metastases and pleural and pericardial effusion), such as dyspnea, cough, and exercise intolerance.

Diagnosis

Radiography

- Survey thoracic radiographs usually identify an intrathoracic mass.
- If survey films are unremarkable, a barium esophagram is indicated to identify the location and severity of obstruction.

Endoscopy

Endoscopy determines the extent of esophageal obstruction and helps characterize whether it is extramural or intramural. A stenotic region with normal-appearing mucosa is indicative of extramural compression by a periesophageal mass rather than stricture or primary neoplasia of the esophagus.

Biopsy

The diagnosis depends on identifying the cause of the offending mass lesion with fine-needle aspiration or biopsy via thoracotomy.

Treatment

Treatment and prognosis are determined by the underlying cause of esophageal compression.

ESOPHAGEAL NEOPLASIA

Etiology

Primary esophageal neoplasms are rare. Malignant tumors of the esophagus include squamous cell carcinoma, osteosarcoma, fibrosarcoma, and undifferentiated carcinoma. Metastatic tumors occasionally involve the esophagus, but unless the tumor is large, clinical signs of esophageal disease are absent.

- Esophageal fibrosarcoma and osteosarcoma in dogs can develop after malignant transformation of esophageal granulomas associated with infection by the helminth parasite *S. lupi*. This parasite occurs in the southeastern United States. The life cycle involves a coprophagous beetle that is eaten by the dog or by a transport host (mouse, chicken, bird, reptiles) that is subsequently eaten by the dog.
- Squamous cell carcinoma is the most commonly reported esophageal tumor in cats.
- The most common benign esophageal tumor is leiomyoma.

Clinical Signs

- Animals with esophageal neoplasia have signs of chronic regurgitation, dysphagia, and ptyalism that are slowly but relentlessly progressive.
- Anorexia, weight loss, and cachexia result from inability to retain food or are secondary to the systemic effects of advanced neoplasia and metastasis.
- Signs associated with *S. lupi* infection are often subclinical until late in the disease and include anorexia, lethargy, regurgitation, and dyspnea (with large masses).

Diagnosis

Chronic progressive signs of obstructive esophageal disease in an older animal suggest esophageal neoplasia.

Physical Examination

- Findings may include weight loss and emaciation consistent with the secondary effects of chronic malnutrition.
- Cervical esophageal tumors may be palpable.
- Dyspnea may occur with a large intrathoracic mass or pulmonary metastatic disease.

Radiography

Survey thoracic radiographs may be normal or may reveal a mass in the region of the esophagus. With partial to complete esophageal obstruction, the esophagus may be dilated proximal to the mass and contain air, fluid, or food.

- Evaluate the lungs for metastases.
- Spondylitis of the caudal thoracic vertebrae or hypertrophic osteopathy may be associated with *S. lupi* esophageal granulomas.
- A barium esophagram can confirm the presence of a mass or obstruction, characterize the mass as esophageal or periesophageal in origin, and evaluate the extent of esophageal wall involvement.

Endoscopy and Biopsy

Endoscopy and biopsy are required for definitive diagnosis of esophageal neoplasia.

- If esophageal sarcoma is caused by *S. lupi* infection, adult worms may be seen protruding into the lumen of the esophagus from the affected tissue. *S. lupi* eggs may be detected on fecal sedimentation.
- Squamous cell carcinoma usually appears as a proliferative mass with an irregular, friable, ulcerated surface and causing variable obstruction of the lumen.
- Obstruction may cause the esophagus to be dilated with ingesta or fluid proximal to the tumor site.

Treatment

Successful treatment of esophageal neoplasia requires surgical resection of the tumor (see Chapter 66).

- For best results, it is important to make an early diagnosis before metastasis or extensive esophageal involvement has occurred. In many cases, the tumor is too extensive for complete surgical resection, and thus the prognosis is poor.
- Anthelmintic therapy for *S. lupi* infection includes the following:
  - Doramectin (Dectomax, Pfizer), which reportedly cured six dogs of spirocercosis, at 200 µg/kg SC at 14-day intervals for three doses or at 500 µg/kg PO daily for 6 weeks in refractory cases.
  - Although unproved, fenbendazole (50 mg/kg PO) or ivermectin (200 µg/kg, single oral dose) may be effective against larvae.
- Levamisole is not recommended because it sterilizes but does not kill adult *S. lupi* organisms.

Chapter 66

Surgery of the Esophagus

Ronald M. Bright

In general, the signs of esophageal disease are related to loss of function, to obstruction, or to inflammation of the esophagus and the surrounding structures. Surgery on the esophagus probably requires more skill and precision than any other portion of the alimentary tract. The esophagus is constantly moving, lacks a serosal layer, and does not have omentum to help seal small leaks. If suture line reinforcement is necessary, adjacent muscle, diaphragmatic tissue, or pericardium may be used. Extra-abdominal movement of omentum on a pedicle through a rent in the diaphragm can also be used for this purpose.

ANATOMY

Upper Esophageal Sphincter

The upper esophageal sphincter is located at the proximal end of the esophagus. There is no obvious thickening of the esophageal tissue.

- Sphincter function is performed primarily by the cricopharyngeal muscle.
- Innervation of the cricopharyngeal muscle is from branches of the glossopharyngeal and vagus nerves.
- The blood supply is derived primarily from branches of the cranial thyroid artery.

Lower Esophageal Sphincter

The distal 2 cm of the esophagus is located intra-abdominally below the diaphragm and is thought to have a slightly thickened inner circular muscle that acts as a sphincter.

- Sling fibers from the lesser curvature of the stomach may reinforce the sphincteric function.
- The pinchcock effect of the diaphragmatic hiatus is thought to assist in preventing gastroesophageal reflux.
- Innervation is primarily from the vagus.
- The major portion of the blood supply is derived from the esophageal branch of the left gastric artery.

Body of the Esophagus

- The esophagus has a cervical and thoracic portion.
- The esophagus has four layers—adventitia, muscularis (striated in the dog, smooth muscle in the caudal one-third of the cat), a thin submucosal layer, and mucosa composed of stratified squamous epithelium.
- The blood supply is from the thyroid and esophageal branches of the carotid artery proximally; the bronchoesophageal artery supplies the thoracic and distal portion of the esophagus. A few branches from the left gastric artery are located just above and below the lower esophageal sphincter.

CRICOPHARYNGEAL ACHALASIA

- This rare form of dysphagia is characterized by inadequate relaxation of the cricopharyngeal muscle and affects primarily young animals.
- This condition has recently been determined to be an inherited condition in golden retrievers.

Preoperative Considerations

As described in Chapter 4, perform barium swallow fluoroscopy preoperatively to distinguish cricopharyngeal achalasia from other forms of oropharyngeal dysphagia and to evaluate motility of the body of the esophagus. Evaluate for aspiration pneumonia and treat accordingly.

Surgical Procedure (Cricopharyngeal Myectomy)

Objectives

- Surgically relieve the constriction by removing fibers of the cricopharyngeal muscle.
- Allow unobstructed movement of food from the pharynx to the esophagus while decreasing the incidence of aspiration pneumonia.

Equipment

- Standard surgical pack
- Gelpi or Weitlaner retractors
- Surgical suction and cautery

Technique

1. Place the animal in dorsal recumbency with the legs tied caudally.
2. Aseptically prepare the ventral portion of the neck, from the angle of the mandible to the manubrium.
3. Make a ventral midline cervical incision, starting just cranial to the larynx and extending caudally 15 to 20 cm.
4. Separate the sternohyoideus muscles to expose the trachea and cricothyroideus muscles.
5. Expose the dorsum of the trachea by rotating the larynx and trachea 180 degrees in either direction. If working on the dog's right side, pull the trachea to the right.
6. Remove a thin layer of connective tissue, exposing the dorsal aspect of the cricopharyngeal musculature.
7. Incise the cricopharyngeal musculature on its midline. Gently elevate the muscle from the underlying esophagus with meticulous and careful blunt dissection. Consider placing an inflated Foley catheter or endotracheal tube in the esophagus to help delineate the structures.
8. Elevate the cricopharyngeal muscle laterally and then cranially to the thyropharyngeal muscles.
9. Cut the halves of the muscle belly along their lateral attachments and remove the muscle (Fig. 66-1).
10. Allow the larynx and trachea to return to their normal position, and appose the sternohyoideus muscle with a continuous suture, using 4-0 synthetic absorbable suture.

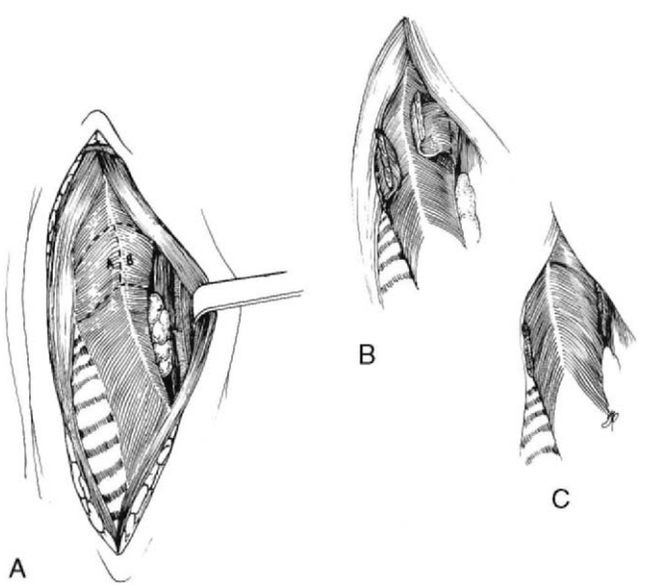

Figure 66-1. Myotomy of the cricopharyngeus muscle for cricopharyngeal achalasia. The cranial esophagus has been exposed via a ventral midline cervical approach. *A,* Rotate the esophagus so that the dorsal aspect is exposed and the cricopharyngeal muscles are seen. *B,* Initially incise on the midline (raphe) to separate the paired muscles. Use care not to perforate the esophagus. *C,* Make two longitudinal incisions laterally, one in each muscle belly, in the cricopharyngeal muscles. Remove each section of muscle.

Postoperative Care and Complications

Short-Term

- Give blenderized food for 48 hours.
- Slowly return to normal diet over the next 48 to 72 hours.
- If *oral phase dysphagia* is present (see Chapter 65), there may not be any improvement seen following surgery.
- If *pharyngeal phase dysphagia* is present (see Chapter 65) concurrently, a cricopharyngeal myectomy may worsen the animal's signs and the aspiration pneumonia.
- Hypomotility of the proximal esophagus may interfere with a successful outcome. Food and liquids pass more easily through the cricopharyngeal sphincter, but decreased clearance by the esophagus enhances the likelihood of stasis and retrograde movement of material into the trachea. Aspiration pneumonia continues to be a problem.

Long-Term

- If nutritional needs are aspiration pneumonia problems are not aggressively treated prior to surgery for cricopharyngeal achalasia, the failure rate is high. Careful section of patients for surgery of this condition is mandatory.

Prognosis

- If there is no concurrent oropharyngeal or esophageal neuromuscular disorder, the prognosis is fair to good.

VASCULAR RING ANOMALY

Preoperative Considerations

- Any young dog or cat with regurgitation should be suspected of having a vascular ring anomaly.
- Most animals with a vascular ring anomaly are presented to the veterinarian at the age of 4 to 10 weeks. Rarely, an animal may reach adulthood before a vascular ring anomaly is diagnosed.
- Persistent right aortic arch (PRAA) accounts for 95% of vascular ring anomalies in dogs.
- Rule out other causes of megaesophagus (see Chapter 65).
- Confirm the diagnosis by contrast esophagography and endoscopy of the esophagus.
- Fluoroscopy can evaluate motility of the esophagus above and below the site of constriction.
- Evaluate the lungs radiographically for aspiration pneumonia. If necessary, institute antibiotic therapy several days preoperatively.

- Debilitated animals may benefit from hyperalimentation via a gastrostomy tube (see Chapter 3) for 7 to 10 days before surgery.

Surgical Procedure

Objectives

- Relieve the constricted portion of the esophagus caused by the vascular ring.
- Allow unobstructed passage of food to the stomach.
- Avoid perforation of the esophagus.

Equipment

- Finochietto rib retractors
- Suction and cautery
- Right-angle forceps
- DeBakey thumb forceps
- Foley catheter or balloon dilator

Technique

1. Place the animal in right lateral recumbency.
2. Aseptically prepare the left lateral thoracic wall from three intercostal spaces above to five spaces below the fourth intercostal space.
3. To approach the vascular ring, perform a thoracotomy through the fourth intercostal space (see Chapter 167 for thoracotomy technique).
4. Identify the ligamentum arteriosus, which is a constricting band encircling the esophagus. In a PRAA, the aorta is on the animal's right side and cannot be seen through a left thoracotomy (see Fig. 85-1).
5. If a PRAA is not the problem, consider vascular anomaly variations, including a left subclavian artery originating from the brachiocephalic trunk and, less commonly, a double aortic arch.
6. Double-ligate (e.g., with 3-0 or 4-0 silk) and divide the constricting vessel.
7. Gently dissect the mediastinum and adventitia away from the esophagus 1 to 2 cm above and below the constricted portion. Dissect any restricting bands of tissue away from the esophagus.

▼ ***Key Point*** The esophageal wall usually is very thin; use great care to avoid perforation during dissection.

8. Pass a large Foley catheter or balloon dilator into the esophagus per os to further expand the esophagus at the site of constriction.

Closure

1. Administer a long-acting local anesthetic agent (e.g., mepivacaine) caudal to the head of the rib above and below the thoracotomy incision.
2. Place a chest tube before closure.
3. Close the thoracotomy incision routinely (see Chapter 167).

Postoperative Care and Complications

Short-Term

- Evacuate the pleural cavity and administer mepivacaine through the indwelling chest tube to control pain as necessary postoperatively. The chest tube usually can be removed within 24 hours.
- Regurgitation may continue to be a problem early in the postoperative period. Feeding blenderized food with the animal in a standing position may be necessary because of concurrent esophageal hypomotility.

Long-Term

- Amelioration of signs followed by a return of regurgitation several weeks after surgery may signal extraluminal scar formation acting as a constricting band.
- Repeated endoscopic balloon dilatation (see Chapter 65) of these strictures sometimes ameliorates signs.
- An esophagoplasty or resection of the stenotic segment may be necessary.

Prognosis

- The prognosis is good in most animals. Animals with severe dilatation of the esophagus cranial to the obstruction have a poor prognosis.
- Although not well documented, it is believed that the younger the patient at the time of surgical correction, the better the prognosis.
- The prognosis is thought to be better in animals in which preoperative fluoroscopy shows
  - Normal or near-normal motility of the esophagus above and below the constriction.
  - Absence of severe esophageal dilatation cranial to the obstruction.

ESOPHAGOTOMY

The most common indication for an esophagotomy is to remove a foreign body that could not be removed by intraluminal retrieval methods.

Preoperative Considerations

- Place a large-bore tube in the esophagus just before an esophagotomy to aspirate esophageal contents, act as a support while incising into the lumen of the esophagus, and help immobilize the esophagus.
- Treat concurrent aspiration pneumonia aggressively before and after esophagotomy.
- Although surgery of the esophagus carries a low risk of postoperative infection, some contamination occurs. Perioperative antibiotics are recommended (given 30 minutes before surgery and repeated once or twice). The antibiotic chosen should be effective against gram-positive pathogens (e.g., a cephalosporin).

Surgical Procedure

Objectives

- Gain access to the lumen of the esophagus to assist in the removal of a foreign body.
- Make the incision over healthy esophageal tissue.
- Handle esophageal tissues gently to preserve blood supply and optimize healing.
- Establish a watertight seal with closure.

Equipment

- Standard general surgery pack and suction unit
- Laparotomy pads to isolate the esophagus and prevent contamination of the surrounding tissues
- Fine-tipped needle holders to assist in delicate placement of sutures during closure
- Long-handled Metzenbaum scissors for thoracic esophagus dissection
- DeBakey thumb forceps

Technique (Cervical)

1. Make a ventral midline cervical incision extending from the manubrium to the larynx.
2. Retract the trachea and carotid sheaths gently to the right side.
3. Isolate the esophagus from surrounding structures with moistened laparotomy pads.
4. Following the insertion of a large-bore orogastric tube, make an incision into the esophagus.

Closure

1. A two-layer closure is preferred:
   a. The first layer incorporates the submucosa and mucosa; use 3-0 or 4-0 monofilament nonabsorbable sutures with the knots tied in the lumen.
   b. The second layer incorporates the muscle and adventitia. Use an absorbable synthetic suture for this layer.
2. Alternatively, close both layers with a single interrupted appositional suture pattern. Place sutures 2 to 3 mm deep and at intervals of 2 to 3 mm.
3. Irrigate the surgical field with a copious amount of sterile saline.
4. If infection is present or tissue trauma excessive, use a closed drainage system with silicone tubing, for 3 to 5 days.

Technique (Cranial Thoracic)

1. To approach the cranial thoracic esophagus (T2–T6), perform a right-sided third or fourth intercostal space thoracotomy.
2. Retract the cranial and middle lung lobes caudally with moistened sponges.
3. If necessary, dissect the azygos vein free and ligate.
4. Dissect the mediastinal pleura overlapping the esophagus to just above and below the proposed site of esophagotomy.

▼ ***Key Point*** Avoid trauma to the vagal nerve trunks located laterally along the esophagus.

Technique (Caudal Thoracic)

1. Perform a right-sided seventh or eighth intercostal space thoracotomy to gain exposure to the caudal one-half of the thoracic esophagus.

Closure

1. Closure of an esophagotomy incision is similar to that described under Cervical Technique.
2. Place a chest tube before thoracotomy closure.

Postoperative Care and Complications

- Remove the chest tube 24 to 48 hours postoperatively unless esophageal perforation and mediastinitis were present.
- Withhold all food and water (NPO) and give intravenous fluid therapy for at least 48 hours.
- If esophageal tissue was devitalized or compromised at the time of esophagotomy, it may be necessary to maintain the NPO period for several weeks.
- Ideally, use a gastrostomy tube for nutritional support during the NPO period (see Chapter 3).
- For the next 5 to 7 days, feed a blenderized diet. Gradually return to a normal diet by postoperative day 10.
- If infection was present at the time of esophagotomy, submit a tissue sample for culture and sensitivity testing and initiate appropriate antimicrobial therapy.

Prognosis

- The prognosis is good if the tissue was viable at the time of esophagotomy.
- If perforation has already occurred and infection is present, the prognosis is poor.

ESOPHAGEAL RESECTION AND ANASTOMOSIS

Indications for resection and anastomosis include foreign bodies, esophageal strictures, neoplasia, and granulomas.

Preoperative Considerations

▼ ***Key Point*** Some type of nutritional support (e.g., via gastrostomy tube) for patients undergoing an esophageal resection and anastomosis should always be part of the preoperative treatment strategy.

- If the site of anastomosis is unhealthy or compromised, a reinforcement or grafting technique may be necessary.
- Many patients requiring esophageal resection are dehydrated and malnourished and may have aspiration pneumonia. Ideally, correct these conditions before resection and anastomosis.

Surgical Procedure

Approaches to the various parts of the esophagus are described under Esophagotomy. Closure following anastomosis and resection is described here.

Objectives

- Resect the lesion and reappose the esophagus under minimal tension.
- Restore esophageal continuity while minimizing the risk of early postoperative leakage or later stricture formation.

Equipment

- Similar to that for esophagotomy plus intestinal non-crushing forceps

Technique—Closure

1. A two-layer closure, using a simple interrupted appositional suture pattern, is preferred (Fig. 66-2).
   a. Use non-crushing forceps (or fingers) to occlude esophageal ends during closure.
   b. Use multiple stay sutures to maintain alignment of the tissues.
2. Close the contralateral adventitial and muscular layers, using 3-0 or 4-0 synthetic non-absorbable sutures.
3. Appose the contralateral mucosal-submucosal layers with 3-0 or 4-0 monofilament non-absorbable sutures with the knot tied in the lumen; follow with closure of the ipsilateral mucosa-submucosa.
4. Close the ipsilateral superficial layers as in Step 2.
5. To relieve excessive tension across the suture line:
   a. A circular myotomy (including only the outer muscular layer) adjacent to the anastomosis can be performed. Injecting saline between the muscle layers helps to identify the outer layer.
   b. Mobilizing the stomach cranially through an enlarged hiatal opening can also help to reduce tension across the suture line.
6. If necessary, reinforce the sutures by bringing omentum on a pedicle through a small rent in the diaphragm or by using pericardial tissue or intercostal musculature.
7. Place a chest tube before thoracotomy closure.

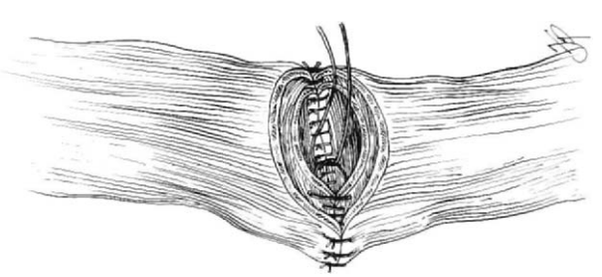

Figure 66-2. Esophageal resection and anastomosis. Close the esophageal layers in the following order: far wall, seromuscular layer; far wall, mucosal layer (knots in the lumen); near wall, mucosal layer (knots in the lumen); near wall, seromuscular layer.

Postoperative Care and Complications

Short-Term

▼ ***Key Point*** Bypass the esophageal anastomotic site and provide nutrition via gastrostomy tube for a minimum of 7 days.

- Monitor closely for fever, which often signals an infection secondary to leakage.
- Allow water consumption and return to oral feeding beginning on day 7. Retain the gastrostomy tube until normal food and water intake can be restored.

Long-Term

- Dysphagia or regurgitation occurring 3 to 6 weeks postoperatively probably indicates a stricture.
- Bougienage or balloon dilatation may be necessary to relieve the postoperative stricture (see Chapter 65 for discussion of esophageal stricture).

Prognosis

- Esophageal surgery of any kind carries a poorer prognosis than surgery on any other portion of the alimentary tract.
- If the anastomosis is done with precision and the tension across the suture line is minimal, fair to good results can be expected.
- Any compromise of the tissue at the anastomotic site carries a guarded to poor prognosis.

ESOPHAGOTRACHEAL/ESOPHAGOBRONCHIAL FISTULAS

Preoperative Considerations

- These fistulas usually are sequelae to a chronic foreign body.
- Most affected animals are high-risk patients because of severe bronchopneumonia.
- It may be necessary to sacrifice a lung lobe to achieve a cure.
- The use of gas anesthesia may cause the stomach to become overinflated if the endotracheal tube is located cranial to the fistula.

Surgical Procedure

Objectives

- Isolate the esophagus and the trachea or bronchus associated with the fistula.
- Close the abnormal communication between the alimentary and respiratory tracts.

Equipment

- General surgical pack
- Laparotomy pads
- Finochietto retractors
- TA stapler (U.S. Surgical Corporation, Norwalk, CT) (optional for lung lobectomy)
- Chest tube

Technique

1. If a lobectomy is contemplated, the approach is through the sixth or seventh intercostal space.
2. Isolate the esophagus and trachea or affected bronchus and dissect around the fistula. Obtain samples for culture and sensitivity testing.
3. Sever the fistula near its respiratory attachment; debride the opening and close using 3-0 or 4-0 non-absorbable sutures.
4. If necessary, enlarge the opening to the esophagus to remove the foreign body if it is still present. The wound is then debrided and the esophageal defect closed in two layers as described previously under Esophagotomy.
5. Remove the affected lung if it is irreversibly damaged.
6. Place a chest tube before the thoracotomy closure.

Postoperative Care and Complications

Short-Term

- Treat concurrent pneumonia, emphysema, or septicemia aggressively, and administer a broad-spectrum antibiotic pending culture and sensitivity testing results.
- If empyema is present, consider leaving the chest tube in for an extended period of time for ongoing evacuation of fluid from the pleural space (see Chapter 3).
- Maintain enteral feeding for an extended period of time via a tube gastrostomy to decrease the likelihood of leakage from the esophageal wound and allow healing of the esophagus.

Long-Term

- Stricture is always a potential sequela to esophageal surgery.

Prognosis

- In most cases, pulmonary involvement is significant, and the mortality rate is high.
- If the degree of pulmonary involvement and esophageal trauma is minimal, the prognosis is better.

ESOPHAGEAL DIVERTICULECTOMY

Preoperative Considerations

- Perioperative antibiotics are necessary to decrease the potentially deleterious effects of bacterial leakage.
- If regurgitation is severe, dehydration may occur; correct with fluid therapy before surgery.

Surgical Procedure

Objectives

- Resect the large diverticula and reconstruct the esophageal wall.
- Remove the primary cause of the diverticulum, including strictures or periesophageal adhesions.

Equipment

- General surgical pack
- Finochietto rib retractors
- Chest tube
- Non-crushing intestinal or vascular clamp

Technique

1. A left eighth intercostal space thoracotomy is used to approach most diverticula because of their epiphrenic location (just cranial to the diaphragm).
2. Isolate the diverticulum by blunt dissection down to its base.
3. Place a non-crushing clamp across the base of the diverticulum.
4. Excise the diverticulum below the clamp and close the esophagus in an open two-layer technique as described previously under Esophagotomy.
5. Place a chest tube before thoracotomy closure.

Postoperative Care and Complications

Short-Term

- Dietary restrictions are the same as those used following esophagotomy. A gastrostomy tube usually is not necessary.
- Monitor for elevated temperature and neutrophilia closely, because these suggest esophageal dehiscence and mediastinitis.
- Before discharge, perform contrast esophagography to evaluate esophageal motility.

Long-Term

- Stricture formation may be a sequela to extensive excision of the esophagus.
- Special dietary management may be necessary for the life of the animal if motility dysfunction remains.

Prognosis

- The prognosis is good if the underlying cause can be corrected.

ESOPHAGEAL STRICTURE REPAIR

Preoperative Considerations

▼ ***Key Point*** Attempt surgical correction of esophageal stricture only after bougienage or balloon dilatation (as described in Chapter 65) is unsuccessful.

- Cervical strictures carry less risk with surgical correction than do those involving the thoracic esophagus.
- Correction of fluid and electrolyte imbalances is imperative before any surgical procedure.

Surgical Procedure

Objectives

- Increase the size of the esophageal lumen by reconstructive procedures or resection.
- Resection of a lesion greater than 3 cm in length may require an esophageal lengthening procedure or a suture line reinforcement technique.

Equipment

- Standard general surgery pack
- Cervical location—Gelpi retractors; thoracic location—Finochietto retractors
- Chest tube (thoracic repair)
- Intestinal non-crushing clamps

Technique—Esophagoplasty

If the stricture is not too wide, a longitudinal full-thickness incision followed by a transverse closure (two-layer) may be adequate to increase lumen size. This is similar to Heineke-Mikulicz pyloroplasty (see Chapter 68).

Patch-Grafting Technique in Cervical Region

1. Resect a partial circumference stricture, leaving a defect.
2. Separate a belly of one of the paired sternohyoideus or sternocephalicus muscles from its attachment to the other belly and reflect it laterally.
3. Transpose the muscle to lie deeply against the esophageal defect. Suture the muscle to the edges of the defect. Be sure that the muscle fills the entire defect.
4. The muscle graft must be mobile enough and of sufficient width to prevent postoperative stricture.

Resection and Anastomosis

This is described previously under Esophageal Resection and Anastomosis.

Postoperative Care and Complications

Short-Term

- Monitor signs of infection that may suggest leakage from the surgical site; the more extensive the resection, the more likely that signs of early leakage will occur.
- Placement of a gastrostomy tube is probably necessary in most cases to prevent leakage and enhance esophageal healing.

Long-Term

- Stricture is likely to recur.
- Lifelong tube gastrostomy to bypass the stricture may be necessary if surgery fails and if the owner is willing to maintain nutrition by this method.

Prognosis

- The more extensive the surgery, the poorer the prognosis.
- Less aggressive procedures (e.g., esophagoplasty) carry a better prognosis.

HIATAL HERNIA

Preoperative Considerations

▼ ***Key Point*** The radiographic presence of a hiatal hernia does not by itself indicate the need for surgical repair.

- The reflux esophagitis that results from hiatal hernia can be managed successfully in most cases with medical therapy alone (see Chapter 65).
- Sphincter reinforcement procedures (e.g., fundoplication) probably are not indicated in most cases of hiatal hernia, because incompetence of the lower esophageal sphincter is seldom a factor in dogs and cats (in contrast to humans).
- Treat gastroesophageal intussusception using similar surgical techniques as described next.

Surgical Procedure

Objectives

- Restore the anatomic relationship of the stomach, diaphragm, and distal esophagus.
- Decrease the size of the enlarged hiatus.
- "Fix" the distal esophagus and stomach to structures below the diaphragm.

Equipment

- General surgery pack
- Abdominal self-retaining retractors
- 28-French orogastric tube
- Malleable (ribbon) retractors

Technique

1. Place the animal in dorsal recumbency with the forelimbs gently drawn forward.
2. Aseptically prepare the ventral midline from the mid-sternum to 2 to 3 cm cranial to the pubis.
3. Pass a 28-French orogastric tube into the stomach per os.
4. Incise the skin and underlying tissues from just below the xiphoid to several centimeters caudal to the umbilicus.
5. Cover the left side of the liver with a saline-soaked laparotomy pad and retract the liver to the right and caudally with a wide malleable retractor.
6. Evaluate the esophageal hiatus for size. Gently dissect the surrounding tissue to expose the margins of the hiatus. Identify and protect the vagus nerves.
7. While an assistant places caudal traction on the stomach, plicate the hiatus with 1-0 or 2-0 non-absorbable sutures (Fig. 66-3).
8. When plication is completed, it should be possible to insert two fingers through the hiatus.

Figure 66-3. Hiatal plication for hiatal hernia. Place the stomach in its normal position and put slight caudal traction on the stomach to expose the distal esophagus and esophageal hiatus. Plicate the esophageal hiatus with non-absorbable sutures, then perform an esophagopexy by placing sutures from the diaphragm to the esophageal wall, being careful not to penetrate the lumen and not to injure the vagus nerves. Perform a pexy of the fundus to the interior body wall *(insets)*. Incise the seromuscular layer of the fundus and then incise the peritoneum and underlying muscle adjacent to the fundic incision. Suture the stomach wall to the body wall as shown.

9. Perform esophagopexy by placing 2-0 non-absorbable sutures between the diaphragm and the lateral aspect of the distal esophagus as it passes through the hiatus; incorporate the muscle layers of the esophagus (see Fig. 66-3).
10. Fix the fundus of the stomach to the left abdominal wall by performing an incisional gastropexy.
11. Make an incision 3 to 4 cm long through the serosa and muscular layers of the stomach. Make a similar incision in the peritoneum and transversalis musculature (see Fig. 66-3).
12. Appose the margins of the two surgical wounds, using six to eight size 1-0 non-absorbable sutures.

Postoperative Care and Complications

Short-Term

- Feed a gruel diet for 3 to 5 days. A return to a normal ration usually is possible thereafter.
- Some animals may need to be fed from an elevated position for an indefinite period of time.
- If severe esophagitis was present before surgery, continue medical therapy for reflux esophagitis (see Chapter 65) with a systemic antacid postoperatively.
  - Omeprazole (0.7 mg/kg PO once daily) is the preferred antacid. Ranitidine (2–4 mg/kg PO q8–12h) or cimetidine (5 mg/kg PO q8h) can be substituted.
  - Administer metoclopramide (0.2–0.4 mg/kg PO q8h) or cisapride (0.5–0.7 mg/kg PO q8h) to most patients for 2 to 3 weeks postoperatively.
- Some dysphagia is common for several days following surgery. However, unrelenting dysphagia suggests that the hiatus has been narrowed too much. Reoperation is necessary in those cases that do not respond to medical therapy and when there are signs of dysphagia beyond 1 week.

Long-Term

- Perform esophagography if signs of regurgitation continue in spite of surgery and follow-up medical therapy.
- If failure of the "pexy" procedure or if incompetence of the lower esophageal sphincter is suspected, surgical intervention is necessary.
  - If a sphincter-reinforcement procedure is indicated, perform the Nissen fundoplication (Fig. 66-4).

Prognosis

- The prognosis is good if aspiration pneumonia is controlled.
- Chronic reflux esophagitis associated with a hiatal hernia may cause various degrees of esophageal stricture. If the pathology is advanced to this degree, the prognosis is poor.

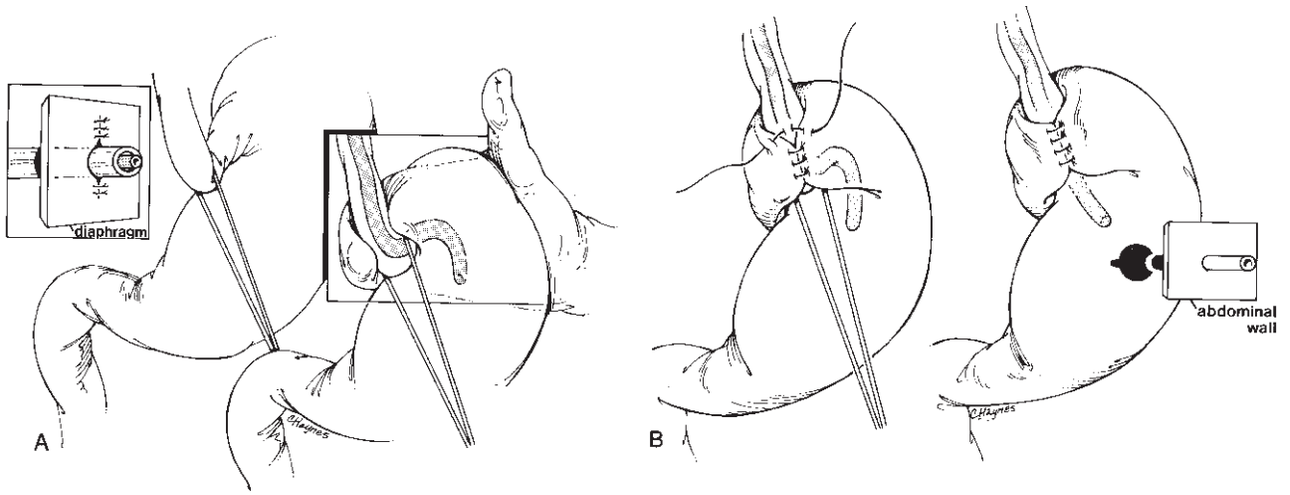

Figure 66-4. Surgical treatment of hiatal hernia. *A,* Place traction on the distal esophagus and wrap the fundus around the esophagus. *B,* Plicate the fundus around the distal esophagus and place a tube gastrostomy.

Chapter 67

Diseases of the Stomach

Susan E. Johnson / Robert G. Sherding / Ronald M. Bright

VOMITING

Vomiting is a common clinical sign associated with many gastrointestinal (GI) and non-gastrointestinal (non-GI) disorders of dogs and cats. Vomiting is a central nervous system reflex that is integrated in the vomiting center of the brain stem. Afferent stimuli can originate from the cerebral cortex, chemoreceptor trigger zone, pharynx, peritoneum, or abdominal viscera. Vomiting must be differentiated from regurgitation, which is the passive expulsion of undigested food indicating a pharyngeal (swallowing) or esophageal disorder (see Chapter 65).

The metabolic consequences of vomiting vary, depending on the volume and composition of the expulsed fluid. Mild vomiting of short duration usually is not accompanied by overt fluid, electrolyte, or acid-base imbalances. Frequent or profuse vomiting can cause metabolic complications such as dehydration; electrolyte imbalances such as hypokalemia, hyponatremia, and hypochloremia; and acid-base imbalances such as metabolic acidosis or metabolic alkalosis. Metabolic alkalosis is most likely to occur in dogs and cats with vomiting secondary to pyloric obstruction. Other potential complications of vomiting include aspiration pneumonia and reflux esophagitis.

Etiology

Vomiting is a clinical sign, rather than a diagnosis, and can be associated with numerous GI and non-GI disorders (Table 67-1).

▼ ***Key Point*** Remember that non-GI disorders commonly cause vomiting; do not overlook these before evaluating for primary GI causes of vomiting.

Clinical Signs

- Vomiting frequently is preceded by nausea (evidenced by hypersalivation, licking of the lips, repeated swallowing), retching, and abdominal contractions.
- Vomitus consists of stomach and duodenal contents such as food, mucus, and foamy or bile-stained fluid with a neutral or acidic pH.
- The term *hematemesis* is used when vomitus contains blood flecks, blood clots, or brown coffee grounds–like material (digested blood).
- Vomitus may contain hair, plant material, or other ingested foreign material that can irritate the stomach.
- Vomiting of undigested or partially digested food more than 12 hours after eating suggests delayed gastric emptying (functional or mechanical).
- Projectile vomiting (the forceful ejection of vomitus from the mouth that may be expelled a considerable distance) usually indicates gastric outlet or upper small bowel obstruction.
- Other clinical signs may be present depending on the underlying cause of vomiting and the presence of complications such as dehydration or electrolyte and acid-base imbalances.

Diagnosis

The diagnostic approach to vomiting is directed toward identifying the underlying disorder (see Table 67-1) and is influenced by whether vomiting is acute or chronic and by the associated historical and physical findings.

Acute Vomiting

Acute vomiting is a common problem in dogs and cats and may be caused by benign, self-limiting disorders such as acute gastritis or serious life-threatening diseases such as acute pancreatitis, intestinal obstruction, or acute renal or hepatic failure (see Table 67-1).

- Extensive diagnostic testing is not necessarily warranted in every dog or cat with acute vomiting, because nonspecific, self-limiting acute gastritis is a common cause of acute vomiting.
- Base the decision to perform further testing in an acutely vomiting dog or cat on historical and physical findings.
  - Further evaluation is usually warranted at initial presentation if abnormal physical findings are detected, such as fever, lethargy, depression,

Table 67-1. CAUSES OF VOMITING IN DOGS AND CATS

Acute Vomiting (<1 wk)	Chronic Vomiting (>1–2 wk)
Gastrointestinal Disorders	*Gastrointestinal Disorders*
Diet-related	Diet-related
Sudden diet change	Food intolerance
Food intolerance or allergy	Food allergy
Dietary indiscretion (e.g., garbage)	Chronic gastritis
Acute gastritis or enteritis	Lymphocytic-plasmacytic
Ingested bacterial enterotoxins	Eosinophilic
Foreign bodies (e.g., bones, plants, plastic, rocks, hairballs)	Granulomatous (e.g., pythiosis)
Ingested chemical irritants or toxins	Foreign bodies (including hairballs)
Drug-induced (e.g., aspirin and other NSAIDs, glucocorticoids, antineoplastics, erythromycin)	Parasites (*Ollulanus*, *Physaloptera*)
Viral enteritis (e.g., canine parvovirus, feline panleukopenia, canine distemper)	Reflux gastritis
Bacterial infection (e.g., *Helicobacter* spp.)	Hypertrophic gastropathy
Parasites (e.g., *Physaloptera*)	Gastrointestinal ulceration
Gastric or intestinal obstruction	Gastric neoplasia
Foreign bodies	Gastric outflow obstruction
Intestinal volvulus	Foreign bodies
Intestinal intussusception	Gastric neoplasia
Gastric dilatation-volvulus	Gastric polyps
Nongastrointestinal Disorders	Hypertrophic gastropathy
Acute pancreatitis	Pyloric stenosis
Acute renal failure	Chronic gastritis
Acute hepatic failure	Granuloma (pythiosis)
Ketoacidotic diabetes mellitus	External compression
Pyometra	Partial gastric dilatation-volvulus
Prostatitis	Gastric motility disorder
Peritonitis	Hiatal hernia
Drug-induced (e.g., cardiac glycosides, narcotics, antineoplastics)	Diaphragmatic hernia
Sepsis	Chronic colitis
CNS disorders (inflammation, edema)	Obstipation
Motion sickness	Partial distal intestinal obstruction
Vestibular disease	*Nongastrointestinal Disorders*
	Renal failure
	Hepatic disease
	Hypoadrenocorticism
	Hyperthyroidism (feline)
	Chronic pancreatitis (feline)
	Heartworm (feline)
	CNS disorders (e.g., inflammatory, neoplastic, visceral epilepsy)
	Lead toxicity
	Sialadenosis

CNS, central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs.

weakness, dehydration, or palpable abdominal abnormalities.
  - A history of possible GI foreign body exposure may warrant abdominal radiographs even if the physical examination is normal.
- If the history and physical examination are unremarkable, further diagnostic evaluation may be postponed and symptomatic therapy may be given on an outpatient basis.
- If vomiting does not resolve in 2 to 3 days or if additional clinical signs develop, further evaluation is indicated.

Chronic Vomiting

Chronic or persistent vomiting is always an indication for further workup.

History

Perform a complete history. Determine the past medical and deworming history, vaccination status, diet, and any recent exposure to medications, toxins, plants, string or other foreign bodies, garbage, or other sick animals.

Characterize vomiting as to duration, frequency, progression, relationship to eating, and other specific features (e.g., presence of hematemesis, foreign material, or partially digested food). Determine if there are other associated clinical signs.

- Is the appetite decreased or increased?
- Has there been weight loss?
- Has there been a change in attitude (depression)?
- Has there been any diarrhea?
- Is polyuria or polydipsia present?
- Is there a history of cough or dyspnea?

Physical Examination

Perform a complete physical examination. However, physical findings are often unremarkable in animals with gastric disorders.

- Perform a complete oropharyngeal examination to detect a sublingual string foreign body (especially in cats).
- Palpate the GI tract for masses, foreign bodies, trichobezoars, thickenings, distention, plication, or pain.
- Evaluate for evidence of non-GI causes of vomiting (e.g., lumpy, enlarged, or small kidneys with renal failure; cranial abdominal pain and fever with pancreatitis; icterus or hepatomegaly with liver failure; or palpable thyroid nodule with feline hyperthyroidism).
- Perform a digital rectal examination to evaluate the character of the feces (e.g., presence of melena, foreign material, blood, and mucus) and to obtain a sample for fecal evaluation.
- Evaluate for systemic effects or complications of vomiting (e.g., dehydration, weakness, and cachexia).
- Findings that suggest potentially serious underlying disease include hematemesis, weakness, severe depression, anorexia, abdominal mass, fever, abdominal pain, abdominal distention, dehydration, and shock.

Laboratory Evaluation

When further diagnostic testing is indicated, a stepwise strategy is recommended.

- Perform routine hematology, biochemistries (including serum amylase and lipase in dogs; serum pancreatic lipase immunoreactivity [PLI] in dogs and cats), urinalysis, survey abdominal radiographs, and miscellaneous ancillary tests, such as serum thyroxine (T_4) in cats greater than 6 years of age, feline leukemia virus (FeLV) antigen test, and feline immunodeficiency virus (FIV) antibody test, as indicated by the history and physical examination. These evaluations are necessary to rule out non-GI disorders that cause vomiting before evaluating for primary GI disorders with contrast radiology, endoscopy, or exploratory laparotomy.
- Routine blood tests are also helpful to detect and characterize metabolic complications of vomiting such as dehydration and electrolyte imbalances.
- Perform a fecal flotation test to diagnose GI parasitism, especially if vomiting is accompanied by diarrhea.
- Evaluate cats for heartworm disease in endemic areas, since vomiting is a frequent presenting sign in cats.
- Perform a fecal occult blood test to detect occult GI bleeding when blood loss is suspected but overt melena is absent.

Radiography

Perform routine ventrodorsal and lateral abdominal radiographs to identify radiopaque foreign bodies, gastric or intestinal obstruction, and abdominal masses or abnormalities of the kidneys, liver, and pancreas.

- Perform barium contrast radiography to evaluate for GI causes of vomiting such as radiolucent foreign bodies, obstruction, and mural thickening or irregularity. Use barium administered by stomach tube as recommended in Chapter 4.
- Barium mixed with food may be better than liquid barium to detect gastric retention disorders.
- Double air-barium contrast gastrography is also useful.
- Use aqueous iodide contrast (iohexol; Omnipaque, Amersham Health) rather than barium if perforation is suspected.
- Barium-impregnated plastic spheres (BIPS) are an alternative to liquid barium for evaluating gastric emptying and GI transit times.

Ultrasonography

Perform abdominal ultrasonography to evaluate for non-GI disorders associated with vomiting that are suspected based on initial blood test results (e.g., pancreatitis and hepatic or renal disease). Ultrasonography may also be helpful to evaluate for primary GI disorders such as intussusception, GI masses, and gastric outflow obstruction.

Endoscopy

Endoscopy of the stomach and proximal duodenum is a non-invasive technique for evaluation of primary upper GI disorders associated with vomiting. Endoscopy is used to visually examine the GI lumen, obtain biopsies, remove foreign bodies, and collect intraluminal juices.

- Endoscopy requires general anesthesia and a flexible fiberoptic endoscope. Appropriate endoscopes for use in evaluating the GI tract of dogs and cats are 100 to 150 cm long with a 7.5- to 9.4-mm-diameter shaft, 2.0- to 2.8-mm biopsy channel, four-way angulation of the tip, and flush and suction capabilities.
- Routinely evaluate the esophagus, stomach, pylorus, and proximal duodenum. Perform mucosal biopsies in all cases because abnormal histologic findings may be present despite a normal gross appearance.

Exploratory Laparotomy

- Exploratory laparotomy is sometimes indicated for diagnosis or treatment of primary GI disorders, especially when endoscopy is not available.
- Obtain full-thickness gastric and intestinal biopsies (see Chapters 68 and 70).

Treatment

Treatment strategies in the vomiting animal are directed toward the following:

- Correction of the underlying cause of vomiting, whenever possible.
- Symptomatic and supportive therapy of vomiting and its metabolic complications.
- Surgery is indicated to remove large gastric foreign bodies, excise localized tumors and deep ulcers, and correct gastric outflow obstruction.

Fluid Therapy

- Give fluids parenterally because vomiting usually precludes adequate oral intake of fluid. Subcutaneous fluid administration can be used to treat mild dehydration in the absence of other systemic signs, but IV fluid therapy is preferred for animals with moderate to severe dehydration. Daily fluid therapy requirements in the vomiting dog or cat depend on the degree of dehydration, ongoing fluid losses, and maintenance needs (see Chapter 5).
- Ideally, base the choice of replacement fluid on serum electrolyte concentrations and blood gas analysis, because the electrolyte and acid-base changes that occur secondary to vomiting may vary considerably. In the absence of such information, use a balanced electrolyte solution such as lactated Ringer's solution,

Plasma-Lyte 148, or 0.9% saline. Additional potassium supplementation (see Chapter 5) usually is necessary because hypokalemia is a common complication of vomiting.
- If metabolic acidosis is present, use an alkalinizing solution such as lactated Ringer's solution or Plasma-Lyte 148. Sodium bicarbonate administration is necessary only in the treatment of severe metabolic acidosis (pH < 7.1–7.2) (see Chapter 5).
- Hypochloremic metabolic alkalosis is most likely to occur with pyloric obstruction. Give 0.9% saline supplemented with potassium chloride.
- For a comprehensive discussion of fluid therapy, refer to Chapter 5.

Dietary Management of Acute Vomiting

- Restrict oral intake of food to minimize vomiting and further fluid loss. Withhold food for at least 12 to 24 hours.
- If vomiting resolves, offer a bland, digestible, moderately fat-restricted diet such as chicken and rice, low-fat cottage cheese and rice, or a commercially available veterinary diet that meets these requirements.
- After 2 to 3 days on the bland diet, gradually reintroduce the animal's routine diet over a period of 2 to 3 days.

Antiemetics

Antiemetics are used for symptomatic control of acute vomiting on a short-term basis or to control profuse vomiting that results in fluid, electrolyte, or acid-base disturbances.

Phenothiazines

Phenothiazine derivatives are broad-spectrum, central-acting antiemetics that inhibit the chemoreceptor trigger zone (CRTZ) at low doses and depress the vomiting center at higher doses. Phenothiazines, especially chlorpromazine (0.5 mg/kg SC, IM, or IV q6–8h), and prochlorperazine (0.5 mg/kg SC, IM, or IV q6–8h) are the most widely used antiemetics.

- Hypotension, a potentially serious side effect, is caused by alpha-adrenergic receptor blockade. Consequently, use phenothiazines cautiously in patients with preexisting dehydration.
- Sedation may occur because of concurrent tranquilizing properties.
- Phenothiazine derivatives decrease the seizure threshold and should not be used in animals with seizure disorders.
- Phenothiazine derivatives are the most effective central-acting antiemetic in cats, regardless of the underlying cause.

Metoclopramide

Metoclopramide (Reglan, Robins) (0.2–0.4 mg/kg PO, IM, or SC q8h or 1–2 mg/kg q24h as a constant-rate IV infusion) possesses both central and peripheral antiemetic properties. Central effects are attributed to antidopaminergic activity at the CRTZ and at higher doses, antagonism of 5-hydroxytryptamine type 3 (5-HT_3) serotonergic receptors. The peripheral antiemetic effect is due to its stimulant effect on GI motility.

- Metoclopramide promotes gastric emptying by increasing the tone and amplitude of gastric contractions and relaxation of the pylorus (Fig. 67-1). Because gastric relaxation and retroperistalsis are key events preceding vomiting, their inhibition may account in part for the drug's peripheral antiemetic effect.
- Metoclopramide is indicated for broad-spectrum antiemetic therapy. It is frequently used to prevent chemotherapy-induced nausea and vomiting.
- It is indicated for control of vomiting associated with parvoviral gastroenteritis because this disorder may be complicated by delayed gastric emptying.
- Metoclopramide may not be as useful a central-acting antiemetic in cats as in dogs because D_2 dopamine receptors are less important in mediating vomiting in cats.
- Metoclopramide should not be used in animals with seizures or those receiving phenothiazines, butyrophenones, narcotics, or anticholinergic drugs.
- Decrease the dose in renal failure.

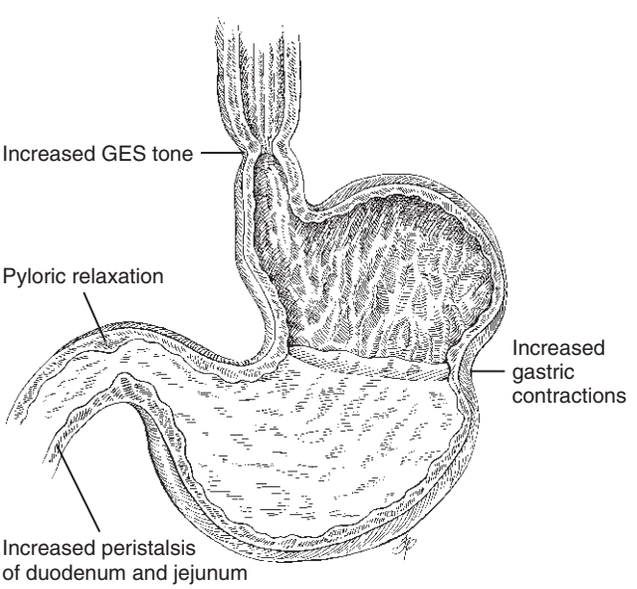

Figure 67-1. Effects of promotility agents such as cisapride and metoclopramide on the gastrointestinal tract. Promotility drugs increase gastroesophageal sphincter (GES) tone and promote gastric emptying by coordinating increased gastric contractions with pyloric relaxation and increased intestinal peristalsis.

Serotonin Antagonists

Ondansetron (Zofran, GlaxoSmithKline) (0.1–0.2 mg/kg SC q8h, 0.5 mg/kg IV loading dose, and 0.5 mg/kg IV infusion q1h or 0.5–1.0 mg/kg PO q6–12h) and dolasetron (Anzemet, Aventis Pharmaceuticals) 0.6 mg/kg q24h (prevention of nausea and vomiting) or 1 mg/kg q24h (control of vomiting) represent a relatively new class of antiemetics known as 5-HT_3 serotonergic receptor antagonists. The site of antiemetic action is the CRTZ and vagal afferent neurons in the intestinal tract.

- They are especially effective for control of chemotherapy-induced vomiting in dogs and cats but are also useful to control vomiting associated with parvoviral enteritis and acute pancreatitis.
- Because they are expensive, ondansetron or dolasetron are not used as first-choice general antiemetics.
- Side effects in dogs include sedation, lip licking, and head shaking.

Butorphanol

Butorphanol (Torbutrol, Fort Dodge), an opiate receptor antagonist, has antiemetic activity presumed to be due to decreased sensitivity of the vomiting center to chemical stimuli. It is effective in controlling vomiting in dogs treated with chemotherapy (especially Cisplatin) at a dose of 0.4 mg/kg IM.

- The only side effect is mild sedation.
- Concurrent analgesic effects may make it a good choice as an antiemetic in dogs with acute pancreatitis.
- Butorphanol can be given as a constant-rate IV infusion (0.1 mg/kg/hr) for control of vomiting in dogs.
- Antiemetic efficacy in cats is unknown.

Anticholinergic Drugs

Avoid the use of anticholinergic drugs such as isopropamide, atropine, and aminopentamide (Centrine, Fort Dodge) for routine symptomatic control of vomiting.

- Although anticholinergics may decrease peripheral afferent stimulation of the vomiting center by relieving GI smooth muscle spasms or inhibiting intestinal secretions, their side effects include xerostomia, mydriasis, tachycardia, urinary retention, ileus, and gastric retention.
- Because delayed gastric emptying caused by anticholinergics can in itself cause vomiting, these drugs should not be used any longer than 3 days in a vomiting patient.

ACUTE GASTRITIS

Acute gastritis is a common disease in dogs and cats. It is usually a mild, self-limiting condition that rarely warrants biopsy confirmation. Clinical diagnosis of acute gastritis often is made when acute vomiting occurs without apparent cause and resolves on its own in 24 to 48 hours.

Etiology

There are numerous potential etiologies of acute gastritis (see Table 67-1), but the cause often is not determined. Possible causes include the following:

- *Dietary indiscretion* is frequently associated with acute gastritis and vomiting. Gastritis is most likely due to ingestion of rancid or spoiled foods that contain fermentation byproducts, bacterial enterotoxins, or mycotoxins.
- *Foreign body ingestion* (e.g., rocks, aluminum foil, small toys, food wrappings, or plastic) can cause mechanical irritation of the gastric mucosa.
- *Ingested plant material* including grass and house plants is a common cause of acute gastritis.
- *Chemical irritants or toxins* (e.g., fertilizers, herbicides, cleaning agents, and heavy metals such as lead) can cause gastric irritation.
- *Drugs* (e.g., aspirin, nonsteroidal anti-inflammatory drugs, and glucocorticoids) can cause acute gastritis, which is frequently accompanied by erosions and ulceration. Antibiotics and chemotherapeutic drugs can also cause acute gastritis, anorexia, and vomiting.
- *Viral infections* such as canine parvovirus, feline panleukopenia, or canine distemper can cause lesions of gastritis in addition to more diffuse intestinal and systemic involvement.
- *Bacterial infections* causing gastritis are uncommon. Gastric spiral bacteria (*Helicobacter* spp.) may play a role in gastritis in some dogs and cats, but these bacteria are also present in many clinically healthy animals.
- *Parasitic infections* of the stomach are uncommon. *Physaloptera* spp. infect dogs and cats but the infection is not consistently associated with clinical signs. *Ollulanus tricuspis* is a cause of chronic gastritis in cats.
- *Systemic disorders* such as uremia, liver disease, neurologic disease, shock, stress, and sepsis may cause secondary gastritis by altering the gastric mucosal barrier, mucosal blood flow, or gastric acidity.

Clinical Signs

- Acute onset of nausea and vomiting
- Acute anorexia, lethargy, and diarrhea (from concurrent enteritis)

Diagnosis

Because acute gastritis is usually self-limiting, diagnostic evaluations are not usually warranted unless specific historical or physical findings suggest a more serious problem. Response to supportive therapy in 1 to 3 days indirectly supports the diagnosis of uncomplicated acute gastritis as the cause of vomiting.

History

Acute vomiting in an otherwise healthy animal suggests the possibility of acute gastritis. Perform a detailed historical evaluation including recent exposure to drugs or other sick animals and the potential for dietary indiscretion.

Physical Examination

The physical examination is usually unremarkable except for dehydration in severe cases.

Treatment

Identify and treat underlying causes when possible.

Dietary Restriction

- Withhold food for 12 to 24 hours.
- Reintroduce food when vomiting has ceased for longer than 24 hours. Offer a bland, digestible, moderately fat-restricted diet such as chicken and rice, low-fat cottage cheese and rice, or a commercially available veterinary diet that meets these requirements.
- After 2 to 3 days on the bland diet, gradually reintroduce the animal's routine diet over a period of 2 to 3 days.

Maintenance of Hydration

- For oral hydration, offer ice cubes, small amounts of water, or an oral glucose and electrolyte solution such as Pedialyte (Ross). Give at frequent intervals to provide daily maintenance requirements.
- Parenteral fluid therapy is indicated to treat dehydration (see the previous discussion of fluid therapy in the vomiting patient and refer to Chapter 5).

Medical Therapy

- Consider using antiemetics for short-term symptomatic control of vomiting (see the previous section on antiemetics) and acid control therapy (see the later section, "Gastroduodenal Ulceration").
- If vomiting does not resolve in 1 to 3 days, pursue further diagnostic evaluation (see under "Vomiting").

GASTRIC FOREIGN BODIES

Gastric foreign bodies are most common in dogs owing to their dietary habits and indiscriminant chewing behavior.

Etiology

Gastric foreign bodies cause clinical signs because of mechanical irritation (e.g., acute or chronic gastritis) or gastric outflow obstruction.

- Gastric foreign bodies frequently seen in dogs include needles, coins, stones, sticks, peach pits, plastic, aluminum foil, cloth, rubber balls, and small toys.
- String and other linear foreign bodies are more likely in cats.

Clinical Signs

Most dogs and cats with a gastric foreign body are presented for acute onset of vomiting. However, if the foreign body goes undiagnosed initially, chronic vomiting may be the primary complaint. Additional clinical signs may be seen if systemic absorption of a toxic component occurs. For example:

- Zinc-induced hemolytic anemia has been described secondary to ingestion of zinc-containing nuts and bolts or pennies minted in 1983 or later.
- Lead-containing foreign bodies may be associated with significant lead absorption and toxicity.
- Neurologic signs due to absorption of aluminum also have been described.

Diagnosis

Consider gastric foreign bodies in all animals with acute vomiting and a history of chewing on foreign objects.

Physical Examination

This is often unremarkable except when gastric foreign bodies are very large and palpable.

Radiography

Abdominal radiographs can identify radiopaque objects (e.g., coins, needles, and other metal objects), radiodense objects, and evidence of gastric outflow obstruction (gas-, fluid-, or food-distended stomach). A barium contrast gastrogram may be necessary to detect radiolucent gastric foreign bodies.

Endoscopy

Endoscopy can confirm a suspected gastric foreign body and, more important, can remove most objects noninvasively. For this reason, endoscopy often is preferable to barium-contrast radiography, unless general anesthesia is contraindicated.

Treatment

When a gastric foreign body is identified radiographically, consider whether immediate removal is necessary.

- Remove the object promptly if it is large, sharp, or potentially toxic (e.g., pennies, nuts and bolts, and lead objects) or if the animal is persistently vomiting, anorexic, or dehydrated.
- Small, non-toxic foreign bodies may pass through the GI tract uneventfully and thus can be managed conservatively if the animal is not symptomatic. Allow a

period of 7 to 10 days while periodically repeating radiographs to monitor progress. If clinical signs develop, immediate removal is recommended.
- Bones are rapidly decalcified and softened, and they do not require removal from the stomach.

Endoscopic Removal

Attempt endoscopic removal of gastric foreign bodies before gastrotomy, because most foreign bodies can be removed in this manner.

Preparation

- Fast the animal 8 to 12 hours before anesthesia to be sure that the stomach is empty, because food can obscure the endoscopic view. Correct fluid, electrolyte, and acid-base imbalances before general anesthesia.
- Repeat abdominal radiographs immediately before induction of anesthesia to confirm that the object remains in the stomach. This avoids an unnecessary procedure if the object has already entered the intestinal tract and is beyond the reach of the endoscope.

Procedure

The key to removing foreign bodies endoscopically is to get a firm grip on the object, using a grasping forceps or a basket retrieval instrument.

- Use forceps for retrieval of needles, coins, and small, soft objects. To remove the foreign body, grasp the object, pull it up near the end of the endoscope, and remove the endoscope, instrument, and foreign body as one unit.
- Use the basket for retrieval of small, round objects such as marbles or stones that cannot be grasped with the forceps. Large smooth objects are also removed with a basket, but they can be especially difficult to maneuver back through the gastroesophageal sphincter (or upper esophageal sphincter).
- Use an overtube (a plastic tube that fits over the shaft of the endoscope and can be advanced over the end of the endoscope) to protect the esophageal mucosa when sharp or pointed objects are withdrawn. An overtube is also useful to assist removal of objects through the gastroesophageal sphincter by maintaining sphincter dilatation.
- After removing the foreign body, perform a thorough examination of the stomach to look for other objects or mucosal lesions. This should be done even if only one object is seen radiographically, because radiolucent objects may not have been detected or multiple objects may have previously adhered to each other, appearing as one. If food obscures the endoscopic view, reposition the animal in the alternate lateral position or in the ventral dorsal position.

Gastrotomy

If endoscopic equipment is unavailable or the object cannot be retrieved endoscopically, gastrotomy is indicated (see Chapter 68).

Postoperative Care and Complications

- Food and water can be given orally 12 to 24 hours after foreign body removal.
- If mucosal injury is severe, treat as for gastric ulcer (see the next section).

GASTRODUODENAL ULCERATION

For the purposes of this discussion, gastroduodenal ulceration is defined as mucosal defects associated with bleeding, which includes petechiae, erosions, and ulcers. Clinical recognition of gastroduodenal ulceration as a complicating factor in many disorders is becoming more common, most likely due to the increased use of endoscopy.

Etiology

Many disorders have been associated with gastroduodenal ulceration (Table 67-2). Ulceration is more likely when two or more risk factors are present. General mechanisms of gastroduodenal ulceration include direct damage to the gastric mucosal barrier, increased gastric acid secretion, delayed gastric epithelial renewal, and decreased gastric mucosal blood flow.

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) (see Table 67-2) are frequent causes of gastric ulceration. These drugs inhibit prostaglandin synthesis, which decreases mucosal blood flow and alters gastric mucus production, thus predisposing to ulceration. Dogs are more susceptible to the ulcerogenic effects of NSAIDs than are humans.

- Both gastric hemorrhage and large perforating ulcers may occur. A predilection for ulceration of the pyloroantral region has been recognized.
- Ulceration is most likely to occur when NSAIDs are given to animals with other risk factors (see Table 67-2).
- Newer NSAIDs that preferentially inhibit cyclooxygenase-2 (COX-2) rather than COX-1 enzymes such as carprofen (Rimadyl, Pfizer), etodolac (EtoGesic, Fort Dodge), deracoxib (Deramaxx, Novartis), meloxicam (Metacam, Merial), and tepoxalin (Zubrin, Schering-Plough) are much less likely to cause GI bleeding. However, they should not be used in the presence of ulcers or inflammatory GI disease or concurrently with glucocorticoids.

Table 67-2. RISK FACTORS FOR GASTRODUODENAL ULCERATION

Drug-induced Gastrointestinal Damage
Nonsteroidal anti-inflammatory drugs
Aspirin
Carprofen*
Deracoxib*
Etodolac*
Flunixin
Ibuprofen
Indomethacin
Ketoprofen
Meloxicam*
Naproxen
Phenylbutazone
Piroxicam
Tepoxalin*
Glucocorticoid drugs
Infiltrative Disease
Gastric neoplasia
Lymphoma
Adenocarcinoma
Leiomyoma; leiomyosarcoma
Eosinophilic gastroenteritis
Lymphocytic plasmacytic gastroenteritis
Gastric pythiosis
Systemic Disorders
Liver disease
Renal failure
Mast cell tumor
Spinal cord disease
Hypoadrenocorticism
Gastrinoma (Zollinger-Ellison syndrome)
Lead poisoning
Cyclic hematopoiesis (gray collies)
Stress conditions
Severe illness
Major surgery
Hypotension and shock
Trauma
Intensive exercise (racing sled dogs)

*COX-2 selective NSAIDs are less likely to cause gastrointestinal hemorrhage and ulceration.

Glucocorticoids

Glucocorticoid therapy has been associated with gastric erosions and bleeding but usually only when combined with other risk factors for ulceration such as NSAIDs or in dogs with spinal cord disease (see Table 67-2). Dexamethasone, especially at high doses, is more likely to cause GI bleeding than is prednisolone.

Chronic Gastritis

Various forms of chronic gastritis may be complicated by mucosal ulcerations, particularly eosinophilic gastritis, lymphocytic-plasmacytic gastritis, granulomatous gastritis, and gastric pythiosis (see the "Chronic Gastritis" section).

Hepatic Disease

Hepatic diseases of all types are commonly associated with ulceration (duodenal more commonly than gastric). Potential mechanisms include decreased mucosal blood flow secondary to portal hypertension, decreased gastric epithelial cell turnover associated with negative nitrogen balance and hypoalbuminemia, increased gastric acid secretion due to impaired degradation of a secretagogue (possibly histamine), or stimulation of gastrin release by increased serum bile acids. Coexisting coagulopathies magnify GI blood loss.

Renal Failure

Renal failure may be associated with GI hemorrhage and ulceration. Multiple factors probably contribute, including decreased mucosal blood flow due to diffuse vascular injury, gastroduodenal reflux, acidosis, and increased concentrations of gastrin with hypersecretion of gastric acid.

Neurologic Disease

Neurologic disease can predispose to GI ulceration, especially in dogs with spinal cord disease that are receiving corticosteroids. Lower GI bleeding and hematochezia appear to be more common than upper GI bleeding. Colonic perforation, septic peritonitis, and sudden death have been reported.

Gastric Neoplasia

Gastric tumors, especially lymphoma and adenocarcinoma, frequently cause mucosal ulceration and hemorrhage (see the "Gastric Neoplasia" section).

Mast Cell Tumors

Cutaneous mast cell tumors can cause GI ulceration through the release of histamine that induces gastric acid hypersecretion. Perform a thorough search for cutaneous masses in all animals with GI bleeding and ulceration to identify a predisposing mast cell tumor.

Gastrinoma

This rare gastrin-producing tumor, arising from the amine precursor uptake and decarboxylation (APUD) cells of the pancreas, causes gastric acid hypersecretion and gastroduodenal ulceration (Zollinger-Ellison syndrome).

- Suspect gastrinoma when ulceration is associated with gastric mucosal hypertrophy or when ulcers respond to medical management but relapse when therapy is discontinued and no underlying cause can be identified.
- Diagnosis is made by documenting hypergastrinemia and identifying the tumor on surgical exploration.
- Most pancreatic gastrinomas are small (<2 cm) and have metastasized to regional lymph nodes and the liver at the time of diagnosis.
- Tumor cytoreduction may be a useful palliative procedure to temporarily control clinical signs along with medical therapy to control ulceration (see "Treatment" in this section).

Stress Conditions

Severe illness, major surgery, trauma, shock, sepsis, hypotension, and exercise (in racing sled dogs) predispose to gastroduodenal bleeding and ulceration. Acutely ill, intensive-care patients are most at risk. Consider a presumptive diagnosis of gastroduodenal ulceration when vomiting or hematemesis occurs in this clinical setting.

Clinical Signs

Clinical signs of gastroduodenal ulcers include anorexia, vomiting, melena, anemia, abdominal pain, and weight loss.

- The vomitus may contain digested blood (coffee-grounds appearance) or fresh blood with clots. Overt hematemesis and melena may not be consistently observed by the owner. Weakness associated with blood loss anemia may occur.
- Ulcer perforation and septic peritonitis are suggested by acute onset of abdominal pain, depression, collapse, and shock. However, early gastroduodenal perforation may be present in animals without dramatic signs of acute abdomen.

Diagnosis

Perform a detailed history. Determine if any ulcerogenic drugs have been administered recently (see Table 67-2).

Physical Examination

- Palpate the abdomen for abdominal pain.
- Evaluate the mucous membranes for evidence of anemia.
- Perform a rectal examination to evaluate for melena.
- If hematemesis and melena are present, evaluate the skin and mucous membranes for hemorrhages, which may suggest that GI bleeding is secondary to a systemic abnormality of hemostasis.
- Perform a thorough examination for cutaneous masses that may be mast cell tumors.

Laboratory Evaluation

Complete Blood Count

Perform a complete blood count (CBC) to assess for anemia.

- Acute GI bleeding is associated with a normocytic normochromic regenerative anemia, whereas chronic blood loss is characterized by iron deficiency and microcytic hypochromic anemia (see Chapter 22).
- With peracute GI bleeding, nonregenerative anemia may be detected initially until the bone marrow has adequate time to respond (3–5 days).
- Iron deficiency is further characterized by decreased serum iron concentration and decreased percentage saturation.
- With active bleeding, anemia is accompanied by hypoproteinemia.
- Neutrophilia and left shift may be seen with severe inflammation and ulcer perforation.

Other Laboratory Tests

- Perform a biochemistry profile to identify underlying liver disease, renal failure, and hypoadrenocorticism (see Chapter 33). Decreased total protein and albumin levels are common with blood loss, but liver disease, renal disease, and malnutrition also may contribute to these changes.
- Evaluate for dehydration and electrolyte imbalances secondary to vomiting.
- Perform blood gas analysis to assess acid-base imbalances.
- Perform a urinalysis to screen for underlying systemic disorders.
- If GI blood loss is suspected and the stool is grossly normal, perform a fecal occult blood test. Perform a fecal flotation to diagnose hookworm infection as a cause of GI blood loss.
- Screen for underlying bleeding disorders with evaluations such as one-stage prothrombin time, activated partial thromboplastin time, platelet count, fibrinogen, and fibrin degradation products (FDPs) (see Chapter 23).
- Perform fine-needle aspiration (or biopsy) of any cutaneous masses to diagnose mast cell tumor.
- If gastrinoma is suspected, evaluate a fasting serum gastrin concentration and measure gastrin after a provocative secretin injection.

Radiography

- Survey abdominal radiographs usually are unremarkable unless ulcer perforation results in pneumoperitoneum or peritoneal effusion (peritonitis).
- A GI contrast study usually outlines large ulcers but is an insensitive method for detecting small ulcers and erosions. If perforation is suspected, use a water-soluble non-ionic iodide contrast agent, such as iohexol (Omnipaque, Amersham Health) rather than barium.

Abdominocentesis

If ulcer perforation is suspected, perform abdominocentesis to detect septic peritonitis. Submit a sample for bacterial culture and antibiotic sensitivity testing.

Endoscopy

Endoscopy is indicated to characterize the location and severity of upper GI bleeding and for visual confirmation of ulceration.

▼ ***Key Point*** Endoscopy is the most reliable procedure for detection of gastric mucosal ulcers and erosions and is preferred over contrast radiography, unless general anesthesia is contraindicated.

- Concurrent gastric mucosal thickening or mass lesions suggest an underlying neoplastic or inflammatory disorder.
- Perform mucosal biopsies, regardless of the gross appearance, to identify predisposing causes such as gastritis or gastric neoplasia.
- If perforation is suspected, perform exploratory laparotomy.

Laparotomy

Laparotomy can be used to diagnose and resect gastroduodenal ulcers.

- Evaluate other abdominal organs, including the kidneys and liver.
- Carefully examine the pancreas to identify gastrinoma nodules.

Treatment

The goals of management of gastroduodenal ulceration include the following:

- Eliminate or control predisposing factors (see Table 67-2).
- Correct fluid, electrolyte, and acid-base imbalances.
- Control any GI bleeding and correct resulting anemia. If the packed cell volume (PCV) is less than 15%, give a blood transfusion (see Chapters 3 and 22).
- Control gastric acid secretion (Fig. 67-2).
- Promote mucosal cytoprotection.

Agents That Control Gastric Acid Secretion

Antacids

Antacids can effectively neutralize gastric acid secretion; however, H_2 blockers or proton pump inhibitors are preferred because of their ease of administration and greater potency (Table 67-3).

H_2 Blockers

These drugs are most commonly used to control acid secretion. They inhibit basal, nocturnal, and meal-stimulated acid secretion by blocking the H_2 receptors on gastric parietal cells (see Fig. 67-2). Several H_2 blockers (e.g., cimetidine, ranitidine, famotidine, and nizatidine) are available that are equally effective but differ in potency, frequency of administration, and potential to inhibit hepatic P-450 enzymes (see Table 67-3).

Text continued on p. 677.

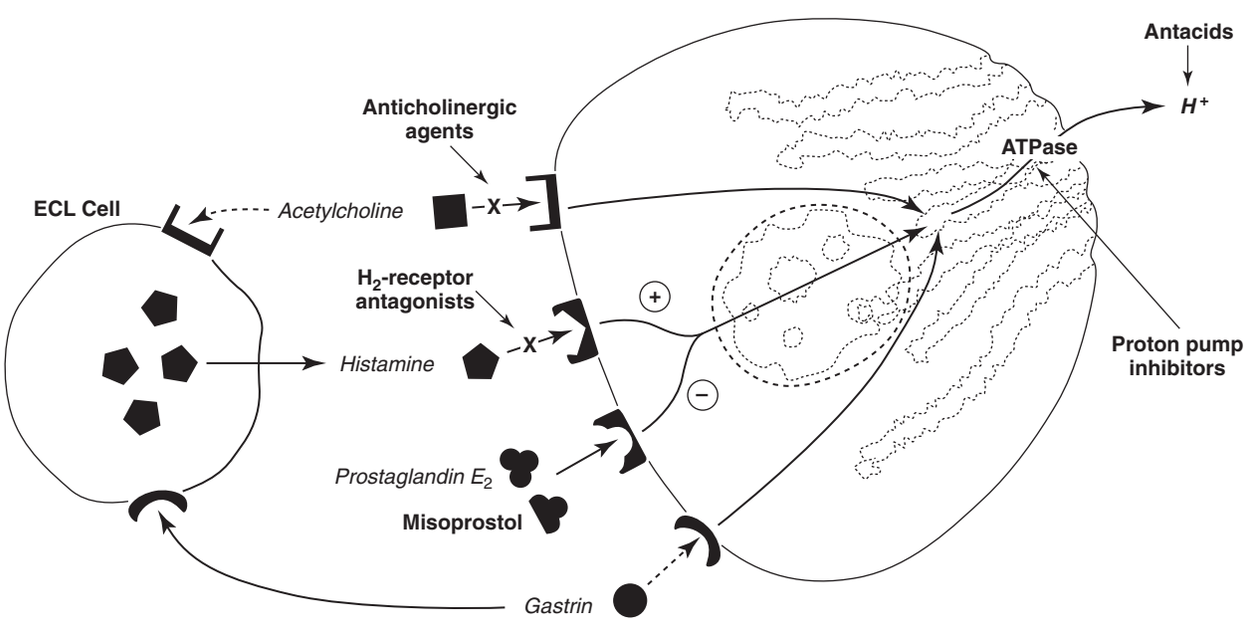

Figure 67-2. Representation of a gastric parietal cell showing the site of action of various therapeutic agents used to decrease gastric acid secretion. H_2 antagonists (blockers) competitively inhibit acid secretion stimulated by histamine, which is released from nearby enterochromaffin-like (ECL) cells by gastrin stimulation. Acetylcholine also indirectly stimulates histamine release from the ECL cells. Use of anticholinergic drugs to inhibit acid secretion is limited by systemic side effects. Prostaglandin (PGE_2) analogues, such as misoprostol, inhibit acid secretion by blocking histamine-induced cyclic adenosine monophosphate production. Proton pump inhibitors such as omeprazole and pantoprazole have broad-spectrum antisecretory activity because they interrupt the final common pathway of acid secretion by inhibiting hydrogen potassium adenosine triphosphatase. Antacids neutralize luminal gastric acid.

Table 67-3. DRUGS USED FOR TREATMENT OF GASTRIC DISEASE

	Product (Manufacturer)	Preparations	Dosage	Special Indications	Comments*
H_2 Receptor Blocker					
Cimetidine	Tagamet (GlaxoSmithKline)	Syrup: 60 mg/ml Tabs: 100 mg (OTC), 200 mg (OTC), 300 mg, 400 mg, 800 mg Injectable: 150 mg/ml	5–10 mg/kg PO or IV q6–8h	Decreases gastric acid secretion	Inhibits hepatic P-450 drug metabolizing enzymes. Decrease the dose of the following drugs if used concurrently: lidocaine, beta-blockers, calcium channel blockers, theophylline, diazepam, metronidazole, quinidine, phenytoin, warfarin. Does not decrease hepatic blood flow. Simultaneous oral administration of cimetidine and sucralfate or cimetidine and metoclopramide is acceptable if using the higher dose range for cimetidine. Separate oral administration from antacids by ≥1 hr. Decrease dosage in renal failure
Ranitidine	Zantac (GlaxoSmithKline)	Syrup: 15 mg/ml Tabs: 75 mg (OTC) 150 mg, 300 mg Injectable: 25 mg/ml	2.0 mg/kg PO or IV q8–12h (dog); 2.5 mg/kg IV q12h or 3.5 mg/kg PO q12h (cat)	Decreases gastric acid secretion. Preferred over cimetidine when concurrently administering drugs dependent on hepatic metabolism.† Less frequent administration than cimetidine. Promotes gastric emptying	4–10 times as potent as cimetidine. Minimal inhibition of hepatic P-450 enzymes. No effect on hepatic blood flow. Separate oral administration from antacids by ≥1 hr. Decrease dose in renal failure. Stimulates GI motility (stomach, small intestine, colon) by inhibiting acetylcholinesterase activity
Famotidine	Pepcid (Merck)	Liquid: 8 mg/ml Tabs: 10 mg (OTC), 20 mg, 40 mg Injectable: 10 mg/ml	0.5–1.0 mg/kg PO or IV q12–24h	Decreases gastric acid secretion. Preferred over cimetidine when concurrently administering drugs dependent on hepatic metabolism.† Once-a-day dosing convenience	20–50 times as potent as cimetidine. No inhibition of hepatic drug metabolizing enzymes and no effect on hepatic blood flow. Decrease dose in renal failure
Nizatidine	Axid (Lilly)	Tabs: 75 mg (OTC) Caps: 150 mg, 300 mg	2.5–5.0 mg/kg PO q24h	Decreases gastric acid secretion. Promotes gastric emptying. Once-a-day dosing	Similar potency as ranitidine. No effect on hepatic P-450 enzymes. Stimulates gastric emptying at antisecretory doses by inhibiting acetylcholinesterase activity, similar to ranitidine

Mucosal Protectant

Sucralfate	Carafate (Axcam Scandipharm)	Tabs: 1 g Liquid: 1 g/10 ml	1 g: large dogs, 0.5 g: small dogs, 0.25 g: cats PO q8–12h	GI erosions or ulcers; NSAID-induced gastritis; reflux esophagitis (susp)	Safe local-acting drug. Potential for nonspecific binding with impaired absorption of simultaneously administered oral drugs. No effect (in dogs) on absorption of the following drugs: digoxin, quinidine, propranolol, aminophylline, diazepam, imipramine, and chlorpromazine. Minor effect on cimetidine absorption, not clinically significant at higher doses of cimetidine (and other H_2 blockers?). Separate phenytoin, tetracycline, and fluoroquinolone antibiotics from sucralfate by ≥2 hr. Antacids interfere with sucralfate binding; give antacids ≥30 min after sucralfate. Contains aluminum—use cautiously in renal failure. Side effect: constipation
Omeprazole	Prilosec (Astra-Zeneca)	Caps: 10 mg, 20 mg, 40 mg (delayed-release with enteric coating) Tabs: 20 mg (OTC) Tabs: 20 mg, 40 mg (with enteric coating)	0.75–1.0 mg/kg PO q12–24h	Severe GI ulceration, unresponsive to H_2 blockers; severe reflux esophagitis, unresponsive to metoclopramide and H_2 blockers; gastrinoma (Zollinger-Ellison) syndrome)	Inhibits subset of hepatic P-450 drug metabolizing enzymes. Decrease the dose of concurrently administered diazepam and phenytoin but not theophylline or propranolol. 2–7 times as potent as cimetidine. No dose adjustment necessary in hepatic or renal failure. Do not administer partial tablet or capsule unless dissolved in HCO_3§
Pantoprazole	Protonix (Wyeth-Ayerst)	Injectable: 4 mg/ml	0.7–1.0 mg/kg PO or IV q24h	Same as omeprazole	Injectable alternative to omeprazole

Prostaglandin Analog

Misoprostol‡	Cytotec (Searle)	Tabs: 100 µg, 200 µg	3–5 µg/kg PO q6h	Prevention of NSAID-induced GI injury	Gastric mucosal cytoprotection at low doses, inhibits gastric acid secretion at higher doses. Side effects: diarrhea, abortion

Promotility Agent

Metoclopramide	Reglan (Robins)	Syrup: 1 mg/ml or 10 mg/ml Tabs: 5 mg, 10 mg Injectable: 5 mg/ml	0.2–0.4 mg/kg PO, IM, or SC 30 min before eating, q8h or 1–2 mg/kg/24 h given in fluids as constant-rate infusion	Central antiemetic (CRTZ) for drug-induced vomiting, parvoviral enteritis, and uremic gastritis; promotility for reflux esophagitis, functional gastric emptying disorder, recurrent gastric hairballs, reflux gastritis, gastric stasis 2° to gastric surgery, ileus	Side effects: anxiety, agitation, tremors, twitching, constipation. Contraindicated in patients with mechanical gastric outflow obstruction or epilepsy. Should not be used in combination with phenothiazines, butyrophenones, or narcotics. Atropine or other anticholinergic drugs antagonize effects of metoclopramide. When oral metoclopramide is given simultaneously with oral cimetidine, decreased cimetidine absorption occurs. Probably not clinically significant if cimetidine given at higher dosage range. Decrease dose in renal failure. Metoclopramide is physically incompatible when mixed with cephalothin sodium, sodium bicarbonate, chloramphenicol sodium succinate, or tetracycline. Light sensitivity of metoclopramide occurs in dextrose solutions after 24 hr

Table continued on following page

Table 67-3. DRUGS USED FOR TREATMENT OF GASTRIC DISEASE—cont'd

	Product (Manufacturer)	Preparations	Dosage	Special Indications	Comments*
Cisapride	Propulsid (Janssen)	Available through compounding pharmacies	0.25–0.5 mg/kg PO q8–12h (dogs); 2.5–5 mg PO q8–12h (cats)	Same promotility indications as metoclopramide but has no central antiemetic effect; has effects on motility of distal small bowel and colon; megacolon in cats, idiopathic megaesophagus in cats	5-HT_4 agonist. Decrease dose in hepatic but not renal failure. Taken off the U.S. market due to fatal arrhythmias in humans
Prucalopride	(Janssen)	Not yet approved		Delayed gastric emptying, constipation	5-HT_4 agonist similar to cisapride. Promotility effects on stomach and colon
Tegaserod	Zelnorm (Novartis)	Tabs: 2 mg, 6 mg	0.05–0.1 mg/kg PO q12h (dogs)	Ileus, pseudoobstruction, constipation	5-HT_4 agonist similar to cisapride. Promotility effects primarily on intestine and colon (not stomach)
Erythromycin	Many	Liquid: 25, 50, and 100 mg/ml Tabs: 250 mg, 333 mg, 500 mg Caps: 125 mg, 250 mg Injectable: 100 mg/ml	0.5–1.0 mg/kg PO q8h	Reflux esophagitis; delayed gastric emptying; postoperative ileus (dogs)	Increases gastroesophageal sphincter pressure. Promotes gastric emptying and small intestine transit by a motilin-like effect. Promotility effects occur at lower dose than the antimicrobial dose
Antacids					
Many available (OTC)	Maalox (Al + Mg) Quick Dissolve Maalox ($CaCO_3$) Mylanta II (Al + Mg + simethicone) Amphojel (AlOH) Tums tabs ($CaCO_3$)	Tabs and liquid	1–2 tabs or 5–10 ml PO q4–6h	Safe and inexpensive treatment of GI ulceration	Potency varies between products. Crush tablets for maximum effectiveness. Difficult to administer in animals. Potential side effects: constipation (AlOH, $CaCO_3$), diarrhea (Mg salts), hypernatremia and alkalosis ($NaHCO_3$), hypercalcemia and acid rebound ($CaCO_3$), phosphate depletion (AlOH); impaired excretion of aluminum and magnesium in renal failure; nonspecific binding of concurrently administered drugs (e.g., cimetidine, ranitidine); interference with binding of sucralfate to GI ulcers

*All drugs that decrease gastric acidity could potentially decrease absorption of orally administered drugs that are weak bases (e.g., ketoconazole), and increase absorption of durgs that are weak acids (e.g., diazepam, aspirin, furosemide).

†Examples include lidocaine, propranolol, theophylline, diazepam, phenytoin, metronidazole, and warfarin.

‡Limited experience with use in cats.

§To prepare as oral suspension, dissolve 20 mg capsule or tab in 10 ml of 8.4% HCO_3 to make a 2 mg/ml solution; good for 7 days.

CRTZ, chemoreceptor trigger zone; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; OTC, over the counter (nonprescription); susp, suspension; 5-HT_4 (serotonin) agonist.

Famotidine is typically the first choice H_2 blocker because it does not inhibit hepatic drug metabolism, it can be given once a day, and it is available in dosing formulations that are easy to use in dogs and cats. In humans, acid suppression declines during continuous use of H_2 blockers due to pharmacologic tolerance. Whether this phenomenon reduces the long-term effectiveness of H_2 blockers for acid control in dogs and cats remains to be determined.

Proton Pump Inhibitors

Omeprazole (Prilosec, AstraZeneca) is a potent inhibitor of gastric acid secretion that acts by inhibiting hydrogen-potassium adenosine triphosphatase (ATPase) (the proton pump) of the gastric parietal cell (see Fig. 67-2). This drug has broad-spectrum antisecretory activity because the proton pump is the final common pathway for HCl production, regardless of initiating stimulus. Because of its long duration of action, omeprazole can be given on a once-daily basis (see Table 67-3).

Agents That Promote Mucosal Cytoprotection

Sucralfate

Sucralfate (Carafate, Axcan Scandipharm) is an aluminum salt that selectively binds to injured gastroesophageal mucosa, forming a protective "bandage." Sucralfate neutralizes acid, inactivates pepsin, adsorbs bile acids and pancreatic enzymes, and stimulates local prostaglandins, which are cytoprotective. It is a safe drug with minimal systemic absorption.

▼ ***Key Point*** For initial treatment of gastric ulcers and erosions, combine an H_2 blocker for acid control with sucralfate for mucosal cytoprotection.

Misoprostol

Misoprostol (Cytotec, Searle) is a synthetic prostaglandin analogue that at low doses (3–5 µg/kg) is cytoprotective and at high doses (10 µg/kg) has antisecretory activity (see Fig. 67-2). The primary indication for use of misoprostol in dogs is to prevent NSAID-induced gastric injury. Side effects of misoprostol (especially at the higher dose) include diarrhea and abortion (see Table 67-3).

Antibiotic Therapy

Give systemic antibiotics when ulcer perforation is suspected or confirmed. Select the antibiotic based on results of culture and sensitivity testing of abdominal fluid or affected tissue. Give parenteral ampicillin or amoxicillin combined with enrofloxacin while awaiting culture results.

Laparotomy

Emergency exploratory laparotomy is indicated when perforation of a gastroduodenal ulcer is suspected or confirmed (see Chapter 76 for detailed description of treatment for peritonitis). Correct fluid, electrolyte, and acid-base imbalances as rapidly as possible before surgery. Treat shock as described in Chapter 156.

Prevention

- COX-2 selective NSAIDs are less likely to be associated with GI bleeding and ulceration than are nonselective NSAIDs like aspirin. Use recommended doses and monitor for occult bleeding, melena, or vomiting to detect early GI bleeding. Do not give glucocorticoids concurrently.
- A wash-out period of 7 days is recommended when switching from one NSAID to another or when discontinuing an NSAID and starting glucocorticoid therapy (or vice versa).
- Misoprostol has been shown to prevent aspirin-induced gastric injury in dogs. Omeprazole also provides some protection against the development of aspirin-induced GI damage in dogs, but cimetidine appears to be ineffective. Once NSAID-induced GI injury occurs, omeprazole is probably more effective for ulcer healing than is misoprostol.
- Use of an H_2 blocker, sucralfate, or omeprazole to prevent ulceration in dogs given glucocorticoids has not been proven to be effective but is widely recommended.
- Pretreatment with omeprazole, misoprostol, cimetidine, or sucralfate is not effective in preventing GI bleeding in dogs with spinal cord disease treated with glucocorticoids.
  - Consider the use of omeprazole or H_2 blockers, if multiple risk factors are present or if any degree of GI bleeding would be poorly tolerated by the patient.

CHRONIC GASTRITIS

Chronic gastritis is a common cause of chronic and episodic vomiting in dogs and cats. Chronic gastritis is classified based on histologic features such as type of inflammatory infiltrate and the presence of fibrosis, atrophy, or mucosal hypertrophy. The most common histologic category is lymphocytic-plasmacytic gastritis, which is a nonspecific tissue reaction to many insults.

Etiology

Regardless of the initial insult, release of inflammatory mediators and vasoactive compounds lead to disruption of the normal gastric mucosal barrier, allowing back diffusion of gastric acid and pepsin. Subsequent inflam-

mation further stimulates acid secretion, which, in turn, promotes further mucosal injury, altered cell membrane permeability, and decreased microvascular blood flow. The end result is varying degrees of gastric erosion, ulceration, hemorrhage, edema, and necrosis.

Idiopathic Chronic Gastritis

The underlying etiology of chronic gastritis is seldom determined. Possible causes include all factors capable of causing acute gastritis (see Table 67-1) in which repeated or persistent exposure occurs.

- In cats, lymphocytic-plasmacytic gastritis is often accompanied by diffuse inflammatory bowel disease (see Chapter 69).
- Gastroduodenal ulcerations may be associated with secondary lymphocytic-plasmacytic gastritis that resolves after ulcer therapy. Conversely, lymphocytic-plasmacytic gastritis may be complicated by gastric erosions and ulcerations.
- Eosinophilic gastritis is discussed later in this chapter.

Physaloptera Infection

The nematode parasite, *Physaloptera rara,* inhabits the stomach and duodenum of dogs and cats and is an infrequent cause of lymphocytic-plasmacytic gastritis and chronic intermittent vomiting. In most infections, only one to five worms are found in the stomach of the host.

- Embryonated eggs passed in the feces are ingested by an intermediate host (cockroach, cricket, or beetle) in which infected larvae develop. Infection occurs when a dog or cat ingests an intermediate or transport host (rodent or snake).
- Diagnosis of *Physaloptera* spp. is difficult. Fecal flotation using either sodium dichromate or magnesium sulfate solution is often recommended, but eggs may not be detected due to the small number of parasites, low fecundity of the female nematodes, and presence of single-sex infection. The clinical diagnosis is usually made by endoscopic detection of the adult worms attached to the stomach mucosa.

Ollulanus Infection

O. tricuspis is a nematode infection of cats associated with chronic fibrosing gastritis.

Pythium Infection

Pythium insidiosum is a fungal infection that can lead to pyogranulomatous gastritis in dogs.

Helicobacter Infection

Gastric spiral bacteria (*Helicobacter* spp.) are a common finding in apparently healthy dogs and cats without clinical signs of GI disease. *Helicobacter* spp. may play a role in chronic gastritis in some dogs and cats, but there is little information on the relationship of *Helicobacter* to gastric disease in these species.

Enterogastric Reflux

Reflux gastritis (or bilious vomiting syndrome) refers to gastric mucosal damage caused by persistent enterogastric reflux of potentially damaging constituents such as bile and pancreatic enzymes. Inappropriate pyloric relaxation predisposes to excess reflux, and impaired gastric motility contributes to delay in clearing previously refluxed material from the stomach. Reflux gastritis is a poorly documented clinical entity in dogs.

Clinical Signs

- Animals with *chronic gastritis* have intermittent vomiting, usually over a period of weeks to months. Vomiting is not consistently associated with eating. Hematemesis and melena may occur if gastritis is associated with mucosal erosions or ulcers.
- Other signs such as depression, anorexia, weight loss, and abdominal pain are present less frequently.
- Signs of *reflux gastritis* include nausea, vomiting of bile-stained fluid or foam early in the morning when the stomach is empty, and abdominal pain. Most animals are otherwise healthy and do not usually vomit any other time of day.

Diagnosis

Confirmation of chronic gastritis requires a gastric mucosal biopsy, obtained by endoscopy or laparotomy.

History and Physical Examination

Obtain a complete history, emphasizing potential exposure to ingested drugs, foreign bodies, chemicals, irritants, and unusual diets (see Table 67-1).

- Response to previous therapy (e.g., a change in diet) may indirectly suggest a dietary intolerance or allergy.
- The physical examination often is unremarkable.

Laboratory Evaluation

- A CBC, biochemical profile, and urinalysis are indicated to exclude non-GI causes of vomiting and to characterize any fluid, electrolyte, or acid-base imbalances resulting from vomiting.
- Test results usually are normal in animals with chronic gastritis unless vomiting is profuse, mucosal erosions or ulcers cause blood loss anemia, or inflammation of the antral and pyloric region results in gastric outflow obstruction.

Radiography

- Survey abdominal radiographs usually are unremarkable.

- Upper GI contrast studies may be normal or show thickening of gastric rugal folds, mucosal irregularity, mass lesions, or delayed gastric emptying. These findings are nonspecific, and gastric biopsy is required to distinguish chronic gastritis from other disorders such as gastric neoplasia.

Endoscopy

Endoscopy is used to obtain mucosal biopsies and is the diagnostic method of choice for confirming chronic gastritis.

- Endoscopically, the gastric mucosa may appear grossly normal or show thickened rugae, mucosal irregularity or friability, hemorrhage, ulceration, or firm areas of fibrosis.
- Severe chronic gastritis may have a diffuse nodular appearance that must be differentiated from gastric lymphoma.

▼ ***Key Point*** Always obtain biopsies because histologic changes in chronic gastritis may be present despite a normal endoscopic appearance.

- Carefully examine the entire gastric and proximal duodenal mucosa for adult *Physaloptera,* which appear as white, 1-cm-long nematodes that may be attached to the mucosa or living free on the mucosal surface. Often only one worm is present. Remove any worms observed by use of the grasping forceps.
- If *O. tricuspis* is suspected, aspirate gastric juice for microscopic examination for adult and larval forms.
- Gastric foreign bodies can be detected and removed.
- In patients with reflux gastritis, large amounts of bile-stained fluid may be present in the stomach and the pylorus may appear wide open.

Laparotomy

- Perform laparotomy to obtain full-thickness gastric biopsies and to correct associated gastric outflow obstruction.
- Full-thickness biopsy may be necessary to differentiate severe lymphocytic gastritis diagnosed by endoscopic biopsy from gastric lymphoma.

Treatment

Eliminate underlying causes of gastritis whenever possible.

- Discontinue implicated drugs (e.g., aspirin).
- Remove gastric foreign bodies.
- Treat *Physaloptera* infections with fenbendazole (50 mg/kg/day PO for 3 days) or pyrantel pamoate (15 mg/kg PO initially and repeat in 2–3 weeks).
- Treat *O. tricuspis* infections with fenbendazole (50 mg/kg/day PO for 3 days) or pyrantel pamoate.
- Avoid further exposure to plants, chemicals, and other irritants.
- In most cases, a specific cause of gastritis cannot be identified, and therefore specific therapy is unavailable.

Dietary Trials

Perform dietary trials in all animals with chronic gastritis because dietary factors or antigens could be the inciting cause. Continue dietary trials for at least 2 to 4 weeks before assessing response to therapy. Feed a controlled diet that is easily digestible, carbohydrate based, and moderately fat restricted. Give frequent small meals. Avoid high-fiber diets or the feeding of only one large meal per day.

- If gastritis is mild, dietary modification may be all that is required to control clinical signs.
- Commercial or homemade hypoallergenic diets (single-protein or novel-protein source) are beneficial in some cases.
- Reflux gastritis often responds to frequent feedings or feeding of a late bedtime meal. Food may be effective because it buffers refluxed duodenal contents and stimulates gastric motility. Metoclopramide also may be effective (see "Gastric Motility Disorders" and Table 67-3).

H_2 Blockers

Reduction of acid secretion with H_2 blockers (discussed previously) may be useful in animals with chronic gastritis even if gross mucosal erosions or ulcerations are absent (see Table 67-3). A 2-week trial is recommended, but long-term therapy may be required, depending on clinical response. Ranitidine and nizatidine also promote gastric emptying, which may be useful for secondary motility disorders that may accompany chronic gastritis.

Anti-inflammatory or Immunosuppressant Drugs

Prednisolone

- If no response is obtained with dietary control and H_2 blocker therapy, give prednisolone (0.5–1 mg/kg PO q12h) for a 2-week trial period.
- If remission occurs, taper this dose over a period of 6 to 8 weeks and maintain alternate-day therapy using the lowest effective dose.

Azathioprine

- Azathioprine (Imuran, Glaxo Wellcome), an immunosuppressive drug, may be useful for treatment of chronic gastritis in dogs that have not responded to prednisolone or when glucocorticoid side effects are a problem.
- The initial dose for dogs is 2 mg/kg PO q24h. The dose can be tapered after a clinical response is obtained, usually by giving the same dose on an alternate-day basis.

- Because of azathioprine's ability to suppress the bone marrow, periodically monitor the CBC to detect neutropenia and thrombocytopenia. Other potential side effects include pancreatitis and hepatotoxicity.
- Azathioprine has been recommended at a lower dose (0.3 mg/kg PO q48h) in cats. However, chlorambucil is a safer alternative (see below).

Chlorambucil

- Chlorambucil, an alkylating antineoplastic or immunosuppressive agent, can be used in cats that fail to respond to corticosteroids. The dose is 20 mg/m^2 PO once every 2 to 3 weeks (refer to Chapter 26 for conversion of body weight to body surface area in m^2).
- Side effects are uncommon but may include myoclonus, cytopenia, and hepatotoxicity.

Promotility Drugs

- Secondary motility disorders may accompany chronic gastritis. If postprandial vomiting occurs, add metoclopramide, or cisapride to the above therapy (see Table 67-3 and Fig. 67-1).

Antibacterial Drugs for Helicobacter

- Although the clinical significance of gastric spiral bacteria (*Helicobacter* spp.) in dogs and cats is unclear, treatment is justified empirically when chronic gastritis is associated with large numbers of spiral bacteria on biopsy.
- Therapy for *Helicobacter* spp. has been extrapolated from human medicine. Single antibiotics are not effective and resistance rapidly develops; thus, effective treatment usually requires "triple therapy" with a combination of three antibiotics or a combination of two antibiotics plus an acid reducer such as omeprazole or an H_2 blocker for potentiation. Antimicrobials commonly used in various combinations include clarithromycin, amoxicillin, metronidazole, tetracycline, and bismuth.
- Only a few controlled therapeutic trials have been done in dogs and cats. It appears that some of the treatment regimens effective for eradicating *Helicobacter pylori* in humans only transiently suppress *Helicobacter* in dogs and cats without eliminating the infection; thus, the optimal treatment protocol for dogs and cats is not yet known.
- The combination of clarithromycin (7.5 mg/kg PO q12h), amoxicillin (20 mg/kg PO q12h), and metronidazole (10 mg/kg PO q12h) for 14 days successfully eliminated *Helicobacter* in 100% of cats in one study and can be used to treat dogs.
- Other commonly used (but unproven) treatments for *Helicobacter* in dogs include the combinations of clarithromycin, amoxicillin, and omeprazole—or amoxicillin, metronidazole, and famotidine—given for 14 to 21 days.

Prognosis

The prognosis for chronic gastritis is variable. If the underlying cause can be identified and corrected, the prognosis for recovery is good. In animals with idiopathic chronic gastritis, long-term dietary and medical management may be required.

EOSINOPHILIC GASTRITIS AND GRANULOMA

Eosinophilic gastritis is characterized by diffuse or focal infiltration of mature eosinophils into the mucosa, submucosa, or muscularis. Variable increases in lymphocytes, plasma cells, and neutrophils may also occur.

- Eosinophilic inflammation of the stomach in dogs occurs as two distinct pathologic forms:
  - Diffuse eosinophilic infiltration of the gastric mucosa and submucosa is most common and is usually associated with generalized eosinophilic gastroenterocolitis.
  - Single or multiple eosinophilic granulomatous lesions (scirrhous eosinophilic gastritis) with transmural eosinophilic inflammation, severe arteritis, and fibrosis occur less frequently.
- In cats, eosinophilic gastritis is usually a manifestation of inflammatory bowel disease, which is similar to eosinophilic gastroenterocolitis in dogs. Rarely, eosinophilic gastroenteritis in cats is associated with hypereosinophilic syndrome (see Chapter 69).

Etiology

The cause of eosinophilic gastritis or granuloma in dogs is unknown. The presence of increased numbers of circulating and tissue eosinophils suggests an allergic or immunologic hypersensitivity, possibly in response to dietary components or parasites.

- Food allergy or hypersensitivity has been proposed but not proven as a cause of eosinophilic gastritis in dogs.
- Microfilariae have been observed on histologic sections in a dog with diffuse eosinophilic gastritis.
- Eosinophilic gastroenteritis with multiple focal eosinophilic granulomas has been described in German shepherds with visceral larva migrans but is not an important clinical cause of eosinophilic gastroenteritis.

Clinical Signs

Dogs with eosinophilic gastritis usually have signs of chronic vomiting, anorexia, and weight loss.

- Eosinophilic gastritis is more likely to be associated with mucosal ulceration and bleeding (suggested by hematemesis and melena) than are other types of chronic gastritis.

- Additional clinical signs may be present if gastritis is a component of diffuse eosinophilic gastroenterocolitis. Small intestinal involvement is characterized by malabsorption and voluminous watery diarrhea, whereas colonic or rectal involvement is characterized by bloody-mucoid diarrhea with tenesmus (see Chapter 69).

Diagnosis

Determine previous diets and clinical responses to dietary changes. A history of dramatic response to previous corticosteroid therapy is consistent with but not specific for eosinophilic gastritis.

Physical Examination

- Weight loss is common.
- Less common findings include pain on palpation of the stomach, or the stomach may feel diffusely rigid and firm. With large focal granulomas, a mass in the stomach wall may be palpated.
- Additional findings that indicate more extensive intestinal involvement include focal or diffuse thickening of the small intestine or colon or mesenteric lymphadenopathy.

Laboratory Evaluation

- A hemogram often reveals eosinophilia, but not in all cases.
- Gastric erosions and ulcerations can cause anemia and hypoproteinemia.
- Heartworm and fecal flotation tests are indicated to identify underlying parasitism.

Radiography and Ultrasonography

- Abdominal radiography is usually normal unless gastric outflow obstruction occurs secondary to transmural involvement or granuloma formation at the antral or pyloric region.
- Contrast radiography may demonstrate irregularity of the gastric mucosa or diffuse or focal thickening of the gastric wall.
- With concurrent intestinal involvement, associated radiographic changes may be identified.
- Abdominal ultrasonography may identify gastric wall thickening, masses, or enlarged mesenteric lymph nodes.

Endoscopy

- Visual endoscopic findings are nonspecific and may mimic other inflammatory and neoplastic diseases. The gross appearance may be normal in some cases.
- Involved areas of the stomach may appear diffusely thickened, with hemorrhages, erosions, or ulcers. Granulomas appear as focal mass lesions.
- Endoscopy is the preferred initial method for biopsy rather than laparotomy, unless mechanical obstruction requiring surgical decompression is present. Obtain multiple biopsies from the stomach and duodenum.
- Cytologic examination of mucosal biopsies reveals increased numbers of eosinophils.
- A disadvantage of endoscopically obtained biopsies is that the depth of the biopsy generally is limited to the mucosa, and deeper layers may be predominantly involved in eosinophilic gastritis.

Laparotomy

- Exploratory laparotomy may reveal diffuse or focal thickening in affected regions of the stomach and GI tract.
- Diffuse involvement of the stomach wall or large focal granulomas may grossly resemble neoplasia.
- Regional lymphadenopathy is common.

Treatment

The treatment of choice for eosinophilic gastritis in dogs is glucocorticoid therapy combined with dietary management.

- If a broad-spectrum anthelmintic has not been administered recently, before initiating glucocorticoids, treat with fenbendazole (Panacur, Intervet), 50 mg/kg daily for 3 days, to eliminate undetected GI parasites as a potential cause of the clinical signs.
- Treatment of eosinophilic gastritis in cats that is a manifestation of hypereosinophilic syndrome is discussed in Chapter 69. Eosinophilic gastritis or gastroenteritis in cats that is associated with focal GI involvement and resembles canine eosinophilic gastroenterocolitis can be managed as outlined next for dogs.

Anti-inflammatory and Immunosuppressant Therapy

- Administer prednisolone, 0.5 to 1 mg/kg PO q12h. Response is prompt and dramatic, usually occurring within 24 to 48 hours.
- Gradually taper the dosage over the following 6 to 8 weeks, decreasing to once daily (given in the morning) and then to alternate days. If the initial treatment period is too short, relapse may occur. If relapse does not occur while tapering the dosage, discontinue therapy at the end of the 6- to 8-week period. Continue to monitor for relapse.
- If side effects are a problem or if higher dosage or continued daily therapy is required, give azathioprine concurrently, as described previously for chronic gastritis.

Dietary Recommendations

Because food hypersensitivity is a potential cause of eosinophilic gastritis, consider a trial with a hypoallergenic diet. Some animals with eosinophilic gastritis may respond to a hypoallergenic diet alone. Institute a

dietary trial even if corticosteroids are being given, because it may decrease the dose of corticosteroids required to control clinical signs.

- Suggested hypoallergenic diets include select protein or novel protein commercial diets consisting of lamb, egg, fish, rabbit, duck, kangaroo, or venison. An alternative approach is to use a diet containing hydrolyzed proteins, which may be less antigenic (Prescription Diet z/d, Hill's, or HA Diet, Purina).
- Choose a protein and carbohydrate source that has not been a part of the animal's diet in the past 6 months.
- Feed the diet exclusively for at least 3 to 4 weeks before determining effectiveness.
- If a hypoallergenic diet is ineffective, try a controlled diet that is easily digested, carbohydrate based, and moderately fat restricted.

Surgery

Perform surgical resection of obstructing granulomas at the antral and pyloric region and follow up with glucocorticoid therapy.

Prognosis

The prognosis for eosinophilic gastritis in dogs is good. Most dogs respond to therapy and many have complete resolution of clinical signs on a long-term basis. In others, relapses occur, and a hypoallergenic diet or corticosteroid therapy is required on a long-term basis.

GASTRIC OUTFLOW OBSTRUCTION

Etiology

Gastric outflow obstruction most commonly is caused by mural, mucosal, and luminal abnormalities involving the antral and pyloric regions of the stomach (see Table 67-1). External compression of the gastric outflow tract is identified less frequently. Common causes of outflow obstruction include the following:

- Foreign bodies often lodge in the pylorus and cause partial or complete outflow obstruction.
- Chronic hypertrophic pyloric gastropathy (CHPG) is a benign disorder of middle-aged to older small-breed dogs that frequently results in outflow obstruction (see "Hypertrophic Gastropathy").
- Pyloric stenosis is hypertrophy of the circular muscle fibers of the pylorus. Congenital pyloric stenosis occurs in young dogs and cats. Acquired muscular pyloric stenosis is sometimes a component of CHPG in older animals.
- Chronic gastritis, especially eosinophilic gastritis and granuloma, that involves the antral and pyloric region can result in outflow obstruction.
- Obstructing granulomas may be a manifestation of fungal gastritis caused by pythiosis or histoplasmosis.
- Gastric ulcers at the pylorus may cause outflow obstruction.
- Gastric neoplasia, especially adenocarcinoma, can obstruct outflow (see under "Gastric Neoplasia").
- Gastric dilatation-volvulus (GDV) is a frequent cause of acute outflow obstruction and is discussed later in this chapter.
- Extrinsic outflow compression may be caused by hepatic or pancreatic inflammation, abscesses, and neoplasia; marked regional lymphadenopathy; and diaphragmatic hernia with gastric displacement.

Clinical Signs

- Vomiting is a consistent sign of gastric outflow obstruction. Typically, undigested food is present in the vomitus greater than 12 hours after eating (the stomach normally empties by 8–10 hours after eating).
- Bile staining of vomitus is usually absent.
- Projectile vomiting suggests gastric outflow obstruction.
- Complete obstruction results in severe, profuse vomiting.
- Abdominal distention caused by an enlarged fluid- or food-filled stomach may occur, especially after eating.
- Anorexia may occur because of a sense of fullness from gastric overdistention.
- Belching may indicate an attempt to release gas from the stomach.
- Weight loss and dehydration may result from chronic vomiting.

Diagnosis

History and Signalment

The history and signalment often indicate a possible underlying cause.

- Persistent vomiting since weaning in young animals suggests congenital pyloric stenosis.
- Acute onset of vomiting in young animals may indicate a foreign body.
- Chronic vomiting with hematemesis is seen with gastric neoplasia, chronic gastritis, and gastric ulcer.
- Chronic intermittent vomiting over weeks to months in middle-aged and older small-breed dogs is consistent with CHPG.
- Acute onset of non-productive retching and gagging accompanied by abdominal distention in large-breed dogs suggests GDV.

Physical Examination

The examination may be unremarkable, or potential findings can include abdominal distention and signs associated with metabolic abnormalities secondary to profuse vomiting, such as weakness and dehydration.

Laboratory Evaluation

- Laboratory findings usually are unremarkable unless profuse vomiting results in fluid, electrolyte, and acid-base disturbances such as dehydration, hypokalemia, hyponatremia, hypochloremia, or metabolic alkalosis.
- Other laboratory findings are variable and depend on the underlying cause of obstruction.

▼ ***Key Point*** Always consider gastric outflow obstruction in vomiting animals with hypochloremic metabolic alkalosis.

Radiography and Ultrasonography

Survey Abdominal Radiography

- The finding of a distended fluid-filled stomach or food present in the stomach greater than 12 hours after eating suggests delayed gastric emptying. The stomach normally empties by 8 to 10 hours after eating; however, emptying times up to 16 hours can be normal in some dogs, especially when fed dry food.
- Identification of the underlying cause of delayed gastric emptying requires further evaluation with contrast radiography, ultrasonography, endoscopy, or exploratory laparotomy.

Barium Contrast Gastrography

- A contrast gastrogram is useful to further evaluate gastric emptying. Liquid barium normally begins to leave the stomach in 5 to 15 minutes, and the stomach is usually empty within 30 to 60 minutes in cats and 1 to 2 hours in dogs.
- The presence of barium in the stomach after 12 to 24 hours confirms delayed gastric emptying.
- Contrast studies can provide important information about the cause of delayed gastric emptying. Potential findings include foreign bodies, thickening or mass lesions of the antral and pyloric region, and narrowing of the pyloric canal (the "beak" sign).

Fluoroscopy and Ultrasonography

Fluoroscopy and ultrasonography may provide information about the outflow tract including intrinsic thickening of the wall of the pyloric antrum or extrinsic compression of the antrum and pylorus by hepatic and pancreatic lesions.

Endoscopy

Endoscopy is useful to identify and remove foreign bodies and to evaluate the antral and pyloric region for outflow obstruction. Fast the patient with suspected delayed gastric emptying for at least 24 hours before endoscopy to ensure that the stomach is empty. If large volumes of fluid are still present, aspirate the fluid through the endoscope to improve visualization.

- Foreign bodies, masses, mucosal proliferations (e.g., CHPG) or thickenings, and ulcers can readily be identified at endoscopy.
- Endoscopic biopsies of affected tissues can be obtained; however, if mechanical outflow obstruction is detected, immediate surgical relief of obstruction and full-thickness biopsies are preferred.
- If the outflow area looks normal and the endoscope is readily passed through the pylorus into the duodenum, mechanical outflow obstruction is much less likely. However, extrinsic compression of the outflow region cannot be fully appreciated with endoscopy and may require an exploratory laparotomy.
- An alternative consideration when the pylorus appears normal is that delayed gastric emptying is caused by a functional motility disturbance (see under "Gastric Motility Disorders") of the stomach rather than by mechanical outflow obstruction.

Treatment

- Give appropriate fluid therapy to correct fluid, electrolyte, and acid-base disturbances before general anesthesia for surgery or endoscopy. Because metabolic imbalances are variable, base the choice of fluid composition on results of electrolyte and blood gas analysis (see the previous discussion of fluid therapy under "Vomiting").
- Metabolic alkalosis may occur secondary to outflow obstruction; manage with non-alkalinizing solutions such as 0.9% saline or Ringer's solution, supplemented with potassium chloride, as described in Chapter 5.
- Surgery is indicated for definitive treatment of gastric outflow obstruction (see Chapter 68).
- If gastric stasis persists after surgical relief of outflow obstruction, give a gastric promotility drug such as metoclopramide, cisapride, or erythromycin to improve gastric emptying (see Fig. 67-1 and Table 67-3). Promotility drugs such as these are contraindicated in the presence of mechanical outflow obstruction.

GASTRIC MOTILITY DISORDERS

Gastric motility disorders that result in weak or ineffective gastric contractions can cause delayed gastric emptying in dogs and cats. These disorders are not well documented in veterinary medicine. Currently, the diagnosis of a gastric motility disorder is presumptive and is based on clinical findings consistent with delayed gastric emptying in the absence of an obstructive lesion.

Etiology

The causes and pathophysiologic mechanisms of gastric motility disorders are poorly understood. Gastric motility is dependent on normal electrical and mechanical

activity of the stomach. Control of gastric motility and emptying is influenced by hormones, autonomic nervous input, and composition of the food. Emptying is prolonged as the fat and protein content, acidity, osmolality, and viscosity of the gastric contents increase.

The following factors may be associated with functional delays in gastric emptying:

- Drug therapy with anticholinergic drugs, adrenergic agonists, or narcotic analgesics can delay gastric emptying.
- Inflammatory lesions such as gastritis, gastric ulcers, *Physaloptera* infection, and parvoviral gastroenteritis can alter gastric motility.
- Acute abdominal inflammation caused by pancreatitis and peritonitis can alter gastric motility.
- Nervous inhibition associated with stress, trauma, pain, or psychogenic input may cause a transient delay in gastric emptying due to increased sympathetic stimulation.
- Metabolic disturbances such as hypokalemia, endotoxemia, and hypothyroidism may delay gastric emptying.
- Neurogenic causes of delayed gastric emptying include dysautonomia and vagal nerve damage.
- Dogs recovering from GDV commonly have gastric myoelectrical and motor abnormalities.
- Prolonged gastric obstruction may be complicated by secondary motility dysfunction.
- In many cases, functional gastric emptying disorders are idiopathic. These disorders may be associated with abnormal gastric electrical conduction disturbances such as tachyarrhythmias.
- Recurrent trichobezoar formation in cats may be related to abnormal migrating motor complexes that impair gastric emptying of indigestible material during fasting.

Clinical Signs

The clinical signs of a gastric motility disorder causing delayed gastric emptying are similar to those of gastric outflow obstruction. These include the following:

- Vomiting of undigested food more than 12 hours after eating
- Abdominal distention and discomfort after eating
- Anorexia and belching

Diagnosis

Perform a complete history to determine if anticholinergics, narcotics, or adrenergic agonists are currently being administered or if other predisposing influences on gastric motility are present.

Laboratory Evaluation

Perform routine screening tests including a CBC, biochemical profile, and urinalysis to detect predisposing metabolic abnormalities. For example, neutropenia associated with acute onset of vomiting, bloody diarrhea, and gastric retention and hypomotility in a young dog suggests parvoviral gastroenteritis.

Radiography

- Perform abdominal radiographs. Delayed gastric emptying is suggested by the finding of a distended fluid-filled stomach or food present in the stomach greater than 12 hours after eating.
- Perform a contrast gastrogram to assess gastric emptying, as described previously under "Gastric Outflow Obstruction." Normal gastric emptying of barium does not exclude a gastric motility disorder because it evaluates only the ability of the stomach to empty liquids and not solids. In functional gastric motility disorders, the gastric outflow region appears normal, but barium may not leave the stomach in a timely fashion.
- Commercially available BIPS have also been used to evaluate gastric emptying time.

Endoscopy

- Endoscopy is a useful non-invasive method to exclude mechanical outflow obstruction as a cause of delayed gastric emptying.
- Fast the patient for at least 24 hours before endoscopy to ensure that the stomach is empty. Large volumes of fluid are often present and should be aspirated through the endoscope to improve visualization.
- In idiopathic gastric motility disorders, the gastric mucosa and pyloric outflow area appear normal. If gastritis is a predisposing cause, gross and microscopic changes will be detected.

Electrogastrogram

Electrogastrograms have been used on a research basis to document abnormal gastric electrical rhythms and may have clinical applications in the future.

Treatment

Whenever possible, identify and correct the underlying cause of a gastric motility disorder. For example, discontinue any anticholinergic drug therapy.

Dietary Management

Diet is an important aspect of treatment for chronic gastric motility disorders.

- Use a diet that is low in fat and high in digestible carbohydrate.
- Feed small amounts at frequent intervals.
- Modify the consistency of the diet. In many instances, the more liquid the diet, the better it empties from the stomach.

Promotility Therapy

The treatment for idiopathic gastric motility disorders is a motility modifier such as metoclopramide, cisapride, erythromycin, or the H_2 blockers ranitidine or nizatidine (see Table 67-3). The effects of metoclopramide and cisapride on the stomach are shown in Figure 67-1.

Metoclopramide

- Although metoclopramide, a dopaminergic antagonist, has traditionally been used as a first choice gastric promotility drug, its effectiveness in promoting gastric emptying may be overstated.
- Give metoclopramide one-half hour before meals at a dose of 0.2 to 0.4 mg/kg PO q8h.

Cisapride

- Cisapride, a serotonergic (5-HT_4) agonist, appears to be more effective than metoclopramide for gastric emptying, but availability of cisapride is limited to compounding pharmacies. Cisapride was taken off the market because of fatal ventricular arrhythmias that occurred in humans but have not been documented in dogs and cats. Cisapride lacks the broad-spectrum central antiemetic effects of metoclopramide.
- Administer cisapride one-half hour before meals at a dosage of 0.25 to 0.5 mg/kg PO q8–12h in dogs and at a dosage of 2.5 to 5.0 mg PO q8–12h in cats.

Other Serotonin Agonist Drugs

- Tegaserod (Zelnorm, Novartis) is a newly marketed 5-HT_4 agonist. However, the intestine and colon are the predominate site of its promotility effects and it may not be useful for treatment of delayed gastric emptying.
- Prucalopride (Janssen Pharmaceutical), another 5-HT_4 agonist, is more likely to be indicated in the treatment of delayed gastric emptying in dogs, but it is not yet available.

Ranitidine and Nizatidine

The H_2 blockers, ranitidine and nizatidine, also have gastric prokinetic effects in dogs and cats (see Table 67-3).

Erythromycin

The antibiotic erythromycin has a prokinetic effect on the stomach of dogs, mimicking the effects of the hormone motilin. The promotility effect occurs at lower doses (0.5–1.0 mg/kg PO or IV q8h) than the antimicrobial effect.

HYPERTROPHIC GASTROPATHY

The term *hypertrophic gastropathy* is used to describe a heterogeneous group of poorly understood disorders associated with focal, multifocal, or diffuse hypertrophic changes of the gastric mucosa of dogs. Hypertrophic gastropathy appears to be quite rare in cats. Various other names have been used, including CHPG, hypertrophic gastritis, gastric polyps, and acquired pyloric stenosis or hypertrophy. These disorders may be variations of the same disease process. Microscopic changes are variable and include hyperplasia of mucosal epithelial cells, glandular hypertrophy, variable inflammatory infiltrates, and mucosal ulceration.

The most commonly recognized form of hypertrophic gastropathy in dogs is a benign disorder associated with mucosal hypertrophy of the antral and pyloric region, resulting in gastric outflow obstruction. Some affected dogs have a component of pyloric muscular hypertrophy. This disorder has been termed *chronic hypertrophic pyloric gastropathy* (CHPG).

Etiology

Little is known about the underlying etiology and pathophysiologic mechanisms of hypertrophic gastropathy; thus, the disease is idiopathic in most cases. Environmental, hormonal, genetic, and immune-mediated mechanisms may play a role.

- Chronic irritation associated with aspirin therapy can result in focal gastric hypertrophy.
- Hormones such as gastrin, cholecystokinin, acetylcholine, and histamine can be trophic to the gastric mucosa. Causes of hypergastrinemia such as chronic renal failure, chronic gastric distention, liver disease, gastrin-secreting tumors, and idiopathic hypertrophy of the antral G-cells (gastrin-secreting cells) may be important considerations in some cases.
- Basenji dogs have hypertrophic gastritis in association with immunoproliferative enteropathy; genetic, immune-mediated, and hormonal (gastrin) factors may play a role.
- Hypertrophic gastritis involving the body of the stomach has been described in the Drentse patrijshond breed of dog. Affected dogs also have red blood cell stomatocytosis and hemolytic anemia.
- Hyperplastic polyps involving the pylorus have been described in young, related French bulldogs with chronic vomiting and gastric outflow obstruction.
- CHPG is most common in highly excitable, nervous small-breed dogs; underlying neuroendocrine or stress-related mechanisms have been proposed.

Clinical Signs

Chronic vomiting is the most consistent clinical sign. Anorexia, weight loss, abdominal distention, and belch-

ing are less frequent signs. Vomiting occurs at variable intervals after eating.

- If hypertrophic changes cause outflow obstruction, undigested food may be present in the vomitus greater than 12 hours after eating.
- Hematemesis and melena may be detected in association with mucosal ulceration.
- Dogs with CHPG often are otherwise healthy and are presented because of chronic intermittent vomiting for a duration of weeks to months (sometimes years).
- Basenji dogs with immunoproliferative enteropathy and hypertrophic gastritis usually have concurrent chronic diarrhea, anorexia, and weight loss.

Diagnosis

Hypertrophic gastropathy is most common in middle-aged or older small-breed dogs such as Lhasa apsos, Shih Tzus, and miniature poodles. Males are affected more commonly than females. A history of chronic intermittent vomiting is typical.

Physical Examination

- Potential findings include weight loss and abdominal distension due to a fluid- or food-filled stomach.
- If significant GI blood loss occurs, pale mucous membranes due to anemia may be detected.

Laboratory Evaluation

- Laboratory evaluation often is unremarkable.
- If profuse vomiting has occurred, laboratory findings may reflect dehydration or electrolyte imbalances. Metabolic alkalosis may occur secondary to gastric outflow obstruction.
- If hypertrophic gastropathy is associated with gastric ulceration, evaluate serum gastrin concentration to detect underlying hypergastrinemia (e.g., gastrinoma).
- Iron deficiency anemia may result from chronic GI blood loss.

Radiography and Ultrasonography

- Perform survey abdominal radiographs to detect a fluid-filled distended stomach or food remaining in the stomach greater than 12 hours after eating. These findings are consistent with a gastric retention disorder.
- Perform a contrast gastrogram (see under "Gastric Outflow Obstruction"). Findings consistent with CHPG include delayed gastric emptying, filling defects in the antral and pyloric region due to hypertrophied mucosa, and narrowing of the pyloric canal. With other types of hypertrophic gastropathy, potential findings include focal, multifocal, or diffusely thickened gastric rugae. Radiographic features of hypertrophic gastropathy are not specific and mimic other inflammatory and infiltrative disorders.
- Ultrasonography can demonstrate thickening of the gastric wall at the antral and pyloric region.

Endoscopy

- Endoscopy can confirm focal, multifocal, or diffusely thickened mucosal folds. Moderate gastric distention with air is required so that normal-sized gastric rugal folds do not appear falsely thickened.
- With CHPG, the lesions predominantly involve the antrum and pyloric region, causing partial or complete pyloric obstruction. Hypertrophied mucosa may form polypoid masses. Mucosal ulceration or hemorrhage is not typical.
- Endoscopically obtained biopsies are inadequate to diagnose hypertrophic gastropathy because they are too superficial to demonstrate the lesion.

Surgery

- Definitive diagnosis of hypertrophic gastritis requires full-thickness biopsies obtained surgically.
- Excisional biopsies are indicated when possible to help relieve the obstruction.

Treatment

- Surgical excision of abnormal tissue and relief of outflow obstruction is the treatment of choice for CHPG (see Chapter 68). Response to surgery is usually good to excellent, and most dogs are clinically normal after relief of obstruction. If gastric atony persists after surgery, a promotility drug such as cisapride or metoclopramide may be needed.
- If hypertrophic gastropathy is associated with gastric erosions or ulcerations, institute antiulcer therapy with H_2 blockers and sucralfate as described under "Gastroduodenal Ulceration."
- When hypertrophic gastropathy is accompanied by a significant inflammatory infiltrate, consider treatment with prednisolone as described under "Chronic Gastritis."
- For treatment of basenji dogs with hypertrophic gastritis and immunoproliferative enteropathy see Chapter 69.

GASTRIC NEOPLASIA

The clinical presentation of gastric neoplasia in dogs and cats is influenced by the size and location of the tumor, whether it is benign or malignant, and whether it is associated with outflow obstruction, altered gastric motility, or mucosal ulceration and bleeding.

Etiology

Malignant Neoplasia

▼ ***Key Point*** Gastric adenocarcinoma is the most common gastric neoplasm in dogs.

- In dogs, gastric adenocarcinoma occurs most commonly in the antral and pyloric region and may appear as a raised plaque or mass with a central ulcerated area or as a diffuse infiltration of the gastric wall. Metastases to the regional lymph nodes, liver, adrenals, and lungs are common. Gastric adenocarcinoma is rare in cats.

▼ ***Key Point*** Lymphoma is the most common gastric neoplasm in cats.

- Cats with gastric lymphoma usually are FeLV negative. Lymphoma may appear as multiple, raised, white mucosal masses or as diffuse infiltration of the gastric wall. Mucosal ulceration is common.
- Other, less common primary malignant neoplasms include leiomyosarcoma and fibrosarcoma.

Benign Neoplasia

- Benign adenomatous polyps occur infrequently in dogs and cats. Polyps probably develop in response to chronic gastric mucosal damage or irritation. They appear as single or multiple, pedunculated or polypoid nodules that vary in size from millimeters to centimeters. A predilection for the proximal duodenum within 1 cm of the pylorus has been noted in cats. Clinical signs usually are absent unless pyloric obstruction occurs. Polyps usually are an incidental finding at endoscopy or necropsy.
- Leiomyomas are the second most common gastric tumor in dogs. These tumors arise from the muscle layers of the gastric wall; clinical signs may be absent unless the mechanical effects of the mass alter motility or cause outflow obstruction. A predilection for the gastroesophageal junction has been noted. Mucosal ulceration occasionally occurs.

Clinical Signs

Malignant Neoplasia

Dogs and cats with malignant gastric neoplasia are usually presented because of chronic progressive vomiting.

- If pyloric outflow obstruction occurs, clinical signs reflect delayed gastric emptying.
- Hematemesis and melena are common with adenocarcinoma because of mucosal ulceration. Other signs include anorexia, weight loss, and chronic debilitation.

Benign Neoplasia

Clinical signs may be absent with benign neoplasms or polyps unless pyloric obstruction occurs.

Diagnosis

Gastric neoplasia is an important consideration in older dogs and cats with a history of chronic progressive vomiting and hematemesis.

Physical Examination

- Findings often include weight loss and cachexia.
- Palpable abnormalities of the stomach usually are absent, although, rarely, a gastric mass may be palpable.
- Pale mucous membranes and melena are associated with mucosal ulceration and blood loss anemia.
- Gastric perforation and peritonitis are associated with abdominal distention, pain, collapse, and shock.
- Additional findings such as ascites, jaundice, and dyspnea reflect metastatic disease.

Laboratory Evaluation

Laboratory evaluation is variable and depends on secondary complications such as blood loss anemia, perforation, metastatic disease, and metabolic complications of vomiting. Paraneoplastic hypoglycemia may occur in dogs with gastric leiomyosarcoma.

Radiography

- Survey abdominal radiographs may be unremarkable or suggest outflow obstruction, a thickened gastric wall, or mass lesions.
- Barium contrast radiography often reveals mass lesions, filling defects, ulcers, and diffuse thickening of the gastric wall. Rigidity of the gastric wall seen repeatedly on sequential radiographs suggests an infiltrative lesion.
- Delayed gastric emptying can result from pyloric outflow obstruction.
- Perform thoracic films to screen for pulmonary metastases.

Endoscopy

Endoscopy is useful to confirm lesions suggested on radiography and to obtain biopsies of affected tissues. Gastric neoplasia that does not involve the mucosa or results in a mass effect can be difficult to detect endoscopically, and a full-thickness biopsy obtained surgically is often necessary.

- Adenocarcinoma may appear as raised plaques, polypoid lesions, or a diffuse infiltrating lesion. Mucosal ulceration is common.

- Gastric lymphoma appears as single or multiple white nodules or as diffuse infiltration of the mucosa with irregular thickening of the mucosal folds. With diffuse infiltration of the gastric wall, the stomach may lack distensibility.
- Leiomyomas are smooth mass lesions with a normal overlying mucosa unless complicated by ulceration.
- Polyps appear as small, smooth, or raspberry-like masses on a stalk.

Surgery

Surgical exploration is an important diagnostic method for gastric neoplasia.

- Palpate all areas of the stomach to identify affected areas.
- Obtain full-thickness biopsies.
- Evaluate regional lymph nodes and the liver for metastases.

Treatment

- The treatment of choice for gastric neoplasia is surgical resection of the tumor by partial gastrectomy (see Chapter 68). Because the antral and pyloric regions are often involved, a gastroduodenostomy or gastrojejunostomy may be necessary.
- For treatment of lymphoma, use chemotherapy as described in Chapters 26 and 27, with or without prior surgical resection of large solitary gastric masses.

Prognosis

- The prognosis for benign neoplasms after surgical removal is good.
- The prognosis for adenocarcinoma is poor.
- Some cats with lymphoma localized to the stomach may have a good to excellent response to chemotherapy.

GASTRIC DILATATION-VOLVULUS

GDV is an acute, life-threatening disorder that is a medical and surgical emergency. Early recognition and treatment are essential for a successful outcome. Gastric dilatation refers to distention of the stomach, usually with swallowed air. Gastric dilatation may or may not be complicated by volvulus. GDV occurs when the stomach rotates on its long axis, resulting in complete gastric outflow obstruction. Concurrent obstruction of the gastroesophageal junction precludes relief of fluid and gas accumulation by vomiting or belching. Massive gastric distention impairs venous return through the portal vein and caudal vena cava, causing hypovolemic and endotoxic shock. Passive congestion of the abdominal viscera predisposes to local acidosis and disseminated intravascular coagulation (DIC). The spleen often is displaced concurrently, causing splenic vascular occlusion, congestion, and splenomegaly. Strangulation necrosis of the gastric wall eventually occurs secondary to twisting of the stomach.

Etiology

The cause of GDV is unknown.

- An anatomic predisposition may play a role; large-breed, deep-chested dogs are most commonly affected, and the disorder is rare in small dogs and cats.
- Whether gastric distention due to excess swallowed air precedes volvulus is not known, but if this theory is true, it suggests causes of aerophagia such as gulping of food and water may be important.
- Risk factors for GDV include increasing age, having a first-degree relative affected by GDV, lean body conformation, rapid eating, eating from a raised bowl, eating one meal daily, exercise, stress after a meal, and a fearful temperament.

Clinical Signs

- Acute onset of abdominal distention with tympany
- Non-productive retching
- Salivating, restlessness, and respiratory distress

Diagnosis

Consider GDV in the differential diagnosis of any large-breed, deep-chested dog with acute onset of abdominal distention.

Physical Examination

Examination usually reveals abdominal distention that is tympanitic on percussion and findings indicative of hypovolemia and/or shock, such as increased heart rate, weak femoral pulses, decreased capillary refill time, and pale oral mucous membranes.

Laboratory Evaluation

- After initial stabilization (see "Initial Medical Management") submit blood for a CBC and biochemical evaluation to characterize secondary metabolic imbalances and to identify any other coexistent abnormalities.
- Hypokalemia is the most common electrolyte abnormality in dogs with GDV. Although serum potassium concentration may be normal initially, hypokalemia frequently develops after aggressive fluid therapy and, if surgery is necessary, postoperatively. Prevention of hypokalemia may decrease the frequency of postoperative cardiac arrhythmias and muscle weakness.

- Because a variety of acid-base imbalances may occur secondary to GDV, repeated laboratory assessment and frequent monitoring of blood gases and electrolyte concentrations are recommended.
- Metabolic acidosis is most common and occurs because of decreased effective circulating blood volume, arterial hypoxemia, and lactic acid accumulation.
- Metabolic alkalosis, respiratory alkalosis, respiratory acidosis, and mixed acid-base disorders may also develop.

Radiography

Perform abdominal radiography only after the patient is stabilized medically (see the next section). Minimize stress to the patient during the procedure.

▼ ***Key Point*** Right lateral and ventrodorsal radiographic views of the abdomen are the most useful for diagnosing GDV.

- Radiographic findings suggestive of GDV include overdistention of the stomach with gas, pyloric displacement dorsally and to the left, gastric fundic displacement caudally and to the right, and compartmentalization of the stomach on the lateral view. Splenomegaly is also seen.
- Pneumoperitoneum suggests gastric perforation and requires immediate surgery.
- Thoracic radiography is not essential but may demonstrate microcardia (due to hypovolemia), megaesophagus, or aspiration pneumonia.
- In cases of intermittent bloating or failure of surgical correction following tube decompression, perform a contrast gastrogram (see Chapter 4) to identify malposition of the stomach.

Initial Medical Management

Decompress the Stomach by Orogastric Intubation

- Sedation may be necessary to pass an orogastric tube. Give diazepam (0.1 mg/kg IV slowly) alone or in combination with butorphanol (0.5 mg/kg IV). An alternative is the combination of diazepam-ketamine (50:50), 1 ml/10 kg IV.
- Perform gastric decompression by passing a well-lubricated large-bore orogastric tube. Remove all air and fluid from the stomach and lavage the stomach with 4 to 5 L of warm saline or water. Repeat orogastric decompression as needed during the stabilization period.
- If orogastric decompression is not possible with a tube, use several 18-gauge needles to trocarize the distended stomach. Following decompression with needle trocarization, a subsequent attempt to pass the orogastric tube often is successful.

Place an Intravenous Catheter and Administer Fluids

- While decompression is being performed, place a large-bore catheter in each cephalic vein.
- Treat for shock as described in Chapter 156. Give isotonic crystalloid fluids such as lactated Ringer's solution at an initial rapid rate of 90 ml/kg for the first hour. After shock is controlled and dehydration is corrected, lower to a maintenance rate of administration. Add potassium chloride to the fluid (30 to 40 mEq KCl per liter of fluid) after the initial shock dose of fluids has been given. When blood gas analysis is not available, routine addition of $NaHCO_3$ to fluids is not recommended, because many dogs with GDV have relatively normal blood pH at presentation. Correction of volume depletion and mild metabolic acidosis by lactated Ringer's solution is sufficient unless severe metabolic acidosis is present.
- Alternatively, administer small-volume fluid therapy using 7% NaCl (5 ml/kg) in 6% dextran 70 (HS/D70) (see Chapter 156). Give over 5 to 10 minutes and follow with 20 ml/kg/hr of 0.9% NaCl.
- Place a Foley catheter in the bladder to monitor urine output.

Control Infection and Endotoxemia

- To treat endotoxemia, give prednisolone sodium succinate (10 ml/kg IV). Give a single dose of flunixin meglumine (Banamine, Schering), 1 mg/kg IV, during the initial phase of therapy.
- Give a broad-spectrum antibiotic (cefmetazole, 15 mg/kg IV) or a combination drug therapy (cefazolin, 20 mg/kg IV, and enrofloxacin, 5–10 mg/kg IV).

Monitor and Treat Cardiac Arrhythmias

- Ventricular arrhythmias are the most common.
- To treat ventricular arrhythmias, give a bolus of lidocaine (1–2 mg/kg) IV while monitoring the electrocardiogram. If no conversion is noted within 3 to 5 minutes, repeat this dose. For a comprehensive discussion of diagnosis and treatment of arrhythmias, see Chapter 145.
- If only temporary conversion occurs, start a lidocaine drip. A maintenance effect is achieved with a constant rate infusion of lidocaine at a dosage of 40 to 60 µg/kg/min added to the IV fluids. Lidocaine's effectiveness may be impaired in the presence of hypokalemia.
- If lidocaine boluses are ineffective for controlling ventricular arrhythmias, consider giving procainamide (10–15 mg/kg IM q6h) or quinidine sulfate (6–15 mg/kg IM q6h). If arrhythmias are controlled with parenteral administration of procainamide or quinidine, an oral antiarrhythmic can later be substituted, as described in Chapters 145 and 146.

Surgical Management

Surgical management of GDV is detailed in Chapter 68. The goals of surgical intervention for acute GDV include the following:

- Repositioning of the stomach and spleen
- Resecting devitalized gastric and splenic tissue
- Permanently fixing the stomach (pyloric antrum) to the right abdominal wall to prevent future recurrences of volvulus (see Chapter 68)

Prevention

If medical therapy alone is successful and no evidence of gastric volvulus is detected subsequently on a contrast gastrogram, there is still a 70% to 75% likelihood that the dog will have another episode of GDV. Owner education can help lessen the probability of recurrence.

Instruct the owner to do the following:

- Feed the dog frequent, small portions of food 3 to 5 times per day.
- Limit water intake and do not allow access to water for 1 hour after eating.
- Restrict exercise for at least 1 hour after eating, because this may predispose to GDV.
- Be aware of the early warning signs of GDV (e.g., depression, restlessness, belching, excessive flatulence, and abdominal enlargement), especially when there is a change in the dog's environment—for example, when the dog is boarded or hospitalized, or when a new adult, child, or pet is introduced into the household.
- Consider prophylactic gastropexy in high-risk dogs (see Chapter 68).

Chapter

68 Surgery of the Stomach

Ronald M. Bright

Retrieval of foreign bodies is the most common reason for surgery on the stomach. Surgery of the pylorus is most often indicated for some forms of gastric outflow obstruction. The most common sign related to surgical disease of the stomach is emesis. The stomach has an excellent blood supply and heals rapidly (10–14 days).

ANATOMY

Stomach

- The stomach is a musculoglandular organ capable of undergoing a great amount of distention.
- The stomach is a C-shaped, partially coiled, bulging tube.
- The stomach lies in a transverse plane. The larger part of the stomach (fundus) lies to the left of the midline.
- The esophageal entrance and duodenal exit are dorsal—the former lying to the left of the midline, the latter to the right.
- In the fasting dog, the stomach does not extend caudally beyond the costal arch and is rarely palpable.
- The stomach is divided into four regions: cardia, fundus, body (corpus), and pylorus.
- The stomach has four tunics: mucosa, submucosa, muscularis, and serosa. The submucosa and mucosa layers are easily separated from the overlying seromuscular layers.
- The blood supply to the distal stomach is from a branch of the hepatic artery, giving rise to the right gastric and gastroepiploic arteries.
- The splenic artery gives rise to the left gastroepiploic artery, which supplies the greater curvature.
- The left gastric artery supplies blood to the lesser curvature of the stomach and the distal esophagus.
- Veins are satellites to the arterial branches. Most blood drains from the left side of the stomach via the gastrosplenic vein and from the right side via the gastroduodenal vein. These veins ultimately drain into the portal vein.
- The major innervation is parasympathetic from the vagi and sympathetic from the celiac plexus.

Omentum

- The greater omentum extends caudally from the greater curvature of the stomach to the urinary bladder, forming a double-layered cover of the small intestine.
- A splenic portion of the omentum attaches to the greater curvature to the spleen and a smaller portion attaches to the pancreas.
- The lesser omentum extends from the lesser curvature of the stomach and attaches to the diaphragm, liver, and duodenum.
- The hepatoduodenal and hepatogastric ligaments are loose attachments between the respective components.

Pylorus

- The pylorus is composed of two segments, the antrum and the canal. The antrum is a narrow funnel-shaped chamber leading to the narrowed pyloric canal.
- The inner circular muscle layer is thickened in the pyloric region and functions as a powerful sphincter. An outer longitudinal muscle layer is also present.
- The pylorus has two major functions—to control the emptying of solid food once it becomes reduced to an appropriate size and to prevent excessive duodenogastric reflux.

GASTROTOMY

Preoperative Considerations

▼ ***Key Point*** Serious water and electrolyte abnormalities often accompany conditions that affect the stomach and require gastrotomy. Initiate fluid and electrolyte resuscitation before gastrotomy.

- The most common indication for gastrotomy is to retrieve foreign bodies.
- Endoscopic retrieval of gastric foreign bodies is preferred. When this approach fails, a gastrotomy is indicated.

Surgical Procedure

Objectives

- Access to and exposure of intraluminal contents.
- Collection of biopsy specimens.
- Avoidance of contamination of the peritoneal cavity.

Equipment

- General surgical pack
- Babcock forceps (optional)
- Abdominal self-retaining Balfour retractors
- Laparotomy pads

Technique

1. Make a cranial ventral midline abdominal approach, with the skin incision extending from the xiphoid to the umbilicus.
2. Exteriorize the stomach and isolate it from the other abdominal organs using moistened laparotomy pads.
3. Place two Babcock forceps or two stay sutures 10 to 15 cm apart on a hypovascular area of the stomach, halfway between the lesser and greater curvature.
4. Make a stab incision into the lumen with a #11 blade.
5. Use suction to remove liquids from the stomach.
6. Extend the stab incision with scissors.
7. Do a visual and tactile exploration of the entire stomach.

Closure

1. The first layer is a continuous inverting horizontal mattress (Connell) suture pattern involving only the submucosal and mucosal layers. A simple continuous suture pattern can be substituted. Synthetic 3-0 absorbable suture material is preferred. Use of chromic gut suture material is discouraged, because it breaks down too rapidly when coming in contact with the lumen of the stomach.
2. Close the second layer with a vertical (Lembert) or horizontal (Cushing) continuous inverting pattern.
3. If the gastrotomy closure is likely to incorporate diseased or devitalized tissue, suture a section of vascularized omentum or a serosal patch, employing a loop of jejunum over the wound for additional reinforcement.

Postoperative Care and Complications

Short Term

- Give no food for 24 hours; water is allowed ad libitum.
- Monitor the patient for leakage, especially if the gastrotomy closure involves diseased tissue (neoplasia).
- Emesis may be noted once or twice following gastric surgery and treatment is usually not required.
- Systemic antacids are indicated if ulcers or severe gastritis is observed during surgery (see Chapter 67).

Prognosis

- Good to excellent if the reason for surgery is related to a foreign body.

PARTIAL GASTRECTOMY RELATED TO GASTRIC DILATATION-VOLVULUS

Preoperative Considerations

- Gastrectomy in patients with dilatation-volvulus is a high-risk procedure.
- Initially, attempt to stabilize metabolic abnormalities but rapidly proceed with surgery because gastric rupture may occur.

Surgical Procedure

Objectives

- Resect non-viable gastric tissue and restore gastric continuity.
- Use a stapling technique, if possible, to expedite this high-risk procedure.

Equipment

- General pack
- LDS stapler (U.S. Surgical, Norwalk, CT) (optional)
- TA stapler (U.S. Surgical, Norwalk, CT) (optional)
- Abdominal self-retaining retractor
- Laparotomy pads
- Non-crushing straight Doyen intestinal clamps

Technique

1. The approach to the stomach is similar to that for a gastrotomy.
2. Non-viable tissue is recognized by its lack of bleeding on cut surfaces, bluish-black or greenish discoloration, and severe thinning of the stomach wall on palpation.

▼ ***Key Point*** Do not rely on the appearance of the mucosa alone to determine if full-thickness stomach wall necrosis has occurred.

3. Ligate and divide the appropriate short gastric vessels. LDS stapler apparatus is optimal. This procedure may not be necessary because these vessels are frequently torn.
4. After placement of stay sutures, apply intestinal forceps 2 lateral to the junction of viable and non-viable tissue. The tips of the forceps meet at an approximately 45-degree angle.
5. Use a #10 scalpel blade to cut along the intestinal clamps, leaving a 1-cm margin of healthy tissue outside the intestinal clamps.

Alternate Method of Resection

1. Place a TA stapler parallel to the junction of viable and non-viable tissue, leaving a 1-cm width of normal tissue.
2. After the stapler is engaged and the staples are placed in the tissue, cut the stomach wall next to the blade of the stapler and remove the necrotic tissue.

Closure

1. Without a stapler, the closure is similar to that for a gastrotomy incision.
2. With a stapler, perform the closure before cutting the non-viable tissue away from the TA stapler's blade.
3. Close the abdomen routinely. If gastric rupture has occurred, the abdomen may be left partially open as in treating peritonitis (see Chapter 76).

Postoperative Care and Complications

Short Term

- Refer to the discussion of gastric dilatation-volvulus surgery for postoperative management of metabolic problems.
- Delay feeding for 24 hours.
- Monitor very closely for signs of gastric leakage (fever, vomiting, pneumoperitoneum, peritonitis), especially during the first 96 hours postoperatively.

▼ ***Key Point*** When a partial gastrectomy is performed during surgical therapy for gastric dilatation-volvulus complex, the mortality rate ranges from 30% to 60%.

PARTIAL GASTRECTOMY (DISTAL STOMACH)

Preoperative Considerations

▼ ***Key Point*** Attempts to define the extent and nature of the disease (benign polyp, malignancy, fungal disease, chronic gastric ulcer) by radiography and endoscopic biopsy are extremely important when planning surgical therapy.

Many animals with gastric neoplasia are old and debilitated and are at greater risk during surgery than others.

Surgical Procedure—Partial Gastrectomy and Gastroduodenostomy (Billroth I)

Objectives

- To remove diseased tissue that is benign or, if malignant, is limited to the antrum and/or body of the stomach.
- To correct failed pyloroplasty procedures.
- To maintain an adequate outflow lumen.

Equipment

- Same as that for partial gastrectomy associated with the gastric dilatation-volvulus complex
- GIA stapler (U.S. Surgical, Norwalk, CT)—recommended if a stapler technique is used
- Large straight intestinal clamps

Technique

1. Place the dog in dorsal recumbency with surgical preparation similar to that for gastrotomy.
2. Stapling devices (e.g., the GIA stapler) can be substituted for more traditional suturing techniques.
3. If the diseased tissue is limited to the pylorus, a modification of a Billroth I (von Haberer) technique can be done (Fig. 68-1).
4. If a partial gastrectomy is performed to control ulcer disease, resect the entire antrum.
5. More extensive resection of the pylorus or distal stomach can be done and reconstructed with the original Billroth I (Shoemaker) procedure (see Fig. 68-1).

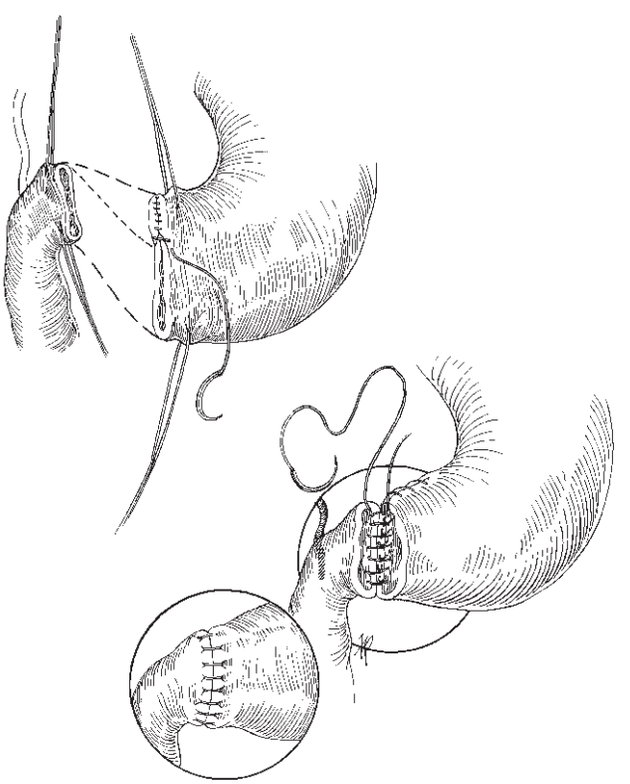

Figure 68-1. Partial gastrectomy with a Billroth I (gastroduodenostomy) repair. *Above,* Lesser curvature of the stomach is closed until lumen disparity is corrected. *Below,* Closure with single interrupted sutures.

6. After the line of resection is determined, ligate and divide the blood vessels supplying the lesser and greater curvature and attached omentum.
7. Mobilize the pylorus after incising the gastrohepatic ligament. Avoid cutting the common bile duct and hepatic arteries.
8. Isolate the area to be resected from the abdominal cavity with moistened laparotomy sponges.
9. Place large, straight non-crushing intestinal forceps above and below the proposed lines of incision.

Closure

1. Use a single-layer interrupted appositional suture pattern to appose the stomach and duodenum. With unequal lumen sizes, first close the lesser curvature side of the stomach until the lumen disparity is corrected (see Fig. 68-1, *top*).
2. Appose the back (far) wall first, placing the knots into the lumen. Synthetic 3-0 absorbable suture (e.g., polydioxanone [PDS]) is recommended.
3. Then appose the near wall.

Surgical Procedure—Partial Gastrectomy and Gastrojejunostomy (Billroth II)

Objectives

- Resect a significant portion of the diseased stomach and all or part of the duodenum.
- Remove the duodenum distal to the common bile duct opening.
- Reestablish continuity of the stomach with the small intestine with a gastrojejunostomy.
- Restore a biliary connection to the duodenal or jejunal stump via a cholecystenterostomy.

Equipment

- Same as that for the Billroth I.

Technique

1. Ligate and divide the appropriate vessels and the common bile duct.
2. Close the duodenal or jejunal stump with a simple interrupted appositional suture pattern using 3-0 synthetic absorbable suture material or a TA stapler.
3. The original Billroth II reconstruction is done by closing the gastric stoma followed by a side-to-side anastomosis of the jejunum to an incision made in the ventral aspect of the stomach (Fig. 68-2).
4. Use a simple interrupted appositional suture pattern to appose the gastric and jejunal segments.
5. For more extensive resections, appose the entire width of the gastric stump to a longitudinal incision made in the jejunum (Fig. 68-3).
6. Use a suture pattern as described in Step 4 for closure.

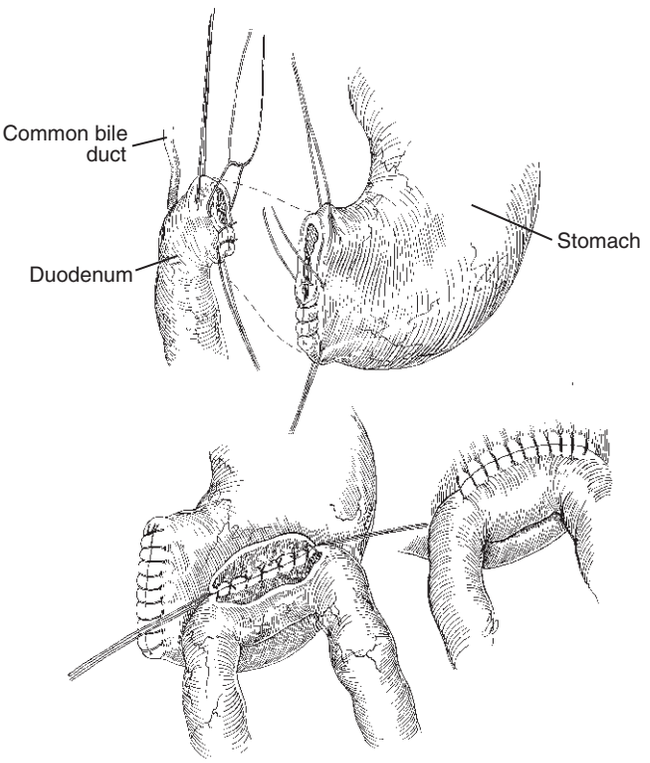

Figure 68-2. Billroth II procedure with side-to-side gastrojejunostomy.

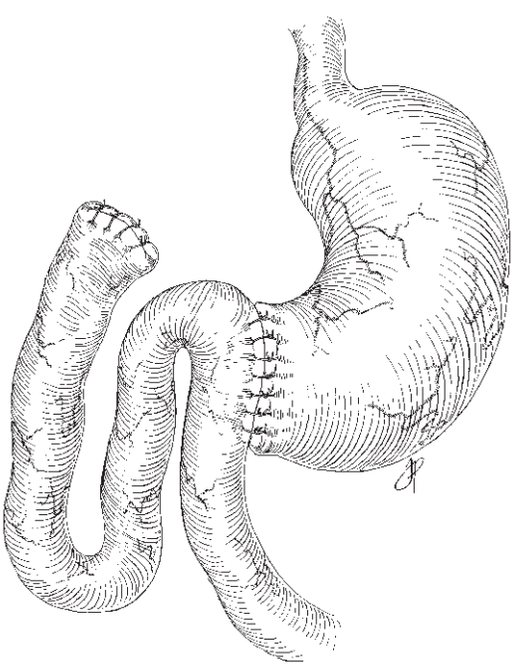

Figure 68-3. Billroth II with anastomosis of the entire gastric stump to a longitudinal incision of the jejunum.

7. Perform a cholecystenterostomy to complete the procedure (see Chapter 72).
8. Place a jejunostomy tube to provide nutrition in the debilitated patient.

Postoperative Care and Complications

Short Term

- Monitor for fever and abdominal pain as early signs of leakage peritonitis.
- Withhold food and water by mouth for 24 hours.
- Offer small amounts of food by mouth (per os) 24 hours after surgery.
- Dumping syndrome (passage of undigested food directly into the jejunum) may initially be a problem.

Long Term

- Dumping syndrome, due to disruption of the normal storage function of the stomach and rapid movement of ingested food into the small intestine, may cause chronic postprandial discomfort, vomiting, and diarrhea.
- Alkaline reflux gastritis may result from disruption of the pyloric sphincter.
- After extensive gastrectomy, multiple small feedings are necessary.

Prognosis

- Good—if the underlying disease is benign or inflammatory.
- Poor—if malignancy is the indication for surgery.

PYLOROMYOTOMY

Preoperative Considerations

- Delay pyloromyotomy until hypochloremic, hypokalemic metabolic alkalosis, which often accompanies the conditions requiring pyloromyotomy, is corrected.
- Direct fluid therapy toward restoring electrolyte *and* water abnormalities.
- In the younger dog or cat, add dextrose to the fluid therapy regimen in an attempt to maintain euglycemia.
- Food and water may be retained in the patient's stomach with outflow obstruction. Therefore, following sedation, place an orogastric tube into the stomach and evacuate the stomach contents.

▼ ***Key Point*** Pyloromyotomy will *not* effectively relieve outflow obstruction caused by mucosal hypertrophy. Pyloromyotomy is primarily indicated for dogs with muscular hypertrophy only (see Chapter 67).

Surgical Procedure

Objectives

- Increase the lumen diameter of the pylorus to enhance gastric emptying.

Equipment

- General surgery pack
- Abdominal self-retaining retractor
- Laparotomy sponges
- Babcock forceps

Technique

1. Place the dog in dorsal recumbency and aseptically prepare for a cranial midline abdominal incision.
2. Incise the skin and underlying tissues to allow an opening to the abdominal cavity extending from the xiphoid to 4 to 5 cm below the umbilicus.
3. Partially incise the gastrohepatic ligament to allow the pylorus to be mobilized.
4. Isolate the stomach with laparotomy sponges.
5. Place a stay suture or a Babcock forceps 3 to 5 cm proximal and distal to the pyloric ring.
6. Make an incision 4 to 5 cm long into a hypovascular area of the serosa overlying the pyloric antrum and canal and extend it distally into the proximal duodenum. The pylorus is at the midpoint of the incision (Fig. 68-4, *top*).
7. Gently incise or dissect away all muscle fibers, using a curved hemostat, to allow the submucosa and mucosa to bulge (see Fig. 68-4, *middle* and *bottom*).
8. Gently replace the stomach into the abdomen.
9. Perform routine ventral abdominal closure.

Postoperative Care and Complications

Short Term

- Treat emesis lasting more than 6 to 8 hours postoperatively with metoclopramide, 0.2 to 0.4 mg/kg subcutaneously (SC) q6h as needed, or constant-rate intravenous (IV) infusion of metoclopramide at 1 to 2 mg/kg/day, which is most effective.
- Maintain fluid therapy for 36 to 48 hours postoperatively.
- Perform frequent monitoring of the packed cell volume, albumin, and blood glucose values, especially in the very young animal.
- Monitor electrolyte values closely in all animals for the first 24 hours.
- Begin feeding soft food 24 hours after surgery unless vomiting continues.

Long Term

- Emesis may continue with little to no improvement noted. This sign may suggest a need to reoperate and perform a more extensive procedure (e.g., pyloroplasty).

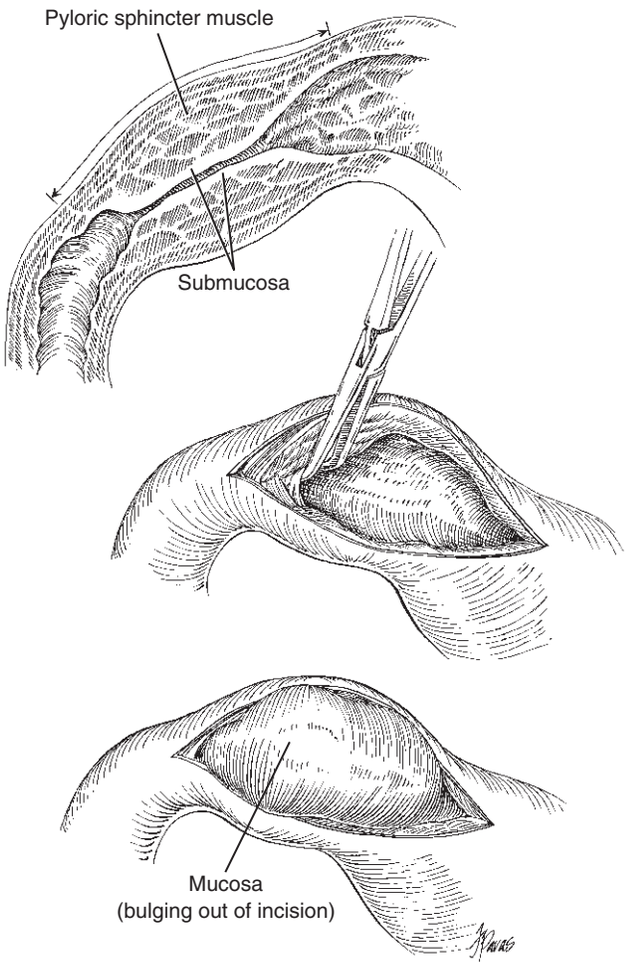

Figure 68-4. Technique for pyloromyotomy.

- Signs of vomiting may recur several days or weeks following surgery. If other causes of vomiting are not identified, reoperation may be necessary.

Prognosis

- Because the underlying disease in most cases is benign, the prognosis is good to excellent.

PYLOROPLASTY

Preoperative Considerations

- See under "Pyloromyotomy."
- Pyloroplasty is indicated for pyloric hypertrophy involving muscle and mucosa or mucosa alone (see Chapter 67). Dogs with severe pyloric hypertrophy may require the Billroth I procedure (see previous discussion).
- Manual and visual inspection of the lumen of the distal stomach, pylorus, and proximal duodenum is possible with a pyloroplasty.

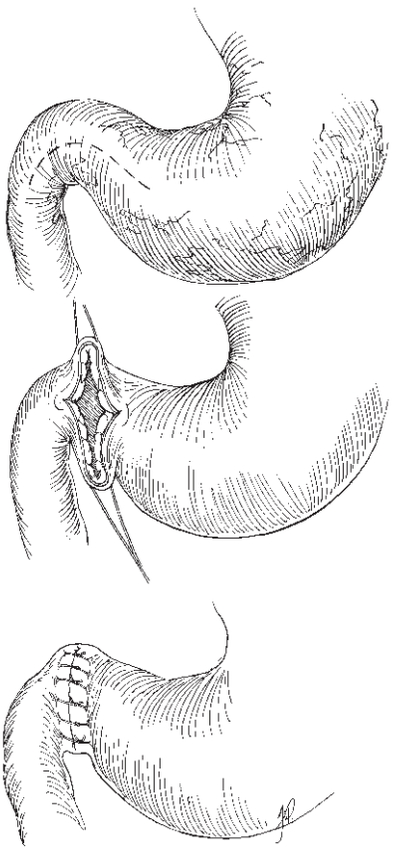

Figure 68-5. Technique for Heineke-Mikulicz pyloroplasty.

Surgical Procedure

Objectives

- Inspect the distal stomach and pylorus for abnormalities.
- Increase the diameter of the gastric outflow tract.

Equipment

- See under "Pyloromyotomy."

Heineke-Mikulicz Pyloroplasty

Technique

1. Place temporary stay sutures or Babcock forceps on the antrum and proximal duodenum proximal and distal to the pyloric ring.
2. Make a full-thickness stab incision into the pylorus using a #11 Bard-Parker scalpel blade. Place a suction tip into the stomach to evacuate contents and bile.
3. Extend the incision with scissors to 1 to 2 cm above and below the pylorus (Fig. 68-5).
4. Remove the stay sutures or Babcock forceps.
5. Close the longitudinal incision transversely with 3-0 synthetic absorbable sutures in a simple interrupted appositional pattern. Stay sutures can be placed on

both sides of the incision to help orient the tissues for closure.
6. Routine abdominal closure follows warm saline lavage of the surgical site.

Y-U Pyloroplasty (Antral Flap Advancement)

Technique

1. Mobilize the pylorus as described under Pyloromyotomy.
2. Place temporary stay sutures 4 to 5 cm above and below the pylorus.
3. Make a Y-shaped incision through the seromuscular tissue overlying the pylorus and distal stomach (Fig. 68-6).
4. Each limb of the Y is approximately 3 to 4 cm in length depending on the size of the animal.
5. The base of the Y extends a small distance (3–4 mm) into the antrum proximal to the pylorus.
6. Trim the V-shaped antral flap to a U-shape. Save the resected tissue and submit for histopathology.
7. Thoroughly palpate and visually examine the stomach and proximal duodenum.
8. Excise hypertrophied tissue via a submucosal resection. Close adjacent mucosa/submucosa in a continuous pattern with 3-0 or 4-0 synthetic absorbable suture.
9. Begin pyloroplasty closure by suturing the base of the U-shaped flap distally to the proximal duodenum with 3-0 or 4-0 synthetic absorbable suture (see Fig. 68-6).
10. A simple interrupted appositional pattern is recommended. If necessary, preplace the sutures to ensure accuracy.
11. Appose the lesser curvature limb of the Y, followed by the greater curvature limb (see Fig. 68-6).

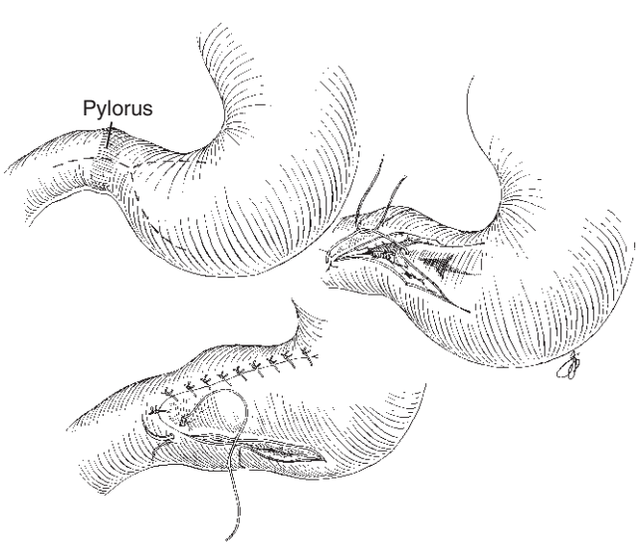

Figure 68-6. Technique for Y-U pyloroplasty.

Postoperative Care and Complications

Short Term

- Same as that for pyloromyotomy.

Long Term

- Emesis containing a significant amount of bile several weeks after surgery may suggest duodenogastric reflux. Consider treatment with metoclopramide.
- Alkaline reflux gastritis resulting from duodenogastric reflux may require long-term therapy with metoclopramide or cisapride to promote normal gastric emptying and an H_2 blocker for acid control.

Prognosis

- Good—if the disease being treated is benign.

ACUTE GASTRIC DILATATION-VOLVULUS

Preoperative Considerations

- Aggressive fluid therapy, cardiac arrhythmia therapy, and orogastric decompression are necessary before any surgical intervention (see Chapter 67).
- Stabilization of most patients can be accomplished in 2 to 3 hours.
- Complicating gastric perforation is considered a surgical emergency.
- Risk factors recently described by Glickman and colleagues (see "Supplemental Reading") are encouraging many surgeons to perform a prophylactic gastropexy in those dogs that are considered to be at great risk for gastric dilatation-volvulus. Some of the more important risk factors include rapid eating, hyperactivity, lean body conformation, aggressive nature, first-degree relative with known gastric dilatation-volvulus, and signalment (Great Dane breed).

Surgical Procedure

Objectives

- Reposition stomach and spleen to their normal anatomic relationship.
- Fix ("pexy") the stomach (pyloric antrum) to the right abdominal wall to prevent future episodes of volvulus.
- Resect devitalized tissue (spleen, stomach).

Equipment

- General surgical pack
- Self-retaining abdominal retractor (Balfour)
- Foley catheter (22–26-French)
- Orogastric tube

Technique

1. Place the dog in dorsal recumbency and surgically prepare from the mid-sternum to 6 to 8 cm below the umbilicus. If a tube gastropexy is used, prepare the right side of the abdominal wall aseptically, halfway up the side of the thoracic and abdominal wall that corresponds with the length of the midline incision.
2. Gently place an orogastric tube into the esophagus and advance it until there is resistance.
3. Derotate the stomach by grasping the pylorus and duodenum, usually located near the gastroesophageal junction, and elevating them to the right side of the body.
4. The fundus, usually on the right side, is depressed and rotated to the left side while the pylorus is being repositioned.
5. Place the orogastric tube within the stomach and perform stomach decompression.
6. Assess the viability of the stomach, and resect necrotic tissue if necessary (see discussion of "Partial Gastrectomy Related to Gastric Dilatation-Volvulus").
7. Splenectomy is usually not done unless there is evidence of splenic torsion or necrosis.
8. Perform a gastropexy procedure on the right side of the dog (regardless of the technique employed). Each of the gastropexy techniques described subsequently is effective. The technique chosen depends on the surgeon's preference.

Tube Gastropexy (22–26-French Foley Catheter)

Technique

1. Tube gastropexy is not considered to be an acceptable "pexy" technique unless it is done concurrently with a partial gastrectomy. Under these circumstances, the tube gastrostomy may be beneficial to wound healing by keeping the remaining stomach decompressed.
2. Place a full-thickness pursestring suture in the midantrum area using 2-0 or 3-0 non-absorbable suture. This suture is left untied (Fig. 68-7).
3. Pull the tip of a Foley catheter through a small right paracostal incision using Carmalt forceps, approximately 4 cm caudal to the costal arch and 4 cm lateral to the incision.
4. Make a stab incision into the middle of the pursestring suture area and advance the tip of the Foley catheter through this and into the stomach (see Fig. 68-7).
5. Inflate the balloon portion of the catheter.
6. Draw the pursestring suture tightly and tie it.
7. Move the stomach to the abdominal wall with traction on the Foley catheter.
8. Preplace six to eight interrupted sutures between the stomach, being sure to penetrate to the submucosa and the abdominal wall. Use nonabsorbable #1 or 1-0 suture material (see Fig. 68-7).

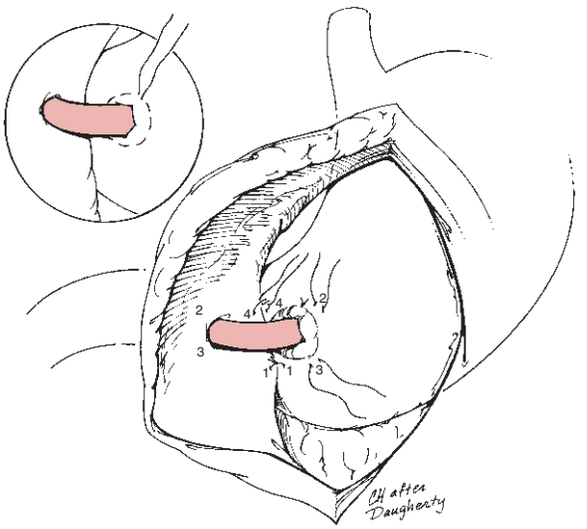

Figure 68-7. Technique for tube gastropexy in the treatment of gastric dilatation-volvulus. *Inset,* Place an untied pursestring suture in the midantrum area. Place a Foley catheter through the body wall, into the pyloric antrum. Connect the stomach and abdominal wall with interrupted sutures. In the figure, points 1 are connected, as are points 2 to each other, and so forth. (Drawing by Carol Haynes, after Daugherty.)

9. Tie the sutures starting dorsally and ending ventrally.
10. Affix the catheter to the skin with a traction suture.

Circumcostal Gastropexy

Technique

1. Place two retention sutures using 1-0 or 2-0 nonabsorbable suture material in the antrum approximately 6 cm apart and midway between the lesser and greater curvature.
2. Make a 3 × 3 cm incision through the seromuscular layer forming an I-shaped configuration (Fig. 68-8, *inset*).
3. The seromuscular flaps are formed by careful dissection between the muscular and submucosa tunics. Place two stay sutures on each flap.
4. Isolate the 11th or 12th rib ventral to the costochondral junction and rotate it laterally with two towel clamps placed 6 cm apart.
5. Expose a 4- to 5-cm length of the rib by incising through the peritoneum and muscle.
6. By blunt dissection remove all tissue attached to the rib.
7. Pass one arm of each stay suture under the rib.
8. Place another stay suture midway down the seromuscular flap found on the greater curvature side. This placement helps pull this flap around the exposed rib.
9. Once the flap is pulled around the rib, tie the two retention sutures.

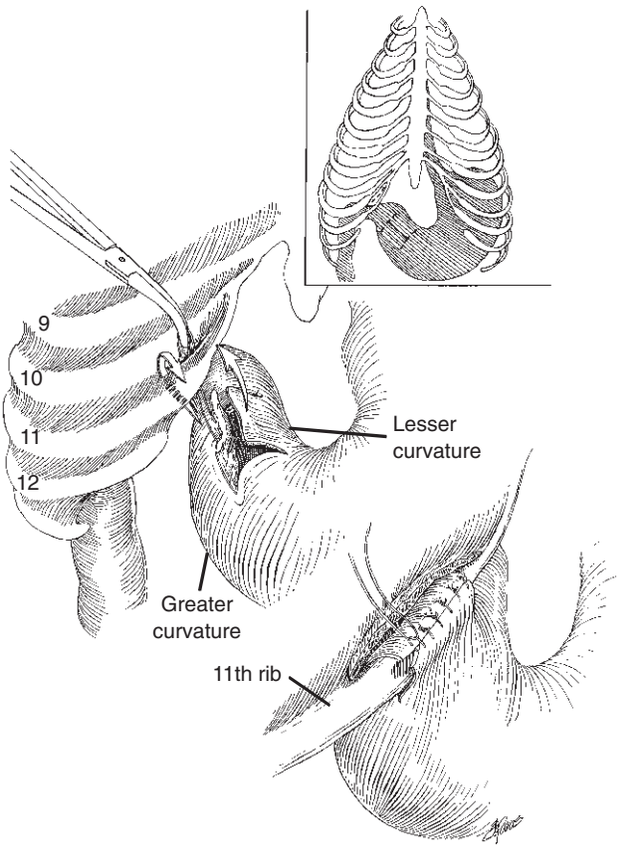

Figure 68-8. Technique for circumcostal gastropexy (for gastric dilatation-volvulus).

10. Suture the seromuscular flap to the opposite flap using 2-0 synthetic absorbable or non-absorbable suture (see Fig. 68-8). Use a simple interrupted full-thickness suture pattern.
11. Suture the peritoneum and musculature on the lateral aspect of the completed flap repair to the seromuscular layer of the stomach with six to eight sutures. This bridges and supports the seromuscular flap suture line.

Belt Loop Gastropexy

Technique

1. A belt loop of muscle is produced by making two parallel transverse incisions 2 to 3 cm apart and 2 to 3 cm in length through the peritoneum and fascia of the transversus abdominis muscle.
2. Bluntly separate the muscle fibers with scissors (Fig. 68-9*A*).
3. Make a 2 × 4 cm tongue-shaped seromuscular flap with the base of the flap along the greater curvature of the antrum (Fig. 68-9*B*).
4. A branch of the gastroepiploic artery is centered at the base of the flap.

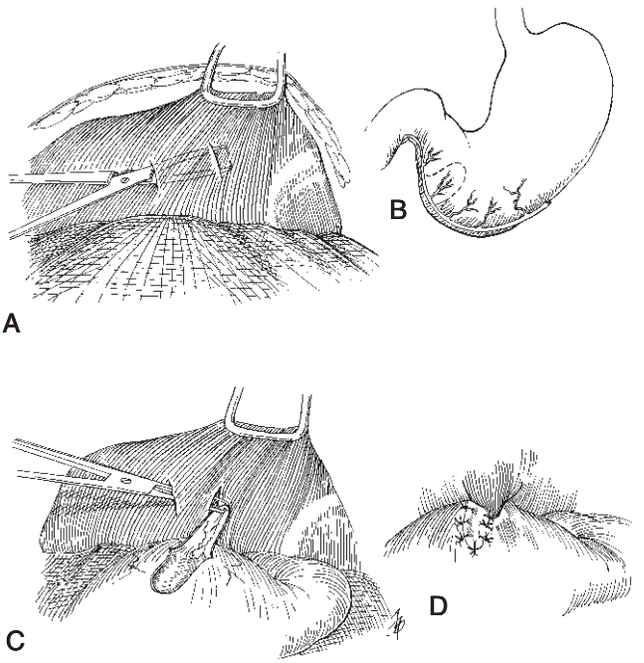

Figure 68-9. Technique for belt loop gastropexy (for gastric dilatation-volvulus). See text for details.

5. When creating the flap, make the base a little wider than the tip of the tongue-shaped flap.
6. Pass the stomach flap through the belt loop in a cranial-to-caudal direction (Fig. 68-9*C*).
7. The flap is now repositioned over its original anatomic location and reattached to adjacent seromuscular tissue with 1-0 monofilament synthetic absorbable or non-absorbable suture (Fig. 68-9*D*).

Muscle Flap Gastropexy

Technique

1. Make a U-shaped incision through the peritoneum and transversus abdominis muscle caudal to the 13th rib on the right lateral side.
2. Undermine and reflect the muscle flap ventrally.
3. Preplace two horizontal mattress sutures using 1-0 non-absorbable material from the base of the U through the seromuscular layer of the antrum and draw the antrum laterally to the right abdominal wall (Fig. 68-10*A*).
4. Tie the sutures and secure them against the body wall (Fig. 68-10*B*).
5. Secure the remaining base of the U to the stomach wall employing a simple continuous suture pattern (Fig. 68-10*C*).
6. Bring the muscle flap to the gastric surface, advancing it a few millimeters beyond the previous suture line.
7. Suture the flap with the same material to the stomach wall to close the myotomy (Fig. 68-10*C*).

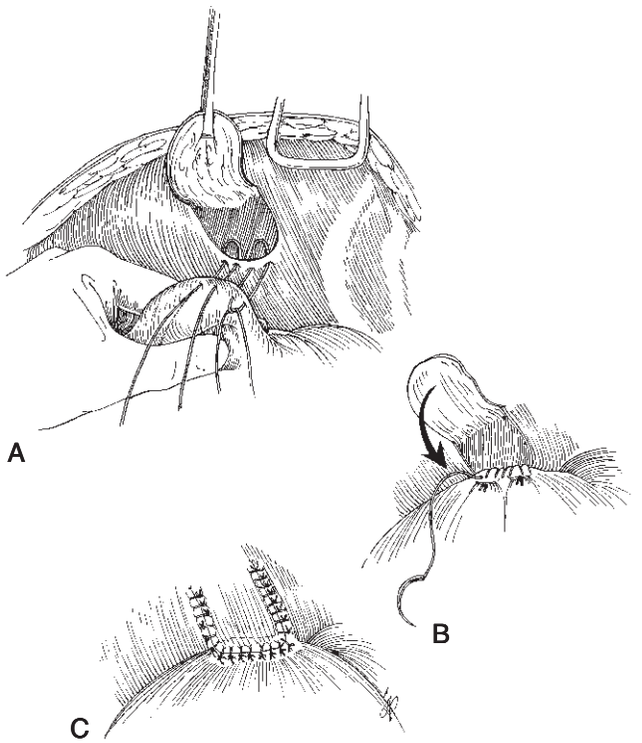

Figure 68-10. Technique for muscle flap gastropexy (for gastric dilatation-volvulus). See text for details.

Incisional Gastropexy

Technique

1. Refer to the incisional gastropexy procedure as described for hiatal hernia in Chapter 66.
2. An incisional gastropexy for gastric dilatation-volvulus differs by always being done on the right side (i.e., antrum to right side of body wall), as for the other gastropexy techniques described here.

Prophylactic Gastropexy

Technique

1. This can be done in a female dog at the time of sterilization by extending the incision cranially.
2. In the older sterilized bitch or male dog, a laparoscopic or laproscopic-assisted technique can be used.
3. The laparoscopic-assisted technique includes two small incisions, one just caudal to the umbilicus (2–3 cm) and the other approximately 3 to 4 cm caudal to the last rib and just lateral to the rectus abdominus muscle.
4. The midline incision allows a trochar cannula (10–12 mm in diameter) to be placed followed by the peritoneal infusion of carbon dioxide. Place a camera and light source through this cannula. Place the other trochar cannula through the small incision behind the right rib. Insert the Babcock forceps through this cannula.
5. Identify the antrum and pull to the incision behind the last rib using the Babcock forceps. Extend this incision to 4 to 6 cm in length to allow the pyloric antrum to be partially exteriorized.
6. Place two stay sutures in the antrum to allow a 4- to 5-cm seromuscular incision to be made between the sutures.
7. Suture the cut edges of the seromuscular layer to the peritoneum and transversus abdominus muscle. Suture the overlying abdominal oblique muscles and subcutaneous tissue and skin to close the incision. Close the midline linea alba incision routinely.

Postoperative Care and Complications

Short Term

- Monitor closely for a minimum of 4 days for cardiac arrhythmias, especially ventricular arrhythmias (see Chapter 145 for details of treatment); hemodynamic abnormalities or circulatory collapse; recurrent gastric retention; and gastric perforation with subsequent peritonitis.
- Maintain fluid therapy and supplement with potassium for a minimum of 48 hours.
- Monitor serum electrolyte, blood gas, hematocrit, total protein, urinary output, and central venous pressure values as necessary.
- Promote gastrointestinal motility with metoclopramide, 0.2 to 0.4 mg/kg SC or PO q6–8h. Treat with systemic antacids and sucralfate (see Chapter 67) if ulceration or necrosis was present at surgery, or if vomiting of bloody fluid is present postoperatively.
- Maintain tube gastropexy under a soft padded bandage so that chewing or dislodgement of the tube is prevented.
- The tube can be used for decompression and administration of fluids, gruel, and medication.
- Feeding can resume 24 to 48 hours after surgery.

Long Term

- Remove the tube (tube gastropexy) 5 to 7 days after placement. Allow the fistula to heal by second intention (contraction and epithelialization).
- Wean the animal slowly off antiarrhythmic drugs if cardiac arrhythmia was a problem and so treated.
- Encourage three to four feedings per day at home.

Prognosis

- Fair to good if partial gastrectomy is not indicated.
- Grave to poor when partial gastrectomy is done.

Chapter 69

Diseases of the Intestines

Robert G. Sherding / Susan E. Johnson

DIARRHEA

Diarrhea results from excessive fecal water content and is the most important clinical sign of intestinal disease in the dog and cat. It is characterized by an abnormal consistency and increase in frequency, fluidity, and volume of feces. The pathogenesis involves derangement of transmucosal water and solute fluxes caused by abnormal digestion, absorption, secretion, permeability, motility, or a combination of these.

Acute versus Chronic Diarrhea

For initial management of diarrhea, consider whether diarrhea is acute or chronic (based on history).

Acute Diarrhea

Acute diarrhea is characterized by sudden onset and short duration (3 weeks or less) of watery or watery-mucoid diarrhea. Diarrhea may be overtly bloody when associated with loss of mucosal integrity. Inappetence, lethargy, and vomiting are frequently associated signs; fever, abdominal pain, and significant dehydration suggest more serious intestinal disease.

- Preliminary diagnostic considerations for diarrhea in the dog and cat should include diet (indiscretion, intolerance, hypersensitivity), medication side effects, toxicity, intestinal parasites (helminths, protozoa), enteric viruses, enteropathogenic bacteria, and a variety of systemic or metabolic disturbances.
- Although there are exceptions, acute diarrhea associated with diet, parasites, and medications generally tends to be mild and self-limiting, whereas acute diarrhea that is severe and life-threatening occurs most frequently in young animals with infectious enteritis (e.g., parvoviral enteritis).
- Diagnostic evaluations in acute diarrhea need not be extensive. Because treatment is mainly supportive and nonspecific, many animals can be managed without determination of a definitive diagnosis. Nevertheless, it is important to identify parasites and enteropathogens that require specific treatments and to identify surgical diseases (e.g., foreign bodies and intussusception).
- Treatment of acute diarrhea is based on rehydration therapy and dietary modification. Symptomatic therapy with antidiarrheal agents may be considered. Nonspecific or mild acute diarrhea often is self-limiting in a day or two without treatment or with restricted food intake.

Chronic Diarrhea

- Diarrhea is categorized as chronic if it has been persistent (3–4 weeks or longer) or has a pattern of episodic recurrence. Chronicity generally excludes simple dietary indiscretion, intoxication, and viral enteritis as causes.

▼ ***Key Point*** Base management of chronic diarrhea on diagnosis rather than symptomatic treatment. Specific intervention or treatment usually is necessary, requiring a specific diagnosis or functional and histopathologic characterization.

- The first step in management is to classify the diarrhea as large or small bowel in origin, based on the history and physical examination. Diagnostic tests and procedures include routine hematologic and serum chemistry evaluations, tests of enteropancreatic function, fecal examinations, radiography, ultrasonography, and endoscopy. Biopsy of the small or large intestine may be necessary.

Small Bowel versus Large Bowel

The anatomic localization of the disease process to the small or large bowel is based on the patient's defecation pattern and fecal characteristics (frequency, volume, consistency, color, odor, composition) (Table 69-1). This distinction is most useful in dogs for determining the direction of subsequent diagnostic evaluations. Diffuse diseases of the gastrointestinal (GI) tract may produce concurrent small and large bowel signs and, sometimes, gastric signs such as vomiting.

Small Bowel Diarrhea

Chronic small bowel diarrhea can be associated with maldigestion and malabsorption and is characterized by

Table 69-1. SMALL BOWEL VERSUS LARGE BOWEL DIARRHEA

Observation	Small Intestine	Large Intestine
Frequency of defecation	Normal to slightly increased	Very increased
Fecal output	Large volumes	Small volumes frequently
Urgency or tenesmus	Absent	Present
Dyschezia	Absent	Present with rectal disease
Mucus in feces	Absent	Present
Exudate (WBC) in feces	Absent	Present sometimes
Hematochezia (red blood)	Rare	Frequent
Melena (digested blood)	Present sometimes	Absent
Steatorrhea	Present sometimes	Absent
Flatulence and borborygmus	Present sometimes	Absent
Weight loss	Present sometimes	Rare
Vomiting	Present sometimes in dogs; frequent in cats	Occasional

WBC, white blood cells.

a high volume without urgency, tenesmus, or marked increase in frequency. Weight loss and decline in body condition (malnutrition) may occur.

- Because of unabsorbed nutrients that are degraded and fermented by intestinal bacteria, the feces are rancid and foul-smelling and the increased production of luminal gas by bacteria results in excessive flatulence and borborygmus.
- Steatorrhea (feces containing an excess of unabsorbed fat) can occur in maldigestive and malabsorptive small bowel diarrhea. In extreme cases, the feces may appear oily, greasy, and pale. Hair around the perineum may also have an oily texture from contact with fatty feces.
- Small bowel diarrhea is generally free of grossly visible mucus or blood. When there is bleeding from a lesion in the proximal GI tract, the blood pigment becomes dark black during transit (melena). In the absence of gastric bleeding, melena generally indicates small intestinal parasitism (e.g., hookworms), infection (viral, bacterial, fungal), ulceration (e.g., drug induced), severe inflammation, or neoplasia.

Large Bowel Diarrhea

Large bowel diarrhea is characterized by frequent urges to defecate (usually greater than 3 times normal frequency), with each defecation producing small quantities of feces that often contain excessive mucus and sometimes fresh red blood.

- Urgency resulting from irritability or inflammation of the distal colon causes frequent premature expulsions of small quantities of feces that would otherwise be insufficient to trigger the defecation reflex. Lapses in housetraining ("accidents") may be caused by urgency and inability to control urges to defecate.
- Straining (tenesmus) may be noted as the patient remains in position for a prolonged time after defecation or makes repeated attempts to defecate within a few minutes. These attempts may produce little or no feces or sometimes just a few drops of mucus, exudate, and blood.
- Because many colonic diseases are associated with mucosal injury, inflammation, or ulceration, abnormal fecal constituents are frequently found in large bowel diarrhea, including (1) fresh red blood (hematochezia) that originates from sites of erosion or ulceration, (2) mucus that originates from the abundant goblet cells in the colon that respond to mucosal injury by an outpouring of mucus, and (3) exudate (leukocytes) that originates from the site of inflammation.

▼ ***Key Point*** Abnormal fecal constituents such as fresh red blood, mucus, and leukocytes are localizing signs indicative of colonic disease.

  - Blood may coat the feces, streaks of blood may be mixed within the feces, or drops of blood may be passed at the end of defecation.
  - Excessive mucus may give the feces a glistening or jelly-like appearance.
  - Exudates are detected by the positive identification of fecal leukocytes using cytology stains.
- Because the principal function of the colon is absorption of water and electrolytes rather than digestion and absorption of nutrients, nutrient malabsorption and steatorrhea are absent in large bowel diarrhea. Thus, dramatic weight loss and wasting are unlikely if the animal is eating, and the daily fecal output (volume or weight of feces) usually is only minimally increased.
- Vomiting is a clinical sign in about 30% of patients with colitis.

DIAGNOSTIC APPROACH FOR DIARRHEA

Initial evaluations are aimed at diagnosis of dietary, parasitic, and infectious causes of diarrhea. This should include fecal examinations, therapeutic deworming trials (fenbendazole, 50 mg/kg PO daily for 3 days), and a 4-week dietary trial using a highly digestible commercial or homemade GI diet, either alone (for small bowel diarrhea) or with psyllium added as a fiber source (for dogs with large bowel diarrhea). If diarrhea persists and the cause is not apparent, additional diagnostic evaluations may include a complete blood count (CBC), serum chemistry profile, urinalysis, additional fecal exams for infectious agents (cytology, toxin assay, and cultures), abdominal imaging (radiography and ultrasonography), and enteropancreatic function tests. Finally, endoscopic examination and biopsy may be indicated.

History

The history is especially helpful for localizing the disease process to the small or large bowel. It also may indicate underlying non-intestinal causes of diarrhea (e.g., renal failure, liver disease, hypoadrenocorticism, or feline hyperthyroidism) and identify important predisposing factors such as breed, diet, environmental factors, current medications, and exposure to parasites, infectious agents, and toxins. The following historical aspects of the diarrhea may be diagnostically useful:

- Mode of onset (abrupt versus gradual)
- Duration (acute versus chronic)
- Clinical course (intermittent, continuous, or progressive)
- Fecal characteristics (small bowel versus large bowel; see previous section)
- Correlation with diet (food intolerances and dietary indiscretions)
- Correlation with medication usage (drug side effects)
- Correlation with stressful events (psychogenic, anxiety, or "irritability" factors)
- Response to previous treatments (prescribed diets, antibiotics, corticosteroids, or fenbendazole)
- Association with other signs (weight loss, vomiting, or polyuria-polydipsia)

▼ ***Key Point*** Consider extraintestinal causes of diarrhea, such as diseases of the pancreas (exocrine pancreatic insufficiency, pancreatitis), liver, kidneys (azotemia), endocrine system (e.g., hypoadrenocorticism and hyperthyroidism), cardiovascular system, and central nervous system (CNS).

Physical Examination

A complete physical examination may reveal important clues about the severity, nature, and cause of diarrhea (Table 69-2), although in many patients the findings are nonspecific.

- Identify physical findings that may indicate underlying systemic disease that could be a cause or consequence of diarrhea.
- Identify abnormalities on abdominal palpation of the intestinal loops and digital palpation of the rectum.

Table 69-2. PHYSICAL FINDINGS IN INTESTINAL DISEASE

Physical Finding	Potential Clinical Associations
General Physical Examination	
Dehydration	Diarrheal fluid loss
Depression/weakness	Electrolyte imbalance, severe debilitation
Emaciation/malnutrition	Chronic malabsorption, protein-losing enteropathy
Dull unthrifty haircoat	Malabsorption of fatty acids, protein, and vitamins
Fever	Infection, transmural inflammation, neoplasia
Edema, ascites, pleural effusion	Protein-losing enteropathy
Pallor (anemia)	Gastrointestinal blood loss, anemia of chronic inflammation
Intestinal Palpation	
Masses	Foreign body, neoplasia, granuloma
Thickened loops	Infiltration (inflammation, lymphoma)
"Sausage loop"	Intussusception
Aggregated loops	Linear intestinal foreign body, peritoneal adhesions
Pain	Inflammation, obstruction, ischemia, peritonitis
Gas or fluid distention	Obstruction, ileus, diarrhea
Mesenteric lymphadenopathy	Inflammation, infection, neoplasia
Rectal Palpation	
Masses	Polyp, granuloma, neoplasia
Circumferential narrowing	Stricture, spasm, neoplasia
Coarse mucosal texture	Colitis, neoplasia

Table 69-3. LABORATORY FINDINGS IN INTESTINAL DISEASE

Abnormal Laboratory Findings	Clinical Associations
Hematologic Findings	
Eosinophilia	Parasitism, eosinophilic enteritis, hypoadrenocorticism, mast cell tumor
Neutrophilia	Bowel inflammation, necrosis, or neoplasia
Neutropenia or "toxic" neutrophils	Parvovirus, FeLV, FIV, endotoxemia, or overwhelming sepsis (e.g., leakage peritonitis)
Monocytosis	Chronic or granulomatous inflammation (e.g., mycosis)
Lymphopenia	Loss of lymphocytes associated with intestinal lymphangiectasia
Anemia	GI blood loss, depressed erythropoiesis (chronic inflammation, neoplasia, malnutrition)
Elevated PCV	Hemoconcentration from GI fluid loss
RBC microcytosis	Iron deficiency (chronic GI blood loss), portosystemic shunt
RBC macrocytosis	RBC regeneration, feline hyperthyroidism, FeLV, nutritional deficiencies (rare)
Serum Biochemical Findings	
Panhypoproteinemia	Protein-losing enteropathy
Hyperglobulinemia	Chronic immune stimulation, basenji enteropathy
Azotemia	Dehydration (prerenal), primary renal failure
Hypokalemia	GI loss of fluid and electrolytes, anorexia
Hyperkalemia/hyponatremia	Hypoadrenocorticism, trichuriasis (rare)
Hypocalcemia	Hypoalbuminemia, lymphangiectasia, pancreatitis
Hypocholesterolemia	Lymphangiectasia, liver disease
Elevated liver enzymes or bile acids	Liver disease
Elevated amylase/lipase	Pancreatitis, enteritis, or azotemia
Elevated thyroxine (T4)	Feline hyperthyroidism

FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; GI, gastrointestinal; PCV, packed cell volume; RBC, red blood cell.

- Inspect the fecal material obtained on the palpation glove for abrasive particles (such as bone chips), blood, and mucus. If indicated, examine the fecal material microscopically for parasites, microorganisms, and inflammatory cells or submit for culture.

Routine Laboratory Tests

- Evaluate a CBC for leukocyte responses and anemia that may be associated with intestinal disease (Table 69-3).
- Perform a serum biochemical profile and urinalysis to identify metabolic or systemic disorders that could cause or result from diarrhea (see Table 69-3).
- Measure serum thyroxin (T4) concentration in all cats over 5 years of age with diarrhea or weight loss to exclude hyperthyroidism as a cause (see Chapter 31).

Fecal Examinations

Fecal examinations are an important aspect of the diagnostic approach to diarrhea and should involve visual inspection (for blood, mucus, and foreign matter), parasite evaluation, and microscopic examinations. Specialized evaluations can include quantitative fecal collection and fat analysis, chemical determinations, cultures, toxin assays, virology, and nuclear scans, but these are used only in selective cases.

▼ ***Key Point*** Examination of feces for parasites should be part of the minimum database for all animals with diarrhea.

- In cases of chronic unresponsive diarrhea, expand the database to include microscopic examination of stained fecal smears for fat, starch, and leukocytes.
- If circumstances suggest infection, perform fecal culture for specific enteropathogenic bacteria *(Salmonella, Campylobacter)* or toxin assay for enterotoxigenic *Clostridium perfringens*.
- Diagnostic methods for intestinal parasites and infectious agents are listed in Table 69-4.

Fecal Examination for Parasites

Fecal examination for parasites can include fecal flotation, zinc sulfate centrifugation-flotation, direct wet smears, and immunoassays. Examine fresh feces within 1 hour of collection. Alternatively, refrigerate feces within 1 hour and examine within 3 days, or preserve feces in formalin for later examination.

Table 69-4. DIAGNOSIS OF INTESTINAL PATHOGENS OF DOGS AND CATS

Pathogen	Method of Diagnosis
Helminths	
Ascarids *(Toxocara, Toxascaris leonina)*	Routine fecal flotation for ova
Hookworms *(Ancylostoma)*	Routine fecal flotation for ova
Whipworms *(Trichuris vulpis)*	Routine fecal flotation for ova; fenbendazole trial
Tapeworms *(Taenia, Dipylidium caninum)*	Fecal proglottids or flotation for ova
Strongyloides	Fecal sediment or Baermann test for larvae
Others (flukes)	Fecal zinc sulfate centrifugation-flotation for ova
Protozoa	
Coccidia (Isospora)	Fecal flotation for oocysts
Cryptosporidium spp.	Microplate ELISA, direct immunofluorescence, PCR, Sheather's flotation
Giardia	Fecal zinc sulfate centrifugation-flotation for cysts; fecal ELISA or IFA; duodenal wash for trophozoites; fenbendazole trial
Tritrichomonas foetus	Fecal wet smear for trophozoites; InPouch TF culture; PCR
Entamoeba histolytica	Fecal wet smear for trophozoites
Balantidium coli	Fecal wet smear for trophozoites
Viruses	
Canine parvovirus	Fecal ELISA (SNAP-Parvo Test) for viral antigen (see Chapter 14)
Feline panleukopenia virus	Signs, leucopenia (see Chapter 14)
Canine coronavirus	Fecal EM, virus culture, PCR (see Chapter 14)
Feline enteric coronavirus and FIP	Signs, serology, fecal EM, PCR, biopsies (see Chapter 10)
Rotaviruses	Fecal EM, virus culture, PCR (see Chapter 14)
Astrovirus	Fecal EM, PCR (see Chapter 14)
Canine distemper virus	Signs (see Chapter 13)
Retroviruses (FeLV, FIV)	FeLV antigen test (ELISA, IFA); FIV antibody test (see Chapters 8, 9)
Rickettsia	
Salmon poisoning *(Neorickettsia helminthoeca)*	Operculated trematode eggs in feces; rickettsia in lymph node cytology (see Chapter 17)
Bacteria	
Salmonella	Fecal culture
Campylobacter jejuni	Fecal microscopy and culture
Yersinia enterocolitica, Y. pseudotuberculosis	Fecal culture
Bacillus piliformis (Tyzzer's disease)	Biopsy (gut, liver) for filamentous bacteria; mouse inoculation
Mycobacterium spp.	Acid-fast bacteria in cytology/biopsy; culture, PCR (see Chapter 19)
Clostridium perfringens, C. difficile	ELISA-based fecal enterotoxin assays; PCR
Enteropathogenic *Escherichia coli* (?)	Fecal culture and toxin assays
Fungi	
Histoplasma capsulatum	Fungi in biopsies/cytologies; serology (see Chapter 20)
Pythium, Zygomycetes	Pythium ELISA; poorly septate hyphae in biopsies (Chapters 20, 40)
Others (*Candida albicans, Aspergillus,* etc.)	Yeast or hyphae in biopsies; fungal culture (see Chapters 20, 40)
Algae *(Prototheca)*	Unicellular algae in cytology or biopsy; fecal culture (Sabouraud's)

ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; FeLV, feline leukemia virus; FIP, feline infectious peritonitis; FIV, feline immunodeficiency virus; IFA, immunofluorescent antibody; PCR, polymerase chain reaction test; Rx, therapeutic response.

- Use routine fecal flotation to identify nematode ova and coccidian oocysts other than *Cryptosporidium.*
- In warm, humid regions (e.g., southern United States) endemic for *Strongyloides* species, perform a direct wet smear, sedimentation, or Baermann procedure to identify larvae in the feces.
- For *Giardia,* use zinc sulfate centrifugation-flotation to identify cysts or an immunoassay to identify fecal antigen. Reliable fecal immunoassays are the point-of-care SNAP Giardia Test Kit (IDEXX), the microplate enzyme-linked immunosorbent assay (ELISA) (Remel), or an immunofluorescent antibody (IFA) test at a commercial lab. Evidence suggests the rapid ELISA test for human *Giardia* is not reliable in animals.
- Use a direct saline smear of fresh feces to detect motile trophozoites of protozoan parasites, including *Giardia, Tritrichomonas, Entamoeba histolytica,* and *Balantidium coli.* This is an insensitive method for diagnosis of *Giardia.* The distinguishing characteristics of each of these protozoa are discussed under "Protozoan Parasites."
- For diagnosis of *Tritrichomonas foetus* infection in cats, fecal culture using InPouch-TF and fecal polymerase chain reaction (PCR) assay are more sensitive than direct fecal smear microscopy.
- For *Cryptosporidium parvum,* a very small coccidian, use fecal antigen immunoassay (microplate ELISA or IFA), Sheather's sugar flotation for oocysts, or modi-

fied acid-fast staining. Evidence suggests the rapid ELISA test for human *Cryptosporidium* is not reliable in animals.
- Diagnosis of occult parasite infections (e.g., *Giardia* and most nematodes including whipworms) can be based on response to a therapeutic trial using fenbendazole (50 mg/kg PO q24h for 3–5 days).

▼ ***Key Point*** Intestinal parasitism can resemble many other small and large bowel disorders. Common examples are hookworms, whipworms, and *Giardia.*

Fecal Examination for Infectious Agents

The diagnosis of infectious diarrhea often depends on the detection of the offending viral, bacterial, or fungal organisms in the feces. Details of diagnosis of these various enteric infections are found in the respective sections of this chapter.

Viruses

Viral diarrhea is generally acute and is confirmed by detection of viral antigen in the feces (ELISA, PCR, etc.) or virus particles by electron microscopy (see Chapter 14).

Bacteria

The common enteropathogenic bacteria in dogs and cats are listed in Table 69-4.

- Specific enteropathogenic bacteria, such as *Salmonella* and *Campylobacter,* can be isolated from fresh feces using appropriate culture media. Cultures are particularly indicated when examination of fecal cytology preparations reveals the presence of numerous fecal leukocytes or *Campylobacter*-like bacteria or when there is an outbreak of diarrhea in groups of animals housed together.
- For diagnosis of *Clostridium perfringens* and *Clostridium difficile* enterotoxigenic diarrhea, use validated fecal ELISA (Techlab, Blacksburg, VA) and PCR assays to detect clostridial enterotoxins. The finding of numerous large gram-positive sporulating rods with a "safety pin" appearance in stained fecal smears is not a reliable indicator of toxin-producing *C. perfringens.* Nontoxigenic *C. perfringens* is part of the normal intestinal flora in dogs and cats; thus, cultures are not useful.

Fungi and Prototheca

The diagnosis of fungal *(Histoplasma, Aspergillus, Pythium, Candida)* and protothecal infections is usually based on identification of the organisms in feces or more often in rectal scrapings *(Histoplasma)*, tissue aspirates, or intestinal biopsies (see Chapters 20 and 40).

- Serodiagnostic tests for presumptive diagnosis of histoplasmosis and pythiosis also are available.
- Affected tissues can be cultured for systemic fungi and *Prototheca* (a rare cause of colitis), but culture growth takes weeks and the isolation rate is low.

Fecal Examination Using Special Stains

Feces can be examined microscopically for abnormal constituents using Sudan, Lugol iodine, Gram, and various other cytologic stains. In each test, one to two drops of fresh feces are stained on a microscope slide and examined. In general, these procedures are relatively insensitive and nonspecific and are affected by many factors, including diet.

Sudan and Iodine Stain

Fecal staining with Sudan for undigested fat and Lugol iodine for undigested starch may suggest exocrine pancreatic insufficiency (maldigestion); however, these evaluations are too insensitive, nonspecific, and diet dependent to be recommended. These procedures have been replaced by more reliable diagnostic tests for exocrine pancreatic insufficiency (see Chapter 73).

Cytology Stain

Routine cytology staining (e.g., new methylene blue, Wright, and Diff-Quik stains) identifies fecal leukocytes that are markers of exudative inflammatory colonic disease. Cytology may occasionally identify neoplastic cells or *Histoplasma* or *Prototheca* organisms. It is advisable to follow up with patients that are positive for fecal leukocytes with colonoscopy and fecal cultures for invasive bacteria such as *Campylobacter* and *Salmonella.*

Gram Stain

With gram staining, the experienced observer may identify large numbers of *C. perfringens* or *Campylobacter*-like spiral bacteria; however, microscopy is much less reliable than toxin assays for *Clostridium* and culture for *Campylobacter.*

Tests for Fecal Occult Blood

These include a simple, in-office qualitative screening test (Hemoccult test) and a more accurate, semiquantitative send-out test (HemoQuant, SmithKline). These tests are sensitive for detecting even very small amounts of GI hemorrhage. Because of this sensitivity, it is recommended that the owner exclude meat from the animal's diet for at least 3 days prior to testing to avoid false-positive results.

- The presence of fecal occult blood signifies a bleeding lesion of the GI tract, which suggests an ulcerative, inflammatory, or neoplastic condition, or a hemostatic abnormality.
- The fecal occult blood test is also indicated to document GI bleeding as a cause of blood loss anemia.

Quantitative Fecal Fat Analysis

This can be used as an intestinal function test to confirm steatorrhea, but it is rarely used because it is cumbersome and impractical to perform and does not differentiate pancreatic maldigestion from intestinal malabsorption. Feces must be collected for a 24- to 72-hour period while the animal is confined and fed a standard diet. The feces are weighed and sent to a commercial laboratory for analysis. Normally, less than 10% of ingested fat is excreted in the feces, or less than 0.3 g/kg/day in dogs and less than 0.4 g/kg/day in cats.

Fecal Proteolytic Activity

Fecal proteolytic activity can be assayed as an indicator of pancreatic secretion of proteases (trypsin) for the diagnosis of exocrine pancreatic insufficiency (EPI). The serum trypsin-like immunoreactivity (TLI) assay is more accurate and is now preferred for the diagnosis of exocrine pancreatic insufficiency in both dogs and cats (see Chapter 73).

Tests for Fecal Protein Loss

See under "Tests for Protein-Losing Enteropathy."

Enteropancreatic Function Tests

The following tests are designed to evaluate digestive and absorptive functions.

Tests for Exocrine Pancreatic Insufficiency

Tests for exocrine pancreatic insufficiency (pancreatic maldigestion), such as serum trypsin-like immunoreactivity and fecal assays for proteolytic activity, are described in Chapter 73.

Serum Folate and Cobalamin Assays

Serum concentrations of folate and cobalamin (vitamin B_{12}) are indicative exocrine pancreatic function (cobalamin), intestinal absorptive function, and the status of the intestinal bacterial flora.

Serum Folate

Folate, a water-soluble B vitamin, is plentiful in most commercial pet foods, and serum concentration depends primarily on the absorptive function of the proximal small intestine.

- Serum folate (normal, dog: 6.5–11.5 µg/L; cat: 9.7–21.6 µg/L) may be decreased in enteropathies that impair absorption in the proximal small intestine or in diffuse small intestinal disease. Widespread malignancy and sulfasalazine treatment also may decrease serum folate.
- Serum folate may be increased with overproliferation of the normal intestinal flora because many species of bacteria synthesize folic acid.
- Serum folate also may be increased by high dietary intake of folic acid, low intestinal pH, exocrine pancreatic insufficiency (32% of cases), and artifactually by hemolysis or heating of the blood specimen.

Serum Cobalamin

Cobalamin, a water-soluble B vitamin, is plentiful in most commercial pet foods, and serum concentration depends on the secretion of pancreatic intrinsic factor necessary for normal cobalamin absorption and on the absorptive function of the ileum.

- Serum cobalamin (normal, dog: 249–733 ng/L; cat: 290–1500 ng/L) is frequently decreased in exocrine pancreatic insufficiency (deficiency of intrinsic factor) and in enteropathies that impair absorption in the distal small intestine, including diffuse small intestinal disease. It also is decreased in presumed small intestinal bacterial overgrowth.
- Because cobalamin has a shorter half-life in cats, cats with chronic intestinal disease are particularly susceptible to developing cobalamin deficiency.
- Prolonged exposure of the blood specimen to bright light may artifactually decrease cobalamin.
- An isolated hereditary defect in cobalamin absorption has been recognized in some dog breeds (giant schnauzer, Border collie, Shar-Pei).

▼ ***Key Point*** In small intestinal bacterial overgrowth, serum folate may be increased due to synthesis of folate by the proliferated bacteria, whereas cobalamin may be decreased because bacteria can utilize or bind the vitamin, making it unavailable for absorption.

Breath Hydrogen Test

This assesses monosaccharide or disaccharide malabsorption or bacterial overgrowth, based on the principle that intestinal bacteria ferment intraluminal carbohydrate and produce hydrogen gas, some of which is absorbed into the blood and excreted by the lungs. This test is impractical for routine clinical use and is affected by diet, gastric emptying, intestinal transit, and the status of the intestinal flora.

Five-Sugar Absorption Tests for Intestinal Permeability

These oral sugar absorption tests are variations on the other carbohydrate absorption tests. A mixture of sugars is used as a noninvasive molecular probe of mucosal permeability and injury based on urine recovery (in a 6-hour urine sample) after oral administration. These sugar probes measure passive diffusion. Lactulose, cellobiose, and raffinose are probes of the large pores of the paracellular pathway, and urine recovery increases with mucosal epithelial damage. Mannitol and rhamnose are probes of the numerous small pores of

the transcellular pathway, and urine recovery decreases with loss of mucosal absorptive surface area (such as villous atrophy). An increase in the lactulose-to-rhamnose ratio is typical of intestinal disease with mucosal damage and increased permeability.

One variation on this procedure involves giving a mixture of lactulose, rhamnose, xylose, methylglucose, and sucrose, and the ratios are determined in 6-hour urine for lactose-to-rhamnose (permeability test), xylose-to-methylglucose (absorption test), and sucrose-to-methylglucose (mucosal digestion test).

In addition to reflecting absorptive function and permeability, results are also affected by gastric emptying, intestinal dilution and transit, systemic distribution, metabolism, and renal clearance. Results have not shown good correlation with clinical disease activity and histologic findings.

Unreliable Absorption Tests

In general, the reliability of oral absorption tests is affected by gastric emptying time, intestinal dilution and transit time, digestion and absorption, systemic distribution, metabolism, and renal excretion. Because of inconsistent results, the following absorption tests are not considered clinically useful in dogs and cats:

- Absorption of glucose substrates (glucose, lactose, starch)—Affected by insulin, etc.
- Xylose absorption—For detection of brush border monosaccharide malabsorption
- Quantitative fecal fat analysis—For detection of fat malabsorption (steatorrhea)
- Oral triglyceride absorption
- Vitamin A absorption
- Bentiromide para-aminobenzoic acid (BT-PABA) absorption

Tests for Protein-Losing Enteropathy

Excessive GI loss of plasma proteins can be documented using fecal assays that quantitate the intestinal loss of specific serum proteins, such as alpha-1-proteinase inhibitor, or an IV dose of ^{51}chromium-labeled albumin, a radiopharmaceutical.

- Alpha-1-proteinase inhibitor is a serum protein similar in molecular size to albumin. The intestinal loss of alpha-1-proteinase inhibitor in protein-losing enteropathy parallels the loss of albumin, except that it is not digested and is excreted intact in the feces. Thus, using a canine-specific assay, alpha-1-proteinase inhibitor can be measured in the feces as a marker for intestinal protein loss in dogs. This test is useful for evaluation of dogs with unexplained hypoproteinemia and for early detection of affected dogs in high-risk breeds, such as the soft-coated wheaten terrier.
- Normal fecal excretion of the alpha-1-proteinase inhibitor is <5.7 µg/g feces in dogs and <1.6 µg/g feces in cats. The assay requires submission of three fresh fecal specimens to the Gastrointestinal Laboratory, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, Texas A&M University, College Station, TX 77843-4474 (website: http://www.cvm.tamu.edu/gilab).

Tests for Bacterial Overgrowth

Direct evidence of small intestinal bacterial overgrowth is conventionally based on quantitative cultures of small intestinal juice; however, because of extensive overlap in the bacterial counts found in normal and diarrheic dogs and cats, the diagnostic criteria for small intestinal bacterial overgrowth in animal patients is uncertain. Indirect evidence of small intestinal bacterial overgrowth is indicated by the following:

- Increased serum folate and decreased serum cobalamin, reflecting increased bacterial metabolic activity
- Abnormal hydrogen breath test results, reflecting increased bacterial fermentation activity
- Increased serum unconjugated bile acids, reflecting increased bacterial deconjugation activity
- Idiopathic chronic small bowel diarrhea that is antibiotic responsive

Tests for Intestinal Motility

Tests for clinically assessing intestinal motility have limited clinical usefulness except for identifying obstruction to flow. These include intestinal transit time of barium, barium-impregnated spheres, or radiopharmaceuticals. The hydrogen breath indirectly reflects transit time of the proximal GI tract.

Radiography and Ultrasonography

Plain Abdominal Radiography

Plain radiography is indicated for detection of intestinal masses or abnormal gas-fluid patterns, especially when mechanical or obstructive disorders are suspected (e.g., intestinal mass, foreign body, or intussusception).

Gastrointestinal Barium Contrast Radiography

Upper GI barium radiography is indicated when other evaluations fail to determine the cause of small bowel diarrhea or when intestinal obstruction is suspected (see Chapter 4). This may help detect obstructive lesions, neoplastic masses, and inflammatory lesions that cause an irregular mucosal pattern or distortion of the bowel wall. In most cases, however, diarrhea involves microscopic and functional changes in the bowel that are not detected by barium radiography.

Barium Enema Contrast Radiography

Barium enema radiography is indicated in selected cases of large bowel diarrhea for evaluating the colon

and cecum for intussusceptions, neoplasms, polyps, strictures, inflammatory lesions, and colonic displacement or malformation. Colonoscopy is generally preferred over barium enema for evaluating the colon because it yields more definitive diagnostic information.

Abdominal Ultrasonography

Ultrasonography is indicated for assessing intestinal wall thickness and layering, for defining intestinal and other abdominal masses, and for evaluating other abdominal organs—e.g., lymph nodes, spleen, pancreas, liver, biliary tract, kidneys, adrenals, and prostate (see Chapter 4).

Endoscopy

▼ ***Key Point*** Endoscopic examination with mucosal biopsy is required for definitive diagnosis or accurate characterization of the disease in many cases of chronic intractable diarrhea in which non-intestinal, dietary, parasitic, and infectious causes have been excluded.

Gastrointestinal Endoscopy

Duodenoscopy with a flexible fiberoptic endoscope can be performed in the anesthetized animal for visual examination of the upper GI tract, including duodenum; for duodenal aspiration (for quantitative bacterial culture or detection of *Giardia* trophozoites); and for directed forceps biopsy of the intestinal mucosa (see Chapter 67 for a description of endoscopic equipment and discussion of gastroscopy).

- The normal duodenal mucosa appears pale pink with a uniformly granular villus pattern.
- Biliary and pancreatic duct papillae and Peyer lymphoid patches are normally seen.
- The mucosa is non-friable and should be free of excessive granularity, hemorrhages, erosions, ulcers, thickened folds, masses, or strictures. Villous lymphatics (lacteals) should not be prominent in the fasted animal.
- The lumen is easily and uniformly distensible with air.

Colonoscopy

Colonoscopy allows direct visualization of the lumen of the colon, sampling of luminal content for culture and exfoliative cytology, and directed forceps biopsy of the ileocolic mucosa.

- Suitable rigid colonoscopes are relatively inexpensive and easy to use. Because colonic diseases are often diffuse, examination and biopsy of the descending colon with a rigid instrument is sufficient for diagnosis in many patients.
- When lesions are located predominantly in the ascending or transverse colon, areas inaccessible with a rigid colonoscope, use a flexible fiberoptic or video colonoscope. A flexible colonoscope can be navigated through the ileocolic sphincter for examination and biopsy of the ileum in some animals.
- The normal colonic mucosa appears pale pink through the colonoscope and reflects light uniformly. It is non-friable, thin enough that the submucosal vessels are visible, and free of erosions, ulcers, thickened folds, masses, or strictures.

Intestinal Biopsy

The least invasive and, in many cases, preferred method for procurement of intestinal biopsies is endoscopy. If endoscopy is not available, or if endoscopic biopsies are inconclusive, consider full-thickness intestinal biopsy by laparotomy (see Chapter 70).

- Obtain multiple biopsies along the length of the gut even if no lesions are visible by gross inspection, which is often the case.
- Biopsy mesenteric lymph nodes and evaluate other abdominal organs, especially the pancreas, liver, and colon.
- Duodenal aspirates or duodenal mucosal impression smears may be examined for *Giardia* trophozoites or cultured quantitatively for aerobic and anaerobic bacterial overgrowth.

Therapeutic Trials

In some cases, the response to a dietary modification or therapeutic drug trial is used as an empirical diagnostic approach, when supported by adequate clinical information. Common therapeutic trials are given in the sections that follow.

Diet Modification

- Commercial GI diet for optimal digestability
- Novel protein diet—For dietary hypersensitivity or food allergy
- Fiber supplemented diet—For fiber-responsive large bowel diarrhea (dogs)

Fenbendazole

- For helminths (especially whipworms)
- For *Giardia*

Metronidazole

- For *Giardia*
- For enteropathogenic bacteria (especially *Clostridium*)
- To suppress flora in bacterial overgrowth
- To treat idiopathic inflammatory bowel disease (via flora effects or immune modulation)

NONSPECIFIC TREATMENT OF DIARRHEA

Dietary, supportive, and symptomatic therapy often is beneficial in diarrhea, especially acute diarrhea. In

severe acute diarrhea, fluid and electrolyte therapy can be lifesaving.

Dietary Management

Acute Diarrhea

- The initial goal is to physiologically "rest" the GI tract by restricting food intake for at least 24 hours.
- When resuming feeding, give bland, low-fat foods in small amounts at frequent intervals. Various commercial diets are available that have been specially formulated for animals with GI disease. Recipes for appropriate homemade diets are available as well. Examples of appropriate foods include boiled rice combined with turkey, boiled skinless chicken, yogurt, or low-fat cottage cheese as protein sources.
- Examples of commercial "intestinal diets" appropriate for nonspecific therapy of diarrhea include Eukanuba Low Residue (Iams), Prescription Diet i/d (Hill's), Low Fat (Waltham), and EN Formula (Purina). Other highly digestible diets can also be used.
- When the diarrhea has been resolved for 48 hours, gradually reintroduce the animal's regular diet.

Chronic Diarrhea

Divide daily food intake into three or four feedings, and use (1) commercial diets designed for GI disease with high digestibility and mild fat restriction (for all types of diarrhea); (2) novel protein diets (for dietary hypersensitivity and inflammatory bowel disease); or (3) fiber-enriched diets (for canine large bowel diarrhea).

Fluid Therapy

- In severe, acute diarrhea, such as occurs with parvoviral enteritis, fluid and electrolyte replacement is essential for management of intestinal fluid loss that may lead to serious dehydration, shock, and death (see Chapter 5).
- Parenteral methods of fluid therapy are preferred in most cases; however, over-the-counter oral glucose-electrolyte solutions (Pedialyte) are available for counterbalancing intestinal fluid losses in cases of mild diarrhea.

Antidiarrheal Drugs

Symptomatic treatment is based on drugs that modify motility, fluid secretion, and absorption or on drugs that act locally within the lumen as protectants or adsorbents.

- In most cases, these drugs are reserved for short-term use, usually for periods of 5 days or less. Some commonly used antidiarrheal drugs and their dosages are listed in Table 69-5.
- The purposes of antidiarrheal drugs are to provide short term relief from diarrhea, to provide relief from bowel discomfort ("crampiness"), and to control intestinal fluid losses.

Opiate and Opioid Narcotic Analgesics

▼ ***Key Point*** Opioid drugs such as loperamide are the most effective all-purpose antidiarrheal agents (see Table 69-5).

Table 69-5. DRUGS USED FOR SYMPTOMATIC TREATMENT OF DIARRHEA

Drug	Product (Manufacturer)	Preparation	Dosage	Frequency
*Narcotic Analgesics**				
Diphenoxylate	Generic	Tab: 2.5 mg Liq: 0.5 mg/ml	0.1–0.2 mg/kg PO	q6–8h
Loperamide	Imodium AD (McNeil)	Cap: 2 mg Liq: 0.2 mg/ml	0.1–0.2 mg/kg PO	q6–8h
Codeine	Many	Tab, Cap, Liq	0.25–0.5 mg/kg PO	q6–8h
Anticholinergics/Antispasmodics				
Aminopentamide	Centrine (Fort Dodge)	Tab: 0.2 mg Inj: 0.5 mg/ml	0.01–0.03 mg/kg SC, IM, PO	q8–12h
Dicyclomine	Generic	Tab: 20 mg Cap: 10 mg	0.2 mg/kg PO	q8–12h
Propantheline	Generic	Tab: 15 mg	0.25 mg/kg PO	q8–12h
Hyoscyamine	Levsin (Schwarz)	Tab: 0.125 mg Liq: 0.025, 0.125 mg/ml	0.003–0.006 mg/kg PO, SC	q8–12h
Antisecretory/Protectant				
Bismuth subsalicylate†	Pepto-Bismol (Procter & Gamble)	Liq: 9, 16 mg/ml	0.5–1.0 ml/kg PO	q6–8h

*Narcotic analgesics are not recommended in bacterial enteritis or liver disease.
†Avoid long-term (>3 days) use in cats because of low tolerance for salicylates.
Cap, capsules; Inj, injectable; Liq, elixir, suspension, or drops; Tab, tablets.

- Examples include loperamide (Imodium A-D), diphenoxylate (Lomotil), paregoric, morphine, and codeine.
- Opioids delay gastric emptying and slow bowel transit by stimulating non-propulsive contractions while decreasing propulsive motility (peristalsis), thereby allowing more contact time for absorption. This promotes fluid and electrolyte absorption.
- Opioids inhibit intestinal fluid loss through modification of mucosal fluid and electrolyte transport.
- Opioids increase anal tone and reduce the discomfort (i.e., crampiness) associated with acute diarrhea.
- Side effects are bloating, cramping, constipation, vomiting, and CNS depression. Use is not recommended with invasive bacterial enteritis.

Anticholinergic Drugs

- Examples include aminopentamide (Centrine), dicyclomine, and propantheline.
- They cause a generalized suppression of all gut motility, including beneficial non-propulsive motility, that may lead to unwanted ileus. The atropine-like antispasmodic action may be beneficial for controlling the urgency and discomfort of anorectal disease in some cases.
- They inhibit intestinal fluid loss, presumably through an antisecretory effect.
- Side effects are GI paralysis (ileus), worsening of diarrhea, constipation, tachycardia, xerostomia, urinary retention, ocular effects, and CNS stimulation.

Protectants and Adsorbents

- Examples include kaolin-pectin (Kaopectate), bismuth (Pepto-Bismol), aluminum and magnesium salts, activated charcoal, cholestyramine, and barium.
- These oral agents remain in the lumen, and they are proposed to adsorb or bind harmful bacteria and bacterial toxins and to provide a protective coating on inflamed mucosal surfaces.
- The efficacy of these drugs is controversial. There is little evidence that they diminish intestinal fluid losses. Large doses are often required, and they are difficult for owners to administer.

Anti-inflammatory Therapy

Non-infectious inflammatory bowel diseases are often treated with corticosteroids or nonsteroidal anti-inflammatory agents (NSAIDs).

Corticosteroids

- Examples include prednisone, prednisolone, dexamethasone, and budesonide.
- Corticosteroids have anti-inflammatory, antisecretory, and mucosal-stimulating properties. The primary indication is for inflammatory bowel disease.

Nonsteroidal Anti-inflammatory Drugs

- Bismuth subsalicylate (Pepto-Bismol) has a mild mucosal anti-inflammatory action in the lumen of the proximal GI tract. Efficacy for small animal diarrhea is infrequent.
- Preparations of 5-aminosalicylic acid (5-ASA) (mesalamine) are poorly absorbed in the proximal GI tract so that they reach the colon where colonic bacteria release the active drug to produce a mucosal anti-inflammatory action for treatment of chronic colitis. Examples include sulfasalazine (Azulfidine), olsalazine (Dipentum), encapsulated mesalamine (Asacol), polymer-coated mesalamine (Pentasa), and mesalamine enema (Rowasa).
- Avoid systemic nonsteroidal anti-inflammatory drugs (e.g., flunixin meglumine, ibuprofen, and aspirin) in dogs and cats with GI disease, or use them cautiously because they cause GI ulceration.

Antibiotic Therapy

Do not use antibiotics routinely as empirical therapy in cases of uncomplicated diarrhea of undetermined cause because of the adverse effects of antibiotics on the normal intestinal flora and the risk of promoting resistant strains of bacteria.

- Use well-chosen antibiotics when specific bacterial enteropathogens, such as *Salmonella, Campylobacter,* or enterotoxigenic *C. perfringens,* are suspected.
- Antibiotics are appropriate in conditions associated with severe mucosal damage and a high risk of secondary sepsis or endotoxemia, such as parvoviral enteritis and hemorrhagic gastroenteritis (HGE). Thus, indications for antibacterial therapy in animals with acute GI disease include bloody diarrhea, fever, leukocytosis, leukopenia, fecal leukocytes, and shock.
- Metronidazole is an antibiotic frequently used in animals with diarrhea. Its potential indications are as follows:
  - To treat *Giardia* (and various other protozoa)
  - To treat certain enteropathogenic bacteria, such as *Clostridium* species
  - To suppress overabundant enteric flora in small intestinal bacterial overgrowth
  - To modify normal enteric flora that may play a role in chronic inflammatory bowel disease
  - To immunomodulate in chronic inflammatory bowel disease

Fenbendazole-Responsive Diarrhea

Fenbendazole (50 mg/kg PO q24h for 3 days) is highly effective for treating common intestinal nematode and *Giardia* infections.

Cobalamin Therapy

Cobalamin (vitamin B_{12}) is vital for many cellular processes, and it is frequently depleted in patients with

chronic small intestinal disease or exocrine pancreatic insufficiency. Cobalamin deficiency can impair intestinal mucosal regeneration and cause villous atrophy and malabsorption, exacerbating diarrhea and contributing to anorexia and depression in patients with chronic GI disease.

- Treat with parenteral cobalamin (1000 µg/ml) when serum levels are decreased, especially if <200 ng/L. Give injections weekly for at least 6 weeks, then every other week for 6 weeks, and then monthly.
- For cats and small dogs: Give 250 µg SC, weekly
- For medium dogs: Give 500 µg SC, weekly
- For large dogs: Give up to 1000 µg SC, weekly

DIETARY DIARRHEA

Etiology

- Diarrhea as a result of indiscriminant eating and chewing behavior is particularly common in dogs. Dietary indiscretions include overeating, ingestion of spoiled garbage or decomposing carrion, and ingestion of abrasive or indigestible foreign material (e.g., bones, stones, hair, plants, wood, cloth, carpeting, foil, or plastic) that can traumatize the GI mucosa.
- Diarrhea may result from an abrupt change in diet. Any change in the composition of the diet should be made in gradual increments over a period of several days to allow adaptation.
- Animals may be intolerant of certain foods, such as lactose ingested as milk, fatty foods, spicy foods, and food additives found in certain commercial diets. Food hypersensitivity to specific protein sources is implicated as a cause of inflammatory bowel disease in dogs and cats.
- Fiber-responsive diarrhea is sometimes seen in dogs.

Diagnosis

Dietary causes of diarrhea usually are identified by careful history-taking and the response to a restricted diet.

- Carefully question the owner about all aspects of diet and environment, including recent changes in type and brand of food, all supplemental feeding practices using "people foods," patterns of chewing behavior involving non-food items (including toys, plants, and haircoat), likelihood of garbage ingestion, and potential for unobserved indiscretions in free-roaming animals.
- Examine the feces for abrasive particles.

Treatment

Dietary diarrhea is self-limiting with feeding of a restricted diet, elimination of identifiable offending substances from the diet, and prevention of indiscriminant eating or chewing behavior. Management of dietary hypersensitivity is discussed under "Chronic Inflammatory Bowel Disease" later in this chapter.

DRUG- AND TOXIN-INDUCED DIARRHEA

Etiology

- Diarrhea is a frequent adverse side effect of many medications, including nonsteroidal anti-inflammatory agents (e.g., aspirin, ibuprofen, indomethacin, phenylbutazone, and flunixin meglumine), digitalis and other cardiac drugs, dithiazanine (Dizan), magnesium-containing compounds, lactulose (for hepatic encephalopathy), some anthelmintics, most anticancer drugs, and many antibacterial drugs (partly from adverse effects on the flora).
- Dexamethasone has been associated with hemorrhagic gastroenterocolitis characterized by erosion, ulceration, necrosis, and sometimes fatal colonic perforation, especially in dogs treated for intervertebral disc disease.
- Many exogenous toxins cause diarrhea, including biologic toxins such as the enterotoxins that cause staphylococcal and clostridial food poisoning and various diarrheogenic chemical poisons, such as heavy metals (lead, arsenic, thallium), insecticides (organophosphate dips, flea treatments), lawn and garden products (insecticides, herbicides, fungicides), and some houseplants.
- Free-roaming animals may drink from stagnant or runoff water polluted or potentially contaminated with toxic industrial, petroleum, or agricultural chemicals.

Diagnosis

Suspect drug- and toxin-induced diarrhea on the basis of history of exposure (or opportunity for exposure), clinical signs, and exclusion of other causes of diarrhea.

- Many medications and most toxins that cause diarrhea also cause vomiting.
- Some toxicities are associated with various extraintestinal signs (e.g., neurologic manifestations of lead and organophosphate toxicity).

Treatment

- Drug-induced diarrhea usually resolves after discontinuation of the offending medication or a reduction in its dosage.
- Toxin-induced diarrhea resolves with symptomatic antidiarrheal therapy, prevention of further exposure to the toxin, and gradual elimination of the substance from the body. However, if the exact toxin is known, consult other sources of information for additional specific treatments and antidotes.

INTESTINAL PARASITES (HELMINTHS)

The majority of intestinal parasite infections are asymptomatic: when clinical signs do occur, diarrhea and weight loss are most common. Young growing animals generally are more frequently and severely parasitized, but never overlook endoparasitism as a possible cause of acute or chronic diarrhea of either small or large bowel type in dogs and cats of all ages. Other intestinal diseases, such as viral or bacterial enteritis, often are complicated by intestinal parasite infection.

The diagnosis of parasitism depends on the identification of eggs, cysts, larvae, trophozoites, or proglottids in the feces (see Table 69-4). Parasites that are notorious for evading detection include *Giardia* in dogs and cats with small bowel diarrhea and whipworms in dogs with large bowel diarrhea. In such cases, response to a therapeutic trial is an indirect method of diagnosis. Anthelmintics used to treat the common parasites are listed in Table 69-6.

Ascarids

Etiology

Ascarid nematodes are the most prevalent intestinal parasites of dogs and cats worldwide. The ascarids of the dog are *Toxocara canis* and the less common *Toxascaris leonina;* those in the cat are *Toxocara cati* and *Toxascaris leonina.*

Life Cycle

Ascarid infection occurs by four routes:

- Prenatal infection results from transplacental migration, which occurs only with *T. canis.* Many puppies are born infected with ascarids because of transplacental migration of the bitch's somatic *T. canis* larvae into the fetus (prenatal infection).
- Milk-borne infection results from transmammary migration, which occurs with both *T. canis* and *T. cati.* Milk-borne infection during nursing is the major source of ascariasis in kittens.
- Infection by ingestion of infective eggs occurs with all three ascarids *(T. canis, T. cati,* and *T. leonine).*
- Infection by ingestion of a paratenic (transport) host *(T. canis, T. cati)* or an intermediate host *(T. leonina).*

Three types of migration pattern occur when an animal is infected:

- Liver-lung migration *(T. canis, T. cati)*
- Migration within the wall of the GI tract (all three ascarids)
- Somatic tissue migration *(T. canis, T. cati)*

Clinical Signs

- Signs of ascariasis occur most often in young puppies and kittens, in which the adult worms in the small intestine may cause abdominal discomfort, whimpering and groaning, potbellied appearance, dull haircoat, unthriftiness, stunted growth, and

Table 69-6. ANTHELMINTICS FOR DOGS AND CATS

Drug	Product (Manufacturer)	Dosage	Efficacy			
			Ascarids	Hookworms	Whipworms	Tapeworms
Dichlorophene	Many products	Dog: Capsule size as directed	++	++	–	+
Diethylcarbamazine*	Many products	Dog: 6.6 mg/kg daily or 110 mg/kg once PO	++	–	–	–
Epsiprantel	Cestex (Pfizer)	Dog: 5.5 mg/kg PO Cat: 2.75 mg/ kg PO	–	–	–	+++
Febantel plus praziquantel and pyrantel	Drontal-Plus (Bayer)	15 mg/kg of febantel	+++	+++	+++	+++
Fenbendazole	Panacur (Intervet)	50 mg/kg PO for 3–5 days	+++	+++	+++	++†
Ivermectin*‡	Heartgard Plus (Merial)	Dog: 6 µg/kg PO monthly	++	++	–	–
Milbemycin oxime*	Interceptor, Sentinel (Novartis)	Dog: 0.5 mg/kg PO monthly	++	++	++	–
Piperazine	Many products	110 mg/kg PO	++	–	–	–
Praziquantel	Droncit (Bayer)	See label; PO, SC, IM	–	–	–	+++
Pyrantel pamoate	Nemex (Pfizer)	10 mg/kg PO if <2.5 kg, 5 mg/kg PO if >2.5 kg	+++	+++	–	–

+++, excellent efficacy; ++, good efficacy; +, minimal efficacy.
*Drugs used concomitantly as heartworm preventatives (see Chapter 152).
†Efficacious for *Taenia* species of tapeworms only; not effective against *Dipylidium caninum.*
‡Consult package insert because of special safety precautions or potential for serious side effects.

diarrhea. Worms frequently are passed in vomitus or diarrhea.
- Rarely, large, tangled masses of worms occlude the lumen in young pups and cause death from intestinal obstruction, intussusception, or intestinal perforation.
- In the neonatal pup, the migration of large numbers of *T. canis* larvae through the lungs can cause severe damage and fatal pneumonia.
- In young animals with light infections and in adults, infection is most commonly asymptomatic or is evidenced merely by a loss of body condition.

Diagnosis

- The diagnosis of ascariasis is readily established by the identification of ascarid eggs in routine fecal flotation.
- Most pups begin passing large numbers of eggs in their feces around 3 weeks of age and continue to shed eggs for most of early puppyhood (4–6 months) until treated.

Treatment

- Numerous effective anthelmintics for ascarids are available (see Table 69-6). Pyrantel pamoate is especially well tolerated and effective in puppies and kittens; it also is effective in controlling hookworms.
- Because many pups are born infected with *T. canis,* treatment is recommended at 2 weeks of age, before eggs are first passed in the feces, and repeated at 4, 6, and 8 weeks to kill all worms derived from prenatal, milk-borne, and ingestion routes of infection.
- Toxocaral visceral larva migrans (VLM) is a serious disease of humans (especially children) produced by the invasion of visceral tissues by migrating *T. canis;* thus, infected pups are considered public health hazards.

Hookworms

Etiology

- *Ancylostoma caninum,* the most common hookworm in the dog, is a voracious bloodsucker.
- *Ancylostoma tubaeforme,* the common hookworm in the cat, is more of a tissue feeder than a bloodsucker and is far less pathogenic than *A. caninum* in dogs.
- *Ancylostoma braziliense* (southern United States) and *Uncinaria stenocephala* (Canada) affect both dogs and cats but are less common than *A. caninum* and *A. tubaeforme* and are only mildly pathogenic.

Life Cycle

Hookworm infection can occur by five routes: prenatal, milk-borne, ingestion of infective larvae (L3), skin penetration by infective larvae, and ingestion of paratenic hosts. Ingestion and cutaneous migration probably are the most common routes of infection. With all routes of infection, eggs are passed in feces after 2 to 3 weeks.

Clinical Signs

Pathogenicity is directly related to the hookworm's bloodsucking activity and capacity for causing intestinal blood loss. Hookworms embed their mouthparts in the mucosa to suck blood and tissue fluid, leaving bleeding, punctiform ulcers as they "graze." Hence, an important consequence of severe hookworm infection is blood loss anemia.

- The clinical signs of ancylostomiasis include tarry (melena) or bloody diarrhea accompanied by pallor, weakness, emaciation, and dehydration.
- Rapidly progressive blood loss anemia may result in acute death of neonates. In other animals, chronic blood loss may cause iron deficiency anemia characterized by erythrocytes that show hypochromasia and microcytosis.
- Acute, pruritic dermatitis occasionally is associated with the active penetration of skin by hookworm larvae.
- Hookworm infections in mature animals often are asymptomatic.

Diagnosis

Young dogs are most often affected, and the diagnosis usually is readily established by identification of the characteristic *Strongyloides* hookworm ova by routine fecal flotation. Ancylostomiasis often is associated with eosinophilia on the CBC.

Treatment

Anthelmintics effective for eradicating hookworms include pyrantel pamoate (safest for young animals), fenbendazole, and febantel (see Table 69-6 for product names and dosages).

- In areas in which *A. caninum* is a frequent problem, routinely treat bitches and pups. Because of prenatal and milk-borne infection, initiate treatment of pups at 2 weeks of age, along with treatment for *T. canis.*

▼ ***Key Point*** Pyrantel pamoate suspension is an excellent anthelmintic for nursing pups because it is safe and is active against both hookworms and ascarids.

- Severely anemic animals should receive whole blood transfusions, iron supplementation, and supportive therapy as needed.

Prevention

- Parasite control is aided by good sanitation and impervious flooring in kennels and dog runs.

- Various commercial products have a combined effect as preventive agents against both heartworms and hookworms (e.g., milbemycin) (see Table 69-6).

Whipworms

Etiology

The canine whipworm, *Trichuris vulpis,* is a common cause of large bowel diarrhea in dogs in many areas. The adult nematode has a predilection for the proximal colon and cecum, where its distinctive threadlike head end, or "whip," firmly embeds deep within the mucosa to feed on blood and tissue fluids, thereby causing colitis and typhlitis.

The feline whipworms, *Trichuris campanula* and *Trichuris serrata,* are rare and usually are not associated with clinical signs.

Life Cycle

- Whipworm infections occur by ingestion of infective ova, and the life cycle is direct.
- The prepatent period is approximately 3 months. Ova may survive and remain infectious in the environment for 4 to 5 years; hence, contaminated ground is probably the major reservoir of infection.

Clinical Signs

- Whipworms infect dogs of all ages. Although there may be minimal clinical signs in light infestations, trichuriasis frequently causes acute, chronic, or intermittent signs of mucoid large bowel-type diarrhea with urgency and sometimes hematochezia.
- Pseudohypoadrenocorticism, characterized by hyperkalemia and hyponatremia in the presence of normal adrenal function, has been associated with severe whipworm diarrhea in several dogs.

Diagnosis

- Definitive diagnosis of whipworm infection requires identification of the characteristic brown, bipolar-operculated, football-shaped ova by routine fecal flotation.
- Repeated fecal examinations may be necessary to identify ova because of the unusually long prepatent period and because it is not uncommon for active infection to be characterized by prolonged periods when ova are not shed in the feces.
- Alternative means of diagnosis of ova-negative, or so-called occult, infections, include the following:
  - Colonoscopic observation of adult whipworms in the bowel lumen
  - Resolution of signs in response to a therapeutic trial of fenbendazole or febantel

Treatment

- Give fenbendazole or febantel for 3 days (see Table 69-6). In refractory cases, a 5-day course is recommended. Routinely repeat treatment at 3 weeks and 3 months, because whipworms are difficult to eradicate.
- Rarely, trichuriasis has been associated with severe transmural granulomatous typhlitis that may be palpable as a tender right-midabdominal mass. This lesion may be refractory to anthelmintics and require typhlectomy.

Prevention

- Because it is virtually impossible to eradicate the parasite from infected ground, frequent reinfection is a common problem. For this reason, collect and properly dispose of feces whenever possible.
- In dogs with frequent access to ground that has been heavily contaminated with whipworm ova (a common situation in many public parks and backyards), reinfection is so frequent that retreatment every 2 to 3 months may be necessary.
- Disinfect concrete runs with dilute sodium hypochlorite bleach.

Strongyloides

Etiology

Strongyloides are tiny (2 mm) rhabdoid nematodes found in warm, humid tropical regions such as the southern Gulf states of the United States.

- In dogs, strongyloidiasis is caused by *Strongyloides stercoralis,* a parasite that burrows in the mucosa of the proximal small bowel.
- In cats, strongyloidiasis is caused by *Strongyloides tumefaciens,* a parasite that burrows within the mucosa of the large intestine.

Life Cycle

- Infection with third-stage larvae is by the oral or cutaneous route, and adult worms develop in the small intestine following migration in the circulation and lung.
- Parthenogenetic female adults produce eggs that hatch within the gut lumen so that first-stage (rhabdoid) larvae are passed in the feces. These larvae may develop into infectious third-stage (filariform) larvae or free-living adults.

Clinical Signs

- *S. stercoralis* is mainly a problem in pups, in which it causes acute hemorrhagic enteritis that is often fatal.
- *S. tumefaciens* infection in cats is usually asymptomatic, but in some cats the parasite causes peculiar tumor-

like, white, nodular (2–3 mm) proliferations in the colonic mucosa and submucosa that are associated with chronic diarrhea and debilitation.

Diagnosis

- Ova containing first-stage *Strongyloides* larvae can be identified in feces by flotation techniques. Free larvae (0.8 to 1.6 mm long × 30 to 80 µm) may be identified by direct microscopic examination of fresh feces or by the Baermann technique.
- In cats, the diagnosis of *S. tumefaciens* also can be established by colonoscopic observation and biopsy of mucosal nodules filled with adult worms.

Treatment

Treat with fenbendazole (50 mg/kg/day PO for 5 days), diethylcarbamazine (100 mg/kg PO once), or pyrantel pamoate (20 mg/kg/day PO for 5 days).

Tapeworms

Etiology

- The most common tapeworm (cestode) of dogs and cats is *Dipylidium caninum.* Fleas and lice are intermediate hosts.
- Several species of *Taenia* can be acquired by dogs and cats (most commonly *Taenia pisiformis* in the dog and *Taenia taeniaeformis* in the cat) from ingestion of cysticercus-infected tissues from intermediate hosts (e.g., rabbits, rodents, sheep, and ungulates).
- Other cestodes that are less common include *Echinococcus, Multiceps, Mesocestoides,* and *Spirometra.*

Clinical Signs

- Tapeworms that parasitize the small bowel of dogs and cats are relatively harmless, rarely causing more than a subtle decline in body condition.
- The proglottids of *D. caninum* are highly motile and may cause anal pruritus as they crawl on the perineum; crawling proglottids are often detected by observant owners in the animal's stool or on the perineum.

Diagnosis

- Tapeworms are diagnosed by the identification of proglottids or ova in the feces.
- *D. caninum* proglottids are distinguished from *Taenia* spp. by their barrel shape and double genital pore. Also, a proglottid can be squashed in a drop of water between a slide and a cover slip to identify the characteristic *D. caninum* egg capsules that contain up to 20 eggs.

Treatment

- Praziquantel and epsiquantel are the most effective all-around drugs for treatment of cestodiasis (see Table 69-6).
- Fenbendazole is effective against *Taenia* species but not *D. caninum.*
- Flea and lice control is important for preventing *D. caninum* reinfection. Control of predation and scavenging helps prevent infection with other cestodes.

PROTOZOAN PARASITES

Coccidia

Etiology

Canine and feline intestinal *Coccidia* are protozoan parasites that belong to the genera *Isospora, Besnoitia, Hammondia, Sarcocystis, Neospora, Toxoplasma,* and *Cryptosporidium.* Most enteric coccidial infections of dogs and cats are commensal and nonpathogenic.

- Primary enteric disease in small animals has been described only with *Isospora* and *Cryptosporidium.*
- *Toxoplasma gondii* and *Neospora caninum* are multisystemic infections discussed in Chapter 21.
- *Isospora* spp. that infect dogs include *I. canis, I. ohioensis, I. burrowsi,* and *I. neorivolta; I. felis* and *I. rivolta* infect cats.

Life Cycle

- Intestinal coccidiosis occurs most commonly by ingestion of infective (sporulated) oocysts from a feces-contaminated environment. *Cryptosporidium* infection is often water borne.
- Infection occurs occasionally from ingestion of infective cyst-containing tissues of paratenic (transport) hosts such as rodents and other prey and ingestion of uncooked meat of herbivores.

Clinical Signs

- Coccidiosis in most animals is an asymptomatic, incidental infection.
- *Coccidia* are opportunists. Clinical disease is usually related to massive oocyst ingestion in newborn animals and is associated with overcrowded, unsanitary, high-stress conditions in settings such as pet shops, kennels, shelters, catteries, and laboratory colonies. Concurrent disease, malnutrition, and immunosuppression are predisposing factors.
- Cryptosporidiosis has complicated canine distemper, feline leukemia virus, feline immunodeficiency virus, and advanced neoplasia.

- Clinical disease usually is characterized by diarrhea that varies from soft to fluid and is occasionally mucoid or bloody. Other signs can include vomiting, lethargy, weight loss, and dehydration. Coccidia have been associated with chronic malabsorption.

Diagnosis

Isospora Coccidia

- Coccidiosis is diagnosed by the identification of oocysts in fresh feces.
- Because many normal dogs and cats harbor intestinal coccidia and these protozoa are generally regarded as minimally pathogenic, the clinical significance of finding coccidial oocysts often is questionable.

Cryptosporidium

- Fecal immunoassay is the preferred method for diagnosis of *Cryptosporidium*. The direct immunofluorescence test (Merifluor, Meridian) and microplate ELISA (ProSpecT, Remel) are most reliable; however, false-negative reactions may occur with some strains.
- Fecal PCR is also used but is not widely available.
- *Cryptosporidium* oocysts can be isolated for identification from feces using concentration techniques, such as Sheather's sugar flotation or formaldehyde-ether sedimentation, or by staining feces with Kinyoun carbol fuchsin stain or modified acid fast stain. Cryptosporidia oocysts are so small (as little as one-tenth the size of common *Isospora* oocysts) that careful examination of slides under oil immersion is necessary to visualize these tiny structures.
- Histologic or electron microscopic identification of *Cryptosporidium* in intestinal biopsies is another means of diagnosis.

Treatment

Identification of oocysts in a healthy animal with normal feces indicates a self-limiting commensal infection and does not necessarily warrant treatment, although treatment may help reduce environmental contamination with oocysts.

Treatment for Isospora

If clinical signs are attributed to coccidiosis, as in young puppies and kittens with diarrhea, treat with one of the following coccidiostats:

- Sulfadimethoxine—50 to 60 mg/kg/day PO for 1 to 3 weeks
- Trimethoprim-sulfa—15 to 30 mg/kg q12–24h PO for 1 week
- Furazolidone—8 to 20 mg/kg/day PO for 1 week
- Amprolium (unapproved for use in dogs but often recommended for treating animals in kennels or other groups of dogs)—20% powder in gelatin capsules, 100 mg q24h for small-breed pups or 200 mg q24h for larger-breed pups, PO for 7 to 12 days; alternatively, 1/4 tsp of 20% powder per four pups mixed with puppy ration or 1 ounce (30 ml) of 9.6% solution per gallon of free-choice water

Treatment for Cryptosporidiosis

Cryptosporidiosis is generally self-limiting in immunocompetent hosts. The infection may be persistent in severely immunocompromised animals or humans.

- The drug of choice for treating *Cryptosporidium* is azithromycin (Zithromax, 7–15 mg/kg PO q12h for 5–7 days).
- Other suggested antibiotics include clindamycin and tylosin, but efficacy is questionable. Nitazoxamide has been used but causes severe vomiting. Paromomycin has been used but causes acute renal failure and deafness.
- Because *Cryptosporidium* are not species specific, zoonotic transmission between animals and humans can occur, sometimes with fatal consequences in the presence of severe immunosuppression. Case studies have implicated pets as a source of human infection.

Giardia

Giardia are pear-shaped, binucleated, flagellated protozoa that infect the small intestine, where they may interfere with mucosal absorption, and sometimes produce diarrhea. There are two forms: motile trophozoites that inhabit the intestinal tract and non-motile infective cysts that are passed through the feces into the environment.

Motile trophozoites attach to the brush border surface of the mucosal epithelium by means of ventral cup-shaped suction discs or float free within the adjacent mucus layer. They are mainly found in the duodenum in the dog and in the jejunum and ileum in the cat.

Life Cycle

The life cycle of *Giardia* is direct, and the usual source of infection is the ingestion of food or water contaminated with cysts. Wild animals are potential reservoirs. The prevalence is highest in young animals and animals confined together in groups.

Clinical Signs

- The majority of *Giardia* infections are subclinical, especially in mature animals.
- Clinically apparent giardiasis occurs most frequently in young dogs and cats and is characterized by intestinal malabsorption with large volumes of foul-smelling, light-colored, watery or cow patty–like diarrhea, steatorrhea, and weight loss. Diarrhea may be acute or chronic, intermittent or continuous, and self-limiting or persistent.

- The severity of giardiasis is enhanced by concomitant viral, bacterial, or helminth infections.

Diagnosis

- Fecal immunoassays for *Giardia* antigen are accurate and convenient. Reliable immunoassays include the point-of-care SNAP Giardia Test Kit (IDEXX), the microplate ELISA (Alexon Trend), or a direct immunofluorescence test available at commercial labs. Evidence suggests that the rapid ELISA test intended for humans is not reliable in animals.
- Microscopic diagnosis of giardiasis depends on identification of cysts (oval, 8 to 12 µm × 7 to 10 µm) by zinc sulfate centrifugation-flotation of feces or of motile flagellated trophozoites (pear-shaped, 9 to 21 µm × 5 to 15 µm × 2 to 4 µm) in fresh diarrheic feces suspended in saline or in duodenal specimens (aspirates, brushings, or impression smears of mucosal biopsies).

▼ ***Key Point*** *Giardia* cysts are identified in feces much more frequently than trophozoites. Negative fecal examinations do not exclude a diagnosis of giardiasis.

- Consider a therapeutic trial of fenbendazole or metronidazole when diagnostics are negative and "occult" giardiasis is suspected.

Treatment

Drugs that are effective for treating giardiasis include metronidazole, fenbendazole, albendazole, febantel, quinacrine, and furazolidone.

▼ ***Key Point*** Fenbendazole is the initial treatment of choice for giardiasis.

- Fenbendazole (Panacur) (50 mg/kg PO q24h for 3 days) is very safe and effective for treating *Giardia* in dogs and probably cats.
- Febantel (Drontal Plus, 15 mg/kg q24h for three doses or a single dose of 30 mg/kg PO) appears to be effective but needs further study.
- Metronidazole (25–30 mg/kg PO q12h for 5–10 days) is usually effective, although up to one-third of infections may be metronidazole resistant. Side effects include anorexia, vomiting, and reversible CNS toxicity (weakness, ataxia, disorientation, seizures, and blindness).
- Albendazole (Valbazen) (25 mg/kg PO q12h for 5 days in cats and 2 days in dogs) is effective but has been associated with severe bone marrow toxicity. For this reason, fenbendazole is preferred.
- Furazolidone (Furoxone, SmithKline) (4 mg/kg PO q12h for 5 days) is effective and convenient for cats, as it is available in a suspension form.

Prevention

Failure to respond to treatment is often the result of repeat exposure and recurrence of infection, especially in groups of animals confined together.

- Decontaminate the environment with quaternary ammonia.
- Bathe animals to remove cysts from the haircoat.
- Treat all animals that are confined together.
- *Giardia* vaccine is available but is not recommended. It does not prevent infection. It may reduce cyst shedding, but this is inconsistent.

Tritrichomonas foetus in Cats

Tritrichomonas foetus is a frequent cause of mild to severe lymphoplasmacytic colitis and chronic large intestinal diarrhea in young cats, especially cats confined in crowded cattery conditions.

Clinical Signs

The diarrhea may wax and wane and is semiformed or "cow pie" in consistency and malodorous. It may contain blood or mucus. The diarrhea often improves transiently in response to antibiotics. Affected cats generally remain otherwise healthy and in good body condition. Diarrhea is often exacerbated by concurrent enteric infections or parasites, especially *Giardia* and *Cryptosporidium*.

Diagnosis

The diagnosis can be confirmed by direct fecal microscopy, fecal culture, or PCR assay.

- Motile trophozoites of *Tritrichomonas foetus* can be identified in fresh fecal wet smears taken directly from the rectum in about 14% of cases. The likelihood of detecting trophozoites is lower in formed feces, desiccated feces, or in cats recently treated with antibiotics.
- Fecal culture is more sensitive for diagnosis than microscopy. Culture requires 0.05 g of freshly voided feces inoculated in special media (InPouch TF, BioMed Diagnostics). The instructions on using this culture system are found at the website below.
- Fecal PCR assay is the most accurate test (high sensitivity and specificity) for detecting *T. foetus*, and information on submitting samples is found at http://www.cvm.ncsu.edu/mbs/gookin_jody.htm.
- Trichomonads may be observed in the superficial mucus and crypts in colonic biopsies.

Treatment

T. foetus is virtually impossible to eradicate with antibiotics. Numerous antibiotic agents have been evaluated without success. Treatment can reduce the number of organisms and improve clinical signs, but it usually does not eliminate the infection.

- Diarrhea often improves with antibiotics but relapses when antibiotics are stopped.
- Other measures include reducing housing density, reducing stress, improving diet, and treating concurrent infections such as *Giardia* and *Cryptosporidium.*
- The long-term prognosis is good based on findings that most infected cats resolve the clinical signs of *T. foetus* infection within 2 years (median, 9 months). However, many of these cats remain subclinically infected for several years. Clinical disease may be prolonged in cats living under dense housing conditions, possibly attributable to stress.

Entamoeba

E. histolytica, primarily a human pathogen, rarely may cause amebic colitis (bloody-mucoid diarrhea) in dogs and cats that drink polluted water.

Diagnosis

Diagnosis is based on identification of ameboid trophozoites with pseudopodial movement in saline smears of fresh diarrheic feces, amebic cysts in zinc sulfate flotation of formed feces, or trophozoites in colon biopsies.

Treatment

Optimal treatment for amebic colitis in dogs and cats is unknown, but response has been seen with metronidazole (25–30 mg/kg PO q12h for 5–10 days) or furazolidone (2.2 mg/kg PO q8h for 7 days).

Balantidium

B. coli, a ciliated protozoan that primarily infects swine, is a rare cause of chronic ulcerative colitis in dogs.

Diagnosis

Diagnosis is based on identification of large (40 to 80 µm × 25 to 45 µm), oval, brown, rapidly swimming ciliated trophozoites with prominent macronuclei in saline suspensions of fresh feces or identification of protozoal cysts in zinc sulfate or sedimentation preparations of feces.

Treatment

Optimal treatment is unknown, but metronidazole (25–30 mg/kg PO q12h for 5–10 days) appears to be effective.

VIRAL INFECTIONS OF THE INTESTINES

Canine Intestinal Viruses

- Canine parvovirus, coronavirus, and rotavirus cause viral enteritis and diarrhea in dogs. Canine parvovirus is an acute, severe, highly contagious enteritis that is prevalent worldwide. Coronavirus and rotavirus are less prevalent and cause relatively mild clinical signs except in neonates. For details concerning intestinal viruses, see Chapter 14.
- Because of its epitheliotropism, canine distemper virus also causes diarrhea (see Chapter 13).

Feline Intestinal Viruses

- The most clinically important primary enteric virus is feline panleukopenia virus (FPV), a parvovirus. Other feline intestinal viruses include enteric coronavirus, rotavirus, and astrovirus (see Chapter 14).
- The intestine may be involved as part of generalized viral infections such as feline leukemia virus (see Chapter 8), feline immunodeficiency virus (see Chapter 9), and feline infectious peritonitis, a coronavirus (see Chapter 10).

BACTERIAL INFECTIONS OF THE INTESTINES

Most enteropathogenic bacteria produce intestinal disease by invading the epithelium (invasive bacteria) or by liberating diarrheogenic enterotoxins (noninvasive or enterotoxigenic bacteria).

Enteropathogenic bacteria of clinical importance include *Salmonella* species, *Campylobacter jejuni, C. perfringens,* and *C. difficile. Yersinia* species and *Bacillus piliformis* are rare and are not discussed here. *Salmonella* and *Campylobacter* are primarily invasive, causing mucosal damage that leads to inflammation, exudation, mucus secretion, and bleeding. Bacterial enterotoxins may also play a role in the pathogenesis of these agents. *C. perfringens* and *C. difficile* are noninvasive and cause diarrhea by an enterotoxigenic mechanism.

▼ ***Key Point*** Because *Salmonella, Campylobacter,* and *Yersinia* also are potentially zoonotic pathogens, pets occasionally are reservoirs for human infection.

Salmonella

Etiology

- Salmonellosis is caused by gram-negative bacilli belonging to the genus *Salmonella* of the family *Enterobacteriaceae. Salmonella* frequently are isolated from the feces of normal dogs and cats, but clinical signs of salmonellosis are uncommon, indicating a prevalent asymptomatic carrier state.
- *Salmonella* infection is transmitted by the fecal-oral route, mainly through ingestion of contaminated food or water. The organisms can survive in the environment for long periods outside the host; thus, fomite transmission also can occur.
- Infected migratory birds have been a source of fatal infections in cats, and raw meat, bone, and raw food

diets have recently been implicated in canine infections.
- Infection risk depends on infectivity of the strain, size of the inoculum, competition from the established flora, age of the host, and host defense factors. Infection rates are greatest in young animals and in group confinement situations with overcrowding and poor sanitation.

Clinical Signs

Manifestations of *Salmonella* infection may be categorized into three syndromes: subclinical carrier state, enterocolitis, and enterocolitis with bacteremia. Virulence of the bacterial strain and host susceptibility play roles in the severity of infection.

- Clinical salmonellosis is relatively uncommon compared with the prevalence of the subclinical carrier state.
- *Salmonella* enterocolitis is characterized by acute watery or mucoid diarrhea (containing blood in severe cases), vomiting, tenesmus, fever, anorexia, lethargy, abdominal pain, and dehydration. Most animals recover in 3 to 4 weeks, although shedding of organisms often persists up to 6 weeks and sometimes persists longer.
- *Salmonella* can cause chronic or intermittent diarrhea in some animals.
- Rarely, *Salmonella* enterocolitis progresses to a potentially fatal bacteremia or endotoxemia with signs of systemic inflammatory response syndrome, shock, and disseminated intravascular coagulation (DIC).

Diagnosis

Suspect salmonellosis in animals that develop acute diarrhea and have identifiable risk factors, such as known or probable exposure, young age, immune deficiency, debilitating illness, or housing in overcrowded or unsanitary conditions.

- Nosocomial outbreaks with high morbidity and mortality have been recorded in hospitalized animals, the greatest risk occurring in the following animals:
  - With severe illness
  - Undergoing major surgery
  - Hospitalized for 5 or more days
  - Receiving glucocorticosteroids, anticancer chemotherapy, or oral antibiotics (especially ampicillin) that upset the normal flora
- Routine diagnostic tests usually are noncontributory, except that a degenerative neutropenia may be found in severe cases with bacteremia and endotoxemia. Feces may contain leukocytes.
- Confirmation of the diagnosis depends on isolation of *Salmonella* spp. from properly cultured fecal specimens or from blood cultures in bacteremic animals.

Treatment

The use of antibiotics in the treatment of salmonellosis is controversial. *Salmonella* invasion that is confined locally to the mucosa produces enterocolitis that is self-limiting and is not likely to be affected by antibiotics.

▼ ***Key Point*** Antibacterial therapy, especially oral, non-absorbable antibiotics that alter the flora, may actually prolong shedding of *Salmonella* organisms and encourage development of a prolonged convalescent carrier state.

Antibiotics are indicated when *Salmonella* invasion becomes severe or complicated by bacteremia and endotoxemia—as indicated by signs such as shock, dehydration, high fever or hypothermia, and extreme depression—or by laboratory findings such as azotemia, electrolyte imbalances, neutropenia, hypoglycemia, hypoproteinemia, or coagulopathy. Peracute onset and severe hematochezia may also be an indication of impending systemic invasion and should prompt antibiotic therapy.

- Base antibiotic selection on culture and sensitivity testing. Most isolates are susceptible to enrofloxacin (Baytril, Bayer) (dog: 5 mg/kg PO q12h; cat: 2.5 mg/kg PO q12h), trimethoprim-sulfa (15 mg/kg PO q12h), or chloramphenicol. Administer antibiotics for 7 to 10 days and reculture feces 1 and 4 weeks after treatment.
- In addition to antibiotics, fluid and electrolyte replacement and identification and correction of underlying predisposing conditions are important aspects of therapy.
- Proper hygiene in handling of infected animals is necessary to prevent fecal-oral or fomite transmission of infection to other animals or to humans.

Prognosis

- The prognosis for most animals with salmonellosis is good, although the mortality rate can be high in outbreaks in extremely susceptible populations (e.g., hospital patients and neonates).
- Prognosis is guarded to poor for animals with extremely bloody diarrhea, fever > 104°F or hypothermia, neutropenia with a left shift, and indications of sepsis with multiorgan failure (DIC, hypoglycemia, azotemia, jaundice).

Campylobacter

C. jejuni organisms are fastidious, microaerophilic, gram-negative, motile, slender, and curved bacteria that are important pathogens of animals and humans worldwide.

Etiology

Many clinically normal dogs and cats shed *Campylobacter* in their feces. Isolation rates vary widely, from less than 1% in confined pet populations to 50% or more in some animal shelters. Thus, conditions of close confinement and poor sanitation apparently provide the greatest opportunity for exposure. The majority of *Campylobacter*-positive dogs are clinically normal carriers.

Clinical Signs

Because it is difficult to produce enteritis with *Campylobacter* experimentally in dogs and cats and because many of the animals that harbor these organisms are asymptomatic, it has been debated whether *Campylobacter* by itself causes diarrhea in dogs and cats unless superimposed on other enteropathogenic infections with viruses, other bacteria, *Giardia,* or helminths.

- Clinical signs associated with *Campylobacter* infection in dogs and cats have been attributed to superficial erosive enterocolitis or enterotoxin-mediated secretory diarrhea. Clinical signs are characterized by watery-mucoid diarrhea, with or without blood and fecal leukocytes, lasting 5 to 15 days and may be accompanied by vomiting or tenesmus.
- Fever is usually mild or absent.
- In some animals the diarrhea appears to be chronic or intermittent.

Diagnosis

- *Presumptive* diagnosis of campylobacteriosis can be made by fecal microscopy; however, this requires an experienced examiner, because spirochetes and other motile bacteria that are part of the normal flora may be mistaken for *Campylobacter*. The presence of fecal leukocytes may also be noted.
  - *Campylobacter*-like organisms are identified as slender, curved, gram-negative rods that are characteristically W-shaped in stained fecal smears and as highly motile, darting, spiral, or S-shaped bacteria in fresh saline fecal smears examined by dark-field or phase-contrast microscopy.
- *Definitive* diagnosis requires isolation of *Campylobacter* from fresh feces using special selective media. Since *Campylobacter* organisms are microaerophilic and difficult to isolate, obtain fecal specimens for culture directly from the rectum and place them in anaerobic transport media immediately after collection.

Treatment and Prognosis

- Effective antibiotics include erythromycin (10–15 mg/kg PO q8h for 7 days; vomiting is a frequent side effect), enrofloxacin (for dogs, Baytril at 5 mg/kg PO q12h for 7 days), or azithromycin (Zithromax at a dosage of 7–15 mg/kg PO q12h for 5–7 days).
- Antibiotics may not eliminate fecal shedding of the organisms, which can persist up to 4 months. Repeat fecal cultures 1 and 4 weeks after treatment.
- Because contact with feces from infected animals is a potential source of infection for humans as well as for other animals, advise owners of infected pets to take standard precautions such as proper disposal of potentially infectious feces, hand washing after handling infected animals, and separating infected animals from infants and small children until post-treatment cultures confirm that infection has been eliminated.
- The prognosis is considered good, although rare fatalities in dogs and cats have been reported.

Clostridium perfringens

Etiology

Enterotoxigenic *C. perfringens* is an important cause of acute and chronic diarrhea in dogs and cats. *C. perfringens* is a large, anaerobic, gram-positive bacillus that normally exists in the intestinal tract of most dogs and cats. Enterotoxin-producing strains of *C. perfringens* can be associated with nonspecific episodes of diarrhea, acute hemorrhagic diarrhea, chronic or recurrent diarrhea, and outbreaks of diarrhea in animal groups.

These bacteria normally reside in the bowel in the vegetative form, but they can release their toxin during sporulation endogenously within the bowel or exogenously in contaminated food. The *cpe* gene that regulates production of *C. perfringens* enterotoxin (CPE) is up-regulated by factors that activate sporulation; thus, the presence of clostridial endospores in feces or food has been suggested as an indirect marker for the presence of CPE. Whether derived endogenously or ingested, CPE causes diarrhea by binding to intestinal epithelium and causing increased permeability, hypersecretion, and cell damage (cytotoxicity).

Endogenous sporulation and the production of CPE can be associated with alteration of the intraluminal environment caused by sudden changes in diet, antibiotic administration, alkaline conditions, immunosuppression, inflammatory bowel disease, or concurrent intestinal infections.

Clinical Signs

Enterotoxigenic *C. perfringens* infection is associated with diarrhea that varies from watery to soft and may contain mucus or blood. Increased frequency is common, and tenesmus may be seen.

- In dogs, enterotoxigenic *C. perfringens* has also been associated with a syndrome of acute hemorrhagic gastroenteritis accompanied by severe hemoconcentration.
- Infection can also cause diarrhea in groups of animals confined together and nosocomial outbreaks in hospitalized animals.

- Clostridial diarrhea is usually self-limiting after a few days, but in some animals diarrhea can persist chronically for weeks to months. Some animals have recurrent episodes of diarrhea.

Diagnosis

Routine hematologic and serum chemistry evaluations are usually normal in animals with clostridial diarrhea. Colonoscopy is not routinely necessary in these cases, but endoscopic findings are usually nonspecific (diffuse hyperemia, increased friability, fresh bleeding, and increased mucus). Biopsies range from minimal abnormalities to catarrhal, lymphoplasmacytic, or suppurative colitis.

A definitive diagnostic test for *C. perfringens*-induced diarrhea is lacking. Further work is needed to determine the role of CPE in canine and feline diarrhea and to define the optimal diagnostic parameters for clostridial diarrhea. Fecal spore counts in stained fecal smears are commonly used for routine cage-side screening; however, studies have not shown a correlation between spore counts and positive assays for CPE or a correlation between either of these diagnostic procedures and the presence or absence of diarrhea. In people, fecal assays for CPE are considered more accurate than spore counts; however, the commercially available CPE assays used in people need to be validated for dogs and cats. In principle, CPE assays should be valid across species.

- The identification of more than five clostridial endospores per oil immersion field (identified by their "safety pin" appearance with Diff-Quik or Wright staining) is considered by many to be presumptive evidence for a diagnosis of enterotoxigenic diarrhea caused by *C. perfringens*. Clostridial spores are generally larger than other bacilli found in feces. Malachite green can be used as a special stain for endospores. Fecal leukocytes also may be present. Unfortunately, the appearance or absence of clostridial spores in the feces does not correlate well with CPE assays or signs; thus, it might be advisable to take into account spore counts, CPE assays, and clinical information before making a diagnosis of clostridial diarrhea.

▼ ***Key Point*** Fecal ELISA assay for CPE is generally more reliable and specific than fecal spore counts.

- Commercial fecal assays for CPE are available in kit form for testing humans. The ELISA test (C. perfringens Enterotoxin Test; Techlab, Blacksburg, VA) appears to be the most reliable in dogs. Another commercial test, reverse passive latex agglutination (RPLA Kit, Oxoid), is insensitive and nonspecific in dogs and thus is not recommended. Use fresh feces only and transport without delay to the laboratory in prechilled diluent at 4°C (freezing should be avoided), because the fecal toxin breaks down after 24 hours.
- Cultures are not useful because non-toxigenic *C. perfringens* is part of the flora in normal dogs and cats and cultures do not reliably distinguish toxigenic and non-toxigenic strains.
- Assays using molecular probes and PCR are being evaluated as improved diagnostic procedures for enterotoxigenic *C. perfringens*.

Treatment

Diarrhea caused by enterotoxigenic *C. perfringens* can be effectively treated with ampicillin (20 mg/kg PO q8h), amoxicillin-clavulanate (12–25 mg/kg PO q12h), tylosin (20–40 mg/kg PO q12h), or clindamycin (5–10 mg/kg PO q12h) for 5 to 7 days. Metronidazole (10–20 mg/kg PO q12h) can also be effective but seems to work less consistently.

- Clostridial diarrhea is usually self-limiting or responsive to antibiotics in 2 to 3 days; however, chronic or recurrent clostridial diarrhea may require long-term antibiotics (e.g., tylosin once daily or every other day) and a fiber-supplemented diet to prevent relapses.
- Commercial fiber-containing diets or regular diets supplemented with psyllium (Metamucil at a dosage of 1–2 tbsp/day for dogs) may help reduce bacterial proliferation and sporulation because fiber is fermented to short-chain fatty acids that acidify bowel contents. Alkaline rather than acid conditions are most favorable for *C. perfringens*. In addition, short-chain fatty acids nourish colonic epithelium and protect against injury.

Clostridium difficile

C. difficile is an anaerobic, gram-positive, spore-forming bacillus. Toxigenic *C. difficile* and its toxin have been isolated from normal dogs and cats and occasionally from animals with mild diarrhea or acute hemorrhagic diarrhea; however, this organism does not appear to be a frequent enteropathogen in dogs and cats. Pseudomembranous colitis as seen in people is not seen in dogs and cats.

Diagnosis

C. difficile can be cultured using selective medium; however, the organism is isolated from normal dogs as well, and culture alone does not confirm the production of diarrheogenic toxins.

Commercial ELISA kits that detect both toxins A and B in feces are recommended, but validation in dogs and cats is needed.

Treatment

Use metronidazole for treatment of suspected or confirmed *C. difficile* infections.

FUNGAL INFECTIONS OF THE INTESTINES

Mycotic infections of the bowel are uncommon; however, fungi are opportunists that capitalize on predisposing factors such as lowered host resistance, malnutrition, antecedent debilitating illness, and prolonged therapy with antimicrobials or corticosteroids. Fungi may cause acute, dysentery-like diarrhea or chronic diarrhea accompanied by emaciation.

Causes of mycotic intestinal disease include *Histoplasma capsulatum, Pythium* spp., *Aspergillus* spp., *Candida albicans,* and other saprophytes. Histoplasmosis is a multisystemic mycotic infection and is discussed in Chapter 20. Intestinal aspergillosis and candidiasis are rare and discussed briefly in Chapter 20.

Intestinal Pythiosis and Zygomycosis

Various poorly septate saprophytic molds and fungi that include *Pythium insidiosum* (pythiosis) and several genera of *Zygomycetes* (zygomycosis) can deeply invade the tissues of the GI tract. These infections were formerly misnamed phycomycosis.

Pythiosis is most common and is seen in young, large-breed dogs that live in the southern Gulf states of the United States. Rare feline cases are characterized by ulcerative gastroenteritis.

Clinical Signs

Pythium and *Zygomycetes* can infect any part of the digestive tract, but lesions most commonly involve the stomach, small intestine, mesentery, and mesenteric lymph nodes, resulting in an extensive granulomatous tissue reaction.

- Signs include chronic intractable diarrhea and vomiting, anorexia, depression, and progressive weight loss.
- Bowel necrosis and ulceration may cause bloody diarrhea in some cases.
- Regions of extensive granulomatous inflammation may produce palpable enteromesenteric masses.
- The infection may disseminate beyond the GI tract to other abdominal viscera.

Diagnosis

- Physical examination may reveal an abdominal mass or marked regional thickening of the bowel.
- The CBC may reveal mild to moderate nonregenerative anemia and mild neutrophilia, with or without a left shift.
- Routine abdominal radiography frequently demonstrates an abdominal mass. Ultrasonography and barium contrast GI radiography often delineate a thickened, stenosed segment of bowel.
- A sensitive and specific ELISA test for presumptive diagnosis of pythiosis is available.
- Confirmation depends on histologic identification of broad, non-septate or sparsely septate hyphae in biopsies of the stomach, intestine, or abdominal lymph nodes. The organisms stain with Gridley or methenamine silver stains and are found mostly within the necrotic regions of granulomas in the submucosa and muscularis mucosa.
- Differentiate intestinal pythiosis from other granulomatous and neoplastic proliferations of the GI tract, including histoplasmosis, lymphoma, and regional (granulomatous) enteritis.
- The extensive tissue reaction can easily be mistaken for neoplasia at laparotomy (or necropsy); thus, careful histologic evaluation including use of fungal stains is essential for accurate diagnosis.

Treatment

Because these fungi are resistant to standard antifungal drugs, the most effective treatment is radical surgical excision of the severely involved segments of bowel (for surgical technique, see Chapter 70). Some animals with pythiosis have been treated successfully with itraconazole and terbinafine in combination or with lipid-complexed amphotericin B as described in Chapter 20. The prognosis is guarded to poor.

INTESTINAL PROTOTHECOSIS

Etiology

Prototheca spp. are ubiquitous unicellular algae that may rarely colonize the lamina propria and submucosa of the intestinal tract of dogs and cause severe necrotizing or ulcerating enterocolitis.

Clinical Signs

- The algae appear to have a predilection for initially invading the colon, resulting in signs of chronic large bowel diarrhea with hematochezia.
- The organisms typically disseminate widely throughout the body and most frequently involve other visceral organs, the eyes, and the CNS.
- Only a cutaneous form has been described in cats.

Diagnosis

- Colonoscopy reveals thickened, corrugated mucosal folds that may be friable or ulcerated.
- Organisms can be identified in feces, cytology preparations (Wright or Gram stain), and biopsies (Gomori or periodic acid-Schiff stain) as clusters of endosporulated, ovoid structures (5–16 µm in length).
- *Prototheca* can also be cultured on Sabouraud's cycloheximide-free dextrose media.

Treatment

Successful treatment of systemic protothecosis in animals is rare. A combination of IV lipid-complexed amphotericin B with itraconazole is suggested (see Chapter 20 for pharmacology and dosages).

CHRONIC INFLAMMATORY BOWEL DISEASE

The term *inflammatory bowel disease* (IBD) refers to a diverse group of chronic enteropathies characterized by idiopathic infiltration of the GI tract mucosa and (sometimes) submucosa with inflammatory cells. The infiltration may involve the stomach, small intestine, colon, or a combination of these and is classified on the basis of the predominant cell type as lymphocytic-plasmacytic, eosinophilic, neutrophilic, granulomatous, or histiocytic. A mixture of inflammatory cells in some lesions makes classification difficult.

Lymphocytic-Plasmacytic Inflammatory Bowel Disease

Etiology

- Lymphocytic-plasmacytic IBD is by far the most common form of IBD in both dogs and cats. The etiology is not determined in most cases; however, genetic, dietary, bacterial, immunologic, and mucosal permeability factors have been implicated.
- The pathogenesis of lymphocytic-plasmacytic IBD may involve a mucosal hypersensitivity reaction to antigens from food, intestinal bacteria, or the intestinal tract itself. This may result from a primary disorder of the intestinal immune system and its regulation or from immune events that occur secondary to mucosal injury and permeability. Chronic inflammation of the bowel may become self-perpetuating when loss of mucosal integrity allows bacterial or dietary proteins to enter the lamina propria, where they incite further immune reaction and inflammation.
- Genetic factors appear to be involved in predisposing certain breeds to lymphocytic-plasmacytic IBD (e.g., German shepherd, basenji, soft-coated wheaten terrier, and Shar-Pei). Basenjis develop a severe form of IBD (also called immunoproliferative enteropathy) that is thought to be related to a genetic disorder of immune regulation, is progressive in nature, and is exacerbated by stress.

Clinical Signs

The most common signs of IBD are vomiting, diarrhea, and weight loss. The signs vary with the region of the GI tract affected and the severity of the mucosal disease. The clinical course is typically waxing and waning and can go on for months to years. Dogs and cats of all ages are affected.

- *Lymphocytic-plasmacytic enteritis* causes chronic diarrhea and weight loss. Vomiting occurs more frequently in cats with IBD.
- *Lymphocytic-plasmacytic colitis* causes chronic large bowel diarrhea characterized by increased frequency of defecation, urgency, tenesmus, increased fecal mucus, and hematochezia. Fecal consistency varies. Intermittent hematochezia may be the only sign of IBD in some cats.
- Signs may be intermittent or persistent. In severely affected dogs, protein-losing enteropathy (ascites, hydrothorax, edema) can occur.
- Some animals with a biopsy diagnosis of lymphocytic-plasmacytic enteritis that fail to respond to treatment or that later relapse and deteriorate rapidly are found to have diffuse intestinal lymphoma.

Diagnosis

Precise criteria for the diagnosis of IBD have not been established. In general, the clinical criteria for diagnosis are (1) chronic signs of GI disease, (2) characteristic mucosal lesions of IBD in endoscopic biopsies, (3) failure to respond to dietary trials, and (4) exclusion of known causes of chronic inflammation of the intestinal tract based on thorough diagnostic evaluation. This last criterion emphasizes that IBD is a diagnosis of exclusion and not a catch-all label to be used as a substitute for diagnostic evaluation. Because lymphocytic-plasmacytic inflammation is a nonspecific lesion, only a thorough diagnostic workup can establish that it is truly idiopathic and not merely an inflammatory response to an undiagnosed condition.

- In the diagnostic evaluation, exclude parasitic (*Giardia, Tritrichomonas,* canine whipworms), infectious *(Campylobacter, Salmonella, Histoplasma)* and other causes of chronic intestinal inflammation.
- The differential diagnosis of lymphocytic-plasmacytic IBD includes dietary hypersensitivity, small intestinal bacterial overgrowth, intestinal lymphoma, intestinal lymphangiectasia, and the other histologic types of chronic IBD.

Laboratory Findings

- Routine hematologic and biochemical parameters typically are unremarkable except for occasional nonspecific findings such as a stress leukogram, hypoproteinemia, hypokalemia, and mildly elevated serum liver enzymes. Basenji enteropathy is associated with hypoalbuminemia and hyperglobulinemia, whereas affected soft-coated wheaten terriers may have hypoalbuminemia with concurrent protein-losing glomerulonephropathy. Cats with IBD may have concurrent cholangitis, pancreatitis, or both.
- Serum vitamin levels (cobalamin, folate, vitamin K) can be decreased from malabsorption. Bleeding and abnormal hemostasis have been associated with vitamin K deficiency in some cats with IBD. Markedly

decreased serum cobalamin is common, especially in cats and Shar-Peis with IBD.

Radiography and Ultrasonography

In most cases, radiographic and ultrasonographic findings are unremarkable and do not aid diagnosis. Some animals have a nonspecific finding of fluid- and gas-distended bowel loops on plain abdominal radiography. Barium contrast radiography occasionally demonstrates diffuse mucosal irregularity and ultrasonography may reveal intestinal thickening, but these are nonspecific findings that merely suggest an infiltrative lesion. In selected cases, contrast radiography and ultrasonography can be helpful nonetheless, because they may discover an unexpected diagnosis other than IBD—for example, pancreatitis, hepatobiliary disease, or intestinal tumors, polyps, granulomas, or malformations (e.g., diverticulum or short colon).

Endoscopic Examination

In animals with GI disease, the spectrum of clinical signs usually suggests the most appropriate region of the GI tract for endoscopic examination. In IBD, however, signs do not always correlate with the region of greatest cellular infiltration, especially in cats. It is not uncommon to find significant involvement of the colon in cats that present with vomiting. Conversely, cats with hematochezia or other colonic signs may have unexpected gastroduodenal lesions. Therefore, it may be advisable in many cases to obtain biopsies from the stomach, duodenum, jejunum (if possible), colon, and ileum (if the ileocolic sphincter can be navigated during colonoscopy).

Endoscopically, the mucosa in IBD may appear to be normal or it may have any of the following abnormalities: erythema, petechiae, increased mucus, increased friability, increased surface granularity, decreased visibility of the colonic submucosal vessels, thickened or increased folds, erosions or ulcers, or decreased distensibility. The mucosal lesions may only be apparent microscopically; thus, a normal endoscopic appearance does not rule out IBD and multiple biopsies should be taken even if there are no endoscopically visible abnormalities.

Mucosal Histopathology

The histopathologic lesion of lymphocytic-plasmacytic IBD is characterized by diffuse infiltration of the lamina propria with mature lymphocytes and plasma cells in association with mucosal damage. For definitive diagnosis of lymphocytic-plasmacytic IBD, there must be abnormal infiltration of lymphocytes and plasma cells, as well as evidence of mucosal damage.

- Pathologists may differ in their interpretation of endoscopic biopsies and in their definition of how many lymphocytes and plasma cells within the lamina propria are too many. Infiltrates assessed to be minimal or mild by an inexperienced pathologist may not be truly abnormal. Various grading systems have been proposed, but these have not correlated well with clinical disease activity.
- In some cases the inflammation is mostly lymphocytic; in others the infiltrate also contains a mixture of other types of inflammatory cells (neutrophils, eosinophils, macrophages). The cellular infiltrate is usually confined to the mucosa but occasionally may extend to the submucosa.
- Additional findings indicative of mucosal damage include architectural distortion (e.g., atrophic or fused villi), fibrosis, and epithelial abnormalities (hyperplasia, degeneration, necrosis, erosion, ulceration, glandular dilation, loss of goblet cells).
- A severe infiltration of lymphocytes that extends beyond the mucosa into the submucosa and muscularis should raise the suspicion of early lymphoma mimicking IBD, and further diagnostics should be recommended.

Evaluation for Dietary Hypersensitivity

Dietary hypersensitivity or food allergy is an immunologically mediated adverse reaction to a protein component in food. A well-controlled dietary trial using a protein elimination diet is the basis for diagnosis of dietary hypersensitivity as a cause of IBD (for additional information on diagnostic food trials, see Chapter 47). The diet is changed to a well-defined, additive-free, highly digestible diet that contains a single source of protein not found in the animal's normal diet. Intake of all other foods or sources of antigen must be eliminated throughout the feeding trial, including table scraps, treats, and flavored medications such as vitamin supplements. The goal is to feed a single protein source to which the animal is not yet sensitized. Although many commercial hypoallergenic diets are available (see the next section), home-prepared single-protein diets are preferred for diagnostic testing purposes. Examples of novel protein sources not likely found in the animal's regular diet might include turkey, duck, lamb, rabbit, venison, fish, or soybeans (tofu). Once dietary hypersensitivity is confirmed with a home-prepared diet, commercial hypoallergenic diets can be substituted for more convenient long-term management.

A cooperative and patient owner is required for a successful elimination diet trial. A minimum of 3 to 4 weeks should be allowed for initial response to an elimination diet. If no improvement has occurred during this time, then dietary hypersensitivity is unlikely and medical therapy should be instituted. If some improvement has been observed, then the trial should continue as it may require 6 weeks or more before improvement is complete.

If there is a substantial improvement with the elimination diet, then the animal can be rechallenged with

its original diet. Recurrence of clinical signs confirms dietary intolerance or hypersensitivity. In addition, once remission is restored with the controlled diet, the animal can then be challenged sequentially with individual dietary components to identify the specific offenders. To do this, individual components of the original diet are added one at a time to the controlled diet while the animal is in remission. With each challenge the animal is monitored for recurrence of signs for 7 to 10 days. If signs recur, then that substance is implicated as an offender.

After several weeks to months of remission on the controlled diet, some animals can be returned to their original diet and remain asymptomatic, but in most cases, specially formulated or novel protein diets may need to be continued indefinitely to prevent relapse. If there is no response to dietary management within 4 to 6 weeks, the animal can be fed a digestible commercial GI diet or returned to its original diet and medical therapy can be instituted.

Treatment

Well-controlled therapeutic trials for chronic IBD in animals are lacking; thus, treatment is largely empirical and based on clinical experience. Because dietary hypersensitivity, parasites (see previous section), and bacterial enteropathogens (see previous section) may cause lymphocytic-plasmacytic IBD, it is appropriate to first consider evaluation and treatment for these possibilities.

In most cases of lymphocytic-plasmacytic IBD, an underlying cause cannot be identified and the most effective treatment is an anti-inflammatory regimen of either corticosteroids or mesalamine (5-ASA derivative) combined with dietary modification (e.g., novel protein diet, hydrolyzed diet, or fiber-enriched diet). If diet and anti-inflammatory drugs fail to control the disease, metronidazole is added for its antibacterial and immunomodulatory properties. Metronidazole can also be used as a single drug to induce or maintain remission in less severe cases. For refractory cases, a cytotoxic immunosuppressive agent such as azathioprine or chlorambucil can be added to the corticosteroid regimen. Cyclosporine may also be beneficial in steroid-refractory cases. Various drugs used to treat IBD and their suggested dosages are indicated in Table 69-7.

Dietary Therapy

Various strategies for dietary modification have been used for treatment of chronic IBD, including novel protein diets, hydrolyzed diets, fiber-enriched diets, diets with adjusted omega-6 and omega-3 fatty acid levels and diets with prebiotics and probiotics. In some animals with IBD, dietary modification produces complete or partial resolution of the signs and sometimes regression of the lesions. Potential explanations for a beneficial response to dietary modification include the effects of the diet on bowel motility, composition of the microflora, mucosal morphology and function, and exposure to food-borne antigens or additives.

- The treatment of IBD associated with dietary hypersensitivity is based on the controlled feeding of a well-defined, additive-free, highly digestible diet that contains a single source of protein not found in the animal's normal diet (i.e., a novel protein to which the animal is not yet sensitized). Home-prepared diets (turkey, duck, lamb, rabbit, venison, white fish, or tofu) are most suitable for diagnostic testing purposes (see previous "Diagnosis" section); however, if the home-prepared diet suggests diet-responsive disease, then a commercial "hypoallergenic" novel protein diet can be substituted and is more convenient and balanced for long-term feeding. Many commercial diets that contain novel protein sources are now marketed for dietary hypersensitivity. A relapse rate of approximately 15% to 20% is to be expected when switching from a home-prepared to a commercial hypoallergenic diet. For long-term feeding of a home-prepared diet, recipes for balanced diets containing novel protein sources can found in veterinary nutrition text books or various reliable websites under supervision of Diplomates of the American College of Veterinary Nutrition.
- An alternative approach is to use a diet containing hydrolyzed proteins (oligopeptides) that may be less antigenic (e.g., Prescription Diet z/d, Hills; or HA Diet, Purina).
- In cases in which hypoallergenic novel protein diets have not been effective, other dietary adjustments may be beneficial as an adjunct to medical therapy for IBD. This includes fiber supplementation (psyllium, bran, canned pumpkin) of the regular diet or switching to a commercial diet enriched with fermentable fiber (e.g., beet pulp) marketed for improving colonic function and ameliorating diarrhea in animals with colitis. Fiber has many beneficial effects on colonic function and helps keep enteropathogens in check. Colonic bacteria metabolize fermentable fiber to short-chain fatty acids that nourish colonic epithelium and protect against mucosal injury.
- Modification of the intestinal bacterial flora is the aim of probiotics (orally administered live bacterial cultures such as *Lactobacillus*) and prebiotics (beneficial dietary carbohydrate substrates such as lactulose and fructo-oligo-saccharides).
- Adjustment of the levels of omega-6 and omega-3 fatty acids in the diet has been proposed to manage bowel inflammation through decreasing inflammatory mediators, although evidence for this is lacking.

Cobalamin Therapy

Cobalamin (vitamin B_{12}) is frequently depleted in patients with chronic IBD, especially cats, and cobalamin deficiency can impair intestinal mucosal

Table 69-7. TREATMENT OF INFLAMMATORY BOWEL DISEASE

Drug	Product (Manufacturer)	Preparations	Dosage
Anti-inflammatory Drugs/Immunosuppressives			
Prednisone*	Many	Tab: 5, 10, 20, 50 mg	Dog: 1–2 mg/kg PO q24h Cat: 2–3 mg/kg PO q24h
Budesonide	Entocort (AstraZeneca)	Cap: 3 mg	Dog: 1–3 mg PO q24h Cat: 1 mg PO q24h
Methylprednisolone acetate	Depo-Medrol (Upjohn)	Inj: 40 mg/ml	Cat: 20 mg IM q2–4wk
Azathioprine†	Imuran; Azasan (Salix)	Tab: 25, 50, 75 mg	Dog: 1–2 mg/kg PO q24–48h Cat: 0.3–0.5 mg/kg PO q24–48h
Chlorambucil	Leukeran (Glaxo)	Tab: 2 mg	0.1–0.2 mg/kg PO q24–48h, or 2–3 mg/m^2 PO q24–48h, or 15–20 mg/m^2 PO once every 3 weeks (cats)
Cyclosporine	Atopica (Novartis)	Cap: 10, 25, 50, 100 mg	5 mg/kg PO q24h
Colonic Anti-inflammatory Drugs			
Sulfasalazine‡	Generic	Tab: 500 mg	Dog: 10–30 mg/kg PO q8–12h Cat: 10–20 mg/kg PO q12–24h
Olsalazine	Dipentum (Celltech)	Cap: 250 mg	Dog: 10–20 mg/kg PO q12h
Mesalamine	Asacol (Procter & Gamble)	Tab: 400 mg	Dog: 10–20 mg/kg PO q8–12h
	Pentasa (Shire)	Tab: 250 mg	
Anti-inflammatory Retention Enemas§			
5-Aminosalicylate	Rowasa (Solvay)	Enema: 4 g/60 ml	To be determined
Hydrocortisone	Cortenema (Reid-Rowell)	Enema: 100 mg/60 ml	20–60 ml rectally q24h
Antibiotics			
Metronidazole	Flagyl (Searle) or generic	Tab: 250 mg, 500 mg	10–20 mg/kg PO q8–12h
Tylosin tartrate¶	Tylan Soluble (Elanco)	Powder: 2270 mg/tsp	Dog: 20–40 mg/kg PO q12h Cat: 10–20 mg/kg PO q12h
Opioid Motility/Secretory Modifier			
Loperamide	Imodium AD	Tab: 2 mg Liq: 0.2 mg/ml	Dog: 0.1–0.2 mg/kg PO q8–12h Cat: 0.1–0.3 mg/kg PO q12–24h
Adjunct Therapy			
Cobalamin	Generic	Inj: 1000 µg/ml	Dog: 250–1000 µg weekly Cat: 250 µg weekly
Psyllium	Metamucil (Procter & Gamble)	Powder	Dog: 1–3 tbsp/day with food Cat: 1–3 tsp/day with food

*In some cats with severe colitis, prednisone dosage may need to be increased to 5 mg/kg/day, divided bid. In dogs, if steroidal side effects become a problem, decrease dosage and combine with azathioprine, metronidazole, or both.
†May cause myelotoxicity, so monitor the complete blood count; formulate as an oral suspension for accurate dosing of cats.
‡Dosage may need to be increased to 25–50 mg/kg q8h to achieve effect in some dogs; may cause keratoconjunctivitis sicca in dogs and salicylate toxicosis in cats.
§Retention enemas for topical therapy of the distal colon may relieve signs of tenesmus and urgency in some animals with proctitis.
¶Tylan Soluble can be mixed with dextrose or cornstarch. Tylosin powder is bitter-tasting and thus best tolerated when mixed with food.
Cap, capsules; Inj, injectable; Liq, elixir, suspension, or drops; Tab, tablets.

regeneration and cause mucosal atrophy, exacerbating diarrhea and making the patient refractory to the usual anti-inflammatory therapy. Thus, evaluate serum cobalamin and treat with parenteral cobalamin (1000 µg/ml) when serum levels are decreased, especially if <100 ng/L. Give injections weekly for at least 6 weeks, then every other week for 6 weeks, and then monthly.

- For cats and small dogs: Give 250 µg SC, weekly
- For medium dogs: Give 500 µg SC, weekly
- For large dogs: Give up to 1000 µg SC, weekly

Corticosteroids

Oral prednisone or prednisolone is the most consistently effective medical therapy (1–2 mg/kg/day for dogs and 2–4 mg/kg/day or a 5-mg total dose q12h for cats) for initial treatment of lymphocytic-plasmacytic IBD. Clinical improvement using this dosage should be noted within 1 to 2 weeks. After 2 weeks of remission, the dosage is tapered in 2- to 4-week increments to the lowest effective alternate-day dosage.

- In some cases dexamethasone seems to be more effective than prednisolone with fewer side effects.
- In cats that are too difficult to medicate orally, periodic injections of methylprednisolone acetate (20 mg IM or SC q2–4wk) may be substituted for oral treatment.
- Budesonide (0.5–1-mg total dose/cat and 0.5–3-mg total dose/dog, PO q24–48h) is an alternative corticosteroid for refractory cases. Budesonide has high

receptor-binding affinity in the mucosa and undergoes extensive first-pass metabolism in the liver. It achieves particularly high mucosal anti-inflammatory activity with less systemic side effects. It may be cost prohibitive for some owners.
- Corticosteroid therapy may be discontinued on a trial basis after 6 to 12 weeks of remission; however, continuous alternate-day therapy is often required to prevent relapse.
- In refractory cases, metronidazole or mesalamine (see the next sections) should be added to the prednisolone regimen. If this fails to control the disease, then the combination of azathioprine in dogs or chlorambucil in cats (see a later section) with prednisolone may be more effective for achieving remission of the disease.

5-Aminosalicylic Acid (Mesalamine)

These drugs exert an anti-inflammatory effect targeted at the colon through local inhibition of mucosal leukotrienes and prostaglandins. In dogs with IBD, 5-ASA drugs are the initial drugs of choice when the colon alone is involved. Orally administered 5-ASA derivatives are designed to be minimally absorbed during passage through the small intestine so that they reach the colon. These drugs should be used cautiously in cats as some salicylate absorption occurs and cats metabolize salicylates very slowly.

Sulfasalazine

In this drug, 5-ASA is combined with sulfapyridine by an azo bond that prevents significant absorption of the drug so that 75% of it reaches the colon, where bacteria split the bond and release the 5-ASA for its local effect in the colon (see Table 69-7 for dosages).

- The most common adverse side effect of sulfasalazine is keratoconjunctivitis sicca. When it occurs, the decline in tear production is often irreversible. For this reason, it is recommended that a baseline Schirmer tear test be performed at the start of therapy and monitored subsequently at monthly intervals if treatment is long term.
- Less common side effects include allergic dermatitis, nausea and vomiting, and cholestatic jaundice. Rarely, cats may develop anemia.
- Because up to 30% of the salicylate is absorbed and cats metabolize salicylates very slowly, use caution when treating cats with this drug to avoid salicylate toxicity.

Olsalazine (Dipentum)

This newer derivative, consisting of two molecules of azo-bonded 5-ASA, is poorly absorbed so that more than 90% reaches the colon, where the two 5-ASA molecules are then released by the action of colonic bacteria on the azo bond (see Table 69-7 for dosages).

- The advantages of olsalazine over sulfasalazine are that olsalazine contains only 5-ASA (without sulfa) so that side effects are fewer and that a greater percentage of the drug reaches the colon.
- Unfortunately, olsalazine is currently available only in 250-mg capsules, an inconvenient size for dosing most animals.

Polymer-Coated Mesalamine (Asacol)

A pH-sensitive coating prevents release of 5-ASA until the drug reaches the site of inflammation in the colon.

Pentasa

Encapsulation prevents release of 5-ASA until the drug reaches the site of inflammation in the colon.

Mesalamine Suspension Enema

This form of 5-ASA (Rowasa, Reid-Rowell) is available for direct instillation into the rectum. In animals, enema administration of 5-ASA is probably not as effective as the oral route except when proctitis is the principal manifestation.

Metronidazole and Other Antibiotics

Low-dose metronidazole therapy (Flagyl at a dosage of 10–20 mg/kg q12h) is often beneficial either alone or in combination with prednisolone to treat IBD.

- The beneficial effects of metronidazole in any animal with diarrhea might be attributable to an antibacterial effect on enteropathogens (e.g., enterotoxigenic *C. perfringens*), an antiprotozoal effect (e.g., *Giardia*), a reduction of bacterial-derived antigens that could be involved in the immunopathogenesis of IBD, or the immunomodulating effect of the drug on cell-mediated immunity and neutrophil chemotaxis.
- Metronidazole tablets have an unpleasant taste and provoke salivation in most cats and sometimes vomiting. For ease of administration and accurate dosing, a liquid suspension can be formulated on request by many pharmacists or the tablets can be split and placed in gel capsules.
- Dosages of metronidazole exceeding 50 mg/kg/day for prolonged periods (weeks) occasionally cause signs of reversible CNS toxicity (ataxia, weakness, seizures).
- Other antibiotics that might be helpful to control intestinal microflora include tylosin (Tylan) or doxycycline (see Table 69-7).

Azathioprine and Chlorambucil

- In IBD patients refractory to 5-ASA drugs, prednisone, and metronidazole, the combination of azathioprine (Imuran) or chlorambucil (Leukeran) with prednisone may be a more effective immunosuppressive regimen for producing remission of the

disease (see Table 69-7). Besides treating refractory IBD, the addition of azathioprine enables use of a lower dose of corticosteroid to control the disease and thereby minimizes steroidal side effects.

- Azathioprine usually is given as a daily treatment until remission occurs and then decreased to an alternate-day treatment (alternating with every-other-day prednisone) for maintenance. Because of its myelosuppressive toxicity (leukopenia), periodically monitor the CBC of azathioprine-treated animals, especially in the first 2 months, and use lower dosages in cats (see Table 69-7). In cats, formulate azathioprine as an oral suspension to facilitate accurate and safe dosing.
- Chlorambucil (0.1–0.2 mg/kg PO, or 2.0 mg/m^2 PO, q24–48h; alternatively, 15–20 mg/m^2 PO, once every 3 weeks) is an effective alternative to azathioprine that is well tolerated by most cats.

Cyclosporine

Cyclosporine (Atopica, Novartis) (5 mg/kg PO q24h) is useful for treating corticosteroid-refractory IBD. Cyclosporine is a potent immunosuppressive drug that inhibits interleukin-2 and T cell recruitment. Transient anorexia and vomiting are common side effects at the start of treatment but these resolve within 2 weeks.

Motility-Modifying Antidiarrheal Drugs

Adjunctive use of motility-modifying drugs may provide some symptomatic relief for animals with IBD (see Table 69-5 for dosages).

- Opioid drugs such as loperamide (Imodium) and diphenoxylate (Lomotil) may aid control of diarrhea by acting on intestinal smooth muscle to inhibit propulsive movements and by inhibiting mucosal efflux of water and electrolytes.
- Anticholinergic antispasmodics such as dicyclomine (Bentyl) may be beneficial in colitis patients with severe tenesmus and urgency associated with rectocolonic spasm.

Prognosis

- Monitor clinical response using a canine IBD activity index and sequential evaluation of C-reactive protein as a serum marker of inflammation.
- Inform the owner that persistence or recurrence of IBD is likely despite therapy; thus, a realistic expectation is the maintenance of remission or control of relapses rather than a permanent cure.
- The clinical course in basenjis, soft-coated wheaten terriers, and Shar-Peis is often progressive despite treatment.

Eosinophilic Gastroenteritis

Eosinophilic gastroenteritis (EGE) is a relatively uncommon form of IBD that is characterized by diffuse or segmental infiltration of some portion of the GI tract with mature eosinophils, often accompanied by a peripheral eosinophilia.

Etiology

Food allergy and parasitism (e.g., visceral larva migrans) have been proposed as causes, but in most patients evidence for these is lacking and the disease must be considered idiopathic.

Clinical Signs

- One or more layers of the stomach, small intestine, or colon may be affected, resulting in clinical syndromes of chronic vomiting (eosinophilic gastritis) (see Chapter 67), chronic small bowel-type diarrhea (eosinophilic enteritis), chronic large bowel-type diarrhea (eosinophilic colitis), or any combination of these. Weight loss is frequent.
- Diffuse infiltration of the intestinal tract with eosinophils may result in malabsorption (watery diarrhea and weight loss) or protein-losing enteropathy.
- Diarrhea or vomitus may contain blood from mucosal erosions or ulcers.
- Eosinophilic granulomas of the deeper layers of the bowel wall occasionally produce segmental tumor-like thickenings that can cause partial intestinal obstruction.

Diagnosis

- The history may indicate dramatic responsiveness to prior glucocorticoid therapy.
- Palpation may reveal diffusely thickened intestinal loops or a tumor-like intestinal mass (eosinophilic granuloma).
- Laboratory evaluation may reveal peripheral eosinophilia (although not present in all cases), hypoproteinemia, or impaired absorptive function tests.
- Routine fecal flotation is indicated because parasitism can also cause eosinophilic inflammation; it is important to exclude occult whipworm or hookworm infection in dogs by response to a therapeutic trial of an anthelmintic such as fenbendazole (see Table 69-6).
- Barium GI radiography and abdominal ultrasonography may be normal, may indicate thickening and irregularity (mucosal filling defects) of bowel loops, or may delineate sites of partial luminal obstruction caused by eosinophilic granulomas.
- The diagnosis is based on demonstration of eosinophilic inflammation in intestinal biopsies. The endoscopic appearance is similar to that described for lymphocytic-plasmacytic IBD except that mucosal ulceration is more common in EGE. Occasionally, lesions are deep in the submucosa and found only by full-thickness biopsy.

Treatment

- Consider a trial of fenbendazole (Panacur), given at 50 mg/kg daily for 3 days, to rule out GI parasitism.
- Because food allergy is a potential cause of EGE in some animals, a feeding trial using an elimination or novel protein diet (as described for lymphocytic-plasmacytic IBD) can be considered initially; however, dietary therapy alone is seldom effective.
- Oral prednisone usually is the most effective treatment for EGE at an initial dosage of 1 to 2 mg/kg/day for dogs and 2 to 3 mg/kg/day for cats. Clinical signs typically improve rapidly, especially when infiltration is limited to the mucosa. When remission has been maintained for 2 weeks, gradually taper the dosage over an additional 2 to 4 weeks to the lowest effective maintenance dose.
- In some animals the treatment can eventually be discontinued, but in others alternate-day maintenance therapy is required.
- In some patients it may be necessary to add azathioprine to the corticosteroid regimen (as described for lymphocytic-plasmacytic IBD) to facilitate reduction of corticosteroid dosage and side effects or to provide more effective control of the disease.
- Obstructing transmural eosinophilic granulomas involving a localized segment of bowel wall occasionally require surgical excision followed by corticosteroid therapy.

Feline Hypereosinophilic Syndrome

Feline hypereosinophilic syndrome, a rare disease of cats, is characterized by severe eosinophilic GI infiltration accompanied by widespread infiltration of various other organs (liver, spleen, lymph nodes, bone marrow, lung, pancreas, adrenals, skin).

Etiology

The aggressive course and high mortality associated with this syndrome are consistent with malignant neoplasia involving eosinophils (see Chapter 22); thus, it is very distinct from the benign EGE that is confined to the GI tract.

Clinical Signs

- Vomiting, diarrhea (sometimes bloody), anorexia, and weight loss are the most consistent clinical signs.
- Clinical deterioration is rapidly progressive and the disease is eventually fatal.

Diagnosis

- Abdominal palpation may reveal intestinal thickening, hepatosplenomegaly, or mesenteric lymphadenopathy because of the disseminated visceral infiltration of eosinophils.
- Persistent, severe eosinophilia is a consistent CBC finding in affected cats.
- The diagnosis depends on histopathologic confirmation of tissue infiltration and effacement by eosinophils in biopsies of affected organs.

Treatment

- Use high-dose prednisolone (4–6 mg/kg/day for 2–4 weeks) to induce remission, followed by half this dose for 2 to 4 weeks and then by 1 to 2 mg/kg daily or on alternate days for maintenance. Add chlorambucil (see Table 69-7) or other cancer chemotherapeutics in refractory patients.

Prognosis

Unlike EGE confined to the GI tract, feline hypereosinophilic syndrome has a poor prognosis despite treatment.

Regional Granulomatous Enterocolitis

Regional granulomatous enterocolitis (RGE) is an uncommon form of IBD characterized by transmural granulomatous inflammation that results in a stenosing, mass-like thickening of a region of the bowel wall. The ileocolic junction is most often involved, and the mass may incorporate adjacent lymph nodes and mesentery. In some dogs the granulomatous lesions also contain numerous eosinophils (eosinophilic granuloma).

Clinical Signs

The principal clinical sign of RGE is chronic large bowel diarrhea containing mucus and fresh blood, sometimes accompanied by tenesmus and abdominal pain. Additional signs may include weight loss, anorexia, and depression.

Diagnosis

- The diseased segment of bowel may be palpable as a firm mass in the mid-abdomen. The adjacent intestinal loops and mesentery may also be thickened and regional lymph nodes may be enlarged.
- A routine CBC may reveal eosinophilia, neutrophilia, or monocytosis. Panhypoproteinemia due to excessive enteric loss of protein may be found in some animals.
- Barium contrast radiography of the ileum and colon may delineate a thickened or stenosed segment of bowel and ultrasonography may identify an intestinal mass.
- Definitive diagnosis of RGE requires biopsy by colonoscopy or laparotomy. The key feature is transmural granulomatous inflammation. Fibrosis and aggregates of epithelioid cells, giant cells, and eosinophils often are found deep in the lesion. Deep ulceration is common.
- Differentiate RGE from intestinal neoplasia and infectious causes of granulomatous bowel lesions,

such as histoplasmosis (Chapter 20), pythiosis, and mycobacteriosis (Chapter 19). Examine granulomatous lesions by special stains to detect fungi and acid-fast organisms. In cats, feline immunodeficiency virus (Chapter 9) and feline infectious peritonitis (Chapter 10) occasionally are associated with pyogranulomatous IBD.

Treatment

- Medical treatment of regional granulomatous colitis is based on the use of anti-inflammatory and immunosuppressive agents such as olsalazine or sulfasalazine, prednisone, azathioprine, and metronidazole, as described for treatment of lymphocytic-plasmacytic IBD (see Table 69-7).
- If the degree of thickening and cicatrization of the affected segment of bowel produces severe stenosis and obliteration of the lumen, surgical excision of the lesion may be necessary, followed by medical therapy for 6 to 8 weeks or longer to prevent recurrence of the lesion at the surgical site. Always submit the excised lesion for histopathological evaluation.

Histiocytic Ulcerative Colitis

- Histiocytic ulcerative colitis is a chronic idiopathic IBD of young boxer dogs characterized by infiltration of the lamina propria and submucosa of the colon by distinctive histiocytes engorged with deposits that stain positive with periodic acid-Schiff (PAS) stain.
- In addition to boxers, there have been isolated case reports of histiocytic colitis in a cat and a French bulldog, but it is not known if this is the same disease that occurs in boxers.

Clinical Signs

- Affected boxers generally develop severe, unresponsive, bloody-mucoid large bowel diarrhea before 2 years of age.
- Severe weight loss and debilitation occur in dogs with long-standing disease.

Diagnosis

The diagnosis is based on the known breed predisposition and the presence of numerous PAS–positive histiocytes in a colonoscopic biopsy. A mixture of other types of inflammatory cells is also found in the lesion, and usually there is severe mucosal ulceration.

Treatment

- The treatment of choice is enrofloxacin (Baytril at 5 mg/kg PO q12h) alone or in combination with metronidazole, based on evidence that bacteria play a pivotal role in this disease. The optimal duration of therapy is not known, but clinical signs are resolved in most dogs within 3 to 4 weeks of starting enrofloxacin, and recovery has persisted more than 3 years after stopping the antibiotic.
- Anti-inflammatory and immunosuppressive therapy (e.g., olsalazine or sulfasalazine, prednisone, azathioprine, and metronidazole) in single-agent or combination regimens, as described for lymphocytic-plasmacytic colitis, generally only provides temporary palliation of the disease.
- In general, these dogs seem to have less diarrhea on a highly digestible diet than on a high-fiber diet.

Neutrophilic (Suppurative) Enterocolitis

Etiology

- Bacterial enterocolitis (see under "Bacterial Infections of the Intestines")
- Idiopathic (i.e., neutrophilic IBD in the absence of an identifiable infectious cause)

Clinical Signs

- Large bowel diarrhea that can be either acute or chronic.

Diagnosis

- Colonoscopic biopsy shows infiltration of predominantly neutrophils, with variable mucosal ulceration, necrosis, or crypt abscesses.
- Diagnosis is based on tests to exclude bacterial enteropathogens (see under "Bacterial Infections of the Intestines").

Treatment

Give antibiotics (e.g., enrofloxacin, trimethoprim-sulfa, or tylosin) or regimens consisting of sulfasalazine, metronidazole, or anti-inflammatory or immunosuppressive drugs, as described for lymphocytic-plasmacytic IBD (see Table 69-7).

FIBER RESPONSIVE DIARRHEA (IRRITABLE BOWEL SYNDROME)

Etiology

Fiber-responsive diarrhea is characterized by chronic, non-inflammatory, mucoid large bowel diarrhea. The condition has resemblances to irritable bowel syndrome (IBS) seen in people.

Clinical Signs

- Signs associated with myoelectrical dysfunction in humans with IBS are alternating patterns of diarrhea, constipation, and abdominal cramping.
- Evidence for the existence of IBS in animals is circumstantial, but psychomotor diarrhea due to colonic motility dysfunction or neurogenic hyperre-

activity may be a consideration in animals that have intermittent mucoid diarrhea but lack evidence of organic disease.
- Hematochezia is usually absent.
- Large breeds, especially those used as working dogs (e.g., police dogs, Seeing Eye dogs, and sled dogs), and temperamental or excitable dogs seem to be predisposed.

Diagnosis

The diagnosis is based on the complete absence of abnormal findings on diagnostic evaluation, minimal abnormalities on colonoscopic biopsy, and remission of clinical signs in response to modification of diet, particularly supplementation of fiber.

- By definition, IBS is a functional disorder. The diagnosis can be established only by normal colonoscopic biopsy and diligent exclusion of the other known causes of colonic disease, such as dietary, parasitic, infectious, and chronic colitis (IBD).
- At colonoscopy, the colon may appear to be hypermotile or spastic. The mucosa appears normal except for increased intraluminal mucus and an erythematous response to insufflation.

Treatment

Dietary Modification

Supplement a digestible GI diet with added dietary fiber in the form of psyllium (Metamucil) (1–5 tbsp/meal). This is sufficient to produce remission in many cases. Fiber may normalize colonic myoelectrical function and have beneficial effects on fecal consistency, water content, and bulk. In addition, fermentable soluble fiber is fermented by colonic bacteria to short-chain fatty acids that provide an energy source for colonic epithelium, protect against mucosal injury, and acidify bowel contents, which may alter the bacterial flora.

Medical Therapy

- If dietary fiber supplementation is unsuccessful, consider medication to alter motility such as opioid drugs such as loperamide (see Table 69-5 for dosages).
- Consider amitriptylin (Elavil) at 1 to 2 mg/kg PO q12h.
- Light sedation during stressful times may be beneficial in excessively nervous or excitable animals.

PROTEIN-LOSING ENTEROPATHY

GI loss accounts for approximately 40% of the normal daily turnover of plasma proteins. The term *protein-losing enteropathy* refers to a variety of intestinal diseases that are associated with hypoproteinemia caused by an accelerated loss of plasma proteins into the gut. Mechanisms of excessive enteric loss of protein include the following:

- Impaired intestinal lymphatic drainage (e.g., lymphangiectasia) that results in extravasation of protein-rich lymph into the lumen
- Disruption of the mucosal barrier (e.g., inflammation) that results in protein leakage from sites of exudation, bleeding, or increased permeability

Etiology

Severe protein-losing enteropathy occurs most frequently in association with chronic enteropathies, such as the following:

- Idiopathic canine intestinal lymphangiectasia
- Chronic inflammatory small bowel diseases (lymphocytic-plasmacytic enteritis, granulomatous enteritis, eosinophilic enteritis, immunoproliferative enteropathy of basenjis)
- Intestinal histoplasmosis
- Intestinal lymphoma

Intestinal Lymphangiectasia

Lymphangiectasia is a chronic protein-losing enteropathy in dogs, characterized by marked dilation and dysfunction of the intestinal lymphatic network. Impaired intestinal lymph drainage is presumably caused by obstruction to the normal lymphaticovenous flow. It leads to stasis of chyle within dilated lacteals and lymphatics of the bowel wall and mesentery. Overdistended lacteals release intestinal lymph into the gut lumen by rupture or extravasation, causing loss of the constituents of chyle, including plasma proteins, lymphocytes, and lipid (chylomicrons).

Clinical Signs

- The presenting signs of lymphangiectasia usually are attributable to protein-losing enteropathy and include dependent pitting edema of subcutis and limbs, fluid distention of the abdomen (ascites), and respiratory distress (hydrothorax). These manifestations of fluid transudation are the result of hypoalbuminemia and reduced plasma colloidal osmotic pressure.
- Chronic intermittent or persistent diarrhea with a watery or semisolid consistency often is observed, but not all patients have diarrhea.
- Progressive weight loss is common. Clinical signs often develop insidiously.

Diagnosis

▼ ***Key Point*** Typical laboratory findings in intestinal lymphangiectasia include hypoalbuminemia, hypoglobulinemia, lymphocytopenia, hypocholesterolemia, and hypocalcemia.

- Differentiate protein-losing enteropathy from non-enteric causes of hypoproteinemia, such as liver failure (impaired hepatic synthesis of albumin) and renal disease (protein-losing glomerulonephropathy), through liver function testing (Chapter 71) and urine protein determinations (Chapter 77), respectively.
- Radiography can detect or confirm ascites and pleural effusion.
- Fluid analysis of body cavity effusions may be helpful. The effusion associated with lymphangiectasia is usually a transudate. Chylous ascites and chylothorax are found occasionally.
- Cardiac evaluations can exclude right-sided congestive heart failure, which is a rare cause of lymphangiectasia.
- Definitive diagnosis of lymphangiectasia is based on identification of the characteristic lymphatic lesions in biopsies obtained via laparotomy, or less invasively by endoscopy. Laparotomy may reveal the mesentery and serosa to have a prominent, weblike network of distended, milky-white lymphatics along with small, yellow-white nodules and foamy granular deposits (lipogranulomas) adjacent to lymphatics.

Treatment

The major goal in treating intestinal lymphangiectasia is to decrease the enteric loss of plasma proteins so that normal plasma protein levels can be restored and edema and effusions can be controlled. This is accomplished with dietary manipulation and anti-inflammatory therapy as described under "Inflammatory Bowel Disease."

- The plasma protein loss and diarrhea of lymphangiectasia often benefit from anti-inflammatory doses of corticosteroids (prednisone at a dosage 2–3 mg/kg/day PO). When remission has been achieved, adjust the dosage to the lowest effective maintenance level. The addition of metronidazole and azathioprine is helpful in some cases (see Table 69-7).
- Because absorption of dietary long-chain triglycerides (LCTs) is a major stimulus of intestinal lymph flow, restriction of dietary intake of fat may reduce lymph flow, lymphatic distention, and protein loss in lymphangiectasia. Supplement diets with fat-soluble vitamins.

Prognosis

The prognosis and response to therapy is unpredictable. Many patients achieve remission of months to years with combined dietary and anti-inflammatory therapy. However, some animals fail to respond and many eventually relapse to finally succumb to severe protein-calorie depletion, incapacitating effusions, or intractable diarrhea.

VILLOUS ATROPHY

Etiology

Villous atrophy is a lesion of the small intestine characterized by short, blunted mucosal villi and is associated with intestinal malabsorption and chronic diarrhea. The forms of villous atrophy may be categorized as primary or secondary.

Primary Forms

- Gluten-sensitive enteropathy of Irish setters resembles gluten enteropathy of humans (celiac disease, non-tropical sprue). This is inherited as an autosomal recessive trait, mostly in Irish setters in Great Britain and is characterized by partial villous atrophy, deficiency or delayed development of specific microvillus enzymes, and dietary sensitivity to wheat.
- Idiopathic canine villous atrophy is recognized most often in German shepherds.

Secondary Forms

- Sequelae of diffuse infiltrative diseases of the intestines, such as chronic IBD and lymphoma
- Sequelae of enteric infections, such as viruses (coronavirus, rotavirus), bacteria (small intestinal bacterial overgrowth syndrome), and parasites *(Giardia)*

Clinical Signs

Villous atrophy generally causes chronic small bowel-type diarrhea and weight loss. The severity of signs depends on the degree of disruption of the villous absorptive surface area.

Diagnosis

Histologic examination usually is adequate for documentation of villous atrophy. However, because this can be a nonspecific secondary lesion found in various enteropathies, the diagnosis is mainly based on the following:

- Breed predilection (German shepherds, Irish setters in Great Britain)
- Response to withdrawal of wheat from the diet
- Tests or procedures to identify enteric infections (e.g., *Giardia*) or bacterial overgrowth
- Characterization of morphologic and biochemical abnormalities in jejunal biopsies

In some cases, infiltration of lymphocytes and plasma cells and fibrosis make it difficult to determine if the lesion should be categorized as a primary idiopathic villous atrophy or as chronic IBD (lymphocytic-plasmacytic enteritis) with secondary villous atrophy (see under "Lymphocytic-Plasmacytic Inflammatory Bowel Disease").

Treatment

Gluten-Sensitive Enteropathy

In gluten-sensitive Irish setters, the signs and lesions of villous atrophy promptly resolve with complete elimination of wheat and other gluten-containing cereal grains (barley and rye) from the diet. Most commercial dog foods contain gluten; however, diets that are based on rice or corn rather than wheat or gluten-containing grains are commercially available. Wheat restriction must continue for life, and breeding of affected animals is discouraged.

Idiopathic Villous Atrophy

- Dietary management with a gluten-restricted hypoallergenic diet (e.g., Hill's Prescription Diet d/d) is sometimes beneficial.
- Vitamin therapy with folate (5 mg daily PO) and cobalamin (250–1000 µg SC weekly for 6 weeks, then every 2–4 weeks, for 6 months) is indicated if serum levels of these are low.
- Antibiotic therapy is sometimes beneficial, using antibiotics such as oxytetracycline, tylosin, or metronidazole to empirically treat bacterial overgrowth (see under "Small Intestinal Bacterial Overgrowth").
- Prednisone as used for treatment of IBD (1–3 mg/kg/day PO for 4 weeks, followed by tapering to lowest effective alternate-day dosage) may produce clinical improvement in dogs with idiopathic villous atrophy that fail to respond to dietary modification, vitamins, or antibiotics.

Prognosis

The prognosis is guarded, as diarrhea and weight loss often persist despite treatment.

SMALL INTESTINAL BACTERIAL OVERGROWTH

Bacterial overgrowth syndrome is an overproliferation of microflora within the proximal small intestine that results in malabsorption and diarrhea. Human criteria that define bacterial overgrowth as a fasting bacterial count in duodenal juice of greater than 10^5 organisms per milliliter of intestinal contents do not appear to be valid in dogs and cats; thus, definitive evidence of this syndrome in animals is lacking. For this reason, some veterinary gastroenterologists prefer to call this syndrome *antibiotic-responsive diarrhea.*

Etiology

The normal small intestinal microflora is a stable population of aerobic and facultative anaerobic bacteria whose growth is regulated and influenced by a combination of host factors, bacterial interactions, and dietary composition. Mechanical self-cleansing action of normal intestinal motility and continuous downstream flow of ingesta are especially important for preventing bacterial overgrowth.

Because documentation of bacterial overgrowth is difficult, the syndrome may occur more frequently in dogs and cats than is generally recognized. Development of an abnormal small bowel flora should be considered a potential secondary complication in the following situations:

- Intestinal surgery
- Stasis-producing mechanical obstructions such as chronic intestinal foreign bodies and stenosing neoplastic or inflammatory lesions of the gut
- Destructive lesions of the ileocecocolonic junction that allow colono-enteric reflux
- Motility disorders such as idiopathic intestinal pseudo-obstruction
- Immune deficiency states with lack of immunoglobulin A (proposed as the explanation for an apparent breed predilection for overgrowth in German shepherds, basenjis, and Shar-Peis)
- Conditions associated with hyposecretion of gastric acid
- Exocrine pancreatic insufficiency

Clinical Signs

- Bacterial overgrowth typically causes chronic, foul-smelling watery diarrhea, steatorrhea, and weight loss; however, additional presenting clinical signs can depend somewhat on the underlying cause of the abnormal proliferation of flora.
- Diarrhea caused by overgrowth usually does not contain blood or mucus.
- Bacterial overgrowth may be responsible for failure of some dogs with exocrine pancreatic insufficiency to respond adequately to enzyme supplementation.

Diagnosis

Definitive diagnosis of small intestinal bacterial overgrowth requires quantitative aerobic and anaerobic cultures of duodenal juice. Duodenal culture specimens are taken by endoscopy, intestinal intubation, or laparotomy after an 18-hour fast. This is impractical for routine clinical application.

Indirect evidence of bacterial overgrowth in animals with unexplained small bowel diarrhea and malabsorption includes the following observations:

- Responsiveness to antibiotics (e.g., tetracyclines, tylosin, or metronidazole)
- Delayed intestinal transit of barium on radiographs (suggestive of obstruction or poor motility)
- Idiopathic pseudo-obstruction manifested by a dilated, hypomotile segment of gut
- Elevated serum folate and decreased serum cobalamin (because bacteria may synthesize folate and bind with or utilize cobalamin)

- Minimal morphologic abnormalities in intestinal biopsies
- Unlike many other enteropathies, mucosal morphology in bacterial overgrowth may be normal or characterized by mild atrophy of villi and minimal increase in mononuclear cells in the lamina propria
- Failure to obtain the expected treatment response in other intestinal disorders known to be conducive to bacterial overgrowth (such as exocrine pancreatic insufficiency)

Treatment

- Identify and treat underlying disorders or predisposing factors. In animals with stasis caused by anatomic abnormalities, this may include surgery.
- Antibiotic therapy:
  - Oral broad-spectrum antimicrobials and those with activity against anaerobes are recommended, such as tetracycline, oxytetracycline, doxycycline, metronidazole, ampicillin, chloramphenicol, tylosin, and erythromycin.
  - Continue treatment for at least 10 to 14 days and repeat as necessary. Some animals need continuous treatment; others may remain in remission for months after one course of antibiotics.
  - Clinical signs and abnormal function tests usually resolve within the first week of therapy, which in itself is good indirect evidence in support of the diagnosis.
- Treatment with *Lactobacillus* or live yogurt culture usually is not effective for altering the enteric microflora.

INTESTINAL NEOPLASIA

Benign tumors of the intestinal tract include adenomatous polyps, adenomas, and leiomyomas. In dogs these occur most commonly in the rectum and terminal colon. The most common malignant neoplasms of the intestinal tract are adenocarcinoma and lymphoma. Less common malignancies include carcinoid tumors, leiomyosarcoma, fibrosarcoma, mastocytoma, hemangiosarcoma, and anaplastic sarcoma.

Etiology

Adenocarcinoma

- Adenocarcinomas are locally invasive and slow growing and are usually seen in older animals. The most common sites in dogs are the duodenum and colon; in cats, the ileum and distal jejunum are the most common locations.
- Morphologically there are three forms of adenocarcinoma:
  - *Infiltrative*—Thickened stenotic region of the bowel that obstructs the lumen
  - *Ulcerative*—Deep indurated mucosal ulcer with raised edges
  - *Proliferative*—Lobulated expanding intestinal mass
- Mucosal ulceration is frequent, sometimes resulting in melena and blood loss anemia.
- Local invasion of the mesentery, omentum, and regional lymph nodes is common. More widespread metastasis also may occur.

Lymphoma

- GI lymphoma arises from lymphocytes of the gut-associated lymphoid tissue (GALT) and is the most common extranodal lymphoma in dogs and cats (see Chapter 27).
- In cats, intestinal lymphoma occurs mostly over 8 years of age and can be caused by feline leukemia virus (see Chapter 8), although as few as 30% are viremic.
- Morphologically there are two types of intestinal lymphoma:
  - *Diffuse lymphoma*—Diffuse infiltration of the lamina propria and submucosa with neoplastic lymphocytes, causing malabsorption and occasionally deep ulceration; this is difficult to distinguish from IBD
  - *Nodular lymphoma*—Expanding intestinal mass, most often in the ileocecocolic region, causing progressive luminal obstruction
- Metastasis to regional lymph nodes and other organs is common.

Clinical Signs

- Small intestinal neoplasia typically develops insidiously with initial vague signs of anorexia and lethargy, progressing to diarrhea and intermittent vomiting. Weight loss develops and progresses in severity in parallel with tumor growth. Melena, hematemesis, anemia, fever, icterus, and abdominal effusion may also occur.
- Colonic polyps and tumors cause hematochezia, dyschezia, and tenesmus, sometimes with mucoid diarrhea; thus, they are easily confused with inflammatory diseases of the colon and anorectal disease.
- Multifocal GI lymphoma may invade the stomach, small intestine, or colon, in any combination, thereby varying the clinical presentation. Furthermore, signs of extraintestinal involvement of organs such as the liver, spleen, or kidney may add to the clinical signs and physical findings.

Diagnosis

- Abdominal palpation often detects intestinal neoplasia as a firm midabdominal mass, thickened intestinal loops, or mesenteric lymphadenopathy.
- Rectal palpation detects stenosing or polypoid rectal masses. Most adenomatous rectal polyps can be exposed at the anus by everting the rectal mucosa

with gentle traction. Polyps usually appear dark red and lobulated, are extremely friable, and bleed easily.
- Laboratory evaluation may reveal blood loss anemia, neutrophilic leukocytosis with left shift, hypoproteinemia, or elevated serum hepatic enzyme concentrations.
- Radiography, particularly barium contrast, can be helpful for delineating regions of mucosal irregularity, luminal narrowing, and intramural infiltration, thickening, or nodularity. Thoracic radiography is indicated for detection of metastasis.
- Abdominal ultrasonography may be used to detect and define intestinal mass lesions.
- Surgical excision or biopsy of the affected segment of the bowel provides a definitive diagnosis.
- Gastric, duodenal, or colonic lesions are accessible to endoscopic biopsy.
- Percutaneous fine-needle aspiration can be used to make a cytologic diagnosis in selected cases in which the neoplastic intestinal mass or loop can be well delineated by palpation or ultrasonography.

Treatment

- Surgical resection is the treatment of choice for benign tumors such as polyps and, when feasible, for adenocarcinomas and other non-lymphomatous tumors. Unfortunately, many malignant tumors of the intestinal tract are too advanced for successful resection by the time they are recognized clinically. Always submit excised tissue for thorough histopathologic examination, including evaluation of surgical margins.
- Intestinal lymphoma can be treated with anticancer chemotherapy (see Chapters 26 and 27). Long-term remissions are possible in cats with low-grade or lymphocytic ("small cell") lymphoma of the small intestine.
- Treatment strategy and prognosis may be affected by complications such as malabsorption, protein-losing enteropathy, intestinal blood loss anemia, intestinal obstruction, intussusception, intestinal perforation and peritonitis, and metastasis to the liver or kidneys.

INTESTINAL OBSTRUCTION

Etiology

Intestinal obstruction in dogs and cats may be caused by intraluminal objects, intramural thickening or stenosis, and extramural compression. Specific causes include the following:

- Foreign bodies (e.g., bones, toys, cloth, metallic objects, stones, peach pits, acorns, rubber nipples, rubber balls, and linear objects such as string and thread)
- Intussusception
- Intestinal volvulus
- Intestinal torsion
- Incarceration of bowel in a hernia (includes abdominal hernias of all types, diaphragmatic hernia, and internal herniation of gut loops through a tear in the mesentery)
- Adhesions or stricture (post-trauma or post-surgery)
- Intramural abscess, granuloma, or hematoma
- Congenital malformation (stenosis or atresia)
- Intestinal neoplasia

Pathophysiology

Proximal versus Distal Obstruction

The more proximal and complete the obstruction, the more acute and severe the signs and the greater the likelihood of dehydration, electrolyte imbalance, and shock.

- *Proximal obstructions* cause gastric outlet occlusion, leading to persistent vomiting, loss of gastric secretions (hydrochloric acid), and metabolic alkalosis.
- *Distal obstructions* cause varying degrees of metabolic acidosis. Distal and incomplete obstructions can be insidious, with vague, intermittent signs of chronic anorexia and occasional vomiting that span several days or even weeks, leading to progressive starvation.

Simple versus Strangulated Obstruction

Vascular compromise of the obstructed bowel worsens the severity of the condition.

- *Simple obstructions* occlude the lumen without compromising vascular integrity.
- *Strangulated obstructions* cause vascular compromise of the obstructed bowel segment. This occurs most often with intussusception, volvulus, and incarcerated hernia. The sequence of events following strangulation are edema and engorgement of the affected loop, tissue hypoxia and infarction of the bowel wall, accumulation of gut bacteria and toxins in the peritoneal fluid, and rapidly progressive toxemia and shock, culminating in death.

Clinical Signs

The clinical manifestations and consequences of obstruction depend on its location, completeness, and duration, as well as the vascular integrity of the affected bowel segment.

- Acute onset of vomiting, anorexia, and depression are the most consistent clinical signs.
- Other signs may include abdominal distention, diarrhea (watery, hemorrhagic, or melenic), abdominal pain (restlessness, panting, or abnormal body posture), and shock (acute collapse).

Diagnosis

- Abdominal palpation may identify intestinal foreign bodies, intussusceptions ("sausage loop"), or gas- and fluid-distended loops of bowel proximal to the obstruction.
- Radiography often confirms the presence of obstruction and delineates the cause, especially when contrast studies are used.
- Radiographic findings suggesting obstruction include gas or fluid distention (mechanical ileus) of the bowel, delayed transit of contrast material, fixation or displacement of gut loops, luminal filling defects, and foreign objects within the lumen.
- Cats commonly ingest radiolucent linear intestinal foreign bodies (e.g., thread, string, cloth, fishing line, dental floss, and decorative tinsel) that cause aggregation and plication of the bowel and have a distinctive radiographic pattern.
- Laboratory findings often reflect fluid, electrolyte, and acid-base derangements; these vary with location, completeness, and duration of obstruction.
- Leukocytosis with a left shift or degenerative leukopenia accompanied by septic abdominal effusion indicates intestinal ischemia or perforation with peritonitis (see Chapter 76).

Treatment

- Intestinal obstructions are treated surgically. Give close attention to supportive care, especially maintenance of fluid, electrolyte, and acid-base homeostasis before, during, and after surgery (for further information on intestinal surgery, see Chapter 70).
- Treatment includes management of complications such as necrosis or perforation of the bowel, peritonitis (see Chapter 76), and septic shock (see Chapter 156).

Chapter

70 Surgery of the Intestines

Ronald M. Bright

Surgical therapy is indicated for structural disease of the bowel. Most animals that require surgery of the small bowel are physiologically compromised. When obstruction of the small bowel is proximal in location (high obstruction), serious electrolyte and water abnormalities can place these patients at high risk.

Prophylactic antibiotics administered perioperatively are indicated in small bowel surgery.

- Before surgery of the upper and middle small bowel, give a first-generation cephalosporin such as cefazolin (20 mg/kg) intravenously (IV) initially; repeat IV 3 hours later.
- Before surgery of the distal small bowel and large intestine, give a second-generation cephalosporin such as cefmetazole (15 mg/kg) IV or cefoxitin (30 mg/kg) IV; repeat IV 3 hours later.

ANATOMY

- The small intestine extends from the pylorus to the cecum.
- The duodenocolic ligament restricts the movement of the distal duodenum.
- The jejunum is the major portion of the small bowel and is a very mobile structure.
- The major blood supply is from the cranial mesenteric artery.
- A portion of the proximal duodenum is supplied by the celiac artery and shares a source of blood with the right lobe of the pancreas via the pancreaticoduodenal artery.
- The tunica of the small intestine includes the mucosa, submucosa, muscularis, and serosa.
- The submucosal layer provides blood vessels, lymphatics, and nerves. It is also the support or "holding" layer for sutures.

ENTEROTOMY

Preoperative Considerations

- Give perioperative antibiotics, as previously described.
- Attempt to correct electrolyte and water abnormalities before surgery.
- Several factors may contribute to intestinal leakage following resection and anastomosis. Dogs are at higher risk for leakage when there are two or more of the following factors: hypoalbuminemia (<2.5 g/dl), intestinal foreign body, peritonitis.

Surgical Procedure

Objectives

- Gain access to the lumen of the small bowel to remove a foreign body.
- Help define a disease by acquiring a full-thickness biopsy.
- Avoid contamination of the peritoneal cavity.

Equipment

- General surgical pack
- Babcock forceps
- Laparotomy sponges
- Doyen non-crushing intestinal clamps
- #11 Bard-Parker blade
- Fine-tip needle holders
- Ewald thumb forceps

Technique

1. Make a midline abdominal incision to allow access to the small bowel.
2. Isolate the segment of bowel to be entered with moistened laparotomy sponges.
3. Place a 3-0 stay suture at both ends of the proposed enterotomy incision (Babcock forceps may be substituted).
4. Milk bowel contents away from the proposed enterotomy site; place non-crushing intestinal forceps (or an assistant's fingers) across the bowel to minimize spillage.
5. Make a full-thickness stab incision into the lumen, using a #11 Bard-Parker scalpel blade. Place a suction tip in the bowel lumen and remove its contents. Enlarge the incision as needed with Metzenbaum scissors.

6. If removing a foreign body, perform the enterotomy over healthy bowel distal to the foreign body.
7. If a biopsy is needed, excise a 2- to 3-mm strip of bowel parallel to the enterotomy incision.
8. Trim any everted mucosa with scissors.
9. Close the enterotomy incision with 3-0 or 4-0 synthetic absorbable or monofilament non-absorbable suture material on a swaged-on taper-point or taper-cut needle. A full-thickness, simple interrupted or continuous appositional suture pattern is preferred.

▼ ***Key Point*** To minimize tissue trauma, avoid repeatedly grabbing the intestinal wall with thumb forceps.

10. Rinse the enterotomy site thoroughly with warm saline.
11. Use omentum or a jejunal onlay patch to reinforce the suture line. I prefer to use omentum, even in relatively healthy tissue.
12. Some severely debilitated animals may benefit from placement of a jejunostomy tube for postoperative enteral nutritional support. (See Chapter 3 for nutritional support of critical patients.)
13. Perform routine closure of the abdomen.

Postoperative Care and Complications

Short Term

- Monitor for signs of leakage peritonitis by abdominal palpation, body temperature measurements, and a complete blood count (CBC).
- Give food and water the day after surgery.
- Gradually taper off fluid and electrolyte therapy as the animal returns to normal eating and drinking.

Long Term

- Strictures are rare unless an excessive amount of tissue was removed for biopsy and the lumen diameter was compromised.
- Slow leakage from an enterotomy site may become walled off and later be manifested as an abscess.

Prognosis

- The prognosis is fair to good if the enterotomy was done for a foreign body.
- If biopsy indicates neoplasia, the prognosis is poor.
- If biopsy reveals a protein-losing enteropathy due to benign infiltrative disease, the prognosis is poor to guarded (see Chapter 69).

INTESTINAL RESECTION AND ANASTOMOSIS

Indications for intestinal resection and anastomosis include the following:

- Diseases causing bowel necrosis (e.g., foreign body, volvulus, trauma)
- Neoplasia
- Intussusception
- Severe, focal infiltrative bowel disease (e.g., phycomycosis pythiosis, zygomycosis)

Preoperative Considerations

- Administer perioperative antibiotics starting 20 to 40 minutes before surgery, as described previously.
- Although controversy surrounds the choice of suture pattern for intestinal anastomosis, any of several techniques probably is acceptable in the hands of a competent surgeon who follows sound intestinal surgery principles.
- It is probably best to use synthetic monofilament absorbable sutures. Polypropylene used in a continuous pattern has been associated with attaching to foreign bodies after being extruded into the lumen of the bowel and was the cause of pyloric outflow obstruction in a dog following the formation of a granuloma around the suture.
- I prefer the simple interrupted appositional (SIA) suture pattern for intestinal (large or small) anastomoses. This non-crushing technique causes little compromise of the blood supply of the intestinal segments. (Disruption of vascularity is the most common biologic cause of failure of an anastomosis.)

▼ ***Key Point*** Accurate and atraumatic placement of sutures and gentle handling of the bowel gives the best results. Failure of an anastomosis usually is due to poor surgical technique or a combination of the risk factors previously mentioned.

- Assess bowel viability before determining the amount of bowel to be resected. Standard clinical criteria include color, peristalsis, and arterial pulsations.
- In the rare case in which standard criteria are not adequate to determine bowel viability, an intravenous fluorescein dye technique can be used.
- Inject 2 ml of 5% fluorescein dye IV; in a darkened surgery room, evaluate the pattern of fluorescence using #3600 ultraviolet illumination (Wood's lamp).
- A smooth, uniform green-gold color or a finely mottled pattern with no areas of non-fluorescence greater than 3 mm denotes acceptable bowel viability.

Surgical Procedure

Objectives

- Remove the diseased or non-viable segment of bowel and restore bowel continuity with an end-to-end anastomosis.
- Preserve lumen diameter and tissue blood supply.
- Avoid spillage of bowel contents.

Equipment

- General surgical pack
- Doyen non-crushing clamps
- Laparotomy pads
- Abdominal retractors

Technique

1. Make a midline abdominal incision long enough to accommodate a thorough abdominal exploratory procedure.
2. Isolate the affected bowel segment with saline-moistened laparotomy sponges.
3. Isolate and ligate the mesenteric vessels to the affected area. Ligate the arcadial vessels within the mesenteric fat similarly.
4. Place crushing clamps across the bowel at a 60 degree angle to the long axis of the bowel and just inside the arcadial vessels.
5. Milk the ingesta away from the crushing clamps. Place a non-crushing clamp across the viable segments of bowel to be anastomosed, or have an assistant gently hold the bowel segments during the anastomosis.
6. Excise the diseased bowel by incising between the crushing clamp and the arcadial vessel ligation.
7. The mucosal collar may evert around the ends of the transected bowel. This can be trimmed with scissors.
8. Atropine given in a mesenteric vessel at a dose of 0.04 mg/kg has been shown to decrease the amount of mucosal eversion of jejunal segments.
9. Correct lumen disparity by cutting the small lumen at a more acute angle, longitudinally incising the antimesenteric edge of the small end, or oversewing the larger end.
10. Use a 3-0 or 4-0 suture on a small taper-point needle to place the sutures. All knots are extraluminal.
11. Carefully place the first suture at the mesenteric border. The second suture apposes the antimesenteric border. Place sutures approximately 2 to 3 mm apart along the "near" side of the anastomosis. Include the entire thickness of the bowel. Pull down the sutures slowly so as to gently appose the edges of the bowel (SIA pattern). Alternatively, close the bowel in a simple continuous suture pattern (see study by Weisman et al for details).
12. Appose the "far" side or back wall similarly.
13. Gently flush warm sterile saline over the anastomotic site and adjacent lengths of bowel.

▼ ***Key Point*** Do not flush the entire abdominal cavity unless there is gross contamination from the surgery or preexisting peritonitis.

14. Wrap a piece of omentum around the line of anastomosis and gently tack it to the bowel above and below the anastomosis.
15. Close the defect in the mesentery with a continuous suture.
16. If nutritional support is necessary, place a jejunostomy tube before closure of the abdomen.

Postoperative Care and Complications

- Maintain intravenous fluid and electrolyte supplementation until the animal is drinking water.
- Withhold food and fluids for 12 to 24 hours, after which the regular diet can be fed.
- Discontinue antibiotics over the next 4 to 12 hours unless peritonitis was present. In this case, continue empirical antibiotic therapy and modify if necessary based on culture and sensitivity results.
- Monitor for signs of depression, high fever, excessive abdominal tenderness, vomiting, and ileus, which may indicate leakage peritonitis. If warranted, initiate appropriate diagnostic (e.g., abdominocentesis) and therapeutic measures (see Chapter 76).

ENTEROENTEROPEXY/ENTEROPEXY (COLOPEXY)

- Enteroenteropexy, or plication of loops of bowel, is done to prevent recurrence of intussusception and is usually performed at the time of definitive surgical repair of the intussusception.
- Enteropexy, or fixation of bowel to the abdominal wall, is done as part of a tube jejunostomy placement procedure, as a colopexy for treatment of rectal prolapse, or as an adjunctive procedure for correcting rectal sacculation related to a perineal hernia (see Chapter 75).
- These procedures have limited use in dogs and cats.

Surgical Procedures

Objectives

- Prevent recurrent telescoping of bowel following surgical repair of intussusception.
- Diminish likelihood of leakage around a jejunostomy tube as it exits the bowel and enters the abdominal wall.
- Prevent caudal movement of the colon and rectum (colopexy) to correct anorectal prolapse.

Equipment

- General surgical pack
- Balfour abdominal retractor

Technique

Enteroenteropexy

1. Place loops of small bowel side by side to form a series of gentle loops. Suture loops to each other by engaging the seromuscular layers with monofilament

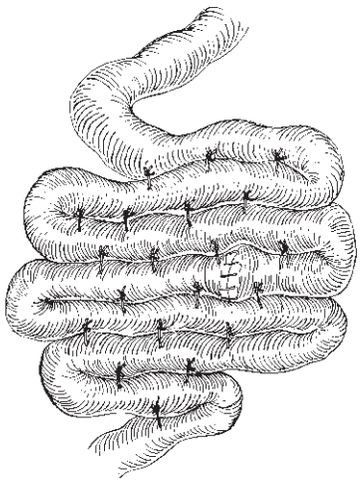

Figure 70-1. Jejunal enteroenteropexy to prevent intussusception via a ventral midline abdominal approach.

non-absorbable suture (Fig. 70-1). Place sutures approximately 6 to 10 cm apart.
2. The amount of bowel to include in the "pexy" procedure is controversial. Some surgeons include the entire small bowel, starting at the descending duodenum and finishing at the ileocecocolic junction. Others include only two or three loops of bowel above and below the point of intussusception. Another option is to include only the distal jejunum and ileum, because most intussusceptions involve the distal small bowel.

Colopexy

1. Reduce the rectal prolapse by placing gentle traction on the descending colon, pulling it cranially.
2. Scarify an 8- to 10-cm portion of the descending colon with a surgical blade along the antimesenteric border.
3. Alternatively, make a longitudinal seromuscular incision along the antimesenteric border. This may result in a more consistent colopexy. Avoid entering the lumen.
4. Make an incision into the peritoneum and underlying musculature in the abdominal wall opposite the segment of prepared colon.
5. Preplace four to six horizontal mattress sutures between the colon and the exposed surface of the abdominal wall (Fig. 70-2). Monofilament non-absorbable suture is preferred.
6. Tie the sutures to securely appose the fresh bleeding surfaces of the colon and abdominal wall (see Fig. 70-2).

Postoperative Care and Complications

- No special feeding limitations are necessary.
- Recurrence of intussusception (following enteroenteropexy) or rectal prolapse (following colopexy) suggests that the pexy site has broken down.

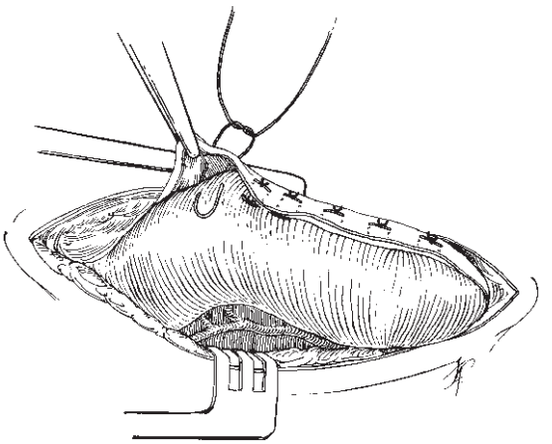

Figure 70-2. Technique for colopexy to prevent recurrence of rectal prolapse.

COLOTOMY

The most common indication for a colotomy is a full-thickness biopsy when diagnosis has eluded other diagnostic procedures. Whenever possible, colonoscopic methods of biopsy are preferred (see Chapter 69). Rarely, a colotomy is done to remove a foreign body.

Preoperative Considerations

- Surgical procedures involving the colon are more likely to be associated with dehiscence than those involving other portions of the gastrointestinal tract.

▼ ***Key Point*** Gentle handling of the colon and the prevention of excessive tension across the suture line will help preserve a good blood supply and promote ideal wound healing.

- The risk of a serious abdominal infection is considerable with colonic surgery.
- To reduce the risk of postoperative sepsis, administer perioperative antibiotics for gram-negative aerobes and anaerobes. Give cefmetazole (15 mg/kg) IV q1.5h for 2 or 3 doses, starting 20 to 30 minutes before surgery. Cefoxitin (30 mg/kg) may be substituted.
- Preoperative mechanical cleansing of the colon via multiple enemas may be indicated. This can be especially helpful to improve exposure of colonic polyps or neoplasms during resection.

Surgical Procedure

Objectives

- Collect tissue for biopsy.
- Remove foreign body in cases of low bowel obstruction.
- Prevent spillage of colonic contents.

Equipment

- General surgery pack
- Babcock forceps
- Laparotomy sponges
- Doyen non-crushing intestinal clamps
- #11 Bard-Parker blade

Technique

1. Make a caudal midline abdominal incision for access to the colon.
2. Pack off the colon with laparotomy sponges at the proposed incision site.
3. Place stay sutures at both ends of the proposed colotomy incision (Babcock forceps can be substituted).
4. Milk the colonic contents away from the incision site and cross-clamp the bowel segment with Doyen clamps.
5. Using a #11 Bard-Parker surgical blade, stab into the lumen of the colon. Remove a full-thickness elliptical piece of tissue with Metzenbaum scissors.
6. Close the colotomy incision side-to-side with 3-0 or 4-0 synthetic absorbable suture (e.g., polydioxanone, PDS) in a simple interrupted appositional pattern. A non-absorbable suture (e.g., polypropylene) may be substituted.
7. Gently irrigate the bowel immediately adjacent to the colotomy incision with warm saline before removing the laparotomy pad. Do not allow irrigation fluid to enter the peritoneal cavity.
8. Cover the colotomy incision line with omentum.
9. Perform routine closure of the abdomen.

Postoperative Care and Complications

Short Term

- Monitor closely for signs of leakage peritonitis for 48 hours.
- Abdominal pain, an unusually high fever, and a neutrophilia with a left shift suggest a need for further diagnostic tests such as radiography and diagnostic peritoneal lavage.

Long Term

- Strictures occur rarely.
- Slow-leakage peritonitis may be masked by antibiotics, or the infected area may be walled off, only to be manifested later as an abscess.

Prognosis

- The prognosis is good if the colotomy is done to remove a foreign body.
- If the biopsy suggests a non-neoplastic process, the prognosis depends on the underlying disease (see Chapter 69).

SUBTOTAL COLECTOMY

The primary indication for subtotal (90–95%) removal of the colon is for palliation of severe or recurrent constipation (obstipation related to megacolon). Idiopathic megacolon in the cat (see Chapter 69) is the most common disease for which surgery is indicated.

▼ ***Key Point*** Meticulous handling and careful apposition of tissue and a tension-free anastomosis are critical for the success of subtotal colectomy.

Preoperative Considerations

- In cats, the ileocolic valve can be resected with few postoperative problems. Reestablishing bowel continuity with an ileocolostomy versus a colocolostomy (when the ileocolic valve is preserved) is technically easier. However, it is preferable to preserve the ileocolic valve. The postoperative convalescent period is shorter and the likelihood of intractable diarrhea secondary to small bowel bacterial overgrowth is diminished.
- Administer prophylactic antibiotics, as described previously.
- Preoperative enemas are not necessary and, in fact, can complicate the surgery because of potential leakage of fluid from the colon.

Surgical Procedure

Objectives

- Palliate signs of constipation or obstipation that are associated with megacolon.
- Remove most of the colon with restoration of continuity by ileocolostomy or colocolostomy.
- Promote movement of bowel contents from the small bowel to the rectum.
- Prevent spillage of colonic contents.

Equipment

- General surgery pack
- Balfour abdominal retractors
- Laparotomy sponges
- Doyen non-crushing straight intestinal clamps
- Carmalt crushing forceps

Technique

1. Make a ventral midline abdominal incision, starting from midway between the xiphoid and umbilicus and coursing caudally to the brim of the pelvis.
2. Exteriorize and carefully isolate the colon and distal small bowel from the rest of the abdominal viscera outside the abdominal cavity.

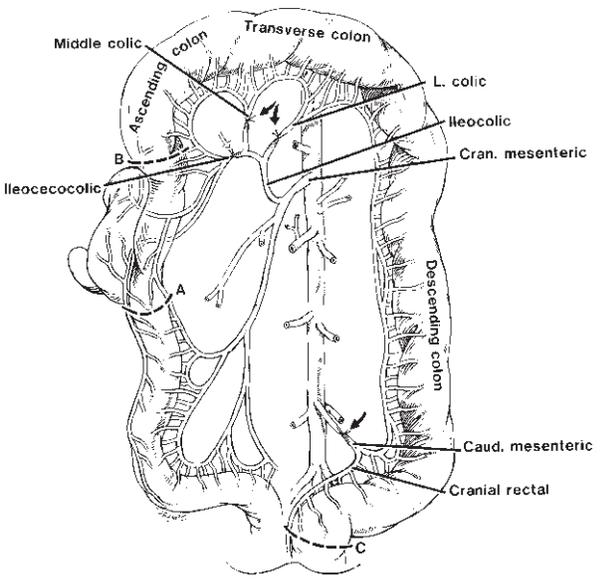

Figure 70-3. Subtotal colectomy. Sites of ligation of colic blood vessels before anastomosis and resection. Colonic resection can either include resection of the ileocecocolic valve (incision at *A*) or preserve the ileocecocolic area (incision at *B*). Distal incision *(C)* made in the colon.

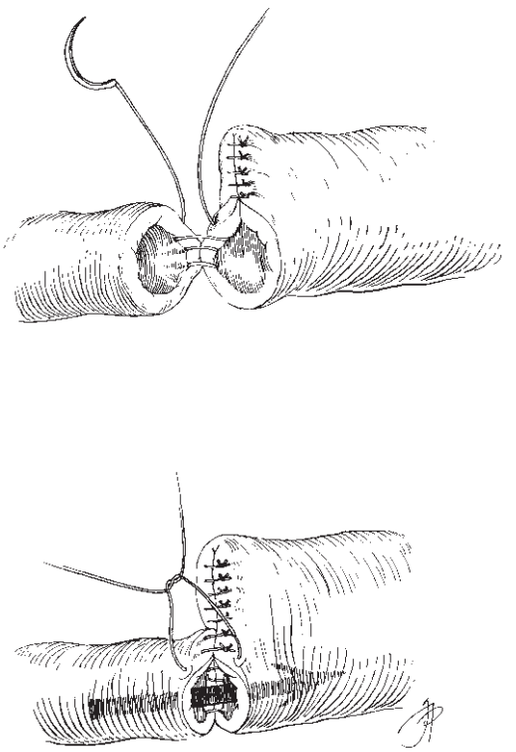

Figure 70-4. Subtotal colectomy. Correction of luminal disparity of the bowel by partial closure of larger segment before anastomosis.

3. Isolate the appropriate colic vessels approximately 1 to 2 cm from the mesenteric side of the colon. Ligate and divide these (Fig. 70-3).
4. If the ileocolic valve is being removed, ligate an additional set of vessels (ileocecocolic artery and vein) (see Fig. 70-3).
5. Caudally, ligate the caudal mesenteric artery and vein.
6. Milk the fecal contents toward the center of the segment of colon to be removed.
7. Place a non-crushing intestinal clamp across the distal colon approximately 1 cm cranial to the brim of the pelvis; if the ileocolic valve is being preserved, place another clamp across the short 1-cm segment of proximal colon remaining below the ileocolic valve.
8. If the ileocolic valve is being resected, place a non-crushing clamp across the ileum just proximal to the ileocolic valve.
9. Use crushing forceps to clamp the colon approximately 1 cm to the inside of the previously placed non-crushing clamps. Transect the colon next to the crushing forceps and the segment of bowel being removed (i.e., the crushing forceps come out with the resected bowel segment).
10. Perform an end-to-end anastomosis using 4-0 polypropylene or a monofilament synthetic absorbable suture in a simple interrupted, full-thickness, appositional suture pattern.
11. Correct any lumen disparity by longitudinally incising the antimesenteric side of the bowel with the smaller lumen. Lumen disparity can also be corrected by partial closure of the larger colonic segment, using the same suture and pattern (Fig. 70-4).
12. Be careful to incorporate the serosa and to ensure accurate and gentle placement of all sutures. Place the sutures at 2- to 3-mm intervals.
13. Gently irrigate the anastomotic site and adjacent 4 to 5 cm of bowel with warm saline. Do not allow fluid to enter the peritoneal cavity.
14. Place an omental patch over the site of anastomosis and gently tack it with one or two sutures below the line of anastomosis.
15. Remove the laparotomy sponges and replace the bowel in the abdominal cavity.
16. Use new gloves and a sterile set of instruments for closure of the midline incision.

Postoperative Care and Complications

Short Term

- Withhold food and liquids for 24 hours.
- Monitor closely for signs of leakage from the anastomosis for 48 to 72 hours.
- Some animals continue to have some tenesmus for 7 to 10 days after surgery.
- Loose stools and increased frequency of defecation occur but usually improve somewhat over a period of weeks to months.
- Continue intravenous fluids for 36 to 48 hours.

Long Term

- The frequency of defecation generally increases by 30% to 50%.
- The stools remain soft indefinitely but often become less fluid and more semiformed within a few weeks.
- Cats do not need a special diet.
- It may be necessary to keep animals on a diet low in volume and high in caloric density for 10 to 14 days. Thereafter, feed a diet that minimizes diarrhea and results in solidly formed stools.

▼ ***Key Point*** Cats seem to adapt well to subtotal colectomy, whereas dogs may have persistent diarrhea postoperatively.

TYPHLECTOMY

Indications for typhlectomy, or surgical removal of the cecum, include the following:

- Typhlitis (cecal inflammation) caused by chronic whipworm infection
- Cecal inversion
- Cecal neoplasia

Preoperative Considerations

- If possible, evert the inverted cecum before its amputation.
- If manual reduction of cecal inversion is not possible because of adhesions, reduction may need to be done through a colotomy incision.
- The cecum is attached to the terminal ileum by the ileocecal fold, which consists of fascia and peritoneum.

Surgical Procedure

Objective

- Remove the cecum without interfering with ileocolic anatomy and function.

Equipment

- General surgery pack
- Doyen non-crushing straight intestinal forceps
- Abdominal retractor

Technique

1. Bluntly dissect the ileocecal fold to free the cecum from its attachments to the ileum.
2. Preserve the ileocecal vessels while ligating and dividing the cecal branches.
3. Carefully incise the remaining attachments of the cecum to the proximal colon.
4. When the cecum is isolated from its attachments and blood supply, double-clamp the base of the cecum with straight intestinal forceps.
5. Amputate the cecum between the two forceps.
6. Oversew the forceps remaining on the base of the cecum with 2-0 or 3-0 synthetic absorbable suture using a Parker-Kerr suture pattern.
7. Place a second layer of a continuous Lembert inverting suture.

Postoperative Care and Complications

Short Term

- Give food and liquids the day after surgery.

Long Term

- Complications are rare.

Prognosis

- The prognosis is good.

Chapter

71 Diseases of the Liver and Biliary Tract

Susan E. Johnson / Robert G. Sherding

DIAGNOSTIC STRATEGY FOR LIVER DISEASE

The liver has many diverse functions related to hepatic blood flow; protein, carbohydrate, and fat metabolism; detoxification and excretion of drugs and toxins; and formation and elimination of bile. Consequently, the clinical and laboratory abnormalities associated with liver failure are diverse.

Overview of the Diagnostic Strategy

- Clinical, laboratory, and imaging studies to identify the presence of liver disease
- Characterization of the functional aspects of the hepatic disease
- Determination of an etiologic or histologic diagnosis, which usually requires a liver biopsy

Acute versus Chronic Disease

The clinical approach and management of patients with hepatic disease is dictated largely by the acute versus chronic nature of the hepatic disorder. Historical, physical, laboratory, and radiographic findings may suggest whether the hepatic disease is acute or chronic, but hepatic biopsy often is required for definitive evaluation. Classifying a disorder as acute or chronic has diagnostic, therapeutic, and prognostic implications.

- In acute hepatic failure, toxic or infectious causes are common, and intensive supportive care is warranted to allow time for hepatic regeneration. The long-term prognosis for recovery is favorable if the animal survives the initial stages.
- Chronic hepatic disorders are more likely to be accompanied by irreversible changes (cirrhosis); thus, the long-term prognosis may not be favorable.

Clinical Signs

Clinical signs of liver disease include those typically associated with hepatic dysfunction, such as jaundice, hepatic encephalopathy (HE), ascites, and excessive bleeding, and nonspecific signs such as vomiting, diarrhea, anorexia, lethargy, and weight loss, which overlap with signs of other body system disorders.

Nonspecific Signs

- *Vomiting* is a common sign of liver disease. Hematemesis suggests gastroduodenal ulceration, a recognized complication of hepatobiliary disease.
- *Diarrhea* occurs less frequently than vomiting and is characteristically small-bowel diarrhea.
- *Anorexia* is a common but nonspecific sign of hepatobiliary disease.
- *Weight loss and stunted growth* are nonspecific signs that suggest chronic rather than acute hepatic disease.

Polyuria and Polydipsia

- Polyuria and polydipsia (PU/PD) may be important presenting clinical signs in dogs with liver disease. The mechanism is multifactorial and includes psychogenic polydipsia, hypercortisolism, and renal concentrating defects.

Signs of Abnormal Bilirubin Excretion

- *Pigmented urine* (bilirubinuria) and *jaundice* (icterus) of the sclera, oral mucous membranes, and skin are classic signs of cholestatic liver disease. However, these findings are not specific for hepatobiliary disease and can also be caused by hemolytic disorders.
- *Acholic (gray) feces* occur secondary to severe cholestasis (usually from common bile duct obstruction), which prevents bilirubin in the bile from entering the intestinal tract and imparting the normal brown color to the feces.

Coagulopathy

- Excessive bleeding (i.e., hemorrhages of the skin and mucous membranes, melena, and hematuria) occasionally is associated with liver disease, especially if hepatic damage is severe or is associated with common bile duct obstruction.
- Subclinical clotting abnormalities may become clinically apparent after liver biopsy, surgery, and development of gastroduodenal ulcers.
- Potential mechanisms for bleeding include primary failure of the hepatocytes to synthesize clotting factors, vitamin K deficiency, and disseminated intravascular coagulation (DIC) (see Chapter 23).

Hepatic Encephalopathy

- HE is a metabolic encephalopathy that occurs secondary to severe liver disease or portosystemic shunting of blood.
- Clinical signs include depression, hypersalivation, behavioral changes, altered consciousness, motor disturbances, seizures, and coma. As with other metabolic encephalopathies, signs typically wax and wane and are interspersed with normal periods.
- Ammonia, mercaptans, short-chain fatty acids, gamma-aminobutyric acid (GABA), and endogenous benzodiazepines are potential encephalopathic toxins that are produced in the colon by bacterial action on various substrates. Because the liver normally detoxifies these substances, systemic concentrations are low. With severe liver disease or portosystemic shunting, these potential toxins reach high concentrations in the systemic circulation and the central nervous system (CNS), resulting in clinical signs.
- Exacerbation of encephalopathy occurs after eating a meal high in protein because protein is a substrate for toxins such as ammonia and mercaptans.
- HE must be differentiated from other metabolic encephalopathies and primary CNS disorders.

Ascites

- Ascites is a common feature of severe chronic liver disease. Mechanisms of ascites and edema formation in liver disease include hypoalbuminemia, portal hypertension, and sodium and water retention.
- Rupture of the biliary tract causing bile peritonitis also is associated with abdominal fluid accumulation.

Signalment and History

- The signalment often provides important clinical information, because breed predilections for specific liver diseases have been recognized, and young animals are more likely to be presented for congenital hepatic disorders such as portosystemic shunt.
- The history is helpful to characterize the clinical course of liver disease as acute or chronic. Recent onset of signs in an animal that was previously healthy suggests acute hepatic failure. However, because of the large functional reserve capacity of the liver, in occult chronic liver disease the clinical signs may be vague and may not be recognized by the owner until the final phase of hepatic decompensation.

▼ ***Key Point*** Chronic hepatic disease can be associated with recent onset of clinical signs and can initially seem to be an acute disease. However, persisting signs of weight loss and ascites and diagnostic findings of hypoalbuminemia and microhepatica are indicative of chronic hepatic disease.

- The history may provide important information regarding the potential for exposure to known causes of hepatic injury such as drug therapy, surgical and anesthetic procedures, and toxins or infectious agents.
- Determine if the animal has a history of intolerance to drugs normally metabolized by the liver, such as sedatives, tranquilizers, anticonvulsants, and anesthetics.
- Determine the current vaccination status and exposure potential for infectious agents known to affect the liver, such as leptospirosis, infectious canine hepatitis, and feline infectious peritonitis (FIP).

Physical Examination

Skin and Mucous Membranes

- Evaluate the sclera, oral mucous membranes, and skin for jaundice. Jaundice is not clinically detectable until serum bilirubin concentrations are >2.5 to 3.0 g/dl. In cats, subtle jaundice often is best detected on the palatine mucosa.
- Evaluate the skin and mucous membranes for evidence of bleeding. Pallor may be detected with blood loss anemia.

Abdominal Palpation

Palpate the abdomen carefully. The normal liver can be difficult to palpate in dogs and cats, and the edges are normally sharp, not rounded.

- Hepatomegaly is caused by passive venous congestion, diffuse inflammation, nodular hyperplasia, cysts, bile engorgement, marked biliary hyperplasia (cats), and infiltration by fat, glycogen, and neoplastic cells.
- Pain on palpation of the liver (hepatodynia) usually indicates acute liver disease. The pain is caused by stretching of the liver capsule and must be differentiated from pain arising in the pancreas, stomach, or spleen.
- Moderate to severe abdominal effusion may be detected.

Neurologic Exam

Perform a neurologic examination in animals with a history of neurologic signs. With HE, the neurologic examination may be normal or suggestive of diffuse cerebral disease (e.g., depression and dementia, disorientation, pacing, circling, head pressing, hypersalivation, seizures, or coma).

Rectal Exam

Perform a rectal examination and obtain a fecal sample to evaluate for melena (indicative of GI bleeding) and acholic feces.

Routine Laboratory Evaluations

Because clinical findings in hepatobiliary disease often are vague, hepatic disease may not be suspected until

biochemical tests identify elevated liver enzyme activity or other evidence of hepatic dysfunction (e.g., hyperbilirubinemia or hypoalbuminemia). Liver function studies such as serum bile acid (SBA) concentrations are used to achieve the following:

- Identify occult liver disease
- Assess liver function when there is increased liver enzyme activity but normal serum bilirubin concentrations
- Determine whether significant hepatic dysfunction is present to warrant performing a liver biopsy
- Monitor response to therapy

Findings consistent with liver disease on routine laboratory tests are described below.

Complete Blood Count

- *Mild to moderate anemia* may occur secondary to liver disease because of blood loss (e.g., gastroduodenal ulceration or coagulopathy) or may be associated with normocytic-normochromic anemia of chronic disease.
- *Erythrocytic microcytosis* is a common finding in dogs and cats with portosystemic shunts. Decreased serum iron concentration, normal to increased serum ferritin concentration, and accumulation of stainable iron in the liver suggests that microcytosis is associated with abnormal iron metabolism (impaired iron transport or sequestration of iron) rather than absolute iron deficiency. Decreased availability of iron for hemoglobin synthesis appears to occur despite adequate tissue iron stores.
- *Target cells and poikilocytosis* (acanthocytes and elliptocytes) may occur in dogs and cats with various types of hepatic disease, due to altered red blood cell (RBC) membranes.

Urinalysis

- *Urine specific gravity* may be isosthenuric or hyposthenuric if liver disease is associated with PU/PD.
- *Bilirubinuria* is a sensitive indicator of abnormal bilirubin metabolism, and this finding precedes hyperbilirubinemia and jaundice. Bilirubinuria imparts a yellow-orange color to the urine. Bilirubin crystals may form in the presence of bilirubinuria.
  - Trace amounts of bilirubin may be found in concentrated urine of normal dogs (especially males).
  - Bilirubinuria is always abnormal in cats and suggests underlying hemolytic or hepatobiliary disease.
- *Urine urobilinogen* is a colorless product of enteric bacterial degradation of bilirubin that is absorbed from the gut. A small portion of urobilinogen escapes the enterohepatic circulation and is excreted in the urine. The finding of urobilinogenuria indicates an intact enterohepatic circulation of bilirubin pigments. The absence of urobilinogenuria in a jaundiced animal suggests common bile duct obstruction. However, this test is not reliable in a clinical setting because many non-hepatic factors affect urine urobilinogen concentration, including altered intestinal flora, GI bleeding, intestinal absorption, renal excretion, urine pH, urine volume, and urine storage.
- *Ammonium biurate crystals* are commonly detected in animals with portosystemic shunts.

▼ ***Key Point*** Suspect liver disease in any cat or dog with ammonium biurate crystalluria (except in dalmatians and bulldogs).

Liver Enzymes

Evaluation of serum liver enzyme activity is used as a screening test to detect liver disease. Increases in liver enzyme activity are not specific for the underlying hepatic disorder. However, liver enzymes can be used to categorize the underlying pathophysiologic mechanism. Increases in liver enzyme activity may occur secondary to hepatocellular injury and leakage (Fig. 71-1), or due to increased production stimulated by bile retention (cholestasis) or drug induction (Fig. 71-2).

Many systemic diseases can secondarily affect the liver (reactive hepatopathy), causing increased liver enzyme activity, but these are not necessarily associated with clinical liver disease. For example, feline hyperthyroidism is commonly associated with increased liver enzyme activity without significant hepatic dysfunction.

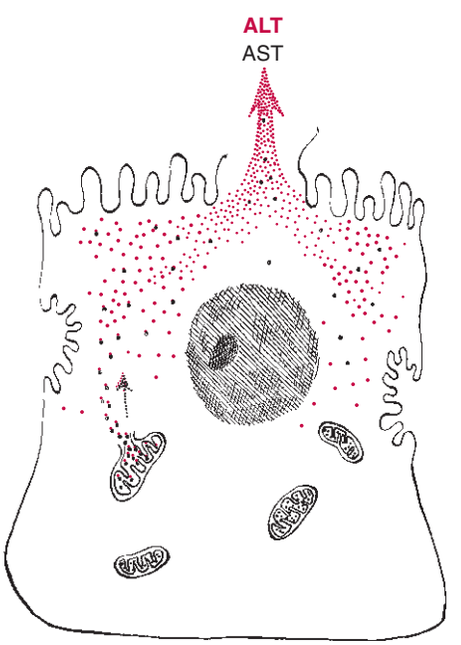

Figure 71-1. With hepatocyte injury, leakage of alanine aminotransferase (ALT) from the cytoplasm results in increased serum activity. Aspartate aminotransferase (AST) is primarily associated with mitochondria but is also present in the cytoplasm. Release of AST from the mitochondria requires a severe insult. Thus, with hepatocyte injury, ALT is more readily released and its activity level will usually be higher than that of serum AST.

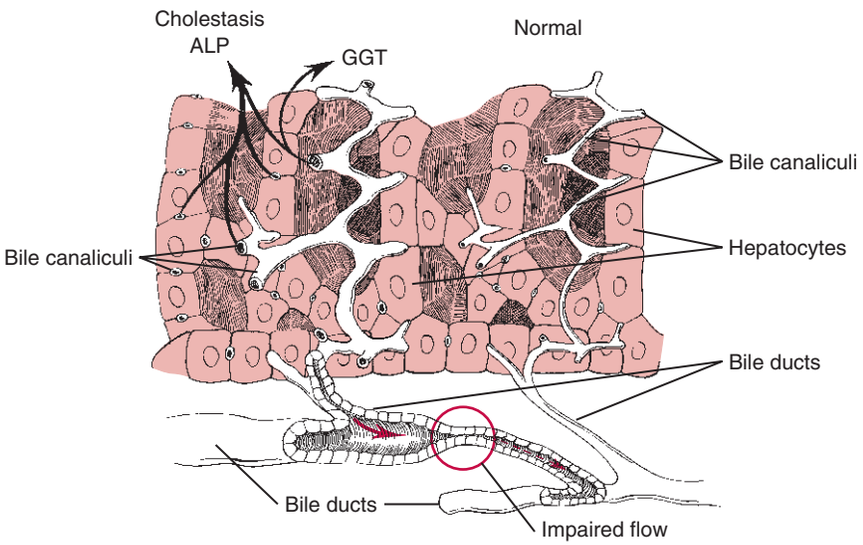

Figure 71-2. Impaired bile flow (cholestasis) causes increased synthesis of alkaline phosphatase (ALP) and gamma-glutamyltransferase (GGT). ALP is a sensitive indicator of cholestasis in dogs but is less sensitive in cats (see text). With cholestatic disorders, increased ALP activity precedes hyperbilirubinemia. ALP and GGT lack specificity in differentiating between intrahepatic and extrahepatic cholestasis.

▼ ***Key Point*** Liver enzymes do not evaluate liver function. Thus, severe hepatic dysfunction may coexist with normal liver enzyme activity; conversely, increased liver enzyme activity may be detected in animals without significant hepatic dysfunction.

Alanine Aminotransferase

Increased alanine aminotransferase (ALT) activity indicates hepatocyte injury with leakage of enzyme from the cytoplasm of the hepatocyte (see Fig. 71-1). The magnitude of ALT increase generally correlates with the number of injured hepatocytes.

- The largest increases in ALT activity occur with hepatocellular necrosis and inflammation (up to 100 times normal). Increases also occur with increased hepatocyte membrane permeability, such as that caused by hypoxia. Severe cholestasis can also cause secondary hepatocyte injury, with increases in ALT up to 20 to 40 times normal. Increased production of ALT by regenerating hepatocytes may account for persisting increases in enzyme activity after resolution of the initial injury.
- Anticonvulsant drug therapy (primidone, phenytoin, and phenobarbital) in dogs can be associated with mild increases in ALT activity (2 times normal) in the absence of obvious hepatocellular injury.
- Corticosteroid therapy or hyperadrenocorticism is associated with mild to moderate (2–10 times normal) increases in ALT activity.
- Small amounts of ALT are present in canine skeletal muscle; it has been shown that severe skeletal muscle degeneration or necrosis (canine muscular dystrophy, necrotizing myopathy, polymyositis) may be associated with increases in ALT activity of 5 to 25 times normal. When increased ALT activity is caused by muscle injury, creatine kinase (CK) and AST activity are also markedly increased. Whether ALT is liver specific in cats remains to be determined.

Aspartate Aminotransferase

Hepatocyte injury is associated with increased AST activity secondary to leakage from mitochondria and cytoplasm of hepatocytes (see Fig. 71-1).

- AST is not liver specific in dogs and cats; it is present in significant quantities in hepatocytes and skeletal muscle tissue.
- Comparison of activities of ALT, AST, and CK, a muscle enzyme, can indicate whether AST activity is increased due to hepatic or muscle injury.

▼ ***Key Point*** Increased AST activity associated with hepatic injury generally parallels but is less than the increase in ALT activity, and CK is normal. Increased AST activity due to skeletal muscle injury is associated with increased CK activity and normal or mildly increased ALT activity.

- In some cats with liver disease, AST may be more sensitive than ALT in detecting hepatic disease.

Alkaline Phosphatase

Increases in serum alkaline phosphatase (ALP) activity are due to accelerated production of this enzyme, stimulated by cholestasis or drug induction (see Fig. 71-2). ALP is a membrane-associated enzyme present in many tissues; however, only liver, bone, and corticosteroid-induced isoenzymes contribute to serum ALP activity. Serum ALP activity in normal dogs and cats is usually due to the liver isoenzyme. An increase in this type of ALP activity indicates intrahepatic or extrahepatic cholestasis.

- Young growing animals or animals with severe bone disease may have mild increases in ALP activity due to the bone isoenzyme.
- Cats generally have smaller increases in serum ALP activity with hepatobiliary disease than do dogs owing to a limited capacity for ALP production and a shorter serum half-life (6 hours in cats versus 72 hours in dogs). Therefore, even small increases in serum ALP activity (2–3 times normal) in cats suggest significant cholestasis.
- Exogenous or endogenous glucocorticoids are associated with hepatic production of a novel isoenzyme of ALP, corticosteroid-induced ALP (CIALP), in dogs but not in cats. The CIALP isoenzyme can be distinguished from the liver isoenzyme (LALP) by levamisole inhibition using an automated analyzer. Increased CIALP activity is a consistent finding in dogs with spontaneous hyperadrenocorticism and absence of this isoenzyme is uncommon in this disorder.

▼ ***Key Point*** Hypercortisolism caused by glucocorticoid therapy or hyperadrenocorticism (Cushing's disease) is the most common pathologic cause of increased serum ALP activity in dogs; it is usually attributed to an increase in CIALP.

- Increase in ALP activity associated with corticosteroid therapy varies considerably with the individual dog and the drug, dose, and duration of therapy. In the first 7 to 10 days of oral or parenteral glucocorticoid therapy, increases in ALP are primarily due to LALP activity. By 7 days, CIALP activity begins to increase, and it predominates in the serum after a month of therapy. Chronic treatment with otic, ophthalmic, and topical preparations is also capable of inducing ALP activity. Increases in CIALP activity do not necessarily imply the presence of iatrogenic hyperadrenocorticism, a suppressed pituitary-adrenal axis, or corticosteroid-induced hepatopathy, nor does it indicate that corticosteroid therapy must be discontinued.
- Increased CIALP activity is a sensitive but not a specific test for exposure to excess glucocorticoids (iatrogenic or endogenous). Increases in CIALP activity may be detected with diabetes mellitus, anticonvulsant drug therapy, primary hepatic disorders including neoplasia, hypothyroidism, and chronic illnesses (associated with disease-related stress and increased endogenous cortisol secretion). In this setting, a mixed pattern of increased CIALP and LALP activity is seen.
- Increased CIALP activity associated with exogenous or endogenous glucocorticoids may be accompanied by mild to moderate (2–10 times normal) increases in ALT activity that typically are of lesser magnitude than increases in ALP activity.
- Anticonvulsant drug therapy is associated with enzyme induction of the liver isoenzyme of ALP in dogs (but not in cats) in the absence of obvious hepatocellular injury. CIALP activity also may be increased in some dogs. Reported maximal increases for induced serum ALP activity include those caused by phenobarbital (30 times normal), primidone (5 times normal), and diphenylhydantoin (3 times normal).

Gamma-Glutamyltransferase

This membrane-associated enzyme is present in many tissues. Increased serum gamma-glutamyltransferase (GGT) activity usually reflects cholestasis and increased production by hepatocytes (see Fig. 71-2).

- Increased GGT activity parallels increased ALP activity in dogs, including increases associated with excess corticosteroids.
- Anticonvulsant therapy causes mild (2–3 times normal) increases in serum GGT activity in dogs.
- In cats, serum GGT is more sensitive for detecting hepatobiliary disease than ALP. Serum GGT activity exceeds serum ALP activity in most hepatobiliary diseases; an exception is hepatic lipidosis, in which GGT activity may be normal or mildly increased despite a moderate to severe elevation of serum ALP.

Other Biochemical Tests

Numerous biochemical tests can be altered by liver disease, including serum bilirubin, albumin, globulin, urea nitrogen, glucose, and cholesterol. Many of these parameters reflect some aspect of liver function; however, they lack sensitivity or specificity for liver disease.

Bilirubin

Increased serum bilirubin concentration occurs secondary to hemolysis or cholestasis. Evaluate for underlying hemolytic disorders by performing a complete blood count (CBC) to detect anemia.

- Fractionation of the total serum bilirubin into conjugated and unconjugated components (van den Bergh test) to distinguish the mechanism of hyperbilirubinemia is of little diagnostic value because there is considerable overlap in hemolytic, hepatocellular, and extrahepatic biliary disorders.
- Lipemia falsely elevates serum bilirubin concentration; the absence of concurrent bilirubinuria suggests pseudohyperbilirubinemia.

Albumin

Albumin is synthesized exclusively by the liver. Because of a large reserve capacity for albumin production, hypoalbuminemia does not occur until the functional hepatic mass is reduced 70% to 80%.

▼ ***Key Point*** Hypoalbuminemia associated with hepatic disease implies chronicity because of the long half-life of albumin.

- With chronic liver disease, fluid retention and dilution of existing serum albumin may also contribute to hypoalbuminemia.
- When the serum albumin is <1.5 g/dl, hypoalbuminemia contributes to the development of ascites and edema.
- Hypoalbuminemia is not specific for liver disease, and other causes of hypoalbuminemia such as urinary and gastrointestinal (GI) loss must be excluded.
- Inappropriate dietary protein restriction should be avoided since it can worsen hypoalbuminemia.

Globulin

- Hyperglobulinemia due to increased gamma globulins occurs in some dogs and cats with chronic liver disease. The most likely mechanism is a systemic response to antigens that escape from the GI tract because of impaired hepatic mononuclear phagocyte system function or portosystemic shunting.
- Significant hypoglobulinemia does not usually occur with liver disease despite the liver's role in the synthesis of alpha and beta globulins.

Blood Urea Nitrogen

Blood urea nitrogen (BUN) concentration may be decreased secondary to liver disease because the liver is responsible for converting ammonia to urea. However, many non-hepatic factors (e.g., PU/PD, fluid diuresis, and low-protein diet) can also decrease BUN levels.

Glucose

Hypoglycemia may occur secondary to hepatic dysfunction because of impaired hepatic gluconeogenesis, decreased hepatic glycogen stores, and decreased hepatic insulin degradation. However, because <30% of liver function is sufficient to maintain euglycemia, hypoglycemia is an insensitive indicator of hepatic function.

- Because it indicates severe liver dysfunction, liver-associated hypoglycemia is a poor prognostic factor, except in dogs and cats with congenital portosystemic shunts.
- Some hepatic neoplasms such as hepatocellular carcinoma and adenoma, leiomyosarcoma, and hemangiosarcoma have been associated with profound hypoglycemia.
- Also consider non-hepatic causes of hypoglycemia such as sepsis, hypoadrenocorticism, and insulinoma (see Chapters 33 and 35).

Cholesterol

- Hypercholesterolemia occurs with acute cholestatic disorders because of increased synthesis of cholesterol and decreased incorporation of cholesterol into bile acids; however, there are many non-hepatic causes of hypercholesterolemia.
- Although cholesterol is synthesized in the liver, hypocholesterolemia secondary to liver disease is uncommon; it has been noted with congenital portosystemic shunts and phenobarbital-induced hepatic disease.

Electrolytes

Serum electrolyte changes secondary to liver disease are variable.

- In acute liver failure, serum electrolyte concentrations are usually normal.
- With chronic liver disease, total body potassium depletion and sodium and water retention are common, and the serum sodium concentration is usually normal or decreased.

Liver Function Tests

Liver function tests can document clinically significant hepatic dysfunction when liver disease is suspected, based on historical, clinical, laboratory, and radiographic findings. SBA determinations have largely replaced the use of organic anion dyes such as sulfobromophthalein (Bromsulphalein) and indocyanine green (ICG). Blood ammonia concentration and ammonia tolerance tests can specifically evaluate the portal circulation (for portosystemic shunts) and detect HE.

▼ ***Key Point*** The test of choice for clinical evaluation of liver function is the combined fasting and 2-hour postprandial SBA test.

Serum and Urine Bile Acids

The normal physiology of bile acid metabolism is shown in Figure 71-3*A*. In health, bile acids are confined to the enterohepatic circulation, and systemic concentrations are low. SBA concentrations increase in the systemic circulation with all types of liver disease (Fig. 71-3*B*). Because the liver has a large reserve capacity for synthesis of bile acids, even severe hepatic dysfunction does not cause decreased SBA concentrations.

Fasting Serum Bile Acid Concentration

A fasting serum bile acid (FSBA) concentration obtained after a 12-hour fast is a sensitive, specific measure of hepatobiliary function in dogs and cats. Normal FSBA values in dogs and cats are <20 µmol/L. When concentrations exceed 30 µmol/L, a liver biopsy may be warranted to evaluate the underlying liver disease.

- Increased concentrations occur with hepatocellular and cholestatic disorders that interfere with hepatic uptake or secretion of bile acids and with portosys-

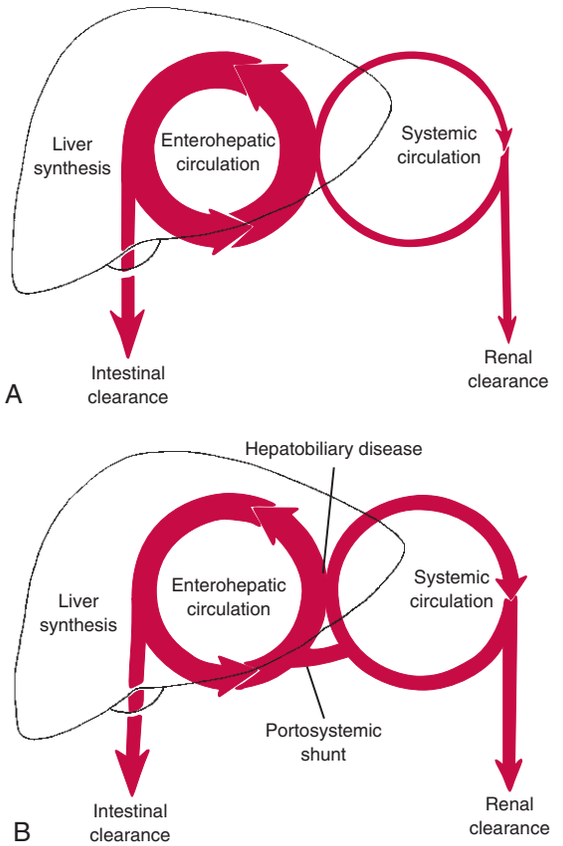

Figure 71-3. *A,* Bile acids are synthesized in the liver, secreted into the biliary system, and stored in the gallbladder during fasting. With ingestion of a meal, cholecystokinin release stimulates gallbladder contraction and entry of bile acids into the intestinal tract. Bile acids are efficiently reabsorbed in the distal ileum and carried in the portal blood back to the liver, thus completing the enterohepatic circulation. In the healthy animal, the liver removes 90% to 95% of bile acids from the portal circulation during the first pass of the enterohepatic circulation. This allows only small amounts of bile acids to escape to the systemic circulation. Normal serum concentrations are therefore low (fasting < 15 µmol/L, postprandial < 25 µmol/L). *B,* Hepatocellular dysfunction or cholestasis interferes with hepatic uptake, storage, and secretion of bile acids. Thus, impaired extraction of bile acids from the portal blood results in increased serum bile acid concentrations. With portosystemic shunting, bile acids in the portal blood are diverted directly into the systemic circulation.

temic shunting, in which bile acids are diverted directly into the systemic circulation (see Fig. 71-3*B*).

- Serial evaluation of SBA concentration to monitor liver function may not have merit unless the SBA concentration returns to normal. This is because there are wide fluctuations in SBA concentration in a given patient with liver disease within a 24-hour period (although all values are abnormal).
- Dogs and cats receiving the oral synthetic bile acid, ursodiol, may have an increase in SBA concentration because of the absorption of the drug and reflection of its presence in the serum.
- Interference in bile acid measurement can occur with hemolysis or lipemia.
- In dogs with unexplained increases in SBA, consider the possibility of small intestinal bacterial overgrowth causing increases in unconjugated bile acids.
- Healthy Maltese dogs were reported to have significantly higher SBA (mean 70 µmol/L ± 50; range 1–362 µmol/L) as measured by the enzymatic spectrophotometric method than as measured by high-performance liquid chromatography, suggesting the presence of additional reacting substances or unusual bile acids in their serum. However, a methodological problem related to lipemia or hemolysis cannot be excluded. It is also possible that these dogs had underlying hepatic microvascular dysplasia.
- When hepatic disease causes hyperbilirubinemia, measurement of SBA concentrations does not provide any additional diagnostic information. SBA concentrations are most helpful diagnostically in dogs and cats with anicteric liver disease.

Postprandial Serum Bile Acid Concentration

Postprandial serum bile acid (PPSBA) concentration is an endogenous challenge test of liver function. Whether PPSBA concentration is a more useful diagnostic test than FSBA concentration remains unclear. In dogs, similar information is provided by either test in most hepatobiliary disorders. Notable exceptions include dogs with portosystemic shunts or cirrhosis, because with these disorders, FSBA can be in the normal range. In cats, the diagnostic efficacy of PPSBA exceeds that of FSBA for all hepatic disorders, including portosystemic shunts. For best diagnostic utility, paired FSBA and 2-hour PPSBA is recommended. To perform the PPSBA concentration test, take the following steps:

- Obtain a serum sample for FSBA concentration, and then feed at least 2 teaspoons of food to small dogs and cats (<5 kg) and at least 2 tablespoons to larger patients.
- To ensure gallbladder contraction, feed a diet high in fat (e.g., Hill's Pet Prescription Diet p/d and Hill's Pet Prescription Diet c/d for cats). For encephalopathic animals in which a high-protein diet is contraindicated, substitute a protein-restricted diet and add a few milliliters of corn oil per feeding.
- Obtain a second serum sample 2 hours after feeding.
- *Results:* In normal dogs and cats, PPSBA concentrations are <25 µmol/L and peak 2 hours after a meal. A liver biopsy may be indicated when concentrations are >30 µmol/L.
- On occasion, FSBA is higher than PPSBA. This probably occurs because of sporadic gallbladder contraction during fasting, which releases bile into the intestinal tract, resulting in increased SBAs.

Urine Bile Acids

Recently, urine bile acids (UBAs) have been investigated as a diagnostic tool in dogs and cats. Normally only small amounts of bile acids are present in the

urine. Liver disease and increased SBA result in increased excretion of bile acids in the urine. Potential advantages of UBA over a random FSBA are that UBA may reflect an average value over time, ease of sample collection, and lack of interference from oral ursodiol administration.

- UBAs are normalized with urine creatinine (Cr), and values are expressed as UBA/Cr (μmol/mg) × 100. Values greater than 7.3 are abnormal in dogs. Values greater than 4.4 are abnormal in cats.
- Timing of urine collection to the 4- to 8-hour postprandial period may improve diagnostic performance, particularly in dogs with congenital portosystemic shunting where sensitivity of UBA (taken 4 to 8 hours after eating) was 100% compared with 84% for FSBA and 98% for PPSBA.
- The role of UBA in the evaluation of hepatobiliary function awaits further clinical evaluation.

Blood Ammonia Concentration

Ammonia is metabolized by the liver, and normal plasma concentrations are low. Measurement of ammonia is technically difficult, and appropriate sample handling requires heparinized blood samples to be stored immediately on ice, cold-centrifuged, and assayed as soon as possible.

- Measurement of blood ammonia concentration primarily is indicated to document HE. However, normal values do not exclude this diagnosis, because other toxins can contribute to the encephalopathy.
- Portosystemic shunting (congenital or acquired) is the most common mechanism of hyperammonemia, but severe, diffuse hepatic disease (especially acute hepatic necrosis) also increases blood ammonia concentrations.
- Blood ammonia values have poor sensitivity in detecting other types of hepatobiliary disease without portosystemic shunting.
- Blood ammonia concentration is not a suitable screening test for congenital portosystemic shunt in young Irish wolfhounds since a transient metabolic hyperammonemia unassociated with liver disease occurs in this breed.
- Congenital urea cycle enzyme deficiency is a rare cause of hyperammonemia.

Ammonia Tolerance Test

This is a more sensitive test than blood ammonia concentration for documenting portosystemic shunting. However, the ammonia tolerance test (ATT) is contraindicated if resting ammonia levels are already increased, because no further diagnostic information will be obtained and performing an ATT can cause signs of HE. *Note:* The ATT is not recommended for use in cats.

- The test is performed in a fasted dog by giving 100 mg/kg of ammonium chloride (do not exceed a total dose of 3 g), either as a dilute solution by stomach tube or as a powder in a gelatin capsule.
- Take a heparinized blood sample before and 30 minutes (stomach tube method) or 45 minutes (capsule method) after administering the ammonium chloride. Vomiting may occur but does not invalidate the test.
- In normal dogs, there is no increase in blood ammonia concentration or a mild increase (<2 times greater than baseline). In dogs with portosystemic shunting, results are consistently abnormal (up to 10 times baseline values).
- The ATT and paired FSBA and PPSBA tests have equal sensitivity in detecting portosystemic shunting. Consequently, the SBA testing has largely replaced blood ammonia and ATT. Paired FSBA and PPSBA provide a better screening test because it detects a broader range of hepatobiliary disorders, and bile acids are stable, permitting routine laboratory analysis.

Protein C

Protein C, an anticoagulant protein synthesized in the liver, has been investigated as a clinical marker of liver disease. Preliminary results show decreased protein C concentrations in 100% of dogs with liver failure, 98% of dogs with portosystemic shunt, and 30% of dogs with hepatic microvascular dysplasia. The role of protein C in the detection of liver disease awaits further clinical studies.

Parameters of Hemostasis

The liver plays a central role in the coagulation and fibrinolytic systems. The liver is responsible for synthesis of all coagulation factors except factor 8, von Willebrand factor. Fibrinogen, antithrombin, and protein C are all synthesized in the liver and can be decreased with hepatic dysfunction. Activated coagulation factors and fibrinolytic enzymes are also cleared by the liver.

- Mechanisms of excessive bleeding associated with hepatobiliary disease include primary failure of hepatocytes to synthesize clotting factors, DIC, and vitamin K deficiency. Vitamin K deficiency in hepatobiliary disease is usually caused by malabsorption of vitamin K secondary to complete bile duct obstruction. However, a vitamin K–responsive coagulopathy may sometimes be detected in dogs and cats with severe hepatic insufficiency, possibly due to marked intrahepatic cholestasis causing vitamin K malabsorption or the inability of the liver to reactivate vitamin K from its inactive (epoxide) form.
- Clinical evidence of bleeding secondary to hepatobiliary disease is uncommon; however, the frequency of abnormal coagulation tests is much higher.

Coagulation Tests

- Measure prothrombin time (PT) to evaluate the extrinsic coagulation system and activated partial

thromboplastin time (APTT) to evaluate the intrinsic coagulation system. These tests can be abnormal in the presence of liver disease. Activated coagulation time also can be used as a rapid screening test for abnormalities of the intrinsic coagulation system. For further discussion of these tests, see Chapter 23.

- The PIVKA (proteins induced by vitamin K absence) clotting time is a more sensitive test than PT or APTT to detect bleeding tendencies in dogs and cats with liver disease. Normalization of PIVKA clotting time may occur after treatment with vitamin K_1.
- The combination of prolonged PT and APTT, low plasma fibrinogen, increased fibrin degradation products, fragmented RBCs, and thrombocytopenia suggests DIC (see Chapter 23).

Thrombocytopenia and Platelet Dysfunction

- Thrombocytopenia may occur secondary to splenic sequestration of platelets associated with portal hypertension or consumption of platelets from DIC.
- Platelet function defects also have been documented in dogs with liver disease, which may account for clinical bleeding tendencies in the presence of normal coagulation tests and platelet numbers. Use mucosal bleeding time to detect platelet function abnormalities.

Blood Gas Analysis

Various acid-base imbalances may occur secondary to liver disease, including respiratory alkalosis, metabolic alkalosis, metabolic acidosis, and mixed acid-base disturbances.

Abdominal Fluid Analysis

- Ascitic fluid that accumulates secondary to liver disease and hypoalbuminemia is usually a transudate. With hepatic venous congestion from vena caval obstruction or cardiac causes, the fluid typically is a modified transudate with protein concentration > 2.5 g/dl.
- Rupture of the biliary tract is associated with bile peritonitis. Grossly, the abdominal fluid appears yellow or green. Chemical tests for bilirubin are positive, and concentrations of bilirubin are higher in abdominal fluid than in serum. Cytologic examination reveals a mixed inflammatory infiltrate and bile-laden macrophages. Bacteria may be seen if bile peritonitis is complicated by sepsis.

Diagnostic Imaging

Survey Radiography

Abdominal radiographs are useful to evaluate for the following:

- Changes in liver size (hepatomegaly, microhepatica)
- Altered tissue characteristics such as mineralized hepatic densities (choleliths) and radiolucencies (abscesses)
- Presence of abdominal effusion

If hepatic neoplasia is suspected, take thoracic films to evaluate for pulmonary metastases.

Ultrasonography

Ultrasonography can be used to image the liver noninvasively, especially when abdominal effusion precludes survey radiographic evaluation. A normal ultrasonographic appearance of the liver does not eliminate the possibility of significant hepatic pathology; however, ultrasonography is diagnostically useful to achieve the following:

- Detect focal parenchymal abnormalities such as masses, abscesses, cysts, and regenerative nodules. The ultrasonographic appearance of these focal lesions often is similar, and biopsy is required for differentiation.
- Document that a palpable mass is associated with the liver.
- Investigate disorders of the biliary tract and gallbladder, such as biliary obstruction, cholelithiasis, or gallbladder mucocele.
- Detect vascular lesions such as portosystemic shunts, hepatic arteriovenous fistulas, and hepatic venous congestion.
- Obtain percutaneous liver biopsies (see below).
- Identify abnormalities in other abdominal organs that may be a cause or effect of liver disease (e.g., pancreas, spleen, kidneys, bladder, GI tract, adrenal glands, and lymph nodes). For example, urate or uric acid urolithiasis may be detected in animals with portosystemic shunts, the primary tumor may be identified in animals with hepatic metastases, and identification of adrenal gland enlargement may aid the diagnosis of steroid hepatopathy.

Angiography

Angiography is useful to diagnose vascular disorders involving the liver, such as congenital and acquired portosystemic shunts, hepatic arteriovenous fistulas, and vena caval obstruction causing hepatic venous obstruction (see under "Congenital Portosystemic Shunt").

Liver Cytology

Fine-needle aspiration (FNA) of the liver for cytology is commonly performed because it is easy and safe, does not require sedation or anesthesia, and provides rapid preliminary information. However, the diagnostic accuracy of cytology versus histopathology of the liver is controversial. Studies suggest a lack of correlation exists as much as 50% of the time. Cytology of impression smears of liver biopsy tissue correlates better than samples obtained by fine-needle aspirate.

- Cytology of the liver is most useful if the pathologic process is diffuse and architectural relationships (which can be obtained only by histopathology) are not essential to the diagnosis. Examples include vacuolar hepatopathies such as feline hepatic lipidosis,

diffuse hepatic neoplasia, and liver disease associated with infectious agents such as histoplasmosis.
- In cats, primary liver diseases such as lymphoma and cholangitis may be accompanied by hepatic vacuolar changes. These cats may be misdiagnosed as idiopathic hepatic lipidosis if cytology only reflects the vacuolated hepatocytes.
- For focal lesions, accuracy is improved when the fine-needle aspirate is guided by ultrasound.
- Poor correlation of cytology with histopathology occurs in primary inflammatory liver diseases, although it may be better for detection of suppurative inflammation than for lymphocytic-plasmacytic inflammation.

Liver Biopsy

Liver biopsy often is required to definitively characterize the nature and severity of hepatic disease, to differentiate acute from chronic disorders, and to assess response to therapy. Selection of the best procedure for obtaining a liver biopsy depends on numerous factors, including liver size, presence of coagulopathy, diffuse versus focal hepatic lesions, presence of biliary tract obstruction, presence of other intra-abdominal abnormalities, likelihood of surgical resection of a mass, tolerance of general anesthesia, available equipment, and expertise of the clinician.

▼ ***Key Point*** Perform a hemostasis screen prior to liver biopsy to detect coagulopathy. After the biopsy is performed, monitor for bleeding from the biopsy site.

Biopsy Methods

Ultrasound-Guided Needle Biopsy

This technique is the most common percutaneous method used for liver biopsy. However, it is dependent on the availability of equipment and clinician expertise.

- With ultrasound-guided biopsy, it is possible to obtain tissue from focal lesions (whether superficial or deep within the hepatic parenchyma), avoid structures adjacent to the liver, and monitor post-biopsy bleeding.
- Ultrasound-guided biopsy may be difficult if the liver is small or the ultrasonographer lacks experience.
- Because needle biopsy specimens are smaller than wedge biopsies, they may not be representative of underlying liver pathology. In one study, the morphologic diagnosis made by needle biopsy correlated with the definitive diagnosis obtained by wedge biopsy in only 48% of dogs and cats.

Laparoscopy

Laparoscopy provides direct visualization of the liver and adjacent structures such as the pancreas and extrahepatic biliary tract. Biopsies also are obtained under direct visualization.

- Laparoscopy is a useful alternative to ultrasound-guided needle biopsy when the liver is small.
- It is preferable to ultrasound-guided biopsy when excess bleeding is anticipated and to laparotomy when delayed wound healing (hypoalbuminemia) is anticipated.
- Laparoscopy requires heavy sedation or anesthesia and is subject to equipment availability and clinician expertise.

Laparotomy

Laparotomy is indicated for liver biopsy when a surgically correctable disease is suspected, such as extrahepatic biliary tract obstruction or a single, large hepatic mass (see Chapter 72 for a description of the procedure for surgical biopsy).

- Laparotomy makes it possible to obtain large samples of liver tissue and monitor for post-biopsy bleeding.
- Disadvantages include the need for general anesthesia, the relatively high risk of complications, and the risk of delayed wound healing in hypoalbuminemic patients.

Biopsy Analysis

- To prepare biopsy tissue for histopathology, place samples in 10% buffered formalin and allow them to fix for 24 hours. The volume of fixative should be 20 times the volume of biopsy tissue.
- To prepare needle biopsy samples, gently remove liver tissue from the biopsy needle and place it on tissue paper; fold the paper and place it in a formalin jar.
- Perform routine light microscopy on liver tissue stained with hematoxylin and eosin (H&E).
- Additional stains may be requested, including trichrome for fibrous connective tissue, periodic acid-Schiff (PAS) for glycogen, rhodanine or rubeanic acid for copper, Prussian blue for iron, Congo red for amyloid, oil red O for fat, and silver or acid-fast stains for infectious organisms.
- Submit fresh liver tissue for bacterial and fungal culture as indicated.
- Perform quantitative copper analysis on fresh hepatic tissue.
- Place samples for electron microscopy in chilled, buffered 2.5% glutaraldehyde.

PRINCIPLES OF TREATMENT FOR LIVER DISEASE

Objectives

- Whenever possible, identify and eliminate the inciting or predisposing causes of liver disease. Identifi-

cation of the underlying cause of hepatobiliary disease can provide insight into specific therapy, the likelihood and nature of potential complications, and the prognosis for recovery. (Therapy for individual hepatobiliary disorders is discussed later under specific diseases.)
- Prevent or manage complications of liver failure, including HE, ascites, GI ulceration, coagulopathy, infection, and endotoxemia.
- In patients in which hepatic regeneration and recovery are possible, supportive care allows time for this to occur. In other cases, clinical manifestations of hepatic failure may be minimized for variable periods.

Consider Drug Metabolism

The liver is a major site of drug metabolism, and liver disease may alter drug metabolism. In many cases, hepatic disease is associated with decreased hepatic clearance of a drug, with subsequent potential toxicity.

▼ ***Key Point*** Prior to administering any drug to a patient with hepatic disease, consider whether the drug is metabolized or excreted by the liver, is potentially hepatotoxic, or may exacerbate signs of liver failure.

Avoid drugs that fit the following descriptions:
- Are known to depend primarily on the liver for inactivation or excretion
- Are potential hepatotoxins, such as phenobarbital
- May worsen signs of hepatic failure, such as methionine-containing products, tranquilizers, sedatives, and diuretics (may exacerbate HE) and nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids (may cause GI bleeding and exacerbate HE)

Supportive Therapy for Liver Disease

Supportive measures for patients with liver disease are summarized in Table 71-1.

Restore Fluid, Electrolyte, and Acid-Base Balance

- Maintain normal fluid balance to support hepatic blood flow and microcirculation and prevent complications such as HE, DIC, shock, and renal failure. The composition of the fluid to be given is influenced by the patient's electrolyte and acid-base status and the presence or potential for hypoglycemia (see Table 71-1 for guidelines; also see Chapter 5).
- Avoid alkalinizing agents (e.g., lactate in lactated Ringer's solution and sodium bicarbonate) when HE

Table 71-1. GENERAL THERAPY OF HEPATOBILIARY DISEASE

Therapeutic Goals	Therapeutic Regimen
Fluid Therapy	
Maintain hydration	Use a balanced polyionic solution such as lactated Ringer's solution or Plasma-Lyte 148 IV.[a] Use 0.45% NaCl in patients with ascites or edema.
Prevent hypokalemia	Add 20–30 mEq KCl to each liter of maintenance fluid. Monitor serum potassium daily and adjust as necessary.
Maintain acid-base balance	Avoid alkalosis in HE by using 0.45% or 0.90% saline for IV fluid therapy. Give $NaHCO_3$ or acetate-containing fluids (Plasma-Lyte) rather than lactated fluids for treatment of severe metabolic acidosis. Avoid lactate-containing fluids in cats with severe hepatic lipidosis.
Prevent or control hypoglycemia	To treat hypoglycemia, give 50% dextrose (0.5–1 ml/kg) IV to effect. To maintain normoglycemia, add dextrose to fluids to achieve a 2.5–5.0% solution.
Nutritional Support	
Maintain caloric intake	Provide 40–60 kcal/kg/day of good-quality diet.
Provide adequate vitamins and minerals	Add B vitamins to fluids of anorexic cats. For long-term therapy, give an oral vitamin-mineral (especially B vitamin) supplement. Give vitamin K_1 (0.5–1.5 mg/kg IM or SC q12h for three treatments, then weekly as needed) in biliary obstruction or severe cholestatic liver disease (dogs and cats).
Modify diet to control complications	See specific complications (e.g., HE and ascites).
Control HE	
Modify diet	Give NPO in initial stages of HE. For long-term management, provide a reduced-protein (dairy or vegetable source protein preferred; avoid red meat protein), easily digested, high-carbohydrate diet. Recommend moderate protein restriction of 15–20% dry matter (dogs) or 30–35% dry matter (cats). Increase dietary soluble fiber (psyllium 1–3 tsp/day).
Prevent formation and absorption of enteric toxins	In hepatic coma, give a warm-water cleansing enema initially (10–20 ml/kg) until fluid is clear, followed by retention enema (5–10 ml/kg q8–12h) containing lactulose (30% lactulose with 70% water) and neomycin solution (22 mg/kg) and held for 20–30 minutes or povidone iodine solution (diluted 1:10 with water, 50–200 ml total) and flushed out within 10 minutes. For follow-up oral therapy, give neomycin[b] (22 mg/kg q8–12h PO), metronidazole (7.5 mg/kg q12h PO), or amoxicillin (22 mg/kg q12h PO) combined with lactulose[c] (0.25–0.5 ml/kg q8–12h PO) or lactitol (0.5–0.75 g/kg q12h PO) to achieve two or three soft stools per day; if diarrhea occurs, reduce dose.
Control gastrointestinal hemorrhage	Correct coagulopathy. Treat GI parasites and treat gastric ulcer (famotidine or nizatidine or omeprazole[d] combined with sucralfate[e]). Avoid drugs that exacerbate GI hemorrhage (e.g., aspirin and other NSAIDs or glucocorticoids).

Table continued on following page

Table 71-1. GENERAL THERAPY OF HEPATOBILIARY DISEASE—cont'd

Therapeutic Goals	Therapeutic Regimen
Correct metabolic imbalances (e.g., dehydration, azotemia, hypokalemia, alkalosis, and hypoglycemia)	See fluid therapy above.
Avoid drugs or therapies that exacerbate HE	When possible, avoid sedatives, tranquilizers, anticonvulsants, analgesics, anesthetics, methionine-containing products, diuretics, or stored blood transfusion.
Control seizures	For refractory seizures in dogs, use loading dosages of sodium bromide IV (3% NaBr 600–800 mg/kg over 24 hours) or potassium bromide orally (KBr 100–200 mg/kg q6h for 24 hours), followed by KBr at a dosage of 15–30 mg/kg q12h PO[f] or IV phenobarbital[g] at reduced doses in dogs and cats (monitor serum concentrations to adjust the dose). Avoid benzodiazepines. For status epilepticus, consider general anesthesia with propofol to control seizures. Intubate and use mechanical respirator to maintain pO_2 and pCO_2. Give mannitol (0.5–1 g/kg by IV bolus over 20 minutes) for suspected cerebral edema. For chronic, stable seizure management or long-term therapy in dogs, give potassium bromide (15–30 mg/kg q12h PO in food). For maintenance therapy in cats, consider topiramate (3.125 mg q12h PO initially, then 6.25 mg q12h PO). For short-term perioperative anticonvulsant therapy for congenital PSS, consider felbamate (15–20 mg/kg q8h PO), levetiracetam (20–30 mg/kg q12h), or topiramate[h] (5–10 mg/kg q12h PO) in dogs or topiramate (3.125 mg q12h PO initially, then 6.25 mg q12h PO) in cats.
Control infection	Give systemic antibiotics (see below).
Control ascites and edema	Give a low-sodium diet; combine furosemide (1–2 mg/kg q12h PO)[i] and spironolactone (1–2 mg/kg q12h PO)[g], or spironolactone and hydrochlorothiazide (Aldactazide,[j] 2 mg/kg q12h PO). Use paracentesis for relief of dyspnea or extreme abdominal distention, synthetic colloids such as hetastarch (10–20 ml/kg/day IV in dogs and 10–15 ml/kg/day IV in cats) or human albumin 25% (2 ml/kg in dogs), or plasma transfusion for albumin replacement (25–45 ml/kg).
Control coagulopathy and anemia	Give vitamin K_1 (0.5–1.5 mg/kg q12h, IM or SC for three treatments, then weekly as needed for dogs and cats); fresh plasma or fresh-frozen plasma (10 ml/kg); or a fresh blood transfusion (10–15 ml/kg). For DIC, give heparin (75–100 IU/kg q8–12h SC). For dogs with vWD and liver failure, give DDAVP once (1 µg/kg diluted in 10–20 ml of saline and given IV slowly over 10 minutes or undiluted SC) (effective for 4–6 hours).
Control gastrointestinal ulceration	Give famotidine (0.5–1.0 mg/kg q12–24h PO or IV), nizatidine (2.5–5.0 mg/kg q24h PO), or omeprazole[d] (0.5–1.0 mg/kg q24h PO) and sucralfate[e] (1-g tablet/25 kg q8h PO).
Control infection and endotoxemia	Give systemic antibiotics (e.g., amoxicillin, ampicillin, cephalosporins, aminoglycosides, and metronidazole[k]).

[a] May be given SC if animal is mildly dehydrated and is not vomiting.
[b] Neomycin has been associated with rare ototoxicity and nephrotoxicity; its use should be restricted to acute management of HE.
[c] Crystalline lactulose (powder) is also available commercially (Kristalose, Bertek Pharmaceuticals) as 10- or 20-g packets (syrup concentration is 10 g/15 ml).
[d] Partially metabolized by the liver; use a reduced dose in animals with liver failure. Inhibits hepatic P-450 enzymes.
[e] Beware of drug-associated constipation, which may worsen HE.
[f] Avoid bromide in cats due to cough and asthma-like side effects.
[g] Can be used in dogs and cats with congenital PSS, but avoid in animals with acquired liver disease.
[h] Start at the low end of the dose range due to impaired hepatic metabolism.
[i] Dose may be doubled if there is no effect in 4–7 days.
[j] GD Searle & Co., Chicago, IL.
[k] Partially metabolized by liver. Use a reduced dosage (7.5 mg/kg q12h PO) in animals with liver failure.
DDAVP, desmopressin acetate; DIC, disseminated intravascular coagulation; GI, gastrointestinal; HE, hepatic encephalopathy; NPO, nothing per os; NSAIDs, nonsteroidal anti-inflammatory drugs; vWD, von Willebrand disease.
Adapted from Johnson SE: Liver and biliary tract. In Anderson NV (ed): Veterinary Gastroenterology, 2nd ed. Philadelphia: Lea & Febiger, 1992, p 504.

is present or impending, because alkalosis augments the entry of ammonia into the CNS and can exacerbate signs of HE.

Give Nutritional Support

Nutritional support is important for promoting hepatic regeneration and maintenance of body weight.

- Modify the diet as needed to control complications of hepatic disease, such as HE, hypoproteinemia, and ascites (see Table 71-1).
- Supply the bulk of the calories by carbohydrates, which provide an easily assimilated source of nonprotein calories.
- Avoid high-protein diets that may exacerbate signs of HE. Indiscriminate protein restriction is discouraged, however, because adequate protein intake is important for normal hepatic regeneration and to counteract hypoproteinemia.
- When voluntary food intake is lacking, provide other methods of nutritional support, such as feeding through a gastrostomy tube (see Chapter 3).

Control Complications

Hepatic Encephalopathy

Goals for treatment of HE are summarized in Table 71-1. Restrict dietary protein intake. Increase dietary soluble fiber (see Table 71-1). Prevent formation and absorption of enteric toxins.

- Give antibiotics (e.g., neomycin, amoxicillin, or metronidazole) to alter the urease-producing bacterial population in the colon, thus decreasing conversion of urea to ammonia (see Table 71-1).
- Lactulose, a synthetic disaccharide, often is effective in controlling signs of HE and decreasing arterial blood ammonia concentrations through its actions as a cathartic and colonic acidifier (see Table 71-1). It usually is given in combination with antibiotics.

▼ ***Key Point*** Detect and control GI hemorrhage, which could provide enteric bacteria with a source of protein for toxin production. Give fresh rather than stored blood if a transfusion is required, because stored blood contains substantial amounts of ammonia.

Ascites and Edema

Ascites in liver disease usually is associated with hypoalbuminemia, portal hypertension, and renal retention of sodium and water.

- For treatment of ascites, restrict dietary sodium and use diuretics to promote urinary sodium and water excretion (see Table 71-1).
- For temporary support of plasma colloid osmotic pressure in hypoproteinemic animals, consider plasma transfusion to supply albumin or colloid administration such as hetastarch (see Table 71-1 and Chapter 5).
- Avoid using abdominocentesis to treat ascites except when required for relieving respiratory distress.

Coagulopathy and Anemia

Hemostatic defects associated with hepatobiliary disease can be attributed to primary failure of hepatocytes to synthesize clotting factors, vitamin K deficiency, or DIC.

- Parenteral administration of vitamin K_1 corrects coagulopathy caused by vitamin K deficiency within 24 to 72 hours, but no response is seen when bleeding is caused by hepatocyte failure or DIC (see Table 71-1).
- For treatment of DIC and other coagulopathies, see Chapter 23.

Gastrointestinal Ulceration

Dogs and cats with hepatobiliary disease are at increased risk for GI ulceration. Possible mechanisms include gastric acid hypersecretion, impaired gastric mucosal blood flow secondary to portal hypertension, and decreased gastric epithelial cell turnover.

- GI bleeding is deleterious in patients with HE because blood is a substrate for ammonia production.
- Manage GI ulceration with an H_2 blocker for control of acid secretion and with sucralfate for mucosal cytoprotection, as described in Chapter 67. Famotidine and nizatidine are preferable to cimetidine and ranitidine as H_2 blockers in animals with liver disease, because they do not inhibit hepatic microsomal enzymes.

▼ ***Key Point*** The proton pump inhibitor, omeprazole, inhibits hepatic microsomal enzymes and undergoes hepatic metabolism, making it less predictable for use in animals with liver disease.

Infection and Endotoxemia

An increased incidence of infection may be seen in animals with hepatic disease as enteric bacteria and endotoxins gain access to the systemic circulation as a result of impaired hepatic mononuclear phagocyte system function or portosystemic shunting. Septicemia and endotoxemia may, in turn, perpetuate liver injury.

- Give systemic antibiotics to control extrahepatic infections or sepsis. Penicillins, cephalosporins, or aminoglycosides are good choices because they are eliminated primarily by renal mechanisms.

Renal Failure

Renal dysfunction and azotemia may complicate liver disease, especially chronic liver dysfunction, and can be pre-renal, primary renal, or both.

- Pre-renal mechanisms that decrease effective circulating volume and renal perfusion include dehydration (including that induced by diuretics), hypoalbuminemia, ascites, and overzealous abdominal paracentesis. Appropriate fluid therapy is essential to avoid pre-renal azotemia.
- Primary renal failure may occur with pre-existing renal disease or may result from infectious or toxic agents (e.g., leptospirosis) that affect the liver and kidneys concurrently or secondary to advanced liver disease.

Hepatoprotectants

Consider ancillary treatment with the hepatoprotectants listed in Table 71-2. These do not appear to be toxic when used as described.

- Hepatoprotectants include a varied group of compounds (prescription drugs, nutraceuticals, vitamins) that may protect the liver from injury caused by free radicals, bile salts, drugs, environmental toxins, or other insults.
- Nutraceuticals are products that have characteristics of both a nutrient and a pharmaceutical. They are readily available through health food stores or Inter-

Table 71-2. HEPATOPROTECTANTS

Product	Preparation	Dosage	Mechanism of Action	Comments
S-adenosylmethionine (SAMe)	Denosyl SD4 (Nutramax Labs): 90 and 225 mg tab	20 mg/kg PO q24h (D&C)	Intermediary metabolite: indirect glutathione precursor (antioxidant), choleretic (cats), detoxification. Supports membrane function.	Don't break enteric-coated tablets. Use only foil-wrapped products. Food decreases absorption. No side effects are noted. Can be used in acetaminophen toxicity. Expensive.
Acetylcysteine	10% or 20% solution	Dilute at least 1 : 4 with saline. Give 140 mg/kg IV through 0.25-µm filter over 20–30 min, then 70 mg/kg PO or IV q6h for seven treatments (D&C)	Glutathione precursor.	Antidote for acetaminophen toxicity. May have protective effects for other drug-induced (carprofen, potentiated sulfas, methimazole, diazepam) or toxin-induced liver injury. Safe. May cause nausea and vomiting when given orally.
Milk thistle (Silybin)	Marin (Nutramax Labs: silybin, vitamin E, zinc)* 9-, 24-, or 70-mg tab; Sil-phos (Indea Labs)	6–100 mg total dose PO q24h per package insert (D); 9–18 mg total dose PO q24h (C)	Antioxidant, anti-inflammatory, antifibrotic. Protects against *Amanita* mushroom toxicity (experimental) in dogs.	Silybin has low bioavailability; improved when complexed with phosphatidylcholine (Marin, Sil-phos). Other products have variable potency and absorption.
Vitamin E (alpha-tocopherol)	Many available	50–400 IU PO q24h (D&C)	Membrane-associated antioxidant. Protects liver against oxidative injury.	Natural Vitamin E (d-α tocopherol) has greater bioavailability than synthetic (d,l) form. In severe cholestasis, use water-soluble form.
Ursodiol	Actigall (Ciba): 300-mg caps	15 mg/kg PO q24h (D&C)	Hydrophilic bile acid. Shifts bile acid pool to less toxic hydrophilic bile acids. Choleretic in dogs (cats unknown). Protects hepatocyte membranes. Modulates immune response.	Used in cholestatic disorders; contraindicated in biliary obstruction. Side effects are rare (vomiting). Expensive.
L-carnitine	Many available	250 mg PO q24h (C)	Essential cofactor for transport of fatty acids into mitochondria for oxidation.	May improve fatty acid oxidation in obese cats undergoing weight loss but will not prevent hepatic lipidosis. Used in ancillary treatment of hepatic lipidosis.
Zinc	Zinc acetate: Galzin (Gate Pharmaceuticals); many others available	To decrease Cu absorption: 100-mg elemental zinc PO q12h for 2–3 months, then 50 mg PO q12h (D). For zinc supplementation in chronic liver disease: 1–2 mg/kg PO q12h (D)	Induces intestinal metallothionein, which preferentially binds Cu and decreases absorption. Zinc has antioxidant and antifibrotic effects; supports cell membrane function and immune response.	Many zinc products are available (acetate, sulfate, gluconate). Avoid zinc methionine if impending HE. Calculate dose on elemental zinc content. Monitor blood zinc levels: Ideal = 200–400 µg/dl; avoid >800 µg/dl (hemolysis). Do not give concurrently with Cu chelator (will be chelated). Nausea, vomiting, decreased appetite (less with zinc acetate).
Vitamin C (ascorbic acid)	Many available	100–500 mg PO q24h (D&C)	Free radical scavenger; functions in converting vitamin E back to active form. Acts as pro-oxidant in the presence of high iron, Cu levels.	Avoid in Cu-associated hepatopathy.

C, cats; Cu, copper; D, dogs; HE, hepatic encephalopathy.
*No zinc in the 9 mg tab for cats.

net mail-order sites, yet for many of these products there is a lack of safety and efficacy data.
- Lack of a regulatory mechanism for nutraceuticals is not justification for ignoring the potential therapeutic benefits of some of these products. However, most of these drugs have not been studied adequately in spontaneous hepatobiliary diseases of dogs and cats to prove efficacy.

ACUTE HEPATIC FAILURE

Acute hepatic failure occurs when a sudden severe insult to the liver compromises at least 70% to 80% of functional hepatic tissue. The clinical manifestations and laboratory findings associated with acute hepatic failure reflect general liver failure and are not specific for the underlying cause of injury.

Etiology

Causes of acute hepatic injury in dogs and cats include hepatotoxins, infectious or parasitic agents, systemic or metabolic disorders, or miscellaneous causes of liver injury (Table 71-3). In many cases, a specific cause cannot be identified.

Toxin-Induced Injury

- Hepatic injury may occur after exposure to a wide variety of industrial chemicals, organic solvents, pesticides, heavy metals, and biologic toxins (see Table 71-3). Exposure can be unobserved in a free-roaming animal that drinks from a contaminated water source.
- When hepatic necrosis is severe and widespread, rapid deterioration and death in 3 to 4 days often occur. With less extensive damage, complete recovery is possible.

Drug-Induced Injury

Drug-induced injury is a recognized cause of acute hepatic failure in dogs and cats. The incidence of drug-induced hepatic disease is unknown but is probably underestimated. Hepatic drug reactions are categorized as *dose dependent* or *idiosyncratic*.

Dose-Dependent Hepatotoxins

These hepatotoxins predictably damage the liver in an exposed population. The effect is dose-related and reproducible experimentally. All members of a species are affected at high doses. Toxicity is due to the parent drug or a consistently generated toxic metabolite.

- If a hepatotoxic reaction occurs, lowering the dose, rather than stopping the drug, can be tried.
- Examples of dose-related hepatotoxins include acetaminophen, tetracycline, stanozolol (cats only), and possibly phenobarbital (dogs only).

Idiosyncratic Hepatotoxins

These hepatotoxins cause hepatic injury at therapeutic doses in only a few individuals in the exposed population. These reactions are unpredictable and infrequent; most individuals treated with the drug do not have a reaction, even at high doses. Affected individuals appear to be unusually susceptible, possibly because they generate a unique toxic intermediate metabolite. An immunologic response may or may not be involved. Within susceptible individuals, toxicity may be more pronounced at higher doses. Because of the unpredictable nature of the reaction, they can be difficult to recognize clinically.

- If an idiosyncratic reaction occurs, the drug must be discontinued or it could result in the death of the patient.
- Examples include halothane and methoxyflurane, carprofen and other NSAIDs, lomustine, mebendazole, oxibendazole, potentiated sulfonamides, and methimazole.
- Drugs that have been incriminated as potential hepatotoxins include analgesics, anticonvulsants, and antimicrobials (see Table 71-3). Specific clinical details regarding known drug reactions in dogs and cats are summarized in Table 71-4.

▼ ***Key Point*** Dose-dependent hepatotoxic drugs cause predictable liver injury in all animals of a species, especially at high or excessive doses, whereas idiosyncratic hepatotoxic drugs affect only certain uniquely susceptible animals, even at low or therapeutic doses.

Infectious Agents

Infectious causes of acute hepatic injury (see Table 71-3) include leptospirosis (see Chapter 19), toxoplasmosis (see Chapter 21), histoplasmosis (see Chapter 20), FIP virus (see Chapter 10), and infectious canine hepatitis virus (see Chapter 16).

Miscellaneous Systemic Diseases

Hepatic injury can occur secondary to various systemic conditions, including those discussed below.

Hemolytic Anemia

Hemolysis, especially immune-mediated hemolytic anemia in dogs, can be complicated by centrilobular necrosis attributed to acute hepatocellular hypoxia or DIC-induced sinusoidal thrombosis. The hepatic injury generally resolves with resolution of the anemic crisis.

Anesthesia, Surgical Hypotension, Hypoxia, and Shock

Conditions that decrease liver blood flow can lead to hypoxia and hepatic damage. In the postoperative

Biologic Substances

Aflatoxin (contaminated dog food)
Amanita mushrooms
Blue-green algae
Sago palms
Hymenoptera toxins (hornet sting)
Indigofera sp. (toxic plant)
Pennyroyal oil

Chemicals

Carbon tetrachloride
Dimethylnitrosamine
Galactosamine
Metals (copper, iron, zinc, phosphorus)
Organochloride pesticides
Salt poisoning
Many others

Infectious or Parasitic Agents

Viral

Infectious canine hepatitis (adenovirus I)
Canine herpesvirus
Feline infectious peritonitis (coronavirus)
Feline calicivirus (virulent strains)

Bacterial

Cholangiohepatitis
Leptospirosis
Liver abscess
Bacillus piliformis (Tyzzer's Disease)
Salmonella spp.
Francisella tularensis (Tularemia)

Fungal

Histoplasma
Coccidioides
Blastomyces
Others

Protozoal and Parasitic

Toxoplasma
Babesia
Cytauxzoon felis
Dirofilaria (Postcaval syndrome)

Rickettsial

Ehrlichia canis
Rickettsia rickettsii

Systemic or Metabolic Disorders

Acute pancreatitis
Acute hemolytic anemia
Extraheptic infection, septicemia and endotoxemia
Idopathic feline hepatic lipidosis
Inflammatory bowel disease

Traumatic, Thermal, or Hypoxic Injury

Abdominal trauma
Diaphragmatic hernia with liver entrapment
Heat stroke
Liver lobe torsion
Shock
Surgical hypotension and hypoxia

*Usually causes chronic rather than acute hepatic disease.

Table 71-4. SELECTED HEPATOTOXIC DRUG REACTIONS IN DOGS AND CATS

Drug	Species	Onset of Signs and Key Features	Hepatic Lesions	Suggested Mechanism	Comments
Analgesics					
Acetaminophen (Tylenol, McNeil)	Canine and feline	Initial toxicity is cyanosis and methemoglobinemia. Acute hepatic failure[a] occurs in dogs but is less likely in cats.	Centrilobular necrosis and congestion, vacuolar hepatopathy and bile stasis	Dose-related	Dose-related injury (doses exceeding 200 mg/kg in dogs and 120 mg/kg in cats). Treatment: N-acetylcysteine (140 mg/kg IV or PO initially, then 70 mg/kg IV or PO q6h for 36 hours) and ascorbic acid (30 mg/kg q6h for 36 hours). SAMe (20 mg/kg PO q24h) can also serve as a glutathione source. Cimetidine (5–10 mg/kg IV q8–12h for at least 3 days) inhibits hepatic P-450 enzymes and prevents further conversion of acetaminophen to toxic product.
Carprofen (Rimadyl, Pfizer)	Canine	Acute hepatic failure[a] within 5–30 days after starting drug. Labrador retrievers may be at increased risk.	Hepatocellular necrosis, ballooning degeneration, cholestasis	Idiosyncratic	Evaluate liver and kidney function prior to starting treatment. Concurrent renal tubular necrosis and glucosuria may occur. Rapid recovery in Labradors after stopping drug and giving supportive care. A 50% mortality rate in non-Labrador breeds. Whether dogs with carprofen hepatotoxicity can be safely switched to another NSAID without experiencing a hepatic reaction is unknown.
Anticonvulsants					
Phenobarbital	Canine	Chronic liver disease and cirrhosis. Anorexia, lethargy, weight loss, sedation, PU/PD, icterus, ascites, encephalopathy. ↑ ALP, ↑ ALT, ↑ GGT, ↑ total bilirubin, ↑ SBA, hypoalbuminemia, hypocholesterolemia, coagulopathy.	Hepatocellular hypertrophy and vacuolar hepatopathy (early); bridging portal fibrosis, nodular regeneration, biliary hyperplasia, mild inflammatory infiltrates	Dose- related?	Phenobarbital causes chronic hepatic disease and cirrhosis when given at high doses (serum concentrations >40 µg/ml) or for long periods (months to years). Dogs with phenobarbital hepatotoxicity may improve when dosage is decreased to therapeutic range as determined by serum phenobarbital levels or when potassium bromide therapy is substituted for phenobarbital. Incidence of chronic hepatic disease from long-term anticonvulsant therapy is approximately 6–14%. Hepatocutaneous syndrome has also been described in dogs on long-term phenobarbital therapy.
Diazepam	Feline	Acute hepatic failure[a] within 4–13 days of starting oral drug administration.	Diffuse hepatic necrosis	Idiosyncratic	Most cats with hepatotoxicity die within 15 days of initial administration of drug. In cats treated with oral diazepam, monitor baseline liver enzymes before and within 5 days after starting therapy; if enzymes are increased, discontinue drug and give supportive therapy.
Antimicrobials					
Ketoconazole (Nizoral, Janssen Pharmaceuticals)	Canine and feline	Asymptomatic with ↑ ALT, ↑ ALP, or rarely acute hepatic failure.[a]	Not characterized	Idiosyncratic[b]	May be dose-related phenomenon: >40 mg/kg/day in dogs. In humans, asymptomatic serum enzyme elevations are considered harmless and enzymes usually return to normal despite continued therapy. Therapy should be discontinued if ↑ ALT >3 times normal or if clinical signs or jaundice occur. Recovery is usually uneventful.
Itraconazole (Sporanox, Janssen Pharmaceuticals)	Canine and feline	Asymptomatic with ↑ ALT or anorexia.	Not characterized	Dose- related?	Hepatotoxicity most likely at higher doses. Therapy should be stopped if ↑ ALT >3 times normal or if anorexia occurs. When appetite returns, can reinstitute itraconazole at half the original dose.

Table continued on following page

Table 71-4. SELECTED HEPATOTOXIC DRUG REACTIONS IN DOGS AND CATS—cont'd

Drug	Species	Onset of Signs and Key Features	Hepatic Lesions	Suggested Mechanism	Comments
Tetracycline	Canine and feline	Not characterized.	Vacuolar hepatopathy	Dose-related	Experimental hepatic injury induced by high doses given IV. Avoid in animals with PSS. Unlikely to be clinically important as a hepatotoxin. Not clear whether doxycycline has same effect on liver.
Potentiated sulfonamides[c]	Canine	Acute hepatic failure[a] 5–36 days after starting therapy.	Diffuse necrosis or periportal hepatitis and intrahepatic cholestasis	Idiosyncratic	Multiple exposures may predispose to reaction, but previous exposure to sulfonamides is not required. Dogs with intrahepatic cholestasis recover rapidly after drug withdrawal. High mortality with diffuse hepatic necrosis. Consider treatment with N-acetylcysteine and vitamin C or SAMe to promote detoxification of toxic intermediate, nitroso-SMX.
Steroids					
Glucocorticoids (various types)	Canine	Chronic hepatopathy, but hepatic failure rare. Signs indicative of hypercortisolism (e.g., PU/PD, polyphagia, hepatomegaly, and lethargy). ↑ ALP, usually with induction of steroid isoenzyme of ALP. Mild ↑ ALT; normal total bilirubin. SBA within normal limits or mildly ↑ (<60 µmol/L).	Centrilobular vacuolization due to glycogen accumulation	Dose-related but considerable individual variation	Lesions reversible after treatment is discontinued. Does not occur in cats.
Stanozolol (Winstrol-V, Pharmacia and Upjohn)	Feline	Increased ALT and hyperbilirubinemia; anorexia.	Hepatic lipidosis	Dose-related	Most cats recover after discontinuing stanozolol and after supportive care.
Miscellaneous					
Methimazole (Tapazole, Lilly)	Feline	Acute hepatic failure[a] within 2 months of starting therapy.	Necrosis and cholestasis	Idiosyncratic	Clinical signs resolve within 7 days of stopping therapy. Biochemical resolution by 45 days.
Lomustine (CCNU) (CeeNu, Bristol-Meyers Squibb)	Canine	Chronic liver disease with decreased appetite, weight loss, PU/PD, vomiting, ascites and ↑ ALT, ↑ ALP, hypoalbuminemia.	Hepatocellular vacuolization, mild to moderate periportal inflammation, fibrosis, hemosiderin-laden Kupffer cells	Idiosyncratic	Median time to detection of hepatic disease from last dose of CCNU was 11 weeks (range of 2–49 weeks). Cumulative drug doses and number of doses tends to be higher in dogs that develop hepatotoxicity than in those that do not. Majority of affected dogs die of progressive chronic liver disease.

[a] Typical manifestations of acute hepatic failure include anorexia, depression, vomiting, and jaundice accompanied by ↑ ALT, ↑ ALP, and ↑ serum bilirubin.
[b] For drug reaction accompanied by clinical signs and hyperbilirubinemia.
[c] Includes trimethoprim-sulfadiazine, trimethoprim-sulfamethoxazole, and ormetoprim-sulfadimethoxine.
ALP, alkaline phosphatase; ALT, alanine aminotransferase; GGT, gamma-glutamyltransferase; NSAID, nonsteroidal anti-inflammatory drug; PSS, portosystemic shunt; PU/PD, polyuria/polydipsia; SAMe, S-adenosylmethionine; SBA, serum bile acid.

period it is difficult to differentiate hepatic damage or jaundice caused by the hypoxic effects of anesthesia and surgery from other potential causes, such as toxic injury induced by anesthetic agents (e.g., halothane or methoxyflurane) and other drugs, postoperative infections, endotoxemia, or a combination of these factors.

Acute Pancreatitis

Pancreatitis in dogs and cats often is characterized by increased serum concentrations of liver enzymes resulting from secondary hepatic injury from released enzymes and inflammatory cytokines (see Chapter 73). Hepatic lesions usually resolve with resolution of the pancreatitis and require no special treatment. Less commonly, jaundice results from partial to complete obstruction of the common bile duct associated with peripancreatic inflammation, pancreatic abscess, or pancreatic healing by fibrosis. Surgical intervention to relieve biliary obstruction is indicated in animals with pancreatic abscess or if jaundice persists after resolution of acute pancreatitis, which usually indicates pancreatic fibrosis as a cause of biliary obstruction (see Chapter 73).

Extrahepatic Bacterial Infections

Septicemia and endotoxemia associated with infections such as pneumonia, pyometra, peritonitis, and abscesses can cause jaundice, mild to moderate increases in liver enzyme activity (especially ALP), and increased SBA concentration. Liver biopsy reveals intrahepatic cholestasis without significant necrosis or inflammation. The hepatic injury resolves when the infection is controlled.

Clinical Signs

Clinical signs of acute hepatic failure often are nonspecific and overlap signs of disorders of other body systems. Clinical signs reflect general hepatic dysfunction rather than the specific underlying cause. Signs of extrahepatic or multisystemic disease often provide important diagnostic clues when hepatic injury occurs secondary to acute pancreatitis, hemolytic disease, septicemia or endotoxemia, and many infectious diseases.

- Acute onset of anorexia, lethargy, vomiting, and diarrhea are the most common presenting signs of acute hepatic failure.
- Other potential findings include PU/PD, jaundice, excessive bleeding, and HE.

Diagnosis

- When acute hepatic failure is diagnosed, attempt to identify the underlying cause with a complete history, ancillary diagnostic testing, and if indicated, a liver biopsy. In many cases, a specific cause cannot be identified.
- When acute hepatic failure is accompanied by jaundice, consider diseases of the extrahepatic biliary tract, such as biliary obstruction and rupture. Surgical intervention may provide both diagnostic and therapeutic benefit.

History

Attempt to document recent or potential exposure to any drug, toxin, or infectious disease, especially those listed in Table 71-3.

- Suspect a drug- or toxin-induced cause of acute hepatic failure when clinical and biochemical evidence of acute hepatic dysfunction is associated with recent exposure to a potential hepatotoxin.
- Consider toxin-induced injury even in the absence of known exposure to toxins, because potential hepatotoxins can be present in contaminated dog food (aflatoxins), pond water (cyanobacteria, or "blue-green algae"), and many other unobserved sources.
- Although numerous drugs have been incriminated (see Tables 71-3 and 71-4), remember that an idiosyncratic reaction can occur with *any* drug. With most drug- and toxin-induced disorders, the diagnosis is presumptive and cannot be proved.
- To confirm the diagnosis, discontinue the drug and observe for clinical improvement, which usually occurs within several weeks, even after chronic drug administration. Recurrence of hepatic damage after a challenge dose of the same drug (or inadvertent reexposure) supports the diagnosis of drug-induced hepatotoxicity. *Note:* This is not recommended as a diagnostic procedure because it is potentially dangerous, especially with a drug that causes hepatic necrosis.
- Determine if there is a history of recent surgical or anesthetic procedures that may be associated with drug- or hypoxia-related hepatic damage.
- Evaluate the animal's vaccination status for infectious diseases that can involve the liver, such as leptospirosis and infectious canine hepatitis.
- Determine if there are any subtle chronic signs of illness that suggest that the underlying liver disease may be chronic rather than acute and that the current illness may be exacerbation or decompensation of chronic liver disease.

Physical Examination

Physical findings often reflect general hepatic dysfunction rather than the specific etiology (see previous discussion of physical examination findings under "Diagnostic Strategy for Liver Disease").

- Hepatodynia may occur with any cause of acute hepatic injury that results in swelling and stretching of the liver capsule.
- Findings of weight loss and ascites are indicative of a chronic rather than an acute process.
- Signs of extrahepatic or multisystemic disease may be important clues when liver injury occurs secondary to systemic disorders.
  - For example, fever may be present with infectious causes of hepatic injury such as leptospirosis, infec-

tious canine hepatitis, bacterial cholangitis, liver abscess, systemic mycoses, and extrahepatic infections that secondarily involve the liver.
- Fever and acute abdominal pain are presenting signs of acute pancreatitis but can also occur with cholangitis and hepatic abscess.
- When jaundice is accompanied by pallor, consider immune hemolytic anemia.

Laboratory Evaluation

Acute hepatotoxicity frequently is associated with abnormal serum biochemical analyses, liver function tests, and urinalysis.

- Because diffuse hepatic necrosis is the most common lesion associated with acute hepatic failure, increased ALT activity is the most consistent finding, and values are often markedly increased. Increased ALP activity may also occur.
- Other potential findings include hyperbilirubinemia, increased SBA concentrations, hypoglycemia, hyperammonemia, and coagulopathy. Hypoalbuminemia usually suggests chronic rather than acute liver disease.
- Some hepatotoxins (e.g., carprofen) and infectious agents (e.g., leptospirosis) may concurrently damage the kidneys; thus, biochemical evidence of concomitant renal failure may be present.
- An inflammatory CBC suggests possible acute pancreatitis or underlying infectious disease. Evaluate serum amylase and lipase (dogs) and pancreatic lipase immunoreactivity (PLI) (dogs and cats) to diagnose acute pancreatitis.

Abdominal Imaging

- Liver size on abdominal radiographs usually is normal to increased unless massive hepatic necrosis causes parenchymal collapse and microhepatica.

▼ ***Key Point*** A small liver generally suggests chronic rather than acute hepatic disease.

- Additional radiographic and ultrasonographic findings may be noted, depending on the underlying disorder (Table 71-5).

Liver Biopsy

Perform a liver biopsy when the cause of acute hepatic failure is not suggested by preliminary laboratory evaluation.

- Histopathologic examination of hepatic tissue can help establish the cause and distinguish between acute and chronic liver disease. Diffuse hepatic necrosis is the histologic lesion most consistently associated with acute hepatic failure.
- If overt bleeding is present, liver biopsy may be contraindicated.

Ancillary Diagnostic Procedures

Perform ancillary diagnostic procedures (see Table 71-5) to diagnose underlying causes of acute hepatic failure.

Treatment

- Management of the patient with acute hepatic failure is first directed toward supportive therapy (see Table 71-1). In many cases, even though the cause remains unidentified or specific therapy is unavailable, supportive care alone may allow adequate time for hepatic regeneration to occur.
- Maintenance of fluid, electrolyte, and acid-base balance is the cornerstone of supportive therapy (see Chapter 5).
- Prevent or control complications such as hypoglycemia, HE, coagulopathy, and endotoxemia (see "Principles of Treatment for Liver Disease").
- Whenever possible, institute specific treatment for the underlying cause; for example, administer injectable penicillin or amoxicillin for treatment of possible leptospirosis. Discontinue use of a suspect drug to prevent further hepatic injury and observe for clinical improvement.
- With the exception of acetylcysteine for acetaminophen toxicity and milk thistle (silybin) for Amanita mushroom poisoning, no specific antidotes are available for drug- or toxin-induced hepatic injury. However, hepatoprotectants (Table 71-2) may be helpful in treating hepatotoxicity but have not been adequately evaluated.

INFECTIOUS AND PARASITIC HEPATIC DISEASE

The liver can be involved in many systemic infections (Table 71-6). In some disorders, such as leptospirosis and infectious canine hepatitis, the liver is a target organ, and evidence of liver failure dominates the clinical presentation. In other infections, such as many of the systemic protozoal infections, the liver is involved as a result of widespread invasion of organs with a large mononuclear phagocyte population, such as the spleen, lymph nodes, and bone marrow (see Table 71-6). Signs of hepatic dysfunction may or may not be present and may be overshadowed by more obvious extrahepatic involvement. Liver cytology and biopsy can be diagnostically useful for identification of these organisms.

Systemic infections are covered in detail elsewhere in this book. Infections localized to the hepatobiliary tract are covered in greater detail here.

Infectious Causes of Liver Disease

Several specific infectious diseases that involve the liver are listed in Table 71-6 and are discussed elsewhere in

Table 71-5. ANCILLARY DIAGNOSTIC EVALUATIONS FOR HEPATOBILIARY DISEASE

Diagnostic Evaluation	Intended Diagnosis (Rule Out)
Bacterial cultures	
Liver, gallbladder, bile	Bacterial cholangiohepatitis, cholecystitis, hepatic abscess
Blood, urine, infected tissues	Extrahepatic infections and sepsis
Serologic tests (antibody titers)	Leptospirosis
	Mycoses (histoplasmosis, coccidioidomycosis, blastomycosis)
	Toxoplasmosis
	Feline infectious peritonitis
	Bartonellosis
	Other infectious diseases
Microfilaria exam	Heartworm disease
Heartworm antigen or antibody tests	Heartworm disease
Fecal sedimentation (formalin-ether technique)	Liver fluke infection
Serum amylase and lipase	Acute pancreatitis in dogs
Serum pancreatic lipase immunoreactivity	Pancreatitis in cats and dogs
Serum T_4	Feline hyperthyroidism
Coombs' test	Immune hemolytic anemia
Lymph node aspiration cytology	Mycoses
	Lymphoma
Hepatic fine-needle aspiration cytology	Infectious agents (e.g., mycoses)
	Neoplasia (e.g., lymphoma)
	Feline hepatic lipidosis
	Hepatic abscess (ultrasound guided)
Abdominocentesis	Ruptured biliary tract
	Feline infectious peritonitis
	Neoplasia
Thoracic radiography	Mycoses
	Toxoplasmosis
	Heartworm disease
	Metastatic neoplasia
	Diaphragmatic hernia
Abdominal radiography	Hepatic abscesses
	Emphysematous cholecystitis
	Cholelithiasis
	Pancreatitis
Abdominal ultrasonography	Focal and diffuse hepatic parenchymal abnormalities
	Biliary or gallbladder disease
	Portosystemic shunt(s)
	Hepatic arteriovenous fistulas
	Pancreatic disease
	Diaphragmatic hernia
Angiography	
Portogram	Portosystemic shunt(s)
	Portal vein obstruction
Hepatic venography	Obstruction of caudal vena cava and hepatic veins
Celiac arteriography	Hepatic arteriovenous fistulas
Nuclear imaging	
Portal scintigraphy	Portosystemic shunting

Modified from Johnson SE: Diseases of the liver. In Ettinger SJ, Feldman EC (eds): Textbook of Veterinary Internal Medicine, vol. 2, 4th ed. Philadelphia: WB Saunders, 1995, p 1316.

this book, including leptospirosis (see Chapter 19), ehrlichiosis and rickettsial diseases (Chapter 17), toxoplasmosis (see Chapter 21), systemic mycoses (see Chapter 20), FIP virus (see Chapter 10), and infectious canine hepatitis virus (see Chapter 16).

Hepatic Abscess

Hepatic abscesses from bacterial infection of the liver occur uncommonly in dogs and cats. Abscesses may form as a solitary large mass, multiple small masses scattered throughout the liver, or microabscesses that are only detected histologically.

Etiology

- Potential sources of bacteria include hematogenous spread, translocation of intestinal bacteria into the portal blood, ascension via bile ducts, penetrating abdominal and caudal thoracic wounds, and direct extension from local suppurative diseases. Umbilical infections are the most common cause of hepatic

Table 71-6. INFECTIOUS DISEASES WITH POTENTIAL HEPATOBILIARY INVOLVEMENT*

Disease	Agent	Refer To
Viral		
Infectious canine hepatitis	Canine adenovirus I	Chapter 16
Systemic neonatal herpesvirus	Canine herpesvirus	Chapter 16
Canine acidophil cell hepatitis	Unknown	Chapter 16
Feline infectious peritonitis	Feline coronavirus	Chapter 10
Feline systemic hemorrhagic-like febrile disease	Feline calicivirus (virulent strains)	Chapter 11
Bacterial		
Leptospirosis	*Leptospira interrogans sensu strictu*	Chapter 19
Acute hepatic failure	Serovars *icterohaemorrhagiae, canicola, autumnalis, pomona, bratislava, bataviae, hardjo,* and *Leptospira kirshneri* serovar *grippotyphosa*	
Chronic hepatitis	Serovars *grippotyphosa* and *australis*	
Tyzzer's disease	*Bacillus piliformis*	Chapter 69
Nocardiosis	*Nocardia* species	Chapter 19
Actinomycosis	*Actinomyces* species	Chapter 19
Tuberculosis	*Mycobacterium tuberculosis, M. bovis, M. avium*	Chapter 19
Salmonellosis	*Salmonella typhimurium*	Chapter 69
Brucellosis	*Brucella canis*	Chapter 19
Bartonellosis (dogs)	*Bartonella henselae, B. clarridgeiae*	Chapter 19
Hepatic abscess	Gram-negative bacteria (especially *Escherichia coli*), anaerobes, mixed infections common, *Staphylococcus* species (puppies)	
Cholangitis/cholangiohepatitis	Gram-negative bacteria (especially *Escherichia coli*), anaerobes	
Cholecystitis	Gram-negative bacteria (especially *Escherichia coli*), *Campylobacter jejuni, Clostridium* species	
Yersiniosis	*Yersinia pestis*	Chapter 19
Tularemia	*Francisella tularensis*	Chapter 19
Fungal		
Histoplasmosis	*Histoplasma capsulatum*	Chapter 20
Blastomycosis	*Blastomyces dermatitidis*	Chapter 20
Coccidioidomycosis	*Coccidioides immitis*	Chapter 20
Aspergillosis	*Aspergillus terreus*	Chapter 20

Canine schistosomiasis	*Heterobilharzia americana*	
Visceral larval migrans	*Toxocara canis*	
Liver flukes	*Platynosomum concinnum* (feline) *Amphimerus pseudofelineus* (feline)	
Canine hepatic capillariasis	*Capillaria hepatica*	
Canine hepatic alveolar echinococcosis	*Echinococcus multilocularis*	

*Not necessarily associated with clinical hepatobiliary disease.

abscesses in puppies *(Staphylococcus)* and kittens *(Streptococcus).*

- *Escherichia coli* and anaerobic bacteria are most commonly identified; mixed bacterial infections are common.
- Hypoxia of hepatic tissue caused by hepatic neoplasia, liver lobe torsion, or trauma may predispose the patient to abscess formation, because small numbers of anaerobes (e.g., *Clostridium* spp.) normally are present in the liver and can proliferate under these conditions.
- Systemic diseases that are associated with immunosuppression (e.g., feline leukemia virus and feline immunodeficiency virus) or that predispose the

patient to infection (e.g., diabetes mellitus) may predispose the patient to hepatic abscesses.
- Systemic infections (urinary tract infection, pneumonia), pancreatitis, gallbladder rupture, and previous surgical liver biopsy have also been associated with hepatic abscesses.

Clinical Signs

- Signs are attributed to sepsis, inflammation, and hepatic dysfunction and include anorexia, lethargy, fever, vomiting, and diarrhea.
- Rupture of a hepatic abscess leads rapidly to peritonitis, septic shock, and death.

Diagnosis

- Physical examination findings are often vague but may include depression, fever, hepatomegaly, abdominal tenderness, and abdominal effusion.
- Potential laboratory findings include neutrophilia with a left shift (or neutropenia and degenerative left shift if rupture occurs), thrombocytopenia, markedly increased ALT and ALP activity (although they may be in the normal range), hyperglobulinemia, hyperbilirubinemia, hypoglycemia, and septic suppurative abdominal effusion. Increased ALT and ALP activity occur in less than 50% of cats with hepatic abscesses.
- Radiolucent areas may be seen on abdominal radiographs when gas-producing organisms are involved. Ultrasonography may reveal one or more parenchymal abscess cavities. They appear as poorly echogenic lesions that may be round, oval, or irregular in shape. Ultrasound-guided FNA for cytology and culture may be diagnostic.
- Diagnosis often is established at exploratory laparotomy to determine the cause of septic peritonitis.
- Perform aerobic and anaerobic cultures of abdominal effusion, blood, and hepatic tissue.

Treatment

- Treatment of large, unifocal hepatic abscesses requires surgical excision of the affected liver lobe (see Chapter 72).
- Ultrasound-guided percutaneous abscess drainage has been advocated for medical management of single lesions. No complications were observed in one series of cases.
- Initiate broad-spectrum antibiotics such as intravenous penicillin combined with an aminoglycoside (e.g., gentamicin or amikacin) while awaiting culture results. Monitor renal function during aminoglycoside therapy, and base further therapy on results of sensitivity testing. Give long-term antibiotic therapy (but not aminoglycosides) for at least 6 to 8 weeks.
- The mortality rate was high (79%) in a recent series of cats with hepatic abscesses as compared with dogs (50%).

Liver Fluke Infection

Liver fluke infection is uncommon in cats and rare in dogs. Infection usually is asymptomatic but may cause clinical biliary tract disease when associated with marked biliary fibrosis, cholangitis, cholangiohepatitis, or extrahepatic bile duct obstruction. Cholangiocarcinoma has been reported in cats chronically infected with *Platynosomum concinnum.*

Etiology

- *P. concinnum (Platynosomum fastosum)* is the most important liver fluke in cats and is found in tropical and subtropical geographic areas, including Hawaii, Florida, and the Caribbean. In endemic areas, the prevalence of infection is high.
- Other liver flukes that have been identified in cats include *Amphimerus pseudofelineus (Opisthorchis pseudofelineus), Opisthorchis tenuicollis, Opisthorchis sinensis,* and *Metorchis conjunctus (Metorchis complexus).*
- Liver flukes require two intermediate hosts for their life cycle. Adult flukes reside in the gallbladder and bile ducts. Embryonated eggs are shed in the feces and ingested by a snail, the first intermediate host for all liver flukes. The house gecko, skink, lizard, and Bufo toad are second intermediate hosts for *P. concinnum;* fish are second intermediate hosts for the other species of flukes.

Clinical Signs

- Most infected cats are asymptomatic for liver fluke infection.
- Liver fluke infection occasionally is associated with anorexia, weight loss, diarrhea, vomiting, jaundice, hepatomegaly, abdominal distention, and death.

Diagnosis

- Operculated fluke eggs can be identified in feces by a formalin-ether technique (a sedimentation procedure). Routine methods for flotation do not consistently identify eggs. With complete bile duct obstruction, no eggs will be passed in the feces. Eggs may be identified on cytologic examination of the bile.
- Other laboratory findings are inconsistent and often unremarkable. Eosinophilia, hyperbilirubinemia, and increased serum ALP and ALT activity are sometimes detected.
- A possible relationship between positive feline immunodeficiency virus status and infection with *A. pseudofelineus* has been suggested.
- At laparotomy or necropsy, the bile ducts and gallbladder may be distended and thick walled and may contain inspissated bile and small (<12 mm long) adult flukes. The liver frequently is enlarged. In many cases, no visible abnormalities are present.

Treatment

Minimal information is available about treatment of liver flukes.

- Praziquantel (Droncit), 40 mg/kg, given orally or parenterally once a day for 3 consecutive days, or fenbendazole (Panacur) 50 mg/kg PO q24 for 10 to 14 days, has been suggested.
- Drugs used unsuccessfully include mebendazole, levamisole, thiabendazole, diamphenethide, and rafoxanide. At least one follow-up fecal examination by formalin-ether sedimentation should be performed 30 days following treatment.
- Manage complications such as biliary obstruction and secondary bacterial cholangitis or cholangiohepatitis as described elsewhere in this chapter.

FELINE HEPATIC LIPIDOSIS

Hepatic lipidosis is an excessive accumulation of triglyceride in the liver that occurs when there is an imbalance between the rate of deposition and the rate of mobilization of fat from the liver. It is the most common liver disease in cats and is associated with severe intrahepatic cholestasis and hepatic failure. Mortality is high if the disorder is untreated.

Etiology

General mechanisms of hepatic lipidosis include nutritional, metabolic, hormonal, toxic, and hypoxic liver injury. Diabetes mellitus is a well-recognized and easily diagnosed cause of hepatic lipidosis. Drug- (tetracycline, stanozolol) or toxin-induced injury can also cause histologic lesions of lipidosis. Hepatic lipidosis often occurs secondary to other systemic disorders associated with anorexia and a catabolic state, especially cholangitis, pancreatitis, inflammatory bowel disease (IBD), and systemic neoplasia. The term *idiopathic hepatic lipidosis* is used when no other underlying causative disease is identified.

The following mechanisms may be important in the development of idiopathic hepatic lipidosis:

- Cats have higher nutritional requirements for protein, essential amino acids, and essential fatty acids than dogs.
- Systemically ill cats have a propensity for accumulating fat in their hepatocytes.
- Profound anorexia and stress may be associated with hormonal (catecholamines, other) alterations that influence fat metabolism and predispose the patient to peripheral fat mobilization and hepatic fat uptake.
- Obese cats do not seem to be able to adapt to metabolism of fat for energy during periods of starvation.

▼ ***Key Point*** Persistent anorexia and rapid weight loss are hallmarks of severe hepatic lipidosis. It most commonly develops in overweight cats that experience prolonged (usually >2 weeks) inappetence, sometimes triggered by a stressful event.

- The exact mechanism or biochemical aberration in cats with hepatic lipidosis is unknown. However, there appears to be an imbalance in the mobilization of peripheral fat, the hepatic use of fatty acids for energy, and the hepatic dispersal of triglycerides.

Clinical Signs

- Hepatic lipidosis is a disease of middle-aged or older cats without breed or gender predilection. Many affected cats are obese prior to the onset of disease.
- Prolonged anorexia, often several weeks in duration, is the most consistent clinical sign.
- Other findings include lethargy, vomiting, constipation or diarrhea, and weight loss. Weight loss can be dramatic and may exceed 25% of the previous weight.
- Overt signs of HE (hypersalivation, severe depression, stupor) are uncommon.
- Overt bleeding occurs in 20% of cases.

Diagnosis

Clinical findings and laboratory evaluation in cats with hepatic lipidosis suggest hepatic disease, but liver biopsy is required to distinguish hepatic lipidosis from other causes of hepatic disease such as cholangitis, FIP, and neoplasia. When hepatic lipidosis occurs secondary to another disorder, additional testing is required to identify the primary disease (e.g., pancreatic lipase immunoreactivity for pancreatitis or GI endoscopy and biopsy for IBD).

History

The history may reveal precipitating causes of anorexia such as stressful events (e.g., boarding, surgery, or change in living arrangements), a diet change for weight reduction, or non-hepatic diseases associated with anorexia.

Physical Examination

- Findings include hepatomegaly, jaundice, muscle wasting, seborrhea, and pallor.
- Ventroflexion of the head and neck occurs in some cats and may represent muscle weakness associated with electrolyte imbalances (hypokalemia, hypophosphatemia) or thiamine deficiency.

Laboratory Evaluation

- Hematologic findings are nonspecific and include a nonregenerative, normocytic, normochromic anemia with poikilocytosis and mature neutrophilia and lymphopenia (stress response). Hemolysis may occur secondary to hypophosphatemia or Heinz bodies.

- Serum ALP, ALT, and AST activities; FSBA and PPSBA concentrations; and total serum bilirubin concentration usually are increased. Increases in liver enzymes precede increases in total bilirubin and bile acids.

▼ ***Key Point*** Serum ALP activity is generally higher in cats with lipidosis than with other hepatic diseases. Serum GGT activity, which usually parallels or exceeds serum ALP activity in most feline hepatic diseases, is normal or only mildly increased in hepatic lipidosis.

- Other potential findings include hypokalemia, hyperammonemia, hypoalbuminemia, and decreased BUN. Many affected cats have abnormal coagulation tests, especially PIVKA values and hypofibrinogenemia. In one study, PIVKA values improved in 50% of the cats treated with vitamin K_1, suggesting acquired vitamin K deficiency.
- Consider serum pancreatic lipase immunoreactivity to evaluate for concurrent pancreatitis.
- Consider serum cobalamin (B_{12}) levels if an underlying intestinal disorder suspected.

Radiography and Ultrasonography

- Radiographically, the liver is normal to increased in size.
- Ultrasonographic findings include hepatomegaly and diffuse hyperechogenicity of the liver. Ascites is rare. Evaluate for concurrent pancreatitis or other disorders causing secondary hepatic lipidosis.

Fine-Needle Aspiration Cytology

- FNA cytology is a less invasive alternative to liver biopsy that can provide similar information. Results of FNA cytology occasionally can be misleading because the small sample size may not be representative of the pathologic process in the liver.
- Correct coagulopathy with vitamin K_1 prior to performing liver aspirate or liver biopsy.
- On cytologic evaluation, hepatocytes are foamy and vacuolated, and inflammatory cells are absent.

Liver Biopsy

Liver biopsy is required for definitive diagnosis but is not routinely performed unless there is failure to respond to appropriate therapy or a high level of suspicion of another primary hepatic disorder.

- Grossly, the liver is enlarged, yellow, greasy, and friable with rounded edges. Biopsy specimens usually float in formalin.
- On routine H&E staining, there is severe vacuolization of hepatocytes (>50% of acinar unit involved).
- Oil red O stain performed on formalin-fixed (non–paraffin-embedded) frozen tissue can confirm excess fat in the vacuoles.
- Inflammation or necrosis usually is absent.

Treatment

Because of lack of information regarding the underlying cause, treatment is primarily supportive. The greatest success has been with aggressive nutritional support. During initial stabilization, correct dehydration, electrolyte imbalances, coagulopathies and any complications of liver failure. A nasogastric tube can be placed for short-term nutritional support. CliniCare (Abbott Veterinary Diets) can be used initially through the nasogastric tube while stabilizing the patient prior to anesthesia for a longer-term feeding tube (gastrostomy or esophagostomy tube).

Initial Fluid Therapy

- Use intravenous fluid therapy with a balanced electrolyte solution supplemented with potassium chloride in the initial stages of treatment (see Table 71-1). Hepatic lactate metabolism may be impaired in cats with hepatic lipidosis; thus, avoid lactated Ringer's solution.
- If hypokalemia persists despite supplementation, evaluate serum magnesium concentration to see if hypomagnesemia is the cause of refractory hypokalemia.

▼ ***Key Point*** Avoid dextrose supplementation unless hypoglycemia is documented, because glucose may promote hepatic lipid accumulation if caloric needs are not being adequately met.

- Monitor serum phosphorus concentration and treat with IV potassium phosphate if levels decline to <2 mg/dl (see Chapter 5). Hemolysis may occur secondary to severe hypophosphatemia.
- Abnormal blood coagulation test results and excess bleeding occasionally respond to vitamin K_1 therapy, suggesting severe cholestasis and vitamin K malabsorption (see Table 71-1). Consider fresh blood transfusion as needed for management of anemia.
- Treat HE as described in Table 71-1, using a low-protein diet, lactulose, and amoxicillin, neomycin, or metronidazole.
- Consider antibiotic therapy with amoxicillin to prevent infection secondary to compromised hepatic clearance of enteric organisms. Avoid tetracycline because it can predispose the patient to hepatic lipid accumulation.

Nutritional Therapy

- Provide the daily caloric requirement (40–60 kcal/kg of body weight per day) via nasogastric, esophagostomy, or gastrostomy tube. An endoscopically placed gastrostomy tube is preferable because long-term nutritional therapy (at least 3–6 weeks) is necessary in most cases. Nasogastric tubes are adequate for

short-term management and are preferable to force-feeding. Techniques for placement of indwelling feeding tubes are described in Chapter 3.

- Feed Maximum Calorie (Iams), Prescription Diet a/d (Hill's Pet Nutrition), or other complete and balanced feline diet that can be delivered through a tube in small feedings.
- Initially, give one-fourth to one-half of the daily dietary caloric requirement through the tube, divided into 4 to 6 feedings per day. Gradually increase the total amount fed over 3 to 4 days until maintenance requirements are achieved.
- Use a restricted-protein diet only if hyperammonemia or overt signs of HE occur.

▼ ***Key Point*** Do not rely on appetite stimulant medications, because they rarely achieve the consistent caloric intake required for effective reversal of lipidosis. Avoid diazepam, in particular, because it has been associated with idiosyncratic hepatic necrosis in cats.

- If vomiting or delayed gastric emptying is a problem, give metoclopramide (0.4 mg/kg SC q8h, 30 minutes before feeding), or feed a liquid enteral diet by constant rate infusion into the feeding tube. Dilution of the diet with water may also improve tolerance.

Dietary Supplements

Numerous vitamins and supplements have been empirically recommended in the treatment of idiopathic hepatic lipidosis, but further controlled studies are needed to determine clinical usefulness. Consider each of the following:

- ***B complex vitamins*** added to the fluids (1–2 ml).
- ***Cobalamin*** **(B_{12})**, 250 µg SC initially while awaiting serum cobalamin levels. If decreased serum cobalamin is documented (usually indicating primary intestinal disease), continue it long term (see Chapter 69).
- ***Thiamine*** (if severe ventroflexion of neck), at a dosage of 50 to 100 mg PO q24h, for 1 week (or added to IV fluids).
- ***L-Carnitine,*** 250 to 500 mg PO q24h, as an essential cofactor for fatty acid oxidation (for relative carnitine deficiency).
- ***Taurine,*** at a dosage of 250 to 500 mg PO q24h, for the initial 7 to 10 days. Plasma taurine is decreased in many cats with hepatic lipidosis, and taurine is required for bile acid conjugation.
- ***Vitamin E*** (water-soluble form), 50 to 100 units total dose per cat PO q24h, as an antioxidant.
- ***S-adenosylmethionine (SAMe)*** (Denosyl SD, Nutramax Labs), 20 to 40 mg PO q24h, as a glutathione source, because decreased hepatic glutathione levels occur in hepatic lipidosis.

Response to Treatment and Prognosis

- With aggressive nutritional and supportive care, approximately 60% to 85% of cats with lipidosis respond within 3 to 6 weeks. Biochemical improvement (decreases in bilirubin, ALP, and ALT) is usually seen within 1 to 2 weeks of initiating tube feeding. Normalization may take several weeks. Do not remove the tube until the cat is eating on its own for at least a week.
- Recurrence is rare and there is no evidence of residual hepatic damage.
- The earlier treatment is initiated, the better the prognosis.

▼ ***Key Point*** Monitor serum liver enzymes and institute nutritional support early in obese cats that become inappetent or undergo rapid weight loss secondary to other disease processes.

- Consider the potential for lipidosis in any obese cat placed on a reducing diet. Monitor liver enzymes to evaluate for onset of lipidosis. Consider l-carnitine supplementation (250 mg/cat/day) in obese cats undergoing dietary weight reduction.

CANINE VACUOLAR HEPATOPATHIES

The term *vacuolar hepatopathy* is used to describe the cytologic or histologic appearance of hepatocytes, which contain either discrete cytoplasmic vacuoles (usually fat) or *cytoplasmic rarefaction,* a term used to describe ballooned cells with less cytoplasmic density but devoid of distinct vacuoles.

- Cytoplasmic rarefaction is seen with either hepatocellular hydropic degeneration (increased cellular water) or *steroid hepatopathy* (increased glycogen) and cannot be differentiated without special stains. Glycogen is PAS positive.
- Vacuoles containing lipid (fat) can be confirmed by oil red O staining of formalin-fixed, non-paraffin embedded frozen tissue.
- Vacuolar hepatopathy is a common histologic diagnosis in dogs. Clinical associations are numerous and are listed in Table 71-7.

Glucocorticoid Hepatopathy (Steroid Hepatopathy)

Glucocorticoid hepatopathy, or steroid hepatopathy, is a commonly recognized sequela of glucocorticoid administration in dogs. Glucocorticoids cause hepatic glycogen accumulation and hepatomegaly (see Table 71-4). Steroid hepatopathy is a benign, reversible hepatic lesion that, with rare exceptions, is not associated with clinical liver dysfunction. The most important

Table 71-7. DIFFERENTIAL DIAGNOSES FOR CANINE VACUOLAR HEPATOPATHY

Glucocorticoid therapy
Including oral, parenteral, topical (eye, ear, skin)
Hyperadrenocorticism
Pituitary or adrenal origin
Atypical form (normal cortisol but increased adrenal steroid hormones, especially 17-OH progesterone)
Idiopathic vacuolar hepatopathy
Scottish terriers (progesterone?)
Others
Reactive hepatopathy
Common lesion in dogs with other systemic illnesses
Chronic (>4 weeks) illness (increased endogenous corticosteroids?)
Hepatic nodular regeneration
Hyperlipidemia
Diabetes mellitus
Idiopathic hyperlipidemia (miniature schnauzers, Shetland sheepdog, others?)
Hypothyroidism (severe)
Hepatocutaneous syndrome
Tetracycline administration
Glycogen and lysosomal storage disorders

clinical significance of this disorder is that it can easily be mistaken for a more serious hepatic disease.

▼ ***Key Point*** To avoid unnecessary diagnostic and therapeutic measures, remember that increased serum ALP activity and hepatomegaly are commonly caused by glucocorticoid therapy in dogs.

- Recognition of steroid hepatopathy often alerts the clinician to the presence of previously unsuspected spontaneous hyperadrenocorticism in dogs without a history of glucocorticoid therapy (see Chapter 33).
- Cats are resistant to the hepatic effects of glucocorticoids, and development of steroid hepatopathy is rare.

Etiology

- Glucocorticoid hepatopathy has been associated with numerous glucocorticoids including cortisone, prednisone, prednisolone, dexamethasone, and triamcinolone. Lesions of steroid hepatopathy can develop within 7 to 14 days of corticosteroid administration.
- Endogenous production of excess glucocorticoids caused by spontaneous hyperadrenocorticism also results in steroid hepatopathy. Hepatic lesions are identical to those seen with exogenous administration of glucocorticoids.
- Dogs with atypical hyperadrenocorticism can also develop lesions of steroid hepatopathy. These dogs present with clinical signs and laboratory findings typical for hyperadrenocorticism, but cortisol levels in response to adrenocorticotropic hormone (ACTH) or after low-dose dexamethasone are normal. Excess production of sex hormones, especially 17-hydroxyprogesterone, has been described (see Chapter 33).
- Individual variation in susceptibility to steroid hepatopathy also appears to play a role.
- Dogs that are chronically stressed (>4 weeks) due to other systemic illnesses (e.g., severe dental disease, chronic inflammation or infection, or neoplasia) may also develop this hepatic lesion, presumably due to stress-induced endogenous glucocorticoid release.

Clinical Signs

- Clinical signs reflect the systemic effects of hypercortisolism rather than hepatic disease and include PU/PD and polyphagia in an otherwise healthy dog.
- Dogs with other chronic illnesses do not typically have PU/PD but may show signs pertaining to their underlying disorder.

Diagnosis

Suspect steroid hepatopathy in any dog with hepatomegaly and increased serum ALP activity that has a history of recent glucocorticoid therapy and/or clinical signs of hyperadrenocorticism.

▼ ***Key Point*** Significant amounts of glucocorticoid can be absorbed from topical and ocular medications as well as from oral and injectable preparations.

History and Physical Examination

- Evaluate for previous glucocorticoid therapy within the past 3 months.
- Hepatomegaly, which may be quite massive, frequently is detected.
- Other findings in dogs with hyperadrenocorticism or exogenous glucocorticoid administration include abdominal distention and thinning of the skin and haircoat.

Laboratory Evaluation

- Increased serum ALP activity is the most consistent biochemical abnormality detected in dogs with this hepatic lesion. After glucocorticoid administration, the initial increase in ALP activity is attributed to the liver isoenzyme rather than the corticosteroid-induced isoenzyme (CIALP; see previous discussion). This increase can occur within 2 to 3 days of glucocorticoid therapy and often is as high as 150 times normal. After 7 to 10 days the ALP elevation becomes progressively more attributable to increased CIALP. The increase in CIALP can persist several months after exposure to corticosteroids.
- Increased CIALP activity is a consistent finding in dogs with spontaneous hyperadrenocorticism,

and absence of this isoenzyme is uncommon in this disorder.
- In contrast, ALT activity is normal or only mildly increased.
- SBA concentrations are normal or mildly increased (<60 µmol/L).
- Total serum bilirubin, serum albumin, blood ammonia concentration, and hemostatic tests typically are normal.
- Other findings characteristic of hypercortisolism include mature neutrophilia, lymphopenia, eosinopenia, monocytosis, and hypercholesterolemia.

Radiography and Ultrasonography

- Hepatomegaly usually is detected on abdominal radiographs.
- Ultrasonography reveals hepatomegaly and diffuse or multifocal increase in liver echogenicity. Adrenomegaly may be detected in dogs with underlying spontaneous hyperadrenocorticism.

Liver Biopsy

- Grossly, the liver is enlarged, smooth, pale, and friable. Microscopically, hepatic lesions are characterized by cytoplasmic rarefaction in a patchy distribution.
- PAS staining reveals that hepatocytes contain glycogen.
- When hepatic biopsy suggests steroid hepatopathy and a history of glucocorticoid administration is lacking, perform diagnostic tests for endogenous hyperadrenocorticism including the atypical form (see Chapter 33). If tests for hyperadrenocorticism are negative, evaluate for other disorders associated with vacuolar hepatopathy (Table 71-7).

Treatment

▼ ***Key Point*** Steroid hepatopathy does not require any specific therapy for the liver.

- Steroid hepatopathy is reversible after withdrawal of exogenous glucocorticoids or treatment of spontaneous hyperadrenocorticism.
- The length of time required for complete resolution is unpredictable, varying from weeks to months.

Vacuolar Hepatopathy in Scottish Terriers

Scottish terriers with diffuse vacuolar hepatopathy similar to steroid hepatopathy have been recently described. Increased levels of adrenal steroids (especially progesterone and 17-OH progesterone) have been documented. Progesterones, which are precursors of glucocorticoids, have intrinsic glucocorticoid activity and can promote hepatic glycogen accumulation.

Clinical Signs

Most dogs are asymptomatic although a few dogs may have mild PU/PD. Some dogs eventually develop typical signs of spontaneous hyperadrenocorticism.

Diagnosis

- Laboratory features include marked elevations in ALP activity (predominantly CIALP) with normal GGT and ALT activity. Total bilirubin concentrations are normal. SBA concentrations are normal or mildly increased.
- On abdominal ultrasonography, the liver is enlarged and hyperechoic. Adrenal glands appear normal. Liver biopsy reveals diffuse vacuolar hepatopathy, and PAS stains are positive for glycogen.
- Evaluation for spontaneous hyperadrenocorticism reveals normal ACTH stimulation and low-dose dexamethasone suppression tests. However, testing for adrenal sex hormones before and after ACTH reveals increased progesterone, 17-OH progesterone or other adrenal steroid hormones with normal cortisol levels (Clinical Endocrinology Service, College of Veterinary Medicine, University of Tennessee, 2407 River Drive, Room A105, Knoxville, TN 37996; telephone: 865-974-5638).

Treatment

- Although treatment with ketoconazole or mitotane will decrease ALP levels, no treatment is recommended if dogs are asymptomatic. Preliminary results suggest this is a benign disorder with a favorable long-term prognosis.
- If clinical signs of hyperadrenocorticism develop, these dogs respond to standard treatment (see Chapter 33).

Vacuolar Hepatopathy in Hyperlipidemic Miniature Schnauzers

Idiopathic hyperlipoproteinemia in miniature schnauzers is an inborn error of lipoprotein metabolism characterized by fasting hypertriglyceridemia and hypercholesterolemia. A partial decrease in lipoprotein lipase activity has been described in lipemic compared with non-lipemic miniature schnauzers. Other breeds (such as Shetland sheepdogs) may also be affected.

- Affected dogs typically develop a marked vacuolar hepatopathy. Vacuoles contain both fat and glycogen.
- Rarely, they may develop a nodular liver with stromal collapse and clinical evidence of hepatic insufficiency or severe sludging of bile and cholelithiasis.

Clinical Signs

Clinical findings in hyperlipidemic miniature schnauzers are referable to the lipemia and not hepatic dysfunction.

- Signs include lethargy, abdominal pain, decreased appetite, hepatomegaly, and seizures.
- Recurrent acute pancreatitis is common and many dogs will eventually develop diabetes mellitus.

Diagnosis

- Laboratory findings include moderate to marked increases in ALP and GGT activity. The corticosteroid-induced isoenzyme of ALP typically predominates. Increased ALT activity is variable. SBAs are typically normal or mildly increased. Associations with increased urine protein-to-creatinine ratio and microalbuminuria have also recently been described.
- Abdominal ultrasonography of the liver reveals hepatomegaly and diffuse increase in echogenicity.
- Cytology and biopsy are consistent with vacuolar hepatopathy.

Treatment

Manage hyperlipidemia with a low-fat, high-fiber diet and possibly lipid-lowering drugs. General liver support with hepatoprotectants such as antioxidants and ursodiol may be warranted (see Table 71-2). Avoid the use of corticosteroids.

Superficial Necrolytic Dermatitis (Hepatocutaneous Syndrome)

Superficial necrolytic dermatitis (SND), also called hepatocutaneous syndrome, necrolytic migratory erythema, or metabolic epidermal necrosis, is a crusting, ulcerative dermatopathy that appears to be a complication of hepatic or endocrine pancreatic disease in dogs and cats.

Etiology

The etiology and pathogenesis of this syndrome are poorly understood. In dogs it is most commonly associated with hepatopathy but has also been described with glucagon-producing pancreatic endocrine tumors or glucagon-producing hepatic tumors. The syndrome has also been reported in one cat with a pancreatic carcinoma and two cats with hepatopathy. Many dogs with SND develop diabetes mellitus in the late stages of the disease.

The hepatopathy is usually of unknown origin, although liver disease associated with anticonvulsant therapy and potential exposure to mycotoxins has been suggested. In a recent report, chronic phenobarbital therapy was associated with SND in 44% of cases. Biochemical evaluation, liver function testing, ultrasonographic appearance of the liver, and hepatic biopsy indicate that the hepatopathy of dogs with phenobarbital-related SND is distinctly different from the typical hepatic dysfunction and cirrhosis seen in dogs with phenobarbital hepatotoxicity (see under "Phenobarbital-Associated Hepatic Disease").

Pathogenesis

The dermatologic lesions are similar to necrolytic migratory erythema in humans, which is usually associated with hyperglucagonemia and hypoaminoacidemia secondary to a glucagon-secreting pancreatic tumor. Hyperglucagonemia is believed to cause severe hypoaminoacidemia by stimulating hepatic utilization of amino acids during gluconeogenesis, resulting in a metabolic or nutritional imbalance affecting the skin. Intravenous amino acid infusions can reverse the skin lesions in humans.

- Plasma glucagon levels are increased and most plasma amino acids are decreased in dogs with SND that have an underlying pancreatic endocrine tumor. Dermatologic signs resolve if the tumor can be completely resected.
- Plasma glucagon levels are reported to be normal or only mildly increased in dogs with SND and hepatopathy. However, most of these dogs have severe hypoaminoacidemia and some have responded to dietary supplementation with egg yolks, which are a rich source of amino acids. The plasma amino acid levels in dogs with SND and hepatopathy are significantly lower than in normal dogs or dogs with acute or chronic liver disease, suggesting that the pathogenesis is not simply related to hepatic dysfunction. Hyperglucagonemia may still play a central role in dogs with hepatopathy because glucagon exists in numerous immunoreactive fractions and the assay for this hormone may be insensitive to some glucagon species.
- Alternatively, up-regulation of hepatic amino acid utilization in a hypercatabolic state has also been hypothesized in dogs with SND and hepatopathy. Contributing factors may include hormonal imbalances (glucocorticoids, thyroid supplementation, increased adrenergic stimulation), phenobarbital therapy causing chronic hepatic microsomal enzyme induction, and age-related changes in hepatocellular membrane stability (increased hepatocyte responsiveness to adrenergic stimulation and enhanced amino acid utilization for gluconeogenesis). Aging has also been associated with alterations in hepatic sensitivity to glucagon.
- Other nutritional deficiencies such as zinc, biotin, or essential fatty acids have also been proposed.

Signalment and Clinical Signs

- SND is a disease of older dogs (mean age of 10 years), especially males. Shetland sheepdogs, West Highland white terriers, cocker spaniels, Scottish terriers may be at increased risk.

- Dogs are usually presented for dermatologic signs and lethargy and inappetence. Overt signs of liver failure are unusual.
- SND is characterized by bilaterally symmetrical crusting or erosive lesions of the pads, mucocutaneous junctions, and pressure points (hocks and elbows). The dermatologic manifestations are described in Chapter 49.

Diagnosis

Laboratory Evaluation

- Abnormalities may include nonregenerative anemia, abnormal red cell morphology (poikilocytes and target cells), mild to moderate increases in serum liver enzymes (ALP, ALT, and AST), hyperglycemia, and mild to moderate increases in SBA concentrations. Hypoalbuminemia and hyperbilirubinemia are less consistent findings.
- Other potential features include hypoaminoacidemia, hyperglucagonemia, and elevated insulin levels.

Ultrasonography

- Ultrasound examination of the liver may identify a unique "honeycomb" or "Swiss cheese–like" lesion consisting of 0.5- to 1.5-cm diameter hypoechoic regions surrounded by highly echogenic borders. Dogs with SND related to glucagonoma do not have these characteristic hepatic lesions on ultrasound.
- The pancreas should be evaluated for nodules consistent with neoplasia, although most glucagonomas in the pancreas have not been visualized on ultrasonographic examination.

Liver and Skin Biopsy

- Dermatohistopathology is pathognomonic for SND (see Chapter 49). Lesions consist of parakeratotic hyperkeratosis, intercellular or intracellular edema, and epidermal hyperplasia. Bacteria, dermatophytes, and yeast can be secondary contaminants.
- The liver is usually normal to increased in size and has a striking nodular appearance that grossly mimics cirrhosis. However, the hepatic lesion is not true cirrhosis because microscopically, the fibrous tissue is actually condensed stroma secondary to parenchymal collapse and not due to increased collagen production. Areas of severe parenchymal collapse contain hepatocytes with marked vacuolization (predominantly glycogen accumulation but also some lipid deposition). Regions of collapse surround sharply demarcated nodules of normal hepatic parenchyma. The hepatic lesion is most likely a reflection of underlying nutritional, hormonal, or toxic abnormalities.

Treatment

If a glucagon-producing pancreatic tumor is diagnosed (only 10% of cases), it should be surgically resected. When a toxic or metabolic cause of hepatic injury is identified (e.g., phenobarbital therapy), there is the potential for resolution of the disorder if the cause can be removed. However, most dogs with phenobarbital-associated SND do not improve after discontinuing phenobarbital.

Nutritional Considerations

▼ ***Key Point*** The most effective treatment is IV administration of amino acids.

- Give 10% amino acid solution (Aminosyn, Abbott Labs) at a dosage of 250 to 500 ml per dog (or 25 ml/kg) slowly IV over an 8- to 12-hour period. Repeat this treatment every 7 to 10 days as needed to control the dermatologic lesions. Some dogs show marked improvement after the first treatment. If a patient has not responded after four treatments, it probably won't.
- Despite underlying evidence for hepatic disease, do not restrict protein intake unless overt HE occurs. Feed a diet high in good-quality protein.
- Consider oral protein supplementation with three to six egg yolks q24h or an amino acid supplement (Pro-Mod, Ross Labs) 10 g per 7 kg of body weight (up to a maximum of 40 g) q24h.
- Give an oral multivitamin supplement (including vitamin E).
- Give elemental zinc, 1 mg/kg PO q12h, for possible zinc deficiency.
- Consider essential fatty acid supplementation.

Other Therapy

- Refer to Chapter 49 for recommendations for treating the cutaneous lesions and secondary cutaneous bacterial and fungal infections.
- Manage diabetes mellitus with insulin therapy and a high-fiber diet.
- Consider a long-acting somatostatin analogue (Octreotide, Sandostatin) to inhibit glucagon release.
- Parenteral corticosteroids are contraindicated because of the diabetic or prediabetic state. Topical triamcinolone ointment q12h can be used on a short-term basis to decrease pain and inflammation associated with deep fissures.

Prognosis

The prognosis is poor except in the small percentage of cases in which a glucagon-producing pancreatic tumor is identified and removed. Most dogs die or are euthanized within 5 months of onset of the skin lesions.

HEPATIC AMYLOIDOSIS

Amyloidosis is a progressive systemic disease associated with extracellular deposition of insoluble fibrillar proteins, which results in organ dysfunction. Amyloidosis in dogs and cats is reactive and may occur secondary to chronic inflammatory, infectious, or neoplastic disorders.

- Amyloidosis is a familial disorder in the Chinese Shar-Pei dog and in Abyssinian cats. Although concurrent amyloid deposition occurs in the liver, kidneys, spleen, and adrenal glands, clinical manifestations of renal failure are most common.
- Clinically significant hepatic involvement has been described in Chinese Shar-Pei dogs and Siamese, Oriental shorthair, Devon Rex, Burmese, and domestic shorthaired cats. Diffuse hepatic involvement predisposes patients to spontaneous hepatic rupture because of hepatic vascular fragility and coexistent coagulopathy.

Signalment and Clinical Signs

- Shar-Pei dogs and young cats are at increased risk.
- Clinical signs include anorexia, PU/PD, vomiting, and jaundice.
- Spontaneous rupture of the friable liver may cause acute hemoabdomen with signs of lethargy, hypovolemic shock, or sudden death.

Diagnosis

Physical Examination

Physical examination reveals hepatomegaly. With spontaneous rupture, findings include pale mucous membranes, hypothermia, and abdominal effusion.

Laboratory Evaluation

- Potential laboratory findings include increased ALT activity, hyperbilirubinemia, and increased SBAs.
- Regenerative anemia may occur secondary to hepatic rupture and hemorrhage. Thrombocytopenia and abnormally prolonged clotting times (which may be vitamin K responsive) have been described in some cats.
- Abdominocentesis reveals hemorrhagic abdominal effusion.
- Concurrent renal amyloidosis may cause azotemia and proteinuria (see Chapter 77).

Radiography and Ultrasonography

- Findings on abdominal radiographs may include hepatomegaly and possible abdominal effusion.
- Abdominal ultrasound may reveal a diffusely heterogenous liver with hypoechoic foci.

Liver Cytology and Biopsy

- Diagnosis of hepatic amyloidosis requires liver biopsy with special stains (Congo red) to confirm its presence. However, caution is advised since FNA for cytology or liver biopsy can be complicated by severe hemorrhage.
- Hepatic cytology may suggest amyloid based on the identification of pink amorphous material adjacent to hepatocytes (with a modified Wright-Giemsa stain).
- Grossly, the liver is pale, large, and friable with hemorrhages, hematomas, and capsular tears.
- Histologically, amyloid in the liver appears as a homogenous, amorphous, eosinophilic material within the space of Disse and vessel walls.

Treatment

- Use fluid therapy and blood transfusion to treat acute liver hemorrhage.
- Give vitamin K_1 for the coagulopathy (see Table 71-1).
- Consider colchicine therapy (0.03 mg/kg PO q24–48h), which may be beneficial in Chinese Shar-Pei dogs with hepatic amyloid.
- The long-term prognosis in cats with hepatic amyloidosis is poor.

CANINE CHRONIC HEPATITIS

Chronic hepatitis is a heterogeneous group of necrotizing inflammatory diseases of the liver. The clinical signs of chronic hepatitis initially are vague, such as anorexia, weight loss, and depression; however, as hepatitis becomes advanced, signs of liver failure develop, including jaundice, ascites, coagulopathy, or HE.

With few exceptions, the cause, pathogenesis, natural history, and optimal treatment of these disorders in dogs is unknown. Because the laboratory and histopathologic features often fail to determine the definitive etiology, combined clinical and histologic criteria rather than etiologic classifications generally are used to categorize patients with chronic hepatitis.

Idiopathic Chronic Hepatitis

Idiopathic chronic hepatitis is characterized by clinical signs and persistent laboratory indicators of hepatic disease in association with chronic portal inflammation, piecemeal hepatic necrosis, and fibrosis that frequently progresses to cirrhosis and liver failure.

Etiology

The disease must be considered idiopathic in most dogs; however, it is probable that after an initial inciting hepatocyte injury, immune mechanisms are involved in perpetuating the inflammation.

Signalment and Clinical Signs

- The incidence of idiopathic chronic hepatitis appears to be highest in female dogs.
- The mean age of onset is 5 to 6 years, but adult dogs of any age or breed can be affected.
- Common signs include anorexia, depression, weakness, PU/PD, ascites, jaundice, weight loss, and vomiting.

Diagnosis

The diagnosis is suggested by the clinical signs in conjunction with elevation of serum liver enzyme activity. The diagnosis can be confirmed only by liver biopsy. Historical and physical findings are consistent with chronic liver disease.

Laboratory Evaluation

- Serum ALT activity usually is >10 times normal, reflecting ongoing hepatic injury (inflammation). Serum ALP activity is usually >5 times normal, reflecting intrahepatic cholestasis. Hyperbilirubinemia and bilirubinuria also are common.
- Liver function tests such as SBA concentrations frequently are abnormal, reflecting the degree of liver dysfunction.
- Less consistent findings include hypoalbuminemia, hyperglobulinemia, mild nonregenerative anemia, and abnormal hemostasis. Ascitic fluid, when present, typically is a transudate or modified transudate.

Radiography and Ultrasonography

- Radiographically the liver may appear small, and on ultrasonography nonspecific changes in echogenicity may be detected.

Liver Biopsy

Liver biopsy and histopathology confirm the diagnosis.

- The liver often is small and nodular because of the fibrosis and nodular regeneration of cirrhosis.
- The primary lesion is portal inflammation consisting primarily of lymphocytes and plasma cells and occasional neutrophils and macrophages. The inflammation extends into the hepatic lobule, causing piecemeal necrosis of hepatocytes. These lesions are essential defining criteria for categorization as idiopathic chronic hepatitis.
- Fibrosis usually is present.

▼ ***Key Point*** Perform a quantitative copper analysis and special stains for copper to determine if increased hepatic copper content could be playing a role in chronic hepatitis.

Differential Diagnosis

When chronic hepatitis has been confirmed histologically, look for potential inciting or perpetuating factors. Recognized types of chronic hepatitis are listed in Table 71-8. If none are found, then idiopathic chronic hepatitis is the diagnosis.

Treatment

Treatment includes drug therapy, discussed below, and supportive measures, previously described under "Principles of Treatment for Liver Disease" (see Table 71-1). Treatment recommendations for idiopathic chronic hepatitis in dogs are empirical and clinical studies are lacking.

Glucocorticoids

Glucocorticoid therapy is the cornerstone of treatment for canine chronic hepatitis, yet efficacy has not been well documented. It is not clear whether immunosuppressive doses (as used for immune-mediated disorders) or anti-inflammatory doses are optimal. One retrospective study of dogs with chronic hepatitis suggested that immunosuppressive doses were associated with prolonged survival. Anti-inflammatory doses may nonspecifically decrease hepatic inflammation and release of local cytokines, which contribute to hepatic necrosis and fibrosis.

- Consider glucocorticoid therapy when infectious diseases have been ruled out and characteristic inflammatory infiltrates are detected on liver biopsy.
- Give prednisolone, 1 to 2 mg/kg PO q24h, until clinical remission occurs; then taper gradually to

0.5 mg/kg or the lowest effective dose for alternate-day maintenance.
- Although prednisone must be converted by the liver to its active metabolite, prednisolone, either drug can probably be used, based on the observation that humans with liver disease can still rapidly convert prednisone to prednisolone.
- Potential side effects of glucocorticoid therapy include sodium and water retention (exacerbation of ascites), GI bleeding and catabolic effects (exacerbation of HE), iatrogenic Cushing's disease, and secondary infections.
- Monitor serum biochemistries every 1 to 2 weeks in the initial stages of treatment.
- Consider a follow-up liver biopsy, 2 to 3 months after starting therapy, to confirm remission of the disease.

Azathioprine

Azathioprine is an antimetabolite with anti-inflammatory and immune-modulating effects. When prednisolone alone is ineffective or side effects become objectionable, consider combination therapy using azathioprine and prednisolone (at a lower dose if side effects are a problem).

- Give azathioprine (Imuran, Burroughs Wellcome) at a dosage of 1 to 2 mg/kg PO q24h for induction therapy. For maintenance, give the same dose once every other day while giving prednisolone on the alternate days.
- Because azathioprine may cause bone marrow suppression (neutropenia and thrombocytopenia), monitor periodically with a CBC. Other less common side effects include GI toxicity, pancreatitis, and hepatotoxicity.

Ursodiol

Ursodiol (Actigall) is a synthetic bile acid that has been useful in the treatment of humans with chronic hepatitis. Its use in conjunction with anti-inflammatory therapy in dogs with chronic hepatitis appears promising.

- Ursodiol, a hydrophilic bile acid, is believed to be beneficial by expanding the bile acid pool and displacing potentially hepatotoxic hydrophobic bile acids that may accumulate in cholestasis. It also has membrane-stabilizing, cytoprotective, and immunomodulatory effects on liver cells and promotes choleresis (see Table 71-2).
- Ursodiol appears to be well tolerated in dogs when used at a dosage of 15 mg/kg PO q24h.

Antioxidants

- Free radicals may be generated in chronic hepatitis, and they may contribute to hepatic injury. Antioxidants, such as vitamin E, are important to scavenge free radicals and prevent oxidative injury.
- Give vitamin E at a dosage of 50 to 400 IU PO q24h. Absorption of fat-soluble vitamins may be decreased in chronic cholestatic hepatobiliary disorders. In this setting, a water-soluble form of vitamin E may be preferable.

Prognosis

The response to treatment of idiopathic chronic hepatitis is variable, which is expected because it probably represents a heterogeneous group of diseases.

- Some dogs eventually can be taken off medication and remain in remission, but more often therapy must be continued indefinitely.
- Other dogs fail to respond, especially those that have advanced disease and cirrhosis (the treatment of cirrhosis and its complications is discussed elsewhere in this chapter).

Hepatic Copper Accumulation and Chronic Hepatitis

Copper accumulation in the liver can be associated with significant hepatic injury resulting in acute hepatitis, chronic hepatitis, and cirrhosis. It is one of the few well-documented causes of chronic hepatitis in the dog. The severity of hepatic injury is related to the amount of accumulated copper. Hepatic copper concentration in normal dogs is less than 400 µg/g (ppm) dry weight.

- An inherited metabolic defect in biliary copper excretion causes chronic hepatitis in Bedlington terriers. Copper concentrations range from 850 to 12,000 µg/g dry weight in affected Bedlingtons.
- Hepatic damage in Bedlington terriers does not consistently occur until the copper concentration exceeds 2000 µg/g dry weight. The concentration at which abnormal hepatic copper contributes to hepatic damage in other breeds is unknown and may vary among breeds.
- Copper accumulation in the liver may be a cause or an effect of chronic hepatitis. Because copper normally is excreted in the bile, hepatic copper accumulation can also occur secondary to any cholestatic hepatobiliary disorder (such as idiopathic chronic hepatitis) that impairs bile flow.
- Whether secondary copper accumulation can further contribute to hepatic injury is unclear, but this is an important question with therapeutic implications.
- Other breeds of dogs occasionally are diagnosed with chronic hepatitis and cirrhosis accompanied by increased hepatic copper concentrations. At this advanced stage of disease, it is difficult to know whether copper accumulation is a cause or an effect of the chronic hepatitis. As a general rule, the higher the copper content, the more likely it is to be a primary problem.

Copper-Associated Hepatitis in Bedlington Terriers

Bedlington terriers have a high incidence of an inherited (autosomal recessive) metabolic defect in biliary copper excretion that leads to progressive intrahepatic copper accumulation and chronic liver disease. Because of extensive inbreeding, the prevalence within the breed is quite high (25% affected, 50% carriers).

Etiology

- Hepatic copper content increases with age as a result of defective biliary copper excretion.
- Excess copper is bound to hepatic metallothionein and stored in hepatic lysosomes. When hepatic copper accumulation is >2000 µg/g dry weight, progressive hepatic injury occurs, including focal hepatic necrosis, chronic hepatitis, and eventually cirrhosis. This disease is similar but not identical to Wilson's disease in humans.
- Hepatic injury associated with copper accumulation involves free radical damage to hepatic mitochondria.

Clinical Signs

Clinical signs and presentation vary widely, depending on the stage of disease.

- Most affected dogs are presented as young or middle-aged adults of either sex with signs of hepatic failure of varying severity, including lethargy, depression, weight loss, vomiting, and jaundice. Acute fulminant hepatic failure with rapid deterioration and death occurs in rare instances.
- Some middle-aged and older dogs are presented initially with end-stage liver disease and cirrhosis. In these animals there is a more chronic, insidious clinical course with similar but less severe signs. In the advanced stages of disease, cachexia, jaundice, ascites, and HE can occur.
- Affected dogs may be asymptomatic, especially young dogs in which copper is accumulating but has not yet reached toxic hepatic concentrations.

Diagnosis

Suspect copper-associated hepatitis in any Bedlington terrier with historical, physical, or biochemical evidence of hepatic disease or with vague, unexplained illness. Asymptomatic dogs can be identified only by routine biochemical screening or liver biopsy. Definitive diagnosis requires liver biopsy.

History

- Acute, recurrent episodes of illness are common in many affected dogs. Stressful events such as whelping, showing, shipping, or a change in environment can precipitate these episodes.
- Dogs initially presenting with end-stage cirrhosis often have no history of previous episodes of hepatitis.

Physical Examination

- Findings in dogs with acute hepatitis include depression, lethargy, and dehydration. Hepatomegaly may occur. Jaundice may be detected within 48 hours of onset. Acute copper-induced hemolytic anemia may be a contributing factor.
- With advanced disease, dehydration, emaciation, ascites, HE, and jaundice may be detected. The liver is small and not palpable.
- Asymptomatic dogs are normal on physical examination.

Laboratory Evaluation

- Biochemical findings vary with the stage of disease. Increased serum ALT activity is the most sensitive laboratory indicator of this disease, although up to a third of affected dogs will have normal ALT values. These are mostly younger dogs that are in the early stages of the disease.
- Other serum biochemical abnormalities typical of hepatic dysfunction eventually develop, such as hyperbilirubinemia, bilirubinuria, hypoalbuminemia, increased SBA levels, and prolonged PT and APTT.
- Serum copper levels are not helpful for the diagnosis.
- Acute release of copper from necrotic hepatocytes occasionally causes hemolytic anemia. Laboratory findings include low packed cell volume (PCV), hemoglobinemia, and hemoglobinuria.

Radiography and Ultrasonography

- Abdominal radiographs are unremarkable except when advanced stages of disease are accompanied by microhepatica or ascites.
- Ultrasonography of the liver may be normal in the early stages. As the disease progresses, findings are indicative of diffuse liver disease or microhepatica and cirrhosis.

Liver Biopsy

Liver biopsy is indicated for definitive diagnosis and staging of the disease. Perform liver biopsies in all Bedlingtons being considered for breeding. Dogs should be older than 1 year because unaffected carrier dogs may have transient increases in hepatic copper that return to normal by 1 year of age. The spectrum of gross and microscopic features in the liver parallels the variable expression of the disease.

- The liver can be grossly normal or swollen and smooth with accentuation of the lobules. As cirrhosis

develops, the liver decreases in size and there is a mixture of fine and coarse nodules.
- Histologically, H&E-stained hepatic tissue reveals dark granules in hepatocyte cytoplasm. In the early stages, centrilobular hepatocytes are most affected, but later the distribution is diffuse.
- Histochemical stains for copper, such as rhodanine and rubeanic acid, are positive. These stains correlate well with quantitative copper analysis when values exceed 850 µg/g dry weight.
- Associated histologic hepatic damage is variable. In the most mildly affected animals, only centrilobular copper granules are detected. This progresses to focal hepatitis, lesions of chronic hepatitis, and eventually cirrhosis.

Hepatic Copper Analysis

Perform quantitative copper analysis on fresh hepatic tissue. Copper analyses are available to veterinarians through the veterinary diagnostic laboratories of Michigan State University and Colorado State University. Affected dogs have hepatic copper concentrations of 850 to 12,000 µg/g dry weight.

DNA Testing

- DNA testing is available (www.vetgen.com) that identifies a linked marker located in the chromosome close to the as-yet-unidentified causative gene.
- Carrier, affected, or unaffected dogs can be characterized with 90% accuracy.
- DNA-screened carriers or normal dogs should have annual liver enzyme evaluations. Increases in liver enzyme activity should merit further evaluation of the liver.

Treatment

Specific measures to control hepatic copper accumulation are summarized in Table 71-9. Base the choice of therapy for an individual patient on the severity of existing hepatic damage.

▼ ***Key Point*** Lifelong therapy is necessary because copper reaccumulates if treatment is stopped.

Management of the acute hepatic crisis also involves symptomatic and supportive care to control electrolyte, acid-base, and fluid imbalances and HE (see Table 71-1). Treatment of hemolytic anemia may require a blood transfusion.

Chelator Therapy

- Treat affected dogs with copper accumulation (>1500 µg/g dry weight) and chronic hepatitis with a copper chelator such as penicillamine or trientine hydrochloride, which promotes urinary copper excretion (see Table 71-9).
- For treating an acute hemolytic crisis, trientine hydrochloride (but not penicillamine) may be effective in chelating copper in the circulation.
- There may be other protective effects of penicillamine besides depletion of hepatic copper, because many Bedlington terriers on long-term therapy do not develop hepatic failure despite continued elevated copper levels and ongoing hepatic damage. Penicillamine may induce hepatic metallothionein, which binds and sequesters copper in a non-toxic form. Additional effects that may be beneficial include anti-inflammatory, antifibrotic activity, and immunomodulating effects.

Zinc Therapy

Use oral zinc therapy when hepatic copper concentrations are >400, but <1500 µg/g dry weight to prevent intestinal copper absorption and hepatic copper accumulation. Preliminary information in Bedlington terriers and West Highland white terriers suggests it may also deplete hepatic copper concentrations (see Table 71-9).

Dietary Therapy

Low copper diets are of little value once hepatic copper accumulation has occurred (see Table 71-9) but may be helpful in the early stages to decrease intestinal copper absorption.

Vitamin E Therapy

Administer vitamin E to all dogs with hepatic copper accumulation (see Table 71-9). Hepatic injury associated with hepatic copper overload in Bedlington terriers appears to involve free radical damage to hepatic mitochondria. Vitamin E therapy protects against copper-induced hepatic damage experimentally.

Prognosis

- Dogs with mild to moderate acute hepatic failure usually respond to supportive care.
- If this disease is detected before severe hepatic failure occurs, many dogs can live out their lives with penicillamine therapy.
- The prognosis is poor if there is fulminant hepatic failure or chronic end-stage cirrhosis and failure.

Prevention

- Treatment of affected dogs with minimal hepatic injury is recommended in the hope of preventing acute hepatitis or progression to cirrhosis.
- Zinc therapy is a promising and less expensive alternative to penicillamine in this setting.
- Bedlington terriers used in breeding programs can be certified free of disease through either the Canine Liver Registry at Purdue University or the Liver Registry of the Orthopedic Foundation for Animals in Columbia, Missouri.

Table 71-9. TREATMENT OF HEPATIC COPPER ACCUMULATION

Product	Formulation	Dosage	Side Effects	Comments
Chelate Systemic Cu				
Penicillamine (Cuprimine, MSD; Depen, Wallace)	Cuprimine: 125- and 250-mg caps Depen: 250-mg tabs	15 mg/kg q12h PO given on an empty stomach to improve absorption; do not give concurrently with any medication, including Zinc[a] or vitamin and mineral supplements.	Anorexia and vomiting[b] are common; dermatologic drug eruption or autoimmune-like excretion. Indicated when vesicular lesions of mucocutaneous junctions;[c] reversible renal disease.[c]	Causes systemic Cu chelation and urinary excretion. Indicated when hepatic Cu >1500 µg/g. Takes months to years to produce significant decrease in hepatic Cu concentration (900 µg/g/year)[d], but may produce subjective clinical improvement after a few weeks. May have protective effect in liver beyond chelation: induces hepatic metallothionein, which binds and sequesters Cu in non-toxic form? Not effective for treatment of Cu-associated hemolysis.
Trientine dihydrochloride[e] (Syprine, MSD)	250-mg caps	15 mg/kg q12h PO. Give 1 hour before meals; do not give concurrently with any medication, including zinc[a] or vitamin/mineral supplement.	None noted as yet.	Use as an alternative to penicillamine if vomiting occurs. May be useful for treatment of hemolysis by chelating Cu in blood. More expensive than penicillamine.
Decrease Intestinal Cu Absorption				
Zinc acetate, sulfate, or gluconate to obtain therapeutic zinc	Many available	100-mg elemental zinc PO q12h for 2–3 months, then 50 mg PO q12h for maintenance. Separate administration from meals by >1 hour.	Vomiting,[f] zinc-induced hemolysis at plasma levels >800 µg/dl.	Induces intestinal metallothionein, which preferentially binds Cu and decreases absorption. Takes 3–6 months. Monitor plasma zinc every 2–3 months. Ideal level is 200–400 µg/dl. Do not give concurrently with Cu chelators. Use when hepatic Cu is increased but is <1500 µg/g dry weight.
Decrease Cu Intake				
Cu-restricted diet	Prescription Diet l/d (Hill's) Homemade diets			Low Cu diet may slow further Cu accumulation but won't decopper the liver. Most commercial diets have abundant Cu. Avoid mineral supplements, liver, shell fish, organ meats, chocolate, nuts, mushrooms, cereals.
Antioxidant Therapy[g]				
Vitamin E	Many available	100–400 IU/day, PO.	None noted as yet.	Oxidative damage occurs in Cu-associated liver disease. Vitamin E protects the liver against oxidant damage.

[a] Penicillamine and trientine will chelate zinc (and decrease its absorption) when given concurrently.
[b] Often resolves after several weeks; start at a reduced dose and increase to maintenance after a few days. Giving with food will decrease absorption, but a small amount of milk, cheese, or bread given concurrently may decrease vomiting.
[c] Rare complications; renal compromise more likely with Depen?
[d] In Bedlington terriers; more rapid response in Doberman pinschers and other breeds.
[e] Availability limited; may require a special order direct from manufacturer.
[f] Zinc acetate may be less irritating to the stomach than other formulations. To minimize vomiting, open capsule and mix contents with small amount of tuna or hamburger.
[g] Although vitamin C has antioxidant effects, it should be avoided in dogs with Cu accumulation because it increases Cu's oxidative damage to the liver.
Cu, copper.

Chronic Hepatitis in West Highland White Terriers

West Highland white terriers (WHWTs) have increased risk for developing chronic hepatitis and cirrhosis. Hepatic copper accumulation is found in many WHWTs with chronic hepatitis. Hepatic copper accumulation in WHWTs is a familial trait, but the mode of inheritance has not been established.

Etiology

The etiopathogenesis is unknown. The notable differences between the copper retention in WHWTs and the disease in Bedlington terriers are that WHWTs do not accumulate copper continuously throughout life, the peak hepatic copper concentration in WHWTs occurs by 6 months of age and may even decrease after 1 year of age, and the magnitude of the copper increase is generally lower in WHWTs than in Bedlingtons.

- Many WHWTs have hepatic copper concentrations that range from 200 to 1500 µg/g dry weight, but rarely does the value exceed 2000 µg/g dry weight and clinical illness associated with excess hepatic copper accumulation is uncommon. Some dogs have high hepatic copper (usually <3500 µg/g dry weight) but no evidence of hepatic disease.
- In WHWTs with chronic hepatitis, increased hepatic copper concentration (>2000 µg/g dry weight) appears to be a factor in some but not most affected dogs. When hepatic copper concentrations are <2000 µg/g dry weight, the copper may not be contributing to hepatic injury. These dogs may have idiopathic chronic hepatitis.
- Chronic hepatitis in WHWTs may also occur without increases in hepatic copper.

Clinical Signs

- Affected animals in the early stages of copper accumulation or those with focal hepatitis are usually asymptomatic.
- When widespread necrosis occurs, nonspecific signs of liver disease include anorexia, vomiting, diarrhea, lethargy, and jaundice.
- With advanced disease, jaundice and ascites are common.

Diagnosis

Episodes of hepatic necrosis may be precipitated by stressful events such as whelping or showing.

- The earliest biochemical abnormality associated with hepatic necrosis is increased ALT activity.
- With advanced disease, laboratory findings include increased liver enzyme activity, hyperbilirubinemia, increased SBA levels, hyperammonemia, and hypoalbuminemia. Copper-associated hemolytic anemia has not been documented.
- Liver biopsy for histopathology and quantitative copper analysis are required for definitive diagnosis. Histologic features include copper granules (which are initially centrilobular but become diffusely distributed with time), multifocal hepatitis, subacute bridging necrosis, massive necrosis, and cirrhosis.

Treatment

If chronic hepatitis and cirrhosis are associated with increased hepatic copper (>1500 µg/g dry weight) in a WHWT, initiate treatment for hepatic copper accumulation as described for Bedlingtons (see previous section) and in Table 71-9.

- Preliminary evidence suggests that both penicillamine and zinc acetate can decrease hepatic copper concentrations in WHWTs when given on a long-term basis (see Table 71-9).
- Because hepatic copper accumulation is not continuous throughout life, mature dogs with chronic hepatitis and hepatic copper concentrations <1500 µg/g dry weight may not require chelator therapy. Consider glucocorticoid therapy as described previously for idiopathic chronic hepatitis.

Chronic Hepatitis in Doberman Pinschers

Doberman pinschers are at increased risk to develop chronic hepatitis and cirrhosis. Hepatic copper concentrations are increased in most affected dogs.

Etiology

- The underlying etiopathogenic mechanisms are unknown, but a genetic basis is suggested by the high incidence in this breed. Middle-aged (5–7 years old) female dogs are at increased risk.
- Hepatic copper concentrations are increased (650–4000 µg/g dry weight) in most affected dogs but not to the same magnitude as seen with Bedlington terriers, suggesting a different disease mechanism. The significance of the increased hepatic copper concentration is still under debate.
- Evaluation of Doberman pinschers with subclinical disease has recently provided further information on the role of copper in this disorder. Screening of 106 clinically healthy 3-year-old Doberman pinschers in the Netherlands (for liver enzyme elevations, increased SBA, or copper granules on FNA cytology of liver) with follow-up liver biopsy (including quantitative copper) revealed subclinical hepatitis in 21% of the screened dogs. Affected dogs were followed over 2 to 4 years with repeated liver biopsy and quantitative copper analysis. Persistent hepatitis was only documented in dogs (5 females, 1 male) with initial and final hepatic copper concentrations > 400 µg/g dry weight (939 +/− 299 µg/g dry weight). Those dogs with repeatedly normal hepatic copper levels (<400 µg/g dry weight) did not have persistent

hepatitis on liver biopsy (probably due to other reversible causes). These findings suggest that there is a relationship among copper storage, hepatocellular damage and hepatitis in Doberman pinschers.
- An immune-mediated mechanism of disease in affected Dobermans is supported by the finding of up-regulation of major histocompatibility complex class II antigens in hepatocytes.

Signalment and Clinical Signs

- Middle-aged females are predominantly affected.
- Clinical signs may be mild or absent when the disease is fortuitously diagnosed in the early stages. However, most dogs are diagnosed in the advanced stages of hepatic failure.
- Signs include anorexia, weight loss, lethargy, PU/PD, vomiting, diarrhea, ascites, and jaundice.
- Evidence of excessive bleeding (gingival bleeding, epistaxis, and melena) may be found.
- Signs of HE often predominate in the terminal stages.

Diagnosis

Suspect chronic hepatitis in any Doberman pinscher (especially female) with clinical and biochemical evidence of hepatic disease. Definitive diagnosis requires liver biopsy.

- Common physical examination findings include ascites, jaundice, weight loss, and encephalopathy. Splenomegaly (associated with portal hypertension) is common. The liver is small and not palpable.
- Laboratory findings frequently include increased ALP and ALT activity, hyperbilirubinemia, bilirubinuria, hypoalbuminemia, increased SBA levels, and hyperammonemia. Coagulopathy and thrombocytopenia are common in the advanced stages. Consider concurrent von Willebrand disease in affected dogs with a bleeding disorder, because of its prevalence in this breed (see Chapter 23).
- Radiographic and ultrasonographic findings of microhepatica and ascites are consistent with chronic liver disease and cirrhosis.

Liver Biopsy and Copper Analysis

- Liver biopsy and histopathologic evaluation are necessary to confirm the diagnosis.
- Grossly, the liver is small with micronodular or macronodular cirrhosis.
- Histologically, the earliest lesion is inflammation and fibrosis around the small hepatic vein branches. As the disease progresses, fibrous tissue septa radiate from hepatic vein branches to the portal areas. In the late stage of the disease, lymphoplasmacytic inflammation occurs around larger hepatic veins and portal tracts. Fibrosis and architectural distortion consistent with cirrhosis are present.
- Rhodanine and rubeanic acid stains usually are positive for copper, especially in centrilobular regions. Stains for hepatic iron also are usually positive.
- Quantitative copper analysis reveals mild to moderate copper accumulation (650–4000 µg/g dry weight).

Treatment

Optimal treatment has not been established.

- Institute, as needed, symptomatic and supportive therapy for complications of hepatic failure, including correction of fluid, electrolyte, and acid-base balance and treatment of ascites, HE, and coagulopathies (see Table 71-1 and "Principles of Treatment for Liver Disease").
- Therapy with anti-inflammatory or immunosuppressive drugs such as prednisolone with or without azathioprine may be given, as described previously for idiopathic chronic hepatitis. The efficacy of this treatment remains to be determined, but generally the response is poor, possibly because most dogs are presented in advanced stages of liver failure. Doberman pinschers with subclinical hepatitis treated with low doses of prednisolone (0.1–0.5 mg/kg/day) did not show any significant improvement.
- Consider penicillamine therapy, especially when subclinical hepatitis is diagnosed. Five female Doberman pinschers with persistent subclinical hepatitis and increased hepatic copper concentrations were treated with penicillamine (200 mg PO q12h for 4 months). Mean liver copper concentrations decreased from 1036 to 407 µg/g dry weight and improvement in liver histopathology was noted. Whether histopathologic improvement was related to copper-chelating or anti-inflammatory effects of penicillamine could not be ascertained.
- Consider ursodiol therapy in this cholestatic disorder (see Table 71-2). Vitamin E may also provide a beneficial antioxidant effect.

Prognosis

- When Doberman hepatitis is diagnosed in the advanced stages, treatment usually is unsuccessful. Most dogs die within weeks to months.
- The prognosis may be more favorable if the disease is detected in the subclinical stage, but the optimal therapeutic regimen remains to be determined.

Copper-Associated Hepatitis in Dalmatians

Chronic hepatitis and cirrhosis associated with hepatic copper accumulation has been reported in dalmatians. Cholestasis is not a prominent biochemical or histologic feature until later in the disease, suggesting that hepatic copper accumulation is more likely to be caused by a familial metabolic disorder than to be secondary to

altered hepatic biliary copper excretion. Two of the dogs were related.

Clinical Signs

Most dogs presented initially with acute GI signs (anorexia, vomiting, diarrhea).

Diagnosis

- Biochemical findings revealed markedly increased ALT activity (average 10.8 times above normal range) and moderately increased ALP activity (average 5.5 times above normal range).
- Hyperbilirubinemia and hypoalbuminemia were seen with advanced disease. Glucosuria (in the absence of hyperglycemia) and proteinuria were identified in some dogs.
- Liver biopsy revealed hepatocellular degeneration, necrosis, and inflammation (predominantly lymphocytes or neutrophils). The mean hepatic copper concentration was 3197 µg/g dry weight (range of 754–8390 µg/g dry weight).

Treatment and Prognosis

- Rapid progression of the disease was characteristic.
- Copper chelator therapy may be beneficial if diagnosed before advanced liver disease occurs (see Table 71-9).

Copper-Associated Hepatitis in Skye Terriers

Chronic hepatitis and cirrhosis associated with hepatic copper accumulation (range of 358–2257 µg/g dry weight) has been described in genetically related Skye terriers.

- In the early stages, copper accumulation is absent, and biopsy findings indicate hepatocellular degeneration with cholestasis and mild inflammation.
- Chronic lesions are associated with intracanalicular cholestasis, chronic hepatitis, and cirrhosis.
- Skye terrier hepatitis is speculated to be a result of disturbed bile secretion with secondary accumulation of copper.

Chronic Hepatitis in Cocker Spaniels

American and English cocker spaniels have an increased incidence of chronic hepatitis. The cause is unknown. Hepatic copper accumulation does not appear to be a consistent feature. Accumulation of alpha-1-antitrypsin in hepatocytes, a well-recognized cause of cirrhosis in man, may be important in the pathogenesis.

Clinical Signs

- Male cocker spaniels (average age 5 years) are at increased risk. Despite the chronicity and severity of the underlying hepatic lesions, most affected dogs have a short duration of clinical illness prior to presentation of usually 2 weeks or less.
- Ascites is the most consistent presenting complaint. Other nonspecific signs of liver disease include depression, mild jaundice, melena, dehydration, subcutaneous edema, and coma.

Diagnosis

▼ ***Key Point*** Ascites and profound hypoalbuminemia (mean of 1.7 g/dl) are consistent findings.

- Laboratory findings include mild anemia and mild to moderate increases in serum liver enzyme activity (although some dogs have normal values).
- The total serum bilirubin concentration is normal or mildly increased, suggesting that cholestasis is not a key feature of the disorder. FSBA and PPSBA concentrations are increased.
- Ascitic fluid analysis is consistent with a transudate or modified transudate.
- Radiographic findings include microhepatica and ascites. Ultrasonography often shows a diffuse increase in echogenicity, although some dogs have a normal-appearing liver.
- Liver biopsy reveals chronic periportal hepatitis (lymphocytes, plasma cells, and lesser numbers of neutrophils), portal fibrosis, and micronodular or macronodular cirrhosis.
- Hepatic copper accumulation is not a consistent feature (200–550 µg/g dry weight).

Treatment

Treatment for cocker spaniels with chronic hepatitis consists of general supportive therapy for the complications of liver failure (see "Principles of Treatment for Liver Disease" and Table 71-1).

- Corticosteroid therapy may be beneficial.
- The prognosis is poor and most dogs die within a month of diagnosis. Early diagnosis appears to be the key to long-term survival.

Lobular Dissecting Hepatitis

Lobular dissecting hepatitis is a distinctive histologic form of chronic hepatitis that occurs in young dogs. The median age of 21 affected dogs was 11 months, with 54% of dogs being 7 months or younger. It has been suggested that this is a specific reaction pattern of the liver in neonatal and juvenile dogs to a wide variety of hepatic insults. Standard poodles may be at increased risk for this form of chronic hepatitis.

Clinical Signs

Clinical features are those of advanced hepatic failure and portal hypertension. The most consistent clinical finding is ascites.

Diagnosis

An attempt should be made to identify other causes of chronic hepatic disease (see Table 71-8). Diagnosis requires liver biopsy.

- Liver enzymes are typically increased.
- Hypoalbuminemia and increased SBA concentrations are common.
- The lesion is characterized histologically by lobular hepatitis; inflammation (lymphocytes, plasma cells, macrophages, and neutrophils) is scattered throughout the hepatic lobule rather than concentrated in periportal regions. Bands of collagen and reticulin fibers dissect around single or small groups of hepatocytes and disrupt hepatic lobular architecture. Copper stains are negative or moderately positive, consistent with secondary copper accumulation. The liver is shrunken, pale to tan, with an almost smooth surface and occasional hyperplastic nodules. Multiple acquired portosystemic shunts are present.

Treatment

Optimal treatment has not been determined, but general measures for management of chronic liver failure are appropriate (see Table 71-1).

Acidophil Cell Hepatitis

Acidophil cell hepatitis has been described in Great Britain and is caused by an unidentified transmissible agent that is probably viral but distinct from canine adenovirus type 1 (see Chapter 16).

- It is characterized by acute or chronic hepatitis with slow progression to cirrhosis. Acidophils, which are a consistent histologic feature of the disease, represent dying hepatocytes.
- Signs usually are typical of chronic liver failure.
- Specific treatment has not been described, but general measures for management of chronic liver failure are appropriate.

PHENOBARBITAL-ASSOCIATED HEPATIC DISEASE

Long-term phenobarbital therapy for control of seizures has been associated with chronic hepatic disease and cirrhosis in dogs (see Table 71-4). Most dogs have been treated with phenobarbital for months to years before the liver disease is apparent. Chronic phenobarbital therapy also is rarely associated with SND (hepatocutaneous syndrome) in dogs (see previous discussion in this chapter), which is distinct from the characteristic phenobarbital-associated chronic hepatic disease and cirrhosis described in this section.

Etiology

- The mechanism of phenobarbital-induced injury is not known, but higher doses, higher blood levels (>40 µg/ml), and long duration appear to be important factors.
- Prior therapy with phenytoin or primidone may increase the risk of hepatotoxicity.
- Hepatotoxicity has not been described in association with short-term injectable (IV or IM) doses.

Clinical Signs

- Clinical signs are those of chronic hepatic disease and include anorexia, lethargy, weight loss, weakness, PU/PD, coagulopathy, and jaundice. Signs of overdosage (sedation and ataxia) are consistent findings in dogs with phenobarbital hepatotoxicity. Ascites and HE are most likely with advanced hepatic disease.
- When impaired hepatic inactivation of phenobarbital causes increased blood levels, seizure frequency may decrease.
- An increased frequency of seizures may be related to the development of HE.

Diagnosis

Suspect phenobarbital-induced hepatopathy in any dog with a history of chronic phenobarbital therapy and clinical and biochemical evidence of hepatic injury.

Laboratory Evaluation

▼ ***Key Point*** To detect early evidence of hepatic damage, routinely monitor liver enzymes (serum ALP and ALT), total serum bilirubin, cholesterol, albumin, and phenobarbital levels at least every 6 months in all dogs on chronic phenobarbital therapy.

- Mild reversible increases in serum ALP and ALT activity (usually <5 times upper normal limit) are common in dogs treated with phenobarbital related to microsomal enzyme induction rather than hepatocyte injury. The increased ALP is usually attributable to induction of the liver isoenzyme, but sometimes it results from increased CIALP.
- Elevations in ALT and ALP activity greater than 5 times the upper limit of normal or any elevation in AST may be an indicator of hepatotoxicity.
- Increased SBA, hyperbilirubinemia, hypoalbuminemia, and hypocholesterolemia are better indicators of significant hepatic damage.

Radiography and Ultrasonography

▼ ***Key Point*** Dogs on phenobarbital without hepatic injury often have an incidental finding of hepatomegaly.

With phenobarbital-induced chronic hepatic disease, radiographic findings may suggest microhepatica due to cirrhosis. Ultrasonography is useful to further characterize liver changes and to evaluate for other hepatic disorders.

Liver Biopsy

Perform a liver biopsy in dogs on phenobarbital when hepatic function tests are abnormal, liver enzyme activities are greatly increased, clinical signs of hepatic dysfunction are present, or ultrasonographic hepatic abnormalities are detected.

- The most consistent histologic finding in dogs on phenobarbital therapy is hepatocellular hypertrophy with a ground-glass appearance of the cytoplasm. Hypertrophy is due to hyperplasia of smooth endoplasmic reticulum. This finding is commonly identified in dogs without clinical or biochemical evidence of hepatic dysfunction and does not warrant a change in drug therapy.
- Chronic hepatic disease associated with phenobarbital therapy is characterized histologically by biliary hyperplasia, nodular hyperplasia, fibrosis, and cirrhosis. A mild inflammatory infiltrate (neutrophils, lymphocytes, plasma cells) is often present. These lesions are by no means specific for phenobarbital-induced hepatic damage; however, in the absence of other known causes of hepatic damage, circumstantial evidence would support drug therapy as a likely cause.

Treatment

- If possible, discontinue phenobarbital (gradual taper) in dogs with biochemical and histologic evidence of hepatic disease (see Chapter 127).
- Consider replacing phenobarbital with potassium bromide (15–30 mg/kg PO q12h with food) as an anticonvulsant in dogs with phenobarbital-associated hepatotoxicity because of its lack of hepatic metabolism or hepatotoxicity (see Chapter 127).
- Clinical, biochemical, and histologic improvement can occur if phenobarbital is discontinued or used at a reduced dosage prior to severe, end-stage liver disease. Clinical signs improve within days to weeks of decreasing serum phenobarbital levels.
- Additional supportive measures are important in managing dogs with phenobarbital-induced hepatic disease. Control complications such as ascites and HE, as discussed previously (see Table 71-1).
- Consider hepatoprotectants such as ursodiol, SAMe, or vitamin E (see Table 71-2). Corticosteroids are not indicated unless a significant inflammatory component is documented histologically.

Prevention

Despite evidence for hepatotoxicity, phenobarbital is still the drug of choice for long-term control of seizures in dogs.

▼ ***Key Point*** To decrease the likelihood of hepatotoxicity in dogs treated with phenobarbital, monitor serum levels and adjust the dosage so that serum phenobarbital concentrations do not exceed 35 µg/ml.

HEPATIC CIRRHOSIS AND FIBROSIS

Cirrhosis is characterized by diffuse fibrosis and replacement of liver tissue with structurally abnormal regenerative nodules.

Etiology

- Cirrhosis is the irreversible end stage of chronic hepatic injury caused by infection, hepatotoxins (e.g., copper or phenobarbital), immunologic injury (chronic hepatitis), chronic cholestasis (chronic cholangitis in cats), or hypoxia. The common denominator is hepatocyte death, which leads to repair by fibrosis and nodular regeneration.
- When cirrhosis is fully developed, the histologic features of the original inciting injury often are obscured by the cirrhotic changes.

▼ ***Key Point*** Fibrosis, regenerative nodule formation, and structural disruption further compromise adjacent normal hepatocytes, intrahepatic blood flow, and intrahepatic bile flow; thus, cirrhosis eventually reaches a point at which it is self-perpetuating.

Clinical Signs

Cirrhosis causes generalized hepatic dysfunction; thus, the clinical signs are those of chronic hepatic failure. A combination of jaundice, ascites, and HE is highly suggestive of cirrhosis.

Diagnosis

Laboratory Evaluation

Laboratory evidence of liver disease usually precedes the development of cirrhosis but may go undetected because signs at that stage may be insidious and vague.

- Serum liver enzymes usually are increased, although more modestly than during the active injury stage of liver disease.
- Circulating bilirubin, ammonia, and bile acids usually are increased, whereas serum albumin usually is decreased. Hyperglobulinemia is sometimes seen.

- Hemostatic abnormalities may reflect DIC, impaired hepatic synthesis of coagulation factors, or vitamin K deficiency due to cholestasis (least likely).

Radiography and Ultrasonography

▼ ***Key Point*** Microhepatica is common in dogs with cirrhosis, whereas most cats with biliary cirrhosis have hepatomegaly due to marked biliary hyperplasia.

Ultrasonography findings include microhepatica, irregular hepatic margins, focal lesions representing regenerative nodules, and increased parenchymal echogenicity associated with increased fibrous tissue. Splenomegaly and secondary acquired portosystemic shunts also may be detected.

Liver Biopsy

Definitive diagnosis of cirrhosis requires liver biopsy.

- Laparotomy or laparoscopy provides a better appreciation for the gross nodularity of the liver than can be ascertained from blind percutaneous needle biopsy.
- Microscopic features include fibrosis, regenerative nodules, and disruption of normal hepatic architecture.
- Concurrent inflammation may be detected, especially when the inciting cause of cirrhosis is chronic inflammation.

Treatment

Because cirrhosis is essentially irreversible, treatment is mainly supportive, emphasizing measures that control the various complications of severe generalized liver failure, such as ascites, encephalopathy, gastric ulcers, coagulopathies, and infection (see Table 71-1 and "Principles of Treatment for Liver Disease").

If a probable cause or category of injury can be determined, specific treatment directed at preventing further injury may slow progression of cirrhosis. If an underlying cause can be determined (or is suspected), refer to the appropriate section of this chapter for specific details regarding treatment. For example, adjust the drug regimen of dogs receiving phenobarbital (see under "Phenobarbital-Associated Hepatic Disease").

Penicillamine

Use a chelating agent such as penicillamine to treat dogs with copper-positive biopsies (see Table 71-9). Penicillamine also has antifibrotic properties.

Anti-inflammatory Therapy

Treat dogs with histologic features of chronic hepatitis with anti-inflammatory drugs (see under "Idiopathic Chronic Hepatitis"). Prednisolone has antifibrotic properties as well as anti-inflammatory activity; however, weigh the benefits of corticosteroids with the risks of potential adverse effects, such as GI ulceration and bleeding, increased body catabolism that may exacerbate HE, and sodium retention that may exacerbate ascites and edema.

Colchicine

Colchicine (0.025–0.03 mg/kg PO q24h) is an antifibrotic drug used to treat humans with cirrhosis. It acts as a microtubule inhibitor, stimulant of collagenase activity, and inhibitor of collagen deposition. Its benefit in dogs with cirrhosis is unproven. The major side effects in dogs are nausea, vomiting, and diarrhea. In humans, other side effects include bone marrow toxicity and myoneuropathy.

CONGENITAL PORTOSYSTEMIC SHUNTS

Portosystemic shunts (PSSs) are vascular communications between the portal and the systemic venous systems that allow portal blood to access the systemic circulation without first passing through the liver. Clinical signs of HE result from inadequate hepatic clearance of enterically derived toxins such as ammonia, mercaptans, short-chain fatty acids, GABA, and endogenous benzodiazepines. Decreased hepatic blood flow and lack of hepatotrophic factors result in hepatic atrophy.

Etiology

PSS in dogs and cats can be a congenital malformation or develop secondary to portal hypertension.

Single Congenital Portosystemic Shunts

Single PSSs are most common and occur as a congenital developmental malformation. Single shunts are not associated with portal hypertension. Single PSSs can be further categorized as intrahepatic or extrahepatic.

Single Intrahepatic Shunts

- Single intrahepatic shunts provide a communication between the portal vein and the caudal vena cava, often via the left hepatic vein. This results from failure of the fetal ductus venosus to close.
- This type of shunt is most frequent in large-breed dogs.

Single Extrahepatic Shunts

- Single extrahepatic shunts usually connect the portal vein or one of its tributaries (left gastric or splenic vein) with the caudal vena cava cranial to the phrenicoabdominal veins. Less frequently, the anomalous vessel will enter the azygous vein.
- This type of shunt is most frequent in small-breed dogs and cats.

Table 71-10. DISORDERS ASSOCIATED WITH PORTAL HYPERTENSION AND MULTIPLE EXTRAHEPATIC PORTOSYSTEMIC SHUNTS

Chronic hepatitis and cirrhosis
Lobular dissecting hepatitis
Congenital hepatic arteriovenous fistula
Portal vein hypoplasia, including hepatoportal fibrosis variant
Postoperative complication of congenital portosystemic shunt ligation
Chronic biliary obstruction
Portal vein obstruction (thrombosis, neoplasia, extraluminal compression)
Caudal vena cava or main hepatic vein obstruction (kinking, thrombosis, neoplasia)

Multiple Extrahepatic Portosystemic Shunts

Multiple extrahepatic PSSs are collateral vessels that develop as a compensatory response to sustained portal hypertension. These shunts are rudimentary, nonfunctional, microvascular communications between the portal and the systemic veins that are present in normal dogs and cats. With sustained portal hypertension, these vessels enlarge and function to shunt blood into the lower-pressure systemic circulation, thus decreasing portal pressure.

- Multiple extrahepatic PSSs occur secondary to disorders causing portal hypertension (Table 71-10).
- These shunts usually appear as a tortuous plexus of vessels that communicate with the caudal vena cava in the area of the kidneys.
- Diagnosis and therapy are directed toward the underlying liver or portal vascular disorder.

Clinical Signs

The following discussion focuses on single congenital PSS. Clinical signs of congenital PSS are usually referable to the CNS, GI system, or urinary tract (see also under "Signalment," "History," and "Physical Examination" in this section).

Central Nervous System Signs

- Signs of HE often predominate, including episodic weakness, ataxia, head pressing, disorientation, circling, pacing, behavioral changes, amaurotic blindness, seizures, and coma.
- Hypersalivation, seizures, and blindness are more common in cats with PSS than in dogs.
- Clinical signs of encephalopathy tend to wax and wane and are often interspersed with normal periods, reflecting the variable production and absorption of neurotoxic enteric products.

Gastrointestinal Signs

- GI signs of intermittent anorexia, vomiting, and diarrhea are common and are not necessarily accompanied by overt signs of HE.
- Stunted growth, weight loss, failure to gain weight, and unthriftiness are common.

Urinary Signs

▼ ***Key Point*** Urate urolithiasis is an important complication of PSS because of increased urinary excretion of ammonia and uric acid. Renal, cystic, and urethral calculi usually are green and contain an ammonia or uric acid component.

- If urolithiasis is a complicating feature, pollakiuria, dysuria, and hematuria may occur.
- Psychogenic polydipsia and subsequent polyuria are frequent findings in dogs.

Diagnosis

Suspect congenital PSS in the following patients:

- Young dogs and cats with intermittent CNS, GI, or urinary tract signs
- Young animals with unexplained weight loss, failure to grow, unthriftiness, or hypoglycemia
- Dogs (except dalmatians and bulldogs) or cats with urate urolithiasis
- Dogs and cats of any age with clinical and biochemical evidence of hepatic insufficiency (especially HE) and absence of histologic evidence of severe intrahepatic disease

▼ ***Key Point*** In young animals with clinical features of a congenital PSS but without a demonstrable shunt on portography or portal scintigraphy, consider hepatic microvascular dysplasia (see later in this chapter).

Although congenital PSS may be suspected because of historical, physical, laboratory, and radiographic findings, a definitive diagnosis requires identification of a shunt by ultrasonography, contrast radiography, transcolonic or transplenic portal scintigraphy, or exploratory laparotomy.

Signalment

- Congenital PSS is more common in purebred than in mixed-breed dogs. The genetic basis is unknown, although an increased incidence has been recognized in Yorkshire terriers, miniature schnauzers, Irish wolfhounds, Cairn terriers, Maltese dogs, Australian cattle dogs, Old English sheepdogs, Labrador retrievers, and golden retrievers.
- Domestic shorthaired cats are affected more commonly than are purebred cats. Of affected purebreds, Persian and Himalayan cats are at increased risk.
- No sex predilection has been noted. Affected male dogs and cats are often cryptorchid.
- Age is an important diagnostic clue, because most animals develop signs by 6 months of age. A congen-

ital PSS is also a diagnostic consideration in middle-aged and older dogs, because signs may be subtle and occasionally animals go undiagnosed until as old as 10 or 12 years of age.

History

- Many affected animals have a history of stunted growth or failure to gain weight compared with unaffected littermates.
- Prolonged recovery after general anesthesia or excessive sedation after treatment with tranquilizers, anticonvulsants, or organophosphates can be attributed to impaired hepatic metabolism of these substances.
- Signs of encephalopathy may be exacerbated by a protein-rich meal; GI bleeding associated with parasite infection, ulcers, or drug therapy; and administration of methionine-containing urinary acidifiers or lipotrophic agents.
- Clinical improvement after fluid therapy is common and most likely attributed to correction of dehydration and promotion of urinary excretion of ammonia and other toxins. Improvement with broad-spectrum antibiotic therapy reflects the effect of antibiotics on the toxin-producing intestinal flora.

Physical Examination

- Findings may be unremarkable except for small body stature or weight loss.
- The neurologic examination is normal or, if overt signs of HE are present, neurologic findings are consistent with diffuse cerebral disease.
- Ascites and edema are rare unless the shunt is complicated by marked hypoalbuminemia (less than 1 g/dl).
- Many affected cats have copper-colored irises.

Laboratory Evaluation

Routine hematologic and biochemical findings often are unremarkable. Although individual parameters might be only mildly abnormal, test results often reflect a pattern suggesting hepatocellular dysfunction in the absence of significant cholestasis or hepatocellular necrosis.

- Hematologic findings include microcytosis, target cells, poikilocytosis (especially in cats), and mild nonregenerative anemia. Microcytosis is associated with abnormal iron metabolism (impaired iron transport or iron sequestration) rather than absolute iron deficiency. These RBC changes can be subtle but important diagnostic clues in an otherwise normal CBC.
- Urinalysis findings include dilute urine, ammonium biurate crystalluria, and mild bilirubinuria.
- Coagulation tests are normal.
- Hepatocellular dysfunction is suggested by hypoproteinemia, hypoalbuminemia, hypoglobulinemia, hypoglycemia, decreased BUN, and mild hypocholesterolemia. Hypoalbuminemia is a consistent finding in dogs but not in cats. Total serum bilirubin concentration is normal.
- Serum liver enzyme (ALP and ALT) levels are normal to mildly (2–4 times) increased, consistent with a lesion of hepatic atrophy and minimal hepatocellular injury or intrahepatic cholestasis. Increases in ALP activity in these young animals may actually be due to the bone isoenzyme.
- Measure SBA concentrations to document hepatic dysfunction in dogs and cats suspected of having congenital PSS. Fasting SBA concentrations may be normal or increased, but PPSBA concentrations are consistently abnormal and usually exceed 10 µmol/L.

▼ ***Key Point*** The pattern of a normal FSBA concentration with a markedly increased PPSBA level is characteristic of PSS. A consistently normal PPSBA concentration makes a diagnosis of congenital PSS highly unlikely.

- In preliminary studies in dogs with congenital PSS, the sensitivity of urinary bile acids (UBA) (urine sample taken 4 to 8 hours after eating) was 100%, compared with 84% for FSBA and 98% for PPSBA.
- Hyperammonemia is a common finding in animals with PSS, but fasting blood ammonia concentration may be normal. The ATT is consistently abnormal and is equal in sensitivity to PPSBA concentrations for detecting hepatic dysfunction associated with PSS (see "Diagnostic Strategy for Liver Disease").

Radiography and Ultrasonography

Stabilize the patient by instituting therapy for HE prior to giving anesthesia for portography or for surgical correction (see under "Medical Therapy" in this section).

- ***Abdominal radiography*** commonly reveals microhepatica in dogs but not in cats. Mild renomegaly of unknown clinical significance also is common. Intra-abdominal detail may be poor because of lack of abdominal fat. Ammonium urate urinary calculi may be visible on survey radiographs if they contain substantial amounts of magnesium and phosphate.
- ***Routine abdominal ultrasonography*** may demonstrate intrahepatic and extrahepatic shunts. Intrahepatic shunts are more reliably detected with this procedure than are extrahepatic PSS. Urinary calculi also can be identified.
- ***Transcolonic portal scintigraphy*** using technetium 99m pertechnetate is a non-invasive and highly sensitive test (available at some referral institutions) for detecting whether a shunt is present; however, it does not provide reliable anatomic information such as the type and location of the shunt.
- ***Ultrasound-guided transplenic portal scintigraphy*** has recently been described. This procedure provides

more anatomic detail with less radiation exposure than transcolonic portal scintigraphy.

- ***Positive-contrast portography*** is the procedure of choice to accurately characterize the type and location of a PSS. Techniques include splenoportography, mesenteric (or jejunal) portography, and cranial mesenteric or celiac arterial portography. An operative mesenteric portogram is preferred because it allows evaluation of the entire portal vein, does not require special equipment, and results in few complications.

Technique for Mesenteric Portography

1. Place the animal under general anesthesia (see Chapter 2 for anesthesia of the patient with liver disease).
2. Isolate a loop of jejunum through a ventral midline incision.
3. Place two ligatures around a jejunal vein, and place an over-the-needle catheter (Abbocath, Abbott) within the vessel. Tie the ligatures and secure the catheter to the vessel.
4. Temporarily close the abdominal incision.
5. Inject a water-soluble contrast agent (Conray, Mallinckrodt, or Iohexol, Winthrop) as a bolus (2 ml/kg) into the catheter.
6. If a rapid film changer is not available, take a lateral and ventrodorsal radiograph as the final milliliter is injected.

Interpretation

- If a single PSS is identified, it should be further characterized as intrahepatic or extrahepatic, because this has important surgical ramifications (see Chapter 72).
- If multiple extrahepatic PSSs are identified, portal pressure determination and gross and microscopic findings of the liver are used to distinguish between congenital and acquired causes (see the next section).
- Failure to visualize the intrahepatic portal system is not a reliable indicator of vascular atresia but may correlate with a greater occurrence of postoperative complications after complete or partial shunt ligation.

Liver Biopsy

- The liver is grossly small but otherwise fairly normal in appearance.
- In some animals, biopsy findings are unremarkable.
- Liver biopsy lesions can be subtle but most consistently reveal hepatocyte atrophy with small or absent portal veins. Varying degrees of arteriolar hyperplasia, lipogranulomas, and biliary hyperplasia may be seen. Hepatocellular vacuolization is sometimes noted and may be severe. These biopsy findings reflect decreased portal blood flow and are indistinguishable from those seen in animals with hepatic microvascular dysplasia, primary hypoplasia of the portal veins, or portal vein obstruction or after experimental surgical creation of a PSS.
- Microscopic CNS abnormalities include polymicrocavitation of the brain stem and cerebellum and an increased number of astrocytes in the cerebral cortex.

Treatment

Surgery

- The treatment of choice for dogs and cats with a single PSS is surgical attenuation or complete ligation of the shunt (see Chapter 72). Although complete shunt ligation is preferred for improved long-term outcome, concurrent hypoplasia of the portal system (whether as a primary vascular disorder or secondary to prolonged portosystemic shunting), may increase intrahepatic vascular resistance and predispose the patient to portal hypertension. Consequently, attenuate the shunt to the maximum degree that can be tolerated without causing portal hypertension.
- Highly successful alternative approaches for gradual progressive closure of the shunt use surgically placed ameroid constrictors or cellophane bands around the shunt or intravascular thrombogenic coils within the lumen of the shunt (see Chapter 72). Theoretical advantages of slow attenuation of the shunt (over days to weeks) include reduced risk of postoperative portal hypertension and neurologic dysfunction and decreased surgical and anesthetic time.

▼ ***Key Point*** Gradual occlusion of the shunt should allow time for hepatic regeneration, expansion of the portal vascular system, and accommodation of portal blood flow without portal hypertension.

Medical Therapy

Medical management of dogs and cats with PSS is palliative and is directed primarily at control of HE with a moderately protein-restricted diet supplemented with soluble fiber, lactulose, and neomycin (see Table 71-1).

- The short-term response to therapy for HE is often dramatic, and the animal usually is clinically normal even prior to surgical shunt ligation.
- If surgical shunt correction is not feasible or is declined by the owner, long-term medical management may control clinical signs for as long as 2 to 3 years. However, medical management of PSS does not reverse the progressive hepatic atrophy and alterations in carbohydrate, lipid, and protein metabolism.
- Acute decompensation of encephalopathy requires fluid therapy for correction of dehydration, correction of electrolyte and acid-base imbalances, and maintenance of blood glucose levels (see Table 71-1).

- When severe CNS depression or coma prevents the oral administration of lactulose and neomycin, administer these drugs via an enema (see Table 71-1).
- Identify and correct precipitating causes of encephalopathy whenever possible, such as hypoglycemia, GI bleeding from hookworm infection, and hypokalemia (see Table 71-1).
- Management of urate urolithiasis is discussed in Chapter 79.

Perioperative Complications

Other perioperative complications of shunt ligation include seizures, portal hypertension, intra-operative hypothermia and hypoglycemia, anesthetic complications, fever and positive blood cultures, portal vein thrombosis, coagulopathy, acute pancreatitis, and cardiac arrhythmias.

Postoperative Seizures

Occasionally, seizures or status epilepticus are a complication of surgical shunt ligation. Dogs older than 18 months of age may be at increased risk. The pathogenesis is obscure, but seizures do not appear to be caused by simple hypoglycemia or HE. It is possible that the brain may have adapted to an altered metabolism. The prognosis for recovery from this complication is poor. Long-term anticonvulsant therapy is often required if the patient survives the acute postoperative period.

▼ ***Key Point*** Evaluate for identifiable metabolic causes of postoperative seizures, such as hyperammonemia, hypoglycemia, hypoxia, electrolyte imbalances, acid-base imbalances, and systemic hypertension.

- In addition to routine management of HE and correction of underlying metabolic imbalances (including thiamine administration in cats), manage seizures with IV phenobarbital (at reduced doses) or loading doses of potassium bromide (see Table 71-1 and Chapter 127).
- If seizures cannot be controlled, administer IV propofol to induce general anesthesia for 12 to 24 hours. Place an endotracheal tube and use a respirator to maintain pO_2 and pCO_2. Maintain anesthesia by propofol drip or isoflurane gas anesthesia. Consider mannitol (0.5–1 g/kg IV) for control of cerebral edema (see Table 71-1).
- Consider preoperative anticonvulsant therapy to help control or prevent postoperative seizures in PSS patients (see Table 71-1). Felbamate, levetiracetam, or topiramate are possible choices in dogs. Because of the short half-life of these drugs, therapeutic blood levels can be reached within a week. Topiramate can be used in cats. If postoperative seizures do not occur, anticonvulsant therapy can be tapered over a 4-week period after surgery and then discontinued.

Prognosis

Dogs

The prognosis for resolution of signs after total surgical ligation of the shunt in dogs is excellent if the dog survives the immediate postoperative period.

- In dogs with partial shunt ligation, the prognosis is not as good. Although clinical signs may resolve after surgery, and response appears favorable in the first few years, long-term follow-up (>3 years) suggests recurrence of signs will occur in 40% to 50% of dogs with partial shunt ligations.
- If clinical signs recur in dogs that have had partial ligation, reevaluate by transcolonic portal scintigraphy. If shunting persists, perform surgical exploration for complete shunt closure by suture ligation or ameroid constrictor.

Cats

The response to surgical correction of a congenital PSS in cats appears to be less encouraging than in dogs. With partial shunt ligation, clinical improvement is usually noted after surgery, but relapse of neurologic abnormalities is common. Persistent seizures and blindness are also more likely to occur when partial rather than total ligation is performed.

HEPATIC MICROVASCULAR DYSPLASIA

Hepatic microvascular dysplasia (HMD) refers to congenital histologic vascular abnormalities of the liver in dogs (and rarely in cats) that result in abnormally increased SBA concentrations and may be associated with clinical signs of portosystemic shunting of blood. It has been hypothesized (but not proven) that HMD results in intrahepatic microscopic portosystemic shunting of blood. Because the shunt fraction is small compared with shunting that occurs with a single macroscopic congenital PSS, the clinical signs are less severe (or absent) and SBA concentrations are only mildly increased. Portal hypertension is not a clinical feature of HMD for most affected dogs.

- The relationship among HMD, congenital PSS and primary hypoplasia of the portal veins is unclear. These disorders have similar hepatic histologic features (hepatic arteriolar hyperplasia, small or absent portal veins, and hepatic lipogranulomas), which are a stereotypical histologic response of the liver to inadequate portal vein flow. These same histologic findings also develop after experimental surgical creation of a PSS. These disorders may represent varying expressions of a more general developmental vascular disorder.
- It is likely that most animals with PSS have some degree of HMD, which may explain the persistence

of increased SBAs and histologic vascular lesions following complete surgical ligation of a PSS in some cases. If vascular dysplasia accompanying PSS is severe enough (e.g., primary hypoplasia of the portal veins), complete PSS ligation cannot be performed without the development of portal hypertension.

Etiology

HMD has been studied extensively in Cairn terriers, where it is believed to be an inherited disorder. A polygenic mechanism of inheritance is suspected.

Clinical Signs

Affected dogs and cats may be asymptomatic (especially true for Cairn terriers) or show signs similar to those seen with congenital PSS.

- Drug intolerance for products dependent on hepatic metabolism may be the only manifestation in otherwise asymptomatic patients.
- In symptomatic animals, signs are variable and include anorexia, lethargy, vomiting, diarrhea, PU/PD, dysuria and hematuria (due to urate urolithiasis), and HE and seizures.

Diagnosis

Consider HMD in dogs and cats with clinical features of congenital PSS, increased SBA concentrations, and typical liver biopsy findings and in those that do not have a demonstrable shunt.

- In symptomatic animals, it is essential to rigorously pursue the diagnosis of congenital PSS (as described in the previous section), because the clinical and histologic features of HMD alone are similar to those of congenital PSS. Specific surgical correction is the optimal treatment if a shunt is identified.
- Also consider the possibility that a dog or cat with increased SBA concentrations may have HMD and be asymptomatic for the disorder (especially Cairn terriers). An animal with HMD may have clinical signs due to an unrelated non-hepatic disease. Detection of increased SBA concentrations may focus diagnostic efforts on the liver, causing the clinician to overlook the true cause of the clinical signs.

Signalment

- Yorkshire terriers and Cairn terriers are most commonly affected. However, HMD has been diagnosed in many other small breeds of dogs, such as Maltese, dachshund, poodle, Shih Tzu, Lhasa apso, cocker spaniel, and WHWTs.
- Domestic shorthair cats are at increased risk for HMD.
- Dogs with HMD tend to be older at presentation than dogs with congenital PSS.

Physical Examination

Physical examination is often within normal limits unless signs of HE are present.

Laboratory Evaluation

- Dogs with HMD consistently have increased SBA concentrations, but not as increased as in dogs with PSS. A shunting pattern is typically seen: normal or low FSBA concentrations with moderately increased PPSBA concentrations. Indocyanine green clearance values are also consistently abnormal.
- Biochemical findings in dogs with HMD are usually unremarkable except for mild to moderate increases in ALT activity.

▼ ***Key Point*** As opposed to dogs with congenital PSS, dogs with HMD do not usually have microcytosis, hypoalbuminemia, decreased BUN, hypocholesterolemia, hypoglycemia, hyperammonemia, or ammonium biurate crystalluria.

- Preliminary results show that decreased protein C concentrations occur in 98% of dogs with congenital PSS but only 30% of dogs with HMD. Whether this test will be useful for differentiation of PSS versus HMD awaits further clinical studies.

Radiography and Ultrasonography

- Radiographically, the liver is usually normal in size but may be equivocally small in some cases.
- On ultrasonography the liver may be subjectively decreased in size and the portal vasculature may be decreased. Bladder or kidney stones are uncommon.
- Transcolonic portal scintigraphy is usually normal or only mildly abnormal in HMD, as opposed to the increased shunt fractions seen with congenital PSS. Since this is a relatively sensitive method for detecting congenital PSS, a normal exam would make PSS unlikely and support a diagnosis of HMD.
- Portography will fail to identify a large shunting vessel. Cairn terriers with HMD have abnormal truncation of the terminal branches of the portal veins and delayed clearing of contrast, which gives the parenchyma a “blush” appearance.

Liver Biopsy

A wedge biopsy of the liver is preferred over a needle biopsy because the vascular lesions are subtle and a wedge biopsy provides more hepatic lobules for evaluation.

- Grossly, the liver is normal in size and color compared with the small liver seen with congenital PSS.
- The histologic features of HMD are typical for inadequate portal vein flow and include small or absent portal veins, hepatic arteriolar hyperplasia, and

hepatic lipogranulomas. These findings are similar to those seen in dogs with congenital PSS, primary hypoplasia of the portal vein, portal vein obstruction, or after experimental surgical creation of a PSS.

▼ ***Key Point*** Biopsy more than one lobe in HMD because the histologic lesions can vary among liver lobes, with some lobes appearing very abnormal and others appearing normal.

Treatment and Prognosis

- No treatment is indicated for animals whose symptoms are subclinical.
- If clinical signs of HE are present, they can often be successfully managed with a moderately protein-restricted diet. Additional therapy with lactulose and antibiotics is sometimes warranted (see Table 71-1).
- Follow-up in 11 dogs for a mean period of 15 months (range of 1 week to 4.5 years) indicated a good clinical response to dietary therapy alone. Repeated SBA concentrations remained unchanged. How often dogs that are asymptomatic for HMD progress and develop clinical signs is unknown.
- Anecdotal reports suggest some severely affected dogs may develop a progressive hepatopathy with portal hypertension and multiple extrahepatic PSSs, similar to primary hypoplasia of the portal veins (see below).

PRIMARY PORTAL VEIN HYPOPLASIA

Primary portal vein hypoplasia (PPVH) is a congenital abnormality of portal vascular development seen in young medium- to large-breed dogs. Small intrahepatic portal venules are predominantly affected, although hypoplasia of the extrahepatic portal vein may occur in 30% of dogs. Underdevelopment of the portal system leads to obstruction to portal blood flow resulting in portal hypertension and development of multiple extrahepatic PSSs.

- Dogs described in the literature with *idiopathic noncirrhotic portal hypertension* have clinical and pathologic findings that resemble portal vein hypoplasia, and these are now considered the same disorder.
- In addition to the vascular changes, variable amounts of fibrosis may be present in portal areas, leading to the suggestion that *hepatoportal fibrosis* of young dogs is a variant of portal vein hypoplasia.
- It has also been proposed that HMD (discussed in the previous section) is a milder variant of PPVH and that the term HMD should be abandoned. Although histologic features are similar, the clinical presentations of HMD and PPVH are distinctly different. HMD is not typically associated with portal hypertension (or even clinical signs in many cases), whereas the clinical features of PPVH are primarily related to marked portal hypertension and subsequent portosystemic shunting. Thus, we advocate retaining the clinical distinction between HMD and PPVH until definitive clarification is available.

Signalment and Clinical Signs

The mean age is about 2 years. Medium- or large-breed dogs appear to be at increased risk. In one study, one unrelated and three related Doberman pinschers were reported. Related cocker spaniels have also been described.

- Common clinical signs include lethargy, weight loss or stunted growth, intermittent vomiting and diarrhea, ascites, and polydipsia. Neurologic signs of hepatoencephalopathy may occur but are inconsistent.
- The duration of clinical signs may range from a few weeks to a year. Most dogs have persistent signs for 2 to 3 months.

▼ ***Key Point*** Clinical signs of PPVH are similar to those seen in dogs with single congenital PSSs, except that ascites is common in PPVH and rare in dogs with congenital PSS.

Diagnosis

Laboratory Evaluation

- Laboratory findings are consistent with hepatic dysfunction and portosystemic shunting and include microcytosis, hypoalbuminemia, decreased BUN, and mild increases in ALP and ALT (2–4 times normal).
- A pattern of normal to mildly increased FSBA concentrations accompanied by markedly increased PPSBA values is consistent with portosystemic shunting.
- Hyperammonemia and an abnormal ATT are also consistent features.
- Ascitic fluid is typically a transudate.

Radiography and Ultrasonography

- Survey abdominal radiographs reveal microhepatica and poor intra-abdominal contrast.
- Microhepatica and abdominal effusion are common findings on ultrasonography. Liver echotexture is variable. Multiple extrahepatic PSSs appear as enlarged tortuous vessels caudal to the liver. Splenomegaly may also be detected.
- Ultrasonography can also provide important information regarding other disorders associated with portal hypertension, multiple PSSs, and ascites. With chronic end-stage liver disease, the liver may be small and hyperechoic with multiple regenerative nodules. Congenital hepatic arteriovenous fistulas appear as tortuous, anechoic tubular structures in the liver.

Laparotomy and Contrast Portography

Multiple PSSs can be confirmed by contrast portography or at exploratory laparotomy (or necropsy). Multiple PSSs usually appear as multiple tortuous vessels that communicate with the caudal vena cava in the area of the left kidney.

- The portal pressure can be measured to document portal hypertension (normal portal pressure is 6 to 13 cm of water).
- Patency of the portal vein should be verified (by mesenteric portography or at surgery) since portal vein obstruction could cause similar clinical and radiographic features. With PPVH, the extrahepatic portion of the portal vein is patent but may be underdeveloped.
- Congenital hepatic arteriovenous fistulas can be diagnosed by celiac arteriography or exploratory laparotomy.

Liver Biopsy

Liver biopsy is essential to confirm the diagnosis and rule out primary intrahepatic disorders such as chronic hepatitis and cirrhosis that can cause secondary portal hypertension and multiple acquired PSSs and that would have a different treatment and long-term prognosis.

- Grossly, the liver in PPVH is small and smooth or slightly irregular.
- Microscopically, the portal veins in the portal triads are small or absent. Other features include arteriolar hyperplasia, hepatocyte atrophy, and absence of inflammation with variable bile duct proliferation, lymphatic distention, and portal fibrosis (which is sometimes severe).
- Progressive fibrosis has been documented in some dogs with PPVH undergoing serial liver biopsies.

Treatment and Prognosis

Specific treatment for PPVH is not available. Initiate symptomatic therapy to control the consequences of portal hypertension and portosystemic shunting, such as ascites and HE (see Table 71-1 and "Principles of Treatment for Liver Disease"). The long-term prognosis is variable, but some dogs can live for years on medical management. Owners should be discouraged from electing euthanasia for affected dogs until medical management has been tried.

- Avoid indiscriminate dietary protein restriction since it can worsen hypoalbuminemia and promote ascites formation. Although ascites is a common presenting sign, it may resolve over time and diuretics can be discontinued.
- Use H_2 receptor blockers indefinitely because perforated duodenal ulcer is a potential cause of death in PPVH (see Table 71-1).
- Consider colchicine (0.025 mg/kg PO q24h) and ursodiol (15 mg/kg PO q24h) to prevent progressive hepatic fibrosis.

▼ ***Key Point*** Surgical ligation of multiple acquired PSSs is contraindicated. Ligation may result in fatal portal hypertension because shunts form as a protective compensatory response to portal hypertension. Also, do not perform caudal vena caval banding.

HEPATIC ARTERIOVENOUS FISTULA

Intrahepatic arteriovenous (AV) fistulas are vascular communications between the hepatic artery and the portal vein that result in portal hypertension, ascites, and secondary PSSs. They occur rarely in dogs and cats.

Etiology

Intrahepatic AV fistulas may be congenital, which is most common, or acquired as a result of abdominal trauma, hepatic surgery, hepatic neoplasia, cirrhosis, or rupture of a hepatic artery aneurysm.

Clinical Signs

Signs are similar to those of congenital PSS and PPVH and include anorexia, lethargy, vomiting, diarrhea, PU/PD, and encephalopathy in a young animal (usually less than 1.5 years).

Diagnosis

Historical and physical findings are similar to those in congenital PSS, with the notable exception that marked ascites is a consistent finding with hepatic AV fistulas but is uncommon with congenital PSS.

- Other causes of ascites to be differentiated include hypoproteinemia and right-sided congestive heart failure and other causes of portal hypertension and multiple PSSs, such as PPVH (see the preceding section and Table 71-10).
- Auscultate the abdominal wall over the area of the liver for a continuous murmur (bruit) caused by runoff of arterial blood into the portal system.

Laboratory Evaluation

- Laboratory abnormalities are similar to those seen in congenital PSS and PPVH and include hypoproteinemia, normal or mildly increased serum liver enzyme activity, and abnormal liver function tests including FSBA, PPSBA, blood ammonia, and ATT.
- Ascitic fluid typically is a transudate.

Radiography and Ultrasonography

- Survey radiographs show marked ascites.
- On abdominal ultrasonography, hepatic AV fistulas appear as tortuous, anechoic tubular structures in the liver. Multiple extrahepatic PSSs may also be identified.

Laparotomy

- Confirm the diagnosis by celiac arteriography or exploratory laparotomy. Grossly, AV fistulas appear as thin-walled, tortuous, pulsating vascular channels that distort the hepatic parenchyma and elevate the overlying hepatic capsule.

Treatment

Partial hepatectomy is indicated for treatment of hepatic AV fistulas involving one liver lobe (see Chapter 72). Dearterialization is required if multiple lobes are involved.

- Despite resection of involved liver lobes, hepatic function may not return to normal because of persistent shunting of portal blood through acquired PSS or concurrent PPVH.
- Medical management of HE with a moderately protein-restricted diet, lactulose, and antibiotics is indicated (see Table 71-1).

HEPATOBILIARY NEOPLASIA

Neoplasms involving the liver can be categorized as primary hepatic tumors (of either epithelial or mesodermal origin), hemolymphatic tumors, or metastatic tumors (Table 71-11). Hemolymphatic tumors (especially lymphoma) are the most common type of neoplasia involving the liver of cats. Metastatic tumors to the liver are most common in dogs, especially hemangiosarcoma, islet cell carcinoma, pancreatic carcinoma, and fibrosarcoma. Hepatic lymphoma also occurs frequently in dogs.

Primary hepatic tumors occur infrequently in dogs and cats. They are usually of epithelial origin and are derived from either hepatocytes or biliary epithelium. They can be either benign or malignant.

- A benign tumor of the hepatocytes is called a *hepatocellular adenoma* (or hepatoma), and its malignant counterpart is called a *hepatocellular carcinoma.*

▼ ***Key Point*** A hepatocellular carcinoma is the most common primary hepatic tumor in dogs.

- A benign tumor arising from the biliary epithelium is called a *biliary adenoma.* The malignant form is called a *biliary carcinoma.* Biliary carcinomas may be intrahepatic, extrahepatic, or within the gallbladder. The intrahepatic form is most common in dogs and cats. Cystic forms of these tumors (cystadenocarcinoma, cystadenoma) have also been described.

▼ ***Key Point*** Biliary carcinomas and adenomas are the most common primary hepatic tumors in cats.

- Hepatocellular carcinoma and bile duct carcinoma occur in three pathologic forms: (1) solitary, a single large mass in one liver lobe with or without smaller masses in other lobes; (2) multifocal nodular, discrete nodules of varying sizes in several liver lobes; and (3) diffuse, infiltration of large portions of the liver with non-encapsulated, highly invasive neoplastic tissue. Solitary masses are most likely to be successfully resected surgically. In dogs with hepatocellular carcinoma, approximately half of the tumors are solitary and half are multifocal or diffuse. Biliary carcinomas are more likely to be the multifocal or diffuse form.

Table 71-11. HEPATIC NEOPLASIA IN DOGS AND CATS

Primary Hepatic Neoplasia
Epithelial Origin
Hepatocellular carcinoma
Hepatocellular adenoma
Biliary carcinoma (cholangiocarcinoma, biliary cystadenocarcinoma)
Biliary adenoma (including biliary cystadenoma)
Hepatic carcinoid
Mesodermal Origin
Hemangiosarcoma
Hemangioma
Leiomyosarcoma
Fibrosarcoma
Liposarcoma
Myxosarcoma
Osteosarcoma
Myelolipoma
Fibroma
Hemolymphatic Tumors
Lymphoma
Mast cell tumor
Myeloproliferative disorders
Plasma cell tumor
Metastatic Hepatic Neoplasia
Hemangiosarcoma
Islet cell carcinoma
Pancreatic carcinoma
Fibrosarcoma
Osteosarcoma
Transitional cell carcinoma
Intestinal carcinoma
Renal cell carcinoma
Pheochromocytoma
Thyroid carcinoma
Mammary carcinoma

Etiology

The cause of spontaneous primary hepatic neoplasms in dogs and cats is not usually determined. Some potential causes based on reports of experimental and spontaneous hepatic tumors include aflatoxins, nitrosamines, aramite, liver flukes *(Clonorchis* spp. *Platynosomum concinnum),* and radioactive compounds such as strontium-90 and cesium-144. In contrast to humans, no association with viral infections has been identified in spontaneous tumors of dogs and cats.

Clinical Signs

Dogs and cats with hepatic neoplasia usually show vague signs of hepatic dysfunction that often do not appear until the more advanced stages of hepatic disease.

- The most consistent signs in dogs are anorexia, lethargy, weight loss, PU/PD, vomiting, and abdominal distention. Other signs include jaundice, diarrhea, and excessive bleeding.
- Signs of CNS dysfunction such as depression, dementia, or seizures can be attributed to HE, hypoglycemia, or CNS metastases.
- Anorexia and lethargy are the most common presenting signs in cats; ascites and vomiting are uncommon in cats as compared with dogs.
- When the liver is secondarily involved with metastases, the clinical signs may reflect the primary tumor location or other metastatic sites rather than the hepatic involvement.

Diagnosis

Suspect hepatobiliary neoplasia in any older animal with clinical and biochemical evidence of hepatic disease accompanied by hepatomegaly.

Signalment

- Primary hepatic neoplasms are most common in dogs and cats that are older than 10 years of age.
- Labrador retrievers were found to be disproportionately represented in one study of dogs with biliary carcinoma.
- Male dogs and cats may be at increased risk for hepatocellular carcinoma.
- Male cats and female dogs have an increased risk for biliary carcinoma.

Physical Examination

- Findings often include a cranial abdominal mass or marked hepatomegaly. Hepatomegaly is less likely with metastatic tumors.
- Ascites or hemoperitoneum may contribute to abdominal distention. Tumor rupture and hemorrhage is most likely with hepatocellular adenoma, hepatocellular carcinoma, and hepatic hemangiosarcoma.
- Anemia and pale mucous membranes may be attributed to excessive hemorrhage from a ruptured neoplasm or anemia of chronic disease.
- Jaundice is a less frequent finding with hepatic tumors unless the tumor mass causes obstruction of the common bile duct.
- Severe weight loss and cachexia are common but nonspecific findings.
- Myasthenia gravis causing weakness was suspected to be a paraneoplastic syndrome in a dog with biliary carcinoma.

Laboratory Evaluation

Hematologic and biochemical findings in animals with hepatic neoplasia are not specific and are indicative of hepatic disease and its complications.

- Potential hematologic findings include anemia and leukocytosis. Anemia is usually nonregenerative but may be regenerative if associated with excess bleeding or tumor rupture. When hematopoietic or lymphoid malignancies secondarily involve the liver, abnormal cells or pancytopenia may be detected on peripheral blood smears because of concurrent bone marrow involvement.
- Mild to marked increases in serum liver enzyme (ALT and ALP) activity are common in dogs with primary hepatic tumors (60–100% of cases) but less so with metastatic neoplasia. In contrast, most cats with nonhematopoietic hepatic neoplasms have increased serum ALT or AST activity, but serum ALP activity is usually normal. Increased serum AST activity may be the most sensitive indicator of metastatic hepatic disease in dogs (80% of cases) but lacks specificity.
- Hyperbilirubinemia appears to be a more frequent finding in dogs with metastatic neoplasia than in those with primary hepatic tumors (59% versus 25%).
- Hypoglycemia, sometimes severe, occasionally is noted in dogs with hepatocellular carcinoma and less frequently with hepatocellular adenoma, leiomyosarcoma, and hemangiosarcoma. Serum insulin concentrations are normal to decreased. Potential mechanisms of hypoglycemia include excess utilization of glucose by the tumor, release of insulin-like factors from the tumor, release of other substances from the tumor such as somatostatin, and secondary hepatic parenchymal destruction with impaired glycogenolysis or gluconeogenesis.
- Other biochemical findings are quite variable and include hypoalbuminemia, hyperglobulinemia, and increased SBA concentrations. The magnitude of increase in SBA concentrations in dogs with hepatic neoplasia can be quite small; SBA concentrations may be within normal limits.
- Although clinical evidence of impaired hemostasis is infrequent, prolongation of the PT and APTT may be identified in dogs with hepatic neoplasia.

- Analysis of abdominal fluid usually indicates a transudate or modified transudate; however, neoplastic cells or a bloody effusion are occasionally noted.
- Increased serum alpha-fetoprotein concentration may be an indicator of hepatocellular carcinoma and biliary carcinoma in dogs. Increased alpha-fetoprotein secretion also occurs with marked hepatic regeneration and chronic hepatitis. Alpha-fetoprotein concentrations in cats with hepatic neoplasia have not been reported.

Radiography

- Abdominal radiographic findings in animals with hepatic neoplasia include symmetrical or asymmetrical hepatomegaly and ascites.
- Perform thoracic radiographs to detect pulmonary metastases.

Ultrasonography

The diagnosis of hepatic neoplasia cannot be made based on ultrasonographic findings alone; however, ultrasonography often reveals focal, multifocal, or diffuse changes in hepatic echotexture.

- Hepatocellular carcinoma usually appears as a focal hyperechoic mass.
- Primary or secondary neoplasia and nodular hyperplasia often appear as focal or multifocal hypoechoic or mixed echogenic lesions.
- *Target lesions,* consisting of an echogenic center surrounded by a more sonolucent rim, are often neoplastic.
- Hepatic lymphoma is quite variable and may appear as a mild diffuse hyperechogenicity or hypoechogenicity, multifocal hypoechoic lesions, or a mixed echogenic pattern; alternatively, the appearance may be normal.

Liver Biopsy

Definitive diagnosis of hepatic neoplasia requires liver biopsy and histopathologic evaluation.

- *Laparotomy* is the procedure of choice for a single, large hepatic mass because excision of the mass can also be performed concurrently.
- *Ultrasound-guided biopsy* is useful to diagnose focal or diffuse hepatic involvement, but the small size of the biopsy can make differentiation of nodular hyperplasia versus primary hepatic neoplasia difficult. A wedge biopsy obtained at surgery is often necessary.
- *Blind percutaneous needle biopsy* and *FNA* cytology are most useful for diagnosis of diffuse hepatic neoplasias such as lymphoma, myeloproliferative disorder, and mast cell tumor.

Treatment

Surgery

Surgical removal of the affected liver lobe is the treatment of choice for primary hepatic neoplasms such as hepatocellular adenoma or carcinoma that involve a single lobe (see Chapter 72). Early detection prior to metastasis to other liver lobes affords the best chance for surgical control.

- Surgical resection of a bleeding mass may provide palliative therapy despite the presence of metastatic disease.
- Perform a complete exploratory of the abdominal cavity for evidence of metastases, and biopsy hepatic lymph nodes.
- When all lobes are affected, the prognosis is poor.

Chemotherapy

▼ ***Key Point*** Chemotherapy is not an effective means of control for primary liver tumors in dogs and cats.

Secondary hepatic neoplasms such as lymphoma, mast cell tumor, or myeloproliferative disease might temporarily respond to chemotherapeutic intervention (see Chapters 26 through 28).

HEPATIC NODULAR HYPERPLASIA

Nodular hyperplasia of the liver is a common benign postmortem finding in dogs more than 8 years of age. In one study, hepatic nodular hyperplasia was present in all dogs older than 14 years of age. It appears to be an age-related change, but the cause is unknown. It is not a preneoplastic disorder. The number of nodules ranges from just a few to multiple nodules in a random distribution throughout all liver lobes. They may be microscopic or macroscopic with distortion of the hepatic surface. With extensive involvement, nodular hyperplasia can grossly mimic macronodular cirrhosis or neoplasia. Occasionally, single hyperplastic nodules can become quite large and mimic a hepatocellular adenoma both clinically and microscopically.

Clinical Signs

- Nodular hyperplasia is not usually associated with clinical signs.

Diagnosis and Treatment

- Hepatic nodular hyperplasia can cause mild to moderate increases in serum liver enzymes, especially ALP activity. Other tests of liver function are typically normal.

- These benign lesions should be considered in the differential diagnosis when hepatic nodules are identified during ultrasonography, laparoscopy, or surgery. Ultrasonographically, many hyperplastic nodules are not detected because they are isoechoic to adjacent liver tissue. However, they may have a variety of echotextures and appear similar to primary or secondary hepatic neoplasia, requiring histopathology to distinguish these disorders. Preliminary studies suggest magnetic resonance imaging may be useful in differentiating benign from neoplastic focal hepatic lesions in dogs.
- FNA cytology commonly reveals vacuolated hepatocytes suggestive of fat or glycogen accumulation. Extramedullary hematopoiesis composed of predominantly segmented and band neutrophils may also be identified.

▼ ***Key Point*** Needle biopsies often do not provide adequate tissue for pathologists to diagnose nodular hyperplasia.

- If needle biopsy only describes vacuolated hepatocytes, the clinician may be misled to search for causes of metabolic disease, such as hyperadrenocorticism.
- A wedge biopsy may be necessary to differentiate nodular hyperplasia from hepatocellular carcinoma and hepatoma.
- No treatment is required.

HEPATIC CYSTS

Single or multiple diffuse hepatic cysts occasionally are identified in the liver of dogs and cats, usually as incidental findings at necropsy but occasionally in the live animal.

Etiology

Hepatic cysts can be congenital or acquired, although the distinction is often difficult to make. In general, acquired cysts are usually solitary and congenital cysts are often multiple.

- Congenital polycystic disease of the liver and kidneys has been reported in Cairn terriers and WHWTs.
- Polycystic renal disease in cats has been associated with cystic dilation of the intrahepatic bile ducts (see Chapter 77).
- Acquired cysts may represent benign bile duct adenomas or biliary cystadenomas or may occur secondary to trauma.
- Peliosis hepatis, a vasculoproliferative disorder characterized by cystic, blood-filled spaces in the liver, is a rare disease in dogs and cats. Infection with *Bartonella henselae* was confirmed by polymerase chain reaction of liver tissue in a dog with peliosis hepatis.

Clinical Signs

- Most solitary hepatic cysts do not cause any clinical signs unless they compress or displace adjacent structures. Signs are more likely to occur when congenital polycystic disease is accompanied by dilation of the extrahepatic biliary tract.
- Abdominal enlargement secondary to an enlarged cyst or abdominal fluid accumulation can be a presenting sign. Peliosis hepatis may be associated with intra-abdominal hemorrhage.

Diagnosis and Treatment

- Hepatic cysts should be considered in the differential diagnosis of any cavitated hepatic mass lesion detected on palpation, radiography, or ultrasonography.
- Surgery can confirm the diagnosis and allow excision of large solitary cysts (see Chapter 72).

FELINE INFLAMMATORY LIVER DISEASE

Inflammatory diseases of the liver are the second most common type of feline liver disease, after hepatic lipidosis. The cause, pathogenesis, natural history, and optimal treatment of inflammatory liver disease in cats are largely unknown. Various terms have been used to describe these disorders, such as cholangitis or cholangiohepatitis complex, suppurative cholangiohepatitis, non-suppurative cholangiohepatitis, lymphoplasmacytic cholangiohepatitis, lymphocytic cholangitis, progressive lymphocytic cholangitis, lymphocytic portal hepatitis, sclerosing cholangitis, and biliary cirrhosis.

- Recently, the World Small Animal Veterinary Association (WSAVA) Liver Diseases and Pathology Standardization Research Group developed a classification system with the goal of worldwide standardization of terminology for histologic evaluation of liver diseases in dogs and cats.
- The term *cholangitis* is preferred over *cholangiohepatitis* because the inflammation primarily originates in the bile ducts, and extension beyond the limiting plate into the hepatic parenchyma (cholangiohepatitis) is not always a feature. Cholangitis is further divided into neutrophilic (acute or chronic) or lymphocytic cholangitis. This classification scheme will be used for the purposes of the following discussion.

Neutrophilic Cholangitis

Neutrophilic cholangitis (also called *suppurative cholangitis*) is the most common form of cholangitis in cats.

- Histologically, the lesion is characterized by neutrophilic inflammation within the walls or lumen of bile ducts. The neutrophilic inflammation may disrupt the limiting plate and extend into the

hepatic parenchyma, causing necrosis of periportal hepatocytes.

- Chronic neutrophilic cholangitis (previously referred to as lymphoplasmacytic or non-suppurative cholangitis or cholangiohepatitis) is characterized by a mixed inflammatory response (neutrophils plus lymphocytes and plasma cells). Other features of chronicity include marked biliary hyperplasia, concentric periductal fibrosis, and bridging portal fibrosis.

▼ ***Key Point*** Chronic neutrophilic cholangitis may progress to biliary cirrhosis. As opposed to the small liver in dogs with end-stage cirrhosis, cats with biliary cirrhosis typically have hepatomegaly because of profound biliary hyperplasia.

Etiology

▼ ***Key Point*** Acute neutrophilic cholangitis is most likely caused by ascending bacterial infection from the intestine into the biliary tract.

- Bacterial organisms isolated from bile or liver tissue are primarily gram-negative and anaerobic enteric bacteria such as *E. coli* (most common), *Staphylococcus,* alpha-hemolytic *Streptococcus, Bacillus, Actinomyces, Bacteroides,* and *Clostridia.*
- Chronic bacterial infections elsewhere in the body (sinusitis, splenic abscess, pyelonephritis) and septicemia may also be associated with neutrophilic cholangitis.
- Chronic neutrophilic cholangitis may represent a persistent bacterial infection, or the lesion may have been initiated by bacteria but an immune-mediated response may result in a chronic self-perpetuating disorder. Other possible causes of neutrophilic cholangitis may include viral, toxin-induced, or drug-induced disease.
- Infectious agents infrequently associated with lesions of cholangitis in cats include liver flukes (see previous discussion in this chapter), *Toxoplasma*-like organisms, and *Hepatozoon canis.*

Clinical Associations and Predispositions

▼ ***Key Point*** Neutrophilic cholangitis in cats is commonly associated with IBD and chronic subclinical pancreatitis ("triaditis").

- In cats, the pancreatic and bile ducts join into a common channel prior to opening into the duodenum at the sphincter of Oddi. Underlying IBD may be the key feature that predisposes to both cholangitis and pancreatitis. Inflammation of the duodenal mucosa could alter the normal function of the sphincter of Oddi. IBD commonly causes vomiting in cats, and vomiting could raise the intraduodenal pressure and predispose the patient to reflux of duodenal juice into the pancreatic and biliary systems. Since the normal bacterial count in the proximal small intestine is higher in cats than in dogs, it may be more likely to induce pathology in cats.
- Congenital biliary tract malformations or biliary reconstructive surgery may also predispose the patient to ascending bacterial infection.
- Concurrent extrahepatic biliary tract abnormalities include cholecystitis and sludged bile or choleliths, which may cause bile duct obstruction.
- Cats with cholangitis may develop secondary hepatic lipidosis, possibly related to anorexia and weight loss.

Clinical Signs

- *Acute neutrophilic cholangitis* causes acute onset of vomiting, anorexia, lethargy, and weight loss.
- *Chronic neutrophilic cholangitis* causes intermittent or persistent vomiting, anorexia, lethargy, and weight loss lasting weeks to years. Signs of HE, ascites, and excessive bleeding are uncommon unless chronic neutrophilic cholangitis has progressed to biliary cirrhosis.

Diagnosis

Suspect neutrophilic cholangitis in any cat with non-hemolytic jaundice, especially if accompanied by fever (although not all cases are febrile). Definitive diagnosis requires liver biopsy to distinguish this disease from other hepatic disorders, such as hepatic lipidosis, hepatic FIP, and neoplasia.

History and Physical Examination

- Cats with acute neutrophilic cholangitis typically have an acute clinical presentation of short duration (<5 days). Young cats appear to be at increased risk. A history of antibiotic-responsive illness is common.
- In contrast, cats with chronic neutrophilic cholangitis are usually middle age or older.
- Physical examination findings include fever, jaundice, abdominal pain, hepatomegaly, and dehydration. Fever and abdominal pain are more likely with acute cholangitis.

▼ ***Key Point*** Ascites may be present if chronic neutrophilic cholangitis has progressed to cirrhosis.

Laboratory Evaluation

- For both acute and chronic disease, liver enzyme elevations are variable. Although cholangitis is typically considered a cholestatic disorder, the ALP may be normal, especially in the acute form. This may occur because ALP is an induced enzyme with a lag period before it increases in the serum.
- Increased ALT is a more consistent finding and probably indicates inflammation is extending beyond the

portal area and limiting plate, resulting in hepatocellular necrosis (cholangiohepatitis).
- Hyperbilirubinemia and bilirubinuria are common in both the acute and the chronic forms of cholangitis. FSBAs and PPSBAs are consistently increased.

▼ ***Key Point*** Neutrophilia with a left shift is most frequent in cats with the acute form of neutrophilic cholangitis, whereas hyperglobulinemia is a frequent finding in cats with the chronic form.

- Cats with chronic neutrophilic cholangitis frequently have a mild nonregenerative anemia. A coagulopathy may occur secondary to vitamin K malabsorption, hepatocyte failure, or DIC. Hypoalbuminemia, decreased BUN, and hyperammonemia suggest advanced disease.
- Consider evaluating serum cobalamin level (B_{12}) and feline pancreatic lipase immunoreactivity because of the association of neutrophilic cholangitis with IBD and pancreatitis (see Chapters 69 and 73).
- In endemic tropical locations, rule out liver flukes by fecal exams or a therapeutic trial of praziquantel.

Radiography and Ultrasonography

- Abdominal radiographs may reveal a liver that is normal or increased in size. Radiopaque choleliths may also be detected.
- Ultrasonographically, cats with neutrophilic cholangitis have no detectable parenchymal abnormalities, a diffuse hepatic hypoechogenicity, or a coarse or nodular liver texture. This helps differentiate cholangitis from lipidosis, which causes hyperechogenicity of the liver.
- Ultrasonography is also useful to evaluate for concurrent abnormalities of the biliary tract and pancreas, such as common bile duct obstruction, cholelithiasis, sludging of bile, cholecystitis, and pancreatitis.

Liver Biopsy

Definitive diagnosis requires liver biopsy to distinguish neutrophilic cholangitis from other hepatic disorders, such as hepatic lipidosis, hepatic FIP, and neoplasia.

- If concurrent biliary obstruction occurs, obtain a liver biopsy specimen and aerobic and anaerobic bile cultures at laparotomy during surgical relief of the obstruction (see Chapter 72). Duodenal and pancreatic biopsies are also indicated. At laparotomy, the gallbladder and common bile duct frequently are thickened, firm, and distended. Inspissated bile and choleliths may be present.
- In the absence of obstruction, ultrasound-guided liver biopsy is adequate for diagnosis in most cats. Laparoscopic liver biopsy provides larger tissue samples than those obtained with ultrasound guidance. Perform an aerobic and anaerobic bacterial culture of liver tissue (or bile obtained by cholecystocentesis).
- Cytologic evaluation of impression smears of bile or liver tissue has been recommended since bacteria are more easily detected cytologically than histopathologically.

Treatment

General Supportive Care

- Treat neutrophilic cholangitis with fluid therapy, nutritional support, and supplementation of potassium and B vitamins (see Table 71-1).
- Give vitamin K_1 (0.5–1.5 mg/kg SC or IM q12h for three doses) if hemostasis evaluation suggests vitamin K deficiency.
- Avoid dietary protein restriction unless overt signs of HE are present. If concurrent IBD is suspected, dietary modifications may include commercial GI or novel protein diets (see Chapter 69).

Antibiotics

▼ ***Key Point*** Antibiotics are the primary therapy for acute neutrophilic cholangitis. They are also used in the initial therapy of chronic neutrophilic cholangitis prior to initiating glucocorticoid therapy, in order to eliminate any bacterial component.

If possible, base the choice of antibiotic on culture and sensitivity testing results; otherwise, consider the following recommendations: Continue antibiotics for a minimum of 6 to 8 weeks. In some cats with persistent elevation of serum bilirubin and liver enzymes, continue antibiotic therapy for 3 to 6 months.

- For initial treatment, consider ampicillin (20–40 mg/kg PO, IV, IM or SC q8h), amoxicillin (10–20 mg/kg PO, IV, or SC q8–12h), amoxicillin-clavulanate (62.5 mg/cat PO q12h), or a cephalosporin. Combine one of these with metronidazole (7–10 mg/kg PO q12h) for broader spectrum against anaerobes, as well as modulation of cell-mediated immunity and treatment of concurrent IBD.
- For refractory cases, use enrofloxacin (2.5 mg/kg PO, IM, or IV q12h) or a 1-week course of an aminoglycoside.

Prednisolone

- Prednisolone is recommended for treatment of cats with chronic neutrophilic cholangitis because of its anti-inflammatory and immunosuppressive properties. However, efficacy of corticosteroids for treatment of chronic neutrophilic cholangitis has never been proven.
- Give prednisolone, 2 to 4 mg/kg q24h (once daily or divided), until clinical remission, then taper over 6 to 8 weeks to 1 to 2 mg/kg once every other day.

Hepatoprotective Therapy

- Give ursodiol (Actigall, Ciba Geneva) to all cats with neutrophilic cholangitis once extrahepatic biliary obstruction is eliminated because of its hepatoprotective (anti-inflammatory, immunomodulatory, and antifibrotic effects) properties (see Table 71-2). It appears to be well tolerated and safe in cats.
- Consider other hepatoprotectants, such SAMe or vitamin E (see Table 71-2).

Surgery

Surgical intervention is indicated if biliary obstruction (from sludged bile or choleliths) is detected on ultrasound examination. Surgical procedures for the biliary tract are described in Chapter 72. Use supportive care (including treatment of coagulopathy) for stabilization prior to the procedure. Indications for surgical intervention in the treatment of neutrophilic cholangitis include the following:

- Biliary decompression for extrahepatic biliary obstruction
- Sludge removal and bile duct and gallbladder irrigation
- Cholelith removal
- Cholecystectomy for necrotizing cholecystitis

Biliary diversion techniques such as cholecystoduodenostomy and cholecystojejunostomy are most commonly performed when biliary obstruction is present; however, the mortality rate ranges from 23% to 32% within 6 months of surgery. Cats with biliary surgery that did survive had repeated intermittent bouts of fever, vomiting, and anorexia, which responded to antibiotics. Consequently, if biliary obstruction is present, procedures to establish patency of the biliary system without performing a biliary diversion surgery appear preferable.

Prognosis

Cats with acute neurophilic cholangitis may have a complete recovery after treatment with antibiotics. However, some of these cats progress to the chronic form.

▼ ***Key Point*** Many cats with chronic neutrophilic cholangitis continue to have smoldering disease requiring continued treatment for months or years.

Cats with neutrophilic cholangitis that survive less than 1 year commonly have concurrent diseases that probably contribute to their death.

Lymphocytic Cholangitis

Lymphocytic cholangitis (also called *progressive lymphocytic cholangitis or cholangiohepatitis*) is believed to be a distinct form of cholangitis in the cat. It appears to be rare in the United States but has been well described in Europe. An immune-mediated pathogenesis has been suggested. The histologic lesion is characterized by moderate to marked infiltration of small lymphocytes in portal areas, with variable portal fibrosis and bile duct proliferation. As the lesion progresses, the number of lymphocytes decreases but marked fibrosis disrupts the hepatic architecture.

- Persian cats may have a genetic predisposition.
- The most common clinical features are ascites, icterus, generalized lymphadenopathy, and hyperglobulinemia in young cats.
- Concurrent abnormalities of the extrahepatic biliary system, intestine, or pancreas are not seen.
- Treatment options for lymphocytic cholangitis are similar to those described previously for chronic neutrophilic cholangitis.

Lymphocytic Portal Hepatitis

Lymphocytic infiltration of portal areas without bile duct involvement or periportal necrosis is termed *lymphocytic portal hepatitis*. It is believed to be a nonspecific reaction and not a primary disease process.

- Lymphocytic portal hepatitis is a common finding in liver biopsies of cats older than 10 years of age (up to 82% of cats). In contrast, only 10% of cats younger than 10 years had this finding. It is not associated with IBD or pancreatitis. Liver enzyme elevations may or may not be present.
- Whether or not treatment with corticosteroids is indicated is unclear. The mean survival time in 23 cats with lymphocytic portal hepatitis was 29 months; 72% of these cats were not treated with corticosteroids.
- In cats with marked lymphocytic infiltration in the portal areas, it can be difficult to distinguish lymphocytic portal hepatitis or lymphocytic cholangitis from well-differentiated hepatic lymphoma.

CHOLECYSTITIS

Cholecystitis, or inflammation of the gallbladder, is a clinical problem that occurs uncommonly in both dogs and cats. Cholecystitis may be associated with cholangitis, cholangiohepatitis, gallbladder mucocele, cholelithiasis, and choledocholithiasis. Acute necrotic cholecystitis in dogs frequently is complicated by rupture of the gallbladder and septic bile peritonitis.

Etiology

- Bacteria appear to play an important role in cholecystitis. An enteric origin of bacteria seems most likely, because isolates are usually aerobic gram-negative bacteria (especially *E. coli,* but also *Klebsiella, Pseudomonas,* and *Salmonella* spp.) or anaerobes (*Clostridium* spp.). Intestinal bacteria may be refluxed

into the gallbladder, or they may be blood-borne from the hepatic circulation.
- *Campylobacter jejuni* bacteremia and acute cholecystitis have been documented in dogs. Although the GI tract was suspected to be the source of the bacteria, diarrhea was not a presenting clinical sign.
- Gas-producing organisms, such as *E. coli* and *Clostridium,* can cause emphysema of the gallbladder wall. Emphysematous cholecystitis is recognized most frequently in diabetic dogs.
- Cholelithiasis can predispose the patient to cholecystitis by obstructing the cystic duct, causing gallbladder overdistension and stasis, which enables proliferation of anaerobic organisms.
- Anatomic malformations of the gallbladder, biliary obstruction from any cause, and biliary surgery also predispose the patient to biliary infections.

Clinical Signs

- Signs include anorexia, lethargy, fever, abdominal pain, hepatomegaly, vomiting, diarrhea, and jaundice.
- Acute rupture of the gallbladder with septic bile peritonitis causes abdominal distension, collapse, and septic shock (see also Chapter 76).
- Signs may be acute or chronic and persistent or episodic.

Diagnosis

Differentiate cholecystitis from other cholestatic hepatobiliary disorders that have fever, inflammation, and similar clinical findings, such as acute pancreatitis or pancreatic abscess, cholangiohepatitis, cholelithiasis, hepatic abscess, and septicemia or endotoxemia.

Physical Examination

Physical examination findings include fever, cranial abdominal pain, jaundice, and shock (bile or septic peritonitis).

Laboratory Evaluation

- Laboratory findings are characteristic of severe cholestatic hepatobiliary disease, including hyperbilirubinemia, markedly increased ALP and GGT activity, increased ALT activity, increased SBA concentrations, and hypercholesterolemia.
- Other findings suggestive of inflammation or sepsis are neutrophilia with a left shift and hypoglycemia.
- Increased amylase and lipase levels have been reported in dogs with cholecystitis in the absence of clinical pancreatitis.
- Prolonged PT and APTT occur if chronic biliary obstruction causes vitamin K malabsorption.
- Other laboratory findings reflect dehydration and electrolyte and acid-base imbalances secondary to vomiting, dehydration, and sepsis.
- If cholecystitis is complicated by rupture of the gallbladder or biliary tract, abdominal fluid analysis is consistent with septic bile peritonitis. For a general discussion of peritonitis, see Chapter 76.

Radiography and Ultrasonography

- Potential radiographic findings include cholecystolithiasis, emphysema of the gallbladder wall, and, if perforation occurs, abdominal effusion.
- Ultrasonographic findings include distension of the gallbladder and cystic duct, increased echogenicity or hypoechoic thickening of the gallbladder wall, cholecystoliths, and increased echogenicity of gallbladder bile with or without bile sludge. Small amounts of abdominal effusion not evident on survey radiographs may also be identified.
- Ultrasonographic-guided percutaneous cholecystocentesis has been recommended to obtain bile for cytology and culture (aerobic and anaerobic). Perform blood cultures to isolate bacteria associated with bacteremia and acute cholecystitis. Culture for *C. jejuni* requires selective culture techniques.

Surgery

- Findings at exploratory surgery include thickening, necrosis, and rupture of the gallbladder, localized or generalized peritonitis, and calculi or inspissated bile in the gallbladder, cystic duct, or bile duct. Previous gallbladder rupture may be associated with omental or hepatic adhesions.
- Obtain aerobic and anaerobic cultures of the gallbladder mucosa and bile.
- Histologic examination of the gallbladder reveals varying degrees of necrosis, inflammation, and fibrosis.

Treatment

- Give parenteral vitamin K_1 prior to surgery to correct coagulopathy (see Table 71-1).
- Administer antibiotic therapy effective against aerobic gram-negative and anaerobic bacteria, as described previously for bacterial cholangitis (see under "Feline Inflammatory Liver Disease"). For initial treatment of acute cholecystitis with bacteremia or necrotic cholecystitis with septic peritonitis, combine amoxicillin or cephalosporin with an injectable aminoglycoside or enrofloxacin. Long-term treatment (6–8 weeks) with an oral antibiotic is indicated.
- Cholecystectomy is required in most cases (see Chapter 72). Surgically manage complications such as biliary obstruction, cholelithiasis, inspissated bile, and abdominal drainage for septic bile peritonitis (see Chapter 76).

Postoperative Care and Complications

- Correct all fluid, electrolyte, and acid-base imbalances.

- Common postoperative complications include vomiting, diarrhea, anorexia, hypoproteinemia, and hypokalemia.

Prognosis

- Death usually is attributed to sepsis and peritonitis.
- If the animal survives the immediate postoperative period, the long-term prognosis is good and the recurrence of biliary or hepatic disease is unlikely.

GALLBLADDER MUCOCELE

Gallbladder mucocele is an abnormal accumulation of mucus in the gallbladder lumen accompanied by cystic mucosal hyperplasia of the gallbladder mucosa.

- Dogs with gallbladder mucoceles can be asymptomatic early in the course of disease. Clinical and biochemical abnormalities occur when mucoceles are complicated by secondary bacterial infection, extrahepatic biliary obstruction, or marked distention of the gallbladder leading to ischemic necrosis, gallbladder rupture, and bile peritonitis.

▼ ***Key Point*** Gallbladder rupture is a common life-threatening complication of mucocele.

- The incidence of gallbladder mucocele appears to be increasing, and it is one of the most common causes of extrahepatic biliary tract disease in dogs.

Etiology

The cause of gallbladder mucocele formation in dogs is unknown.

- In humans, gallbladder mucoceles form secondary to functional or mechanical biliary obstruction associated with cholecystitis, cholangitis, or cholelithiasis.
- In dogs, it is not clear whether gallbladder mucoceles are a primary gallbladder disorder or whether biliary obstruction leads to increased mucus secretion. However, predisposing disorders causing mechanical biliary obstruction (infiltrative disease of cystic duct, cholelithiasis) are not typically identified. A primary motility disorder of the gallbladder with delayed gallbladder emptying could potentially predispose the patient to functional gallbladder obstruction.
- A primary bacterial or inflammatory disorder of the gallbladder and biliary tract appear unlikely, since aerobic and anaerobic cultures are frequently negative and gallbladder inflammation is inconsistent and, if present, occurs in association with gallbladder wall necrosis.
- Dogs with hyperadrenocorticism (or receiving corticosteroids) appear to be at increased risk for mucocele formation. Experimentally, progestational compounds can induce lesions of gallbladder cystic mucosal hyperplasia in dogs.
- Acute pancreatitis may be a concurrent finding or a postoperative complication of gallbladder mucocele surgery.
- Increased recognition of gallbladder mucoceles in dogs may suggest a role for nutritional or environmental factors, or it may be the result of increased use of abdominal ultrasonography.

Clinical Signs

- Common clinical signs include anorexia, lethargy, vomiting, icterus, diarrhea, weight loss, PU/PD, abdominal discomfort, and abdominal distention.
- Some dogs with gallbladder mucocele are clinically (and biochemically) normal.

Diagnosis

History and Physical Exam

- Gallbladder mucocele appears to be more likely in older (>10 years) small to medium-sized dogs. No sex predilection is apparent. Cocker spaniels and Shetland sheepdogs appear to be at increased risk.
- Signs are usually acute to subacute and less than 3 weeks in duration.
- Physical examination findings include depression, weakness, lethargy, abdominal pain, icterus, fever, hepatomegaly, tachypnea, and tachycardia. Most dogs with gallbladder rupture have abdominal pain.
- Physical examination may be unremarkable.

Laboratory Evaluation

- Hematologic findings often include leukocytosis (mature neutrophilia or neutrophilic with left shift) and monocytosis.
- Increased liver enzyme activity (ALP, ALT, AST, and GGT) and hyperbilirubinemia are common biochemical features. Other less consistent findings include hypercholesterolemia, hyperglobulinemia, hypoalbuminemia, and azotemia.
- Values for serum ALP and ALT, total bilirubin, and WBC count are higher in dogs with gallbladder mucocele and secondary rupture than in dogs without rupture. In one study, all dogs with high venous lactate concentrations had a ruptured gallbladder.

▼ ***Key Point*** Biochemical findings may be normal in some dogs with early gallbladder mucocele formation detected ultrasonographically.

Ultrasonography

▼ ***Key Point*** The ultrasonographic appearance of a gallbladder mucocele is characteristic. The gallbladder bile is echogenic and organized in a stellate or finely striated, "kiwi fruit" pattern.

- As opposed to biliary sludge, a gallbladder mucocele is not gravity dependent.
- Ultrasonographic findings suggestive of secondary gallbladder rupture include loss of gallbladder wall continuity, hyperechoic fat or fluid around the gallbladder, free abdominal fluid, and striated or stellate echogenic material outside the gallbladder.
- Additional findings may include extrahepatic biliary obstruction and pancreatitis.

Laparotomy

- At surgery, the gallbladder is often markedly distended and firm, with dark serosal discoloration.
- The gallbladder contents appear as a shiny, greenish-black to brown gelatinous material that often has a striated pattern.
- If gallbladder rupture has occurred, abdominal contamination with mucocele contents is present.
- Perform a liver biopsy and aerobic and anaerobic bacterial cultures of bile. Perform cholecystectomy, and flush the bile ducts to remove any residual gelatinous material (see Chapter 72). Submit the excised gallbladder for histopathologic examination.

Histopathology

- Histopathology of the gallbladder reveals cystic mucosal hyperplasia. Cholecystitis is an inconsistent finding and is most likely associated with areas of ischemic necrosis and rupture.
- Liver biopsy findings are nonspecific and include mild to moderate portal hepatitis and fibrosis with bile duct proliferation and vacuolar hepatopathy.

Treatment

▼ ***Key Point*** Cholecystectomy is the treatment of choice of gall bladder mucocele.

- Perform cholecystectomy when a gallbladder mucocele is diagnosed ultrasonographically in a dog with clinical and biochemical evidence of hepatobiliary disease. If gallbladder rupture is suspected, emergency surgery is warranted (see "Biliary Rupture").
- Also perform cholecystectomy for treatment of gallbladder mucoceles in dogs without clinical and biochemical abnormalities, since gallbladder rupture is a life-threatening and unpredictable complication.
- Preoperatively stabilize the patient with fluid therapy and antibiotics. Give broad-spectrum antibiotic therapy (amoxicillin combined with enrofloxacin) to treat secondary bacterial infections of the biliary tract or if gallbladder rupture is suspected. Base antibiotic therapy on results of culture and sensitivity testing of bile or peritoneal fluid (rupture) when possible.
- If a coagulopathy is detected, give vitamin K_1 for 24 to 48 hours prior to surgery (see Table 71-1).
- When gallbladder mucocele is diagnosed in an asymptomatic dog and concurrent systemic disorders or risk of anesthesia precludes surgery, consider antibiotic therapy to control secondary bacterial infections and monitor biochemically and ultrasonographically.
- The role of choleretics such as ursodiol to prevent progression of mucocele formation is unclear. Although ursodiol can increase the watery component of bile, it is contraindicated if biliary obstruction is present.

Prognosis

The long-term prognosis after cholecystectomy appears to be excellent if the dog survives the postoperative period.

- Postoperative complications include sepsis and biliary infection, leakage at the surgery site with bile peritonitis, obstruction of the common bile duct by residual mucus, and acute pancreatitis.
- Mortality rates are similar in dogs with gallbladder rupture and prompt surgical intervention compared with dogs without gallbladder rupture.
- Although a dramatic decrease in liver enzymes and bilirubin occurs after surgery, some dogs have mild, persistent liver enzyme elevations that may be due to a concurrent chronic inflammatory hepatopathy.

CHOLELITHIASIS

Cholelithiasis occurs infrequently in dogs and cats. Choleliths may be present in the gallbladder (cholecystolithiasis), common bile duct (choledocholithiasis), or rarely, hepatic and lobar ducts. Most choleliths in dogs and cats consist of insoluble bile pigments. Minor components such as calcium, bile salts, protein, magnesium, phosphorus, iron, carbonate, and cholesterol also have been identified. Cholesterol choleliths, the most common type of stone in humans, are less likely to form in dogs because the cholesterol content of dog bile is lower than that in humans, and dogs have a better capacity for maintaining biliary cholesterol in solution. Little is known about the cholesterol content of cat bile, but cholesterol choleliths have been reported.

Etiology

The cause of spontaneous cholelithiasis in dogs and cats often cannot be determined. It is generally believed that gallstone formation requires initial nidus formation, retention of particles in the gallbladder, and then sustained growth of the cholelith. The following factors may be important in the development of pigment stones:

- Bile stasis and sludged bile are primarily composed of mucin, which may act as a nidus for cholelith for-

mation by subsequently binding calcium bilirubin pigments and cholesterol crystals.
- Cholecystitis and cholangitis can be associated with cholelithiasis, especially in cats (see "Feline Inflammatory Liver Disease"). It is difficult to determine whether choleliths were formed as a consequence of bile stasis, inflammation, and bacterial infection or whether cholelithiasis initiated the inflammation, which led to secondary biliary stasis and infection.
- Bacteria such as *E. coli* contain beta-glucuronidase, which can deconjugate bilirubin to a less soluble form that precipitates with calcium.
- Dietary factors are unlikely with balanced diets; however, dogs fed an experimental diet that is low in protein and fat, high in carbohydrates, and supplemented with cholesterol will form pigment stones. This diet is deficient in taurine, which may contribute to cholelithiasis by precipitating bile acids.

Clinical Signs

Dogs and cats with cholelithiasis often are asymptomatic. Clinical signs are most likely when cholelithiasis is complicated by bacterial infection, extrahepatic bile duct obstruction, perforation of the gallbladder or bile ducts, or secondary hepatic involvement (cholangiohepatitis or biliary cirrhosis).

- Common signs include vomiting, anorexia, weakness, PU/PD, jaundice, weight loss, and dehydration.
- Signs may be acute or chronic and intermittent or persistent. An acute onset is most likely with sudden obstruction of the cystic or common bile duct by the cholelith or rupture of the gallbladder.

Diagnosis

Although it is uncommon, consider cholelithiasis in the differential diagnosis of any dog or cat with cholestatic hepatobiliary disease.

History and Physical Examination

- Aged, small-breed female dogs appear to be at increased risk.
- A long-standing history (months to years) of intermittent jaundice and vomiting is present in some affected animals.
- Physical examination may be unremarkable, or findings may include jaundice, abdominal discomfort, hepatomegaly, fever, and abdominal distention. Fever is usually indicative of concurrent biliary bacterial infection or septic or bile peritonitis. Abdominal distension due to fluid accumulation is seen with secondary rupture of the biliary tract.
- Excessive bleeding may be noted with chronic common bile duct obstruction.
- Acholic feces are indicative of complete bile duct obstruction.

Laboratory Evaluation

Laboratory findings may be unremarkable. Biochemical evaluation of symptomatic patients is not specific for cholelithiasis but is indicative of cholestatic hepatobiliary disease.

- Findings include moderate to marked increases in serum ALP and GGT activity and in cholesterol, SBA, and total serum bilirubin concentrations. Serum ALT activity usually is increased, indicating secondary hepatocyte damage associated with severe cholestasis or cholangiohepatitis.
- Potential hematologic findings include neutrophilia with a left shift, usually indicating bacterial cholangiohepatitis or cholecystitis or complications such as a ruptured gallbladder. A mild, nonregenerative anemia is common.
- With chronic extrahepatic bile duct obstruction, coagulation tests may be affected by vitamin K malabsorption.
- With biliary rupture, abdominocentesis reveals bile peritonitis.

Radiography

- On routine abdominal radiographs, choleliths may appear as radiopaque densities in the area of the gallbladder or bile ducts. However, pigment stones are usually radiolucent unless they contain calcium. Hepatomegaly is common.
- Other findings are determined by the presence of complications such as obstruction (a distended gallbladder), emphysematous cholecystitis (gas density in the area of the gallbladder), and peritonitis (loss of abdominal detail).

Ultrasonography

- Ultrasonography detects both radiolucent and radiopaque choleliths as hyperechoic densities in the gallbladder and bile ducts. Choleliths are differentiated from mural masses by the presence of acoustic shadowing and movement of the density with changes in position of the animal.
- Inspissated or sludged bile also appears in the gallbladder as an echogenic substance, but sludge does not cause acoustic shadowing. Sludged bile may indicate biliary stasis but can also be seen in sick, anorexic animals without clinical biliary tract disease.
- Complications of cholelithiasis can be identified ultrasonographically, such as distention of the gallbladder and bile ducts with cystic or common bile duct obstruction, thickening of the biliary tract associated with inflammation, abdominal fluid accumulation with rupture of the gallbladder, and absence of the gallbladder.

▼ ***Key Point*** Because the majority of choleliths do not cause clinical signs, surgical removal may not always be warranted.

Laparotomy

Perform exploratory laparotomy for definitive diagnosis and treatment of cholelithiasis (see Chapter 72). Pigment choleliths usually are greenish-brown to black and may be single or multiple. Perform the following diagnostic and therapeutic procedures during exploratory laparotomy:

- Evaluate the patency of the gallbladder and bile ducts.
- Remove choleliths for chemical analysis and bacterial culture.
- Identify and repair secondary biliary rupture.
- Collect samples of affected tissue (liver, gallbladder) and bile for aerobic and anaerobic bacterial culture and biopsy.

Histopathologic Evaluation

Histopathologic changes in the gallbladder, bile ducts, and liver may be absent with uncomplicated cholelithiasis. However, mild cholangitis (cholangiohepatitis) and cholecystitis are common.

Treatment and Prognosis

- Institute supportive therapy to correct fluid, electrolyte, and acid-base imbalances prior to surgery. Feed a well-balanced diet.
- If a coagulopathy is detected, give vitamin K_1 for 24 to 48 hours prior to surgery (see Table 71-1).
- Administer systemic antibiotics in animals with inflammatory biliary tract disease and cholelithiasis. Ideally, base the choice of antibiotic on culture and sensitivity testing of bile and hepatic tissue obtained at surgery. See the discussion of antibiotic therapy of biliary infections under "Neutrophilic Cholangitis."
- Management of complications of cholelithiasis, such as biliary obstruction or rupture, is discussed in the next sections. Surgery of the biliary tract is discussed in Chapter 72.
- Little is known about the likelihood of recurrence of cholelithiasis in dogs and cats, but if the underlying mechanism of cholelith formation is not reversed, recurrence is possible.

EXTRAHEPATIC BILIARY OBSTRUCTION

Extrahepatic biliary obstruction of the common bile duct or large hepatic ducts interrupts bile flow into the intestine.

Table 71-12. CAUSES OF EXTRAHEPATIC BILIARY OBSTRUCTION

Cholelithiasis
Inspissated (sludged) bile
Gallbladder mucocele
Cholangitis and cholecystitis
Acute pancreatitis, pancreatic abscess, pancreatic fibrosis
Biliary, hepatic, pancreatic or duodenal neoplasia
Biliary stricture
Biliary hematoma
Liver flukes
Diaphragmatic hernia with entrapment of the gallbladder

Etiology

Biliary obstruction can be a complication of primary biliary tract disorders such as gallbladder mucocele, cholelithiasis, or biliary tumors or can be caused by extrahepatic disorders such as pancreatic fibrosis and pancreatic or duodenal masses (Table 71-12).

Clinical Signs

- Signs of biliary obstruction include anorexia, vomiting, jaundice, weight loss, abdominal pain, diarrhea, acholic feces, and excessive bleeding.
- Diarrhea and steatorrhea are characterized by tan-colored feces and are attributed to failure to secrete bile acids, which results in malabsorption of fat and fat-soluble vitamins such as vitamin K.
- With prolonged extrahepatic biliary obstruction, vitamin K malabsorption and the subsequent decreased synthesis of vitamin K–dependent factors results in a coagulopathy.
- With complete biliary obstruction, the feces may become clay colored (acholic) because of a lack of bile pigments.

Diagnosis

The diagnostic strategy is to identify that biliary obstruction is present and then to identify the underlying cause of obstruction.

Physical Examination

- Findings include jaundice and hepatomegaly due to bile engorgement of the liver.
- A firm, distended gallbladder occasionally is palpated.
- Other findings are dependent on the underlying cause of obstruction, such as palpation of an abdominal mass (pancreatic or biliary neoplasia) and abdominal pain (acute pancreatitis, peritonitis).
- Fever may suggest bacterial cholecystitis or cholangiohepatitis, biliary rupture with peritonitis, pancreatitis, or pancreatic abscess.

Laboratory Evaluation

- Biochemical findings reflect marked cholestasis, including increased serum concentrations of ALP, GGT, cholesterol, bile acids, and bilirubin. Unfortunately, biochemical findings cannot distinguish whether cholestasis is caused by intrahepatic or extrahepatic mechanisms. In general, values for total bilirubin and ALP activity tend to be higher with extrahepatic biliary obstruction. Serum ALT and AST activity are concurrently increased due to secondary hepatic damage.
- On the CBC, a mild neutrophilia and mild, nonregenerative anemia are common. Neutrophilia with a left shift suggests the possibility of acute pancreatitis or abscess, bacterial cholangitis or cholecystitis, or biliary rupture.
- Findings on urinalysis include bilirubinuria and absence of urobilinogen.
- With vitamin K malabsorption, findings include prolonged PT, APTT, and activated clotting time. Platelet function defects have also been documented in dogs with biliary obstruction.

Radiography

Abdominal radiography is frequently non-diagnostic.

- Occasionally, a large, fluid-filled gallbladder can be seen superimposed over the liver. The liver may be normal to increased in size. Chronic biliary obstruction in dogs may lead to biliary cirrhosis and microhepatica.
- Other radiographic findings depend on the underlying cause of obstruction and may include cholelithiasis, emphysematous cholecystitis, pancreatitis, and mass lesions.

Ultrasonography

Ultrasonography is helpful to confirm extrahepatic biliary obstruction and to evaluate the underlying cause.

- In normal dogs, the cystic duct, common bile duct, and intrahepatic ducts are not visible. The common bile duct may be visible in some normal cats but is usually ≤ 4 mm. A common bile duct > 5 mm is suggestive of extrahepatic biliary obstruction.
- With biliary obstruction, the biliary system, including the gallbladder, cystic duct, common bile duct, and intrahepatic ducts, becomes progressively dilated. The earliest detectable change is distension of the gallbladder and cystic duct, which occurs within 24 hours. By 48 hours, the common bile duct also is distended. Distention of intrahepatic ducts is not detected until 4 to 7 days after obstruction. Dilated hepatic biliary ducts are differentiated from hepatic and portal veins by their tortuosity and irregular branching patterns.
- Ultrasonography may identify underlying causes of biliary obstruction such as gallbladder mucocele, cholelithiasis, pancreatitis, or mass lesions.

Hepatobiliary Scintigraphy

Hepatobiliary scintigraphy may be used to confirm biliary obstruction but is available only at tertiary referral centers.

Laparotomy

Exploratory laparotomy usually is required to confirm extrahepatic biliary obstruction and to identify the underlying cause. Perform the following diagnostic procedures:

- Evaluate bile duct and gallbladder patency.
- Identify location and cause of obstruction.
- Evaluate for evidence of secondary rupture of the biliary tract.
- Collect a sample of bile for aerobic and anaerobic bacterial cultures.
- Perform a liver biopsy.

Treatment

Surgery

Specific therapy requires surgery to correct the underlying cause of obstruction (see Chapter 72).

- Prior to surgery, stabilize the patient with fluid therapy. Give vitamin K_1 parenterally for 24 to 48 hours prior to surgery to correct a coagulopathy.
- With complete biliary obstruction, antibiotics do not enter the bile.

Medical Therapy

If biliary obstruction occurs secondary to acute pancreatitis, manage the pancreatitis medically (see Chapter 73) and reserve surgery for those patients in which biliary obstruction does not resolve with resolution of pancreatic inflammation.

BILIARY RUPTURE

Leakage of bile into the abdominal cavity results in chemical peritonitis that can be complicated by sepsis.

Etiology

- Biliary tract rupture is commonly caused by blunt or sharp abdominal trauma from automobile-induced injuries, gunshot injuries, and bite wounds. Rupture of the common bile duct is most likely with blunt abdominal trauma.
- Gallbladder mucocele and necrotizing cholecystitis can be associated with gallbladder rupture.

- Other causes of gallbladder rupture include cholelithiasis, biliary neoplasms, gallbladder infarction, and iatrogenic puncture during percutaneous liver biopsy.

Clinical Signs

- When gallbladder rupture occurs secondary to gallbladder mucocele, cholecystitis or cholelithiasis, acute onset of anorexia, vomiting, diarrhea, jaundice, abdominal pain, fever, and shock may occur.
- Signs of biliary duct rupture secondary to trauma tend to be chronic and develop more slowly than with rupture of the gallbladder. With traumatic biliary rupture, early signs such as abdominal pain and vomiting are frequently overshadowed by more immediate signs of shock, fractures, and other injuries.
- Other signs, such as anorexia, listlessness, weight loss, jaundice, ascites, and acholic feces, do not occur until days or weeks following the traumatic event.

Diagnosis

History and Physical Examination

- A history of recent abdominal trauma and progressive jaundice and abdominal distention suggests the possibility of biliary rupture.
- Physical examination findings consistent with biliary rupture include jaundice, abdominal distension, and acholic feces.
- Abdominal pain is most likely with acute rupture or septic peritonitis.
- Fever may occur with septic peritonitis or cholecystitis.

Laboratory Evaluation

- Laboratory findings include hyperbilirubinemia and increased ALP, ALT, and SBA concentrations.
- Abdominal fluid appears yellow or green. Chemical tests for bilirubin are positive and concentrations of bilirubin are at least 2 times higher in the abdominal fluid than in the serum.
- Cytologic examination reveals mixed inflammatory infiltrate and bile-laden macrophages or free green or yellow-brown material consistent with bile. In some dogs with biliary rupture, bile pigment is not visible but an acellular amorphous blue mucinous extracellular material ("white bile") may be observed. These dogs still have fluid bilirubin concentrations greater than twice the serum value.
- Bacteria may be seen if bile peritonitis is complicated by sepsis.

Radiography and Ultrasonography

- Abdominal radiographs reveal poor abdominal contrast due to fluid accumulation.
- On ultrasonography, the gallbladder may not be visible, and even a small amount of abdominal fluid may be detected.
- Other radiographic and ultrasonographic findings depend on the underlying cause of rupture, such as gallbladder mucocele, cholecystitis, cholelithiasis, and biliary neoplasia.
- When trauma is suspected as the cause of biliary rupture, take thoracic films to detect other complications such as pneumothorax, diaphragmatic hernia, and bile pleuritis.

Laparotomy

Confirm rupture of the biliary tract by laparotomy.

- Rupture of the gallbladder secondary to cholecystitis may be acute or chronic. With chronic gallbladder rupture, omental and hepatic adhesions are common. Biliary fistulas may develop from the gallbladder to other abdominal structures such as the diaphragm. Fistulas between the gall bladder and the diaphragm may result in bile pleuritis and biliary effusion.
- Submit abdominal fluid and affected biliary tissue for aerobic and anaerobic bacterial culture.

Treatment

Surgery is required to repair the biliary rupture and is discussed in Chapter 72. The prognosis is guarded.

▼ ***Key Point*** Dogs with septic peritonitis (positive bacterial cultures of the biliary effusion) are less likely to survive than are dogs with negative culture results.

- Prior to surgery, stabilize the patient with fluid therapy, give vitamin K_1 parenterally for 24 to 48 hours, and give antibiotics.
- Open abdominal drainage is not necessary for dogs with sterile biliary effusions but may be helpful in managing dogs with septic peritonitis (see Chapter 76).

Chapter

72 Surgery of the Liver and Biliary Tract

Stephen J. Birchard

Surgery of the liver and biliary tract is commonly performed in small animals and can be very challenging. Animals frequently are presented with surgical diseases of these organs, such as liver tumors and obstruction or infection of the biliary system. Some of the procedures described in this chapter require specialized training and facilities. Others, such as liver biopsy, partial hepatectomy, and simple exploration of the biliary tract, can be performed in a standard veterinary practice. Regardless of the procedure, preparation for the surgery by reviewing anatomy, pathophysiology, and specific techniques is very important for a successful outcome. Preparation of the patient prior to surgery also is extremely important because most of these diseases have serious metabolic effects.

SURGERY OF THE LIVER

Anatomy

Liver Lobes

- The liver is divided into six lobes: the right lateral, right medial, caudate, quadrate, left medial, and left lateral.
- The caudate lobe is divided into the caudate process and the papillary process.

Liver Attachments

- The major liver attachments to other organs and the body wall are the triangular, hepatogastric, and hepatoduodenal ligaments.
- The falciform ligament extends from the liver to the diaphragm and ventral abdominal wall. This mesenteric remnant can be quite large and fat-filled in obese animals. Consider removing this structure during liver surgery to gain better exposure of the cranial abdominal structures.
- The hepatorenal ligament is a thin fold of peritoneum that extends from the renal fossa of the caudate lobe to the ventral surface of the right kidney.

Blood Supply

Portal Vein

- The portal vein receives blood from the spleen, pancreas, and intestines.
- The major hepatic branches of the portal vein are the right lateral trunk, right medial branch, and left lateral trunk.
- The portal vein is the confluence of the cranial and caudal mesenteric veins and the splenic vein.
- The portal vein can be seen at the base of the mesoduodenum. It forms the ventral boundary of the epiploic foramen.
- The portal vein eventually empties into the liver and supplies approximately 80% of the blood flow of the liver. The remaining 20% comes from the hepatic arteries.
- In the fetus, the ductus venosus connects the portal vein to the caudal vena cava, allowing blood to bypass the liver. This vessel closes soon after birth in normal dogs. If it remains patent, it is called a *patent ductus venosus* and is one of the several types of portosystemic shunts.

Hepatic Arteries and Veins

- The hepatic artery is a branch of the celiac artery. Variable numbers of hepatic artery branches supply the liver lobes. The hepatic arteries are located in the vicinity of the hepatoduodenal ligament and are adjacent to the common bile duct. The cystic artery, which supplies the gallbladder, is a branch of the left branch of the hepatic artery.
- Six to eight large hepatic veins drain the liver lobes to the caudal vena cava.
- The hepatic veins enter the vena cava at the hilus of the liver and are obscured by the liver parenchyma.

Preoperative Considerations

Liver diseases cause a variety of significant hematologic and metabolic disorders in animals. Prior to surgery, perform appropriate diagnostics to confirm the disease and check for involvement of other organs. (See Chapter 71 for diagnosis of liver problems.)

Of particular concern to the surgeon are the following potential problems:

- *Hypoproteinemia*—Evaluate serum proteins and consider administration of plasma, colloids, or hyperalimentation if significantly low.
- *Anemia*—Evaluate the animal's hemogram and establish a baseline packed cell volume so that changes can be kept in perspective. Blood loss before, during, and after liver surgery is common and should be monitored closely.
- *Coagulopathy*—Analyze the animal's coagulation profile and correct abnormalities if possible (see Chapter 23). Fresh whole blood transfusion before or during surgery may be necessary.
- *Diffuse disease*—Hepatic neoplasia may result in metastatic lesions. Thoracic and abdominal radiography and abdominal ultrasonography are helpful in determining the extent of disease.
- *Impaired liver function*—Manage hepatic encephalopathy, if present, medically (see Chapter 71) to stabilize the animal prior to surgery.
- *Hypoglycemia*—Consider giving the animal intravenous (IV) fluids supplemented with glucose before and during surgery (e.g., 5% dextrose in lactated Ringer's solution).

▼ ***Key Point*** Diffuse hepatic disease may cause serious metabolic problems that can be compounded by anesthesia and surgery. Analyze liver function tests, such as serum bile acid and blood ammonia concentrations (see Chapter 71), to determine the animal's ability to undergo anesthesia and surgery.

- *Liver trauma*
  - Thoroughly evaluate all animals with a history of trauma to rule out thoracic trauma such as pneumothorax, pulmonary contusions, and other cardiopulmonary problems (see Chapter 166). Evaluate for damage to other organs such as the urinary tract, gastrointestinal tract, and neurologic and skeletal systems.
  - Animals with liver trauma usually have hemoperitoneum. Severe blood loss will cause clinical signs of shock and should be treated (see Chapter 156 for treatment of hypovolemic shock).

▼ ***Key Point*** Most animals with liver trauma can be treated conservatively (e.g., IV fluids, whole blood transfusion, or autotransfusion of abdominal blood if not contaminated with bacteria or neoplastic cells).

Liver Biopsy and Partial Hepatectomy—Surgical Procedure

Objectives

- Examine the entire liver and biliary system for grossly evident abnormalities.
- Obtain tissues for biopsy or completely remove the lesion by partial hepatectomy.
- Minimize intraoperative blood loss.

Equipment

- Standard general surgery pack and suture
- Balfour and malleable retractors
- Tru-Cut biopsy needle, Anchor Soft Tissue Biopsy Device (Anchor Products Co., Addison, IL), or skin punch biopsy instrument
- Tissue stapling device (e.g., Autosuture TA, U.S. Surgical, Norwalk, CT) (optional)
- Gelfoam

Technique

1. Place the animal in dorsal recumbency and prepare the entire ventral abdomen and caudal one-third of the sternum for aseptic surgery.
2. Perform a standard ventral midline abdominal approach. If additional exposure is necessary, also perform a left or right paracostal abdominal incision or a caudal median sternotomy.
3. Use laparotomy sponges to protect the abdominal wall and place Balfour retractors to expose the liver and associated viscera.
4. Identify areas of liver to be removed or biopsied. If necessary, mobilize involved liver lobes by incising the triangular ligaments. Greater exposure of the liver can be achieved by placing a laparotomy sponge between it and the diaphragm.
5. Liver biopsy can be achieved by a variety of techniques:
   a. Obtain tissue samples from the periphery of the lobe, using the "guillotine" technique.
   b. Use absorbable suture to surround a small segment of liver and tie the suture tight to cut through the parenchyma and strangulate the blood vessels and bile ducts (Fig. 72-1). Alternatively, place the suture in a horizontal mattress pattern.
   c. Excise the tissue distal to the ligature, using a scalpel or Metzenbaum scissors. Check for bleeding and, if necessary, place a small piece of Gelfoam over the cut surface for hemostasis.
   d. Alternatively, use a Tru-Cut needle or skin biopsy punch to obtain small pieces of liver tissue. These are especially helpful if the lesion is centrally located in the liver lobe rather than peripherally. Be sure to include some normal tissue in the biopsy specimen.
6. Remove large lesions by partial hepatectomy (Fig. 72-2):
   a. Divide the liver parenchyma proximal to the lesion, using large crushing clamps or finger fractionation (gently squeezing the liver parenchyma between fingers to isolate vessels). Ligate the

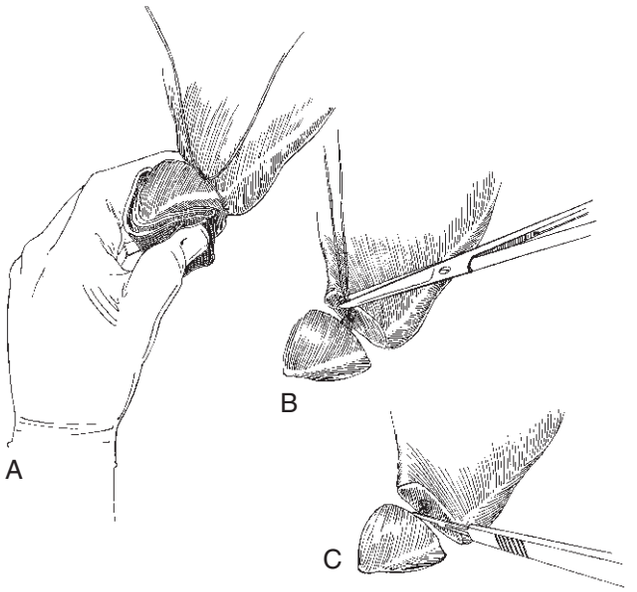

Figure 72-1. Guillotine method for intraoperative liver biopsy. Place a loop of absorbable suture around the tip of a liver lobe and tie tightly to cut through the liver parenchyma, ligating the vessels. Cut the suture ends and then cut the vessels to allow removal of the biopsy specimen.

ducts and vessels with absorbable sutures (e.g., 3-0 or 4-0 chromic catgut).

b. Alternatively, use surgical staples (e.g., U.S. Surgical Autosuture TA) to crush the tissue and ligate the vessels in one step.

c. Complete removal of an entire liver lobe requires carefully placed ligatures to attenuate the large arteries and veins at the liver hilus. Oversew or transfix the vessels to prevent ligature slippage. Place large clamps on the vessels prior to resection of the lobe to prevent cranial retraction of the vessel (Fig. 72-3).

Postoperative Care and Complications

- Monitor for postoperative hemorrhage (oozing of blood from the incision, distention of the peritoneal cavity, pale mucous membranes). Administer blood transfusion if the hematocrit drops below 20%.
- Give supportive therapy with IV fluids and glucose until oral intake of food and water resumes.
- Monitor for evidence of pancreatitis (vomiting, abdominal pain, increased serum amylase and lipase). Delay resuming oral intake and keep on IV fluid therapy until this resolves.
- After massive liver resection, monitor liver function by evaluating bilirubin and serum bile acid concentrations. Liver function reportedly becomes abnormal after resection of 60% or more of the liver.

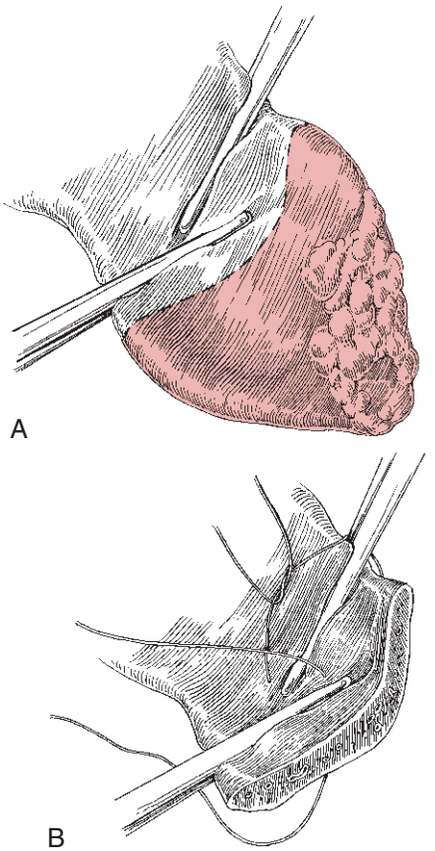

Figure 72-2. Partial hepatectomy. Lesions at the periphery of the liver lobe can be removed by placing crushing clamps across the lobe, proximal to the lesion, and then cutting distal to the clamps. Use absorbable sutures to ligate vessels proximal to the clamps. Tie these ligatures tightly as in the guillotine method for liver biopsy (see Fig. 72-1).

SURGERY FOR PORTOSYSTEMIC SHUNTS

Portosystemic shunts are abnormal vascular communications between the portal vein and a systemic vein. Diagnosis and medical treatment of this condition are discussed in Chapter 71. Animals with portosystemic shunts can initially improve with medical management. However, the definitive and most effective therapy for long-term resolution of clinical signs is surgical attenuation of the shunt vessel. With recent advances in the intraoperative and postoperative management of these animals, morbidity and mortality rates associated with surgery have decreased to very acceptable levels.

Anatomy

Portosystemic shunts are divided anatomically into *extrahepatic* and *intrahepatic* (Fig. 72-4). Definition of shunt anatomy preoperatively is important because

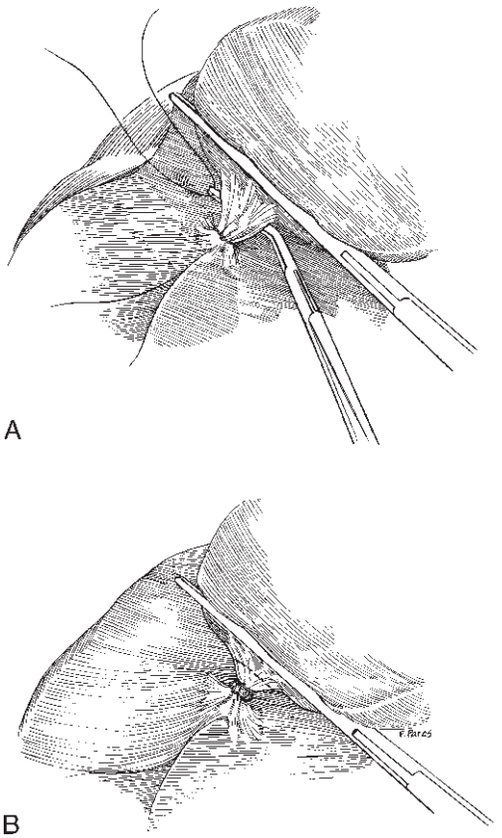

Figure 72-3. Double ligation *(A)* and transection *(B)* in total liver lobectomy.

intrahepatic shunts are much more difficult to correct surgically than are extrahepatic shunts. Also, familiarity with the anatomy helps decrease surgical time and patient morbidity.

Extrahepatic Shunts

Extrahepatic shunts are caudal to the liver. These are vascular communications that usually occur between the portal vein and the caudal vena cava (portacaval shunt) or the azygos vein (portoazygos shunt). Extrahepatic portacaval shunts frequently empty into the left side of the caudal vena cava just adjacent to the epiploic foramen. Shunts involving the left gastric vein can be found near or on the lesser curvature of the stomach.

Intrahepatic Shunts

Intrahepatic shunts communicate with the caudal vena cava within or cranial to the liver parenchyma and can involve either the right or left branches of the hepatic portal vein.

Preoperative positive contrast portography helps differentiate between intrahepatic and extrahepatic shunts. Using these studies, the portal vein can be correlated to the thoracolumbar spine. The first branch of the hepatic portal vein (the right lateral trunk) is located at the 12th thoracic vertebra. If any part of the shunt is caudal to the 13th thoracic vertebra (T13), it is probably extrahepatic. If the entire shunt is cranial to T13, it is probably intrahepatic.

Preoperative Considerations

- Stabilize the animal by medically treating the hepatic encephalopathy for 1 to 2 weeks (see Chapter 71).
- Treat hypoglycemia, if present, with 5% dextrose in a balanced electrolyte solution administered IV.
- If the animal is anorexic, consider giving nutritional support via nasogastric tube or some other feeding device and use a low-protein diet.
- Avoid lactated Ringer's solution for maintenance fluid administration. Lactated Ringer's can make the animal alkalotic and worsen the hepatic encephalopathy.

Anesthesia

▼ ***Key Point*** Animals with portosystemic shunts have markedly reduced capacity to metabolize anesthetic drugs in the liver.

- Avoid using drugs such as the barbiturates and phenothiazine derivatives.

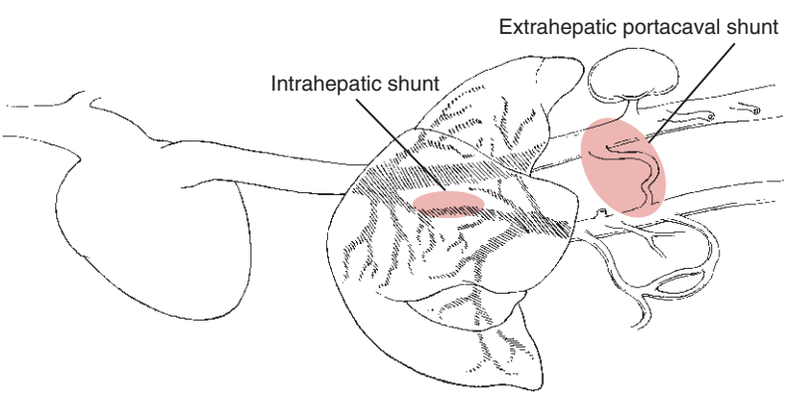

Figure 72-4. Schematic representation of an extrahepatic portacaval shunt and an intrahepatic portacaval shunt.

- Use diazepam (at a reduced dosage; see Chapter 2) as a premedicant, if needed.
- Induce anesthesia via mask induction with isoflurane and oxygen or ketamine/diazepam combination (see Chapter 2).
- Maintain anesthesia with isoflurane and oxygen via endotracheal tube.
- In addition to routine monitoring, monitor blood pressure because changes may occur during manipulation of the shunt.
- Administer 5% dextrose in a balanced electrolyte solution IV during anesthesia and surgery to prevent severe hypoglycemia.

Surgical Procedure

Objectives

- Place a jejunal vein catheter to monitor portal pressures.
- Identify and attenuate the portosystemic shunt to redirect portal blood flow to the liver.
- Avoid causing portal hypertension.

Equipment*

- Standard general surgery pack and retractors (Balfour, malleable)
- Over-the-needle IV catheter (e.g., Sureflo, Terumo Medical, Elkton, MD), water manometer, IV extension set, three-way stopcock, heparinized saline
- Small and large right-angled forceps
- DeBakey tissue-holding forceps
- Ameroid constrictors of various sizes (Research Instruments NW Inc., Sweethome, OR)

Technique

1. Place the animal in dorsal recumbency and prepare the entire ventral abdomen and caudal one-third of the sternum for aseptic surgery.
2. Perform a routine ventral midline abdominal approach. If the shunt is intrahepatic, it also may be necessary to perform a caudal sternotomy.
3. Explore the abdomen and identify the shunt.
   a. *Extrahepatic shunts* usually are found by retracting the duodenum ventrally and to the left, and then following the mesoduodenum cranially and dorsally to the level of the epiploic foramen. Ventral retraction of the lesser omentum usually exposes the shunt entering the left side of the caudal vena cava. Be careful not to injure the hepatic arteries, which lie adjacent to the shunts located in this position. Some shunts can be found by creating a small window in the greater omentum and looking in the vicinity of the splenic vein, or by making a window in the lesser omentum and looking craniodorsal to the lesser curvature of the stomach. Portoazygos shunts are identified by following the abnormal vessel as it courses dorsally through the diaphragm. Shunts in other locations require careful exploration of the cranial abdomen for location. It may be necessary to locate other branches of the portal vein, such as the splenic vein or the left gastric vein, in order to find the shunt.
   b. The location of *intrahepatic shunts* varies. Exposure may be facilitated by median sternotomy and ventral-to-dorsal division of the diaphragm. The intrahepatic shunt may be seen entering the caudal vena cava cranial to the liver. These shunts are usually closely adherent to the peritoneal surface of the diaphragm. Alternatively, the shunt or the branch of the portal vein entering the shunt may be seen and dissected caudal to the liver. Dissection and attenuation of intrahepatic shunts can be very difficult, even for experienced surgeons.
4. Carefully skeletonize a small portion of the shunt vessel and pass an ameroid constrictor around it. The constrictor is composed of a hydroscopic material (casein) encased in a metallic ring. It gradually occludes the shunt over a period of weeks, reducing the incidence of portal hypertension. Choose a constrictor size (range from 3.5–9 mm internal diameter) that allows placement on the shunt with no immediate occlusion of the vessel lumen.
5. If the shunt is too large for an amerioid constrictor, or it is impossible to pass the constrictor around the shunt (common in intrahepatic shunts), perform suture ligation of the shunt using silk suture. Slowly ligate the shunt while monitoring portal pressure via a jejunal vein catheter (over-the-needle IV catheter placed in a jejunal vein and connected to a water monometer).

▼ ***Key Point*** During shunt ligation, do not allow portal pressure to rise >10 cm above the preligation value or to reach an absolute value >20 cm H_2O.

6. Carefully observe the abdominal viscera, especially the pancreas and intestine, for evidence of portal hypertension (e.g., bluish color and congestion of venous vessels). Use both the portal pressure values and tissue appearance to be sure that portal hypertension is not developing during ligation.
   a. Reduce the degree of attenuation if there is any evidence of portal hypertension.
   b. Complete ligation is possible in rare cases; however, many animals respond well to only partial ligation of the shunt.
7. Remove the jejunal catheter and ligate the jejunal vein if necessary.
8. Close the abdominal incision in a routine fashion.

*Also see equipment listed under Median Sternotomy, which may be needed if the shunt is intrahepatic (Chapter 167).

Postoperative Care and Complications

- Monitor for portal hypertension. *Acute* portal hypertension is a life-threatening complication that may develop any time from immediately to several hours postoperatively. Watch for the following clinical signs of postoperative portal hypertension: acute collapse, severe abdominal pain, abdominal distention (ileus), pale mucous membranes, slow capillary refill, and diarrhea with frank blood and mucosal shreds.

▼ ***Key Point*** If acute portal hypertension is suspected, reoperate immediately to remove the shunt ligature.

- *Chronic* portal hypertension usually is manifested by ascites. Treatment generally is not necessary, and the ascites usually resolves in 1 to 3 weeks.
- Prevent hypoglycemia by giving 5% dextrose in saline until the animal resumes oral feeding.
- Add potassium to the fluid to prevent hypokalemia (see Chapter 5 on fluid therapy).
- Continue medical management of hepatic encephalopathy (see Chapter 71).
- If the animal is doing well clinically, discontinue the lactulose and neomycin after 2 to 4 weeks.
- Continue feeding a low-protein diet (e.g., Prescription Diet k/d [Hill's]) until liver function improves significantly. Measure pre- and post-prandial serum bile acid concentrations 3 and 6 months postoperatively to evaluate improvement in liver function. If no clinical improvement is seen, consider follow-up portography and religation of the shunt vessel if continued shunting of blood is seen.

SURGERY OF THE BILIARY TRACT

Anatomy

Gallbladder

- The gallbladder is a pear-shaped sac located between the quadrate and right medial lobes of the liver.
- In a medium-sized dog, it has a capacity of 15 ml.
- Bile drains from the gallbladder to the cystic duct, and then to the common bile duct.
- The gallbladder is divided anatomically into three parts: the fundus (blind end), body (middle portion), and neck.
- Histologically, the gallbladder wall consists of a mucosal lining, layer of smooth muscle fibers, submucosal layer, and serosal covering.
- Blood supply is via the cystic artery, a branch of the hepatic artery.

Bile Ducts

- Hepatic cells discharge bile into minute canaliculi, which coalesce to form interlobar ducts and then hepatic ducts.
- Hepatic ducts and the cystic duct drain into the bile duct (or common bile duct).
- The common bile duct is present in the lesser omentum, and the free portion is about 5 cm in length. It travels through the duodenal wall as an intramural portion that is 1.5 to 2.0 cm in length, and empties into the major duodenal papilla. The minor pancreatic duct in dogs empties immediately adjacent to the opening of the bile duct at the major duodenal papilla. In cats, the common bile duct and major pancreatic duct join and subsequently enter the duodenum at the major papilla as a common duct.

Preoperative Considerations

- Correct dehydration and serum electrolyte imbalances before surgery.
- If the animal is not already being treated for infection, administer prophylactic antibiotics (directed toward gram-negative and anaerobic bacteria).

▼ ***Key Point*** If the bile duct is totally obstructed, coagulopathy may be present because of decreased absorption of vitamin K, with decreased activity of vitamin K–dependent clotting factors.

- Give vitamin K_1 (AquaMEPHYTON) at 1 to 3 mg/kg divided q12h subcutaneously (SC), 36 hours before surgery if necessary. If immediate surgery is required, give a fresh whole blood transfusion.

Cholecystectomy—Surgical Procedure

Cholecystectomy is indicated for severe diseases of the gallbladder, such as damage to the gallbladder or cystic duct secondary to trauma, severe cholecystitis, gallbladder mucocele, neoplasia, and biliary calculi.

Objectives

- Remove the gallbladder while minimizing trauma to surrounding tissues.
- Prevent leakage of bile to the peritoneal cavity.
- Avoid damage to the remainder of the biliary duct system.

Equipment

- Standard general surgery pack and suture
- Small and large gallbladder forceps and other right-angled forceps
- Hemostatic stainless steel clips
- Sterile cotton-tipped applicators

Technique

1. Prepare the animal as previously described for liver biopsy and hepatic surgery.
2. Isolate the gallbladder from the remainder of the peritoneal cavity with moistened laparotomy sponges.

3. Dissect the gallbladder from the liver by blunt dissection. Sterile cotton-tipped applicators are helpful to separate the gallbladder from the surrounding hepatic tissue. Babcock forceps or stay sutures can be used to manipulate the gallbladder during this dissection.
4. Isolate and double-ligate the cystic duct and cystic artery with absorbable sutures or hemostatic clips.
5. Place gallbladder forceps and incise the cystic duct and artery just distal to the forceps. Remove forceps and gallbladder.
6. Submit the gallbladder for aerobic and anaerobic bacterial culture and histopathology.
7. Close the abdominal incision in a routine fashion.

Cholecystotomy—Surgical Procedure

Cholecystotomy is indicated to remove biliary calculi, to flush the gallbladder of inspissated or infected bile, or to facilitate passing a catheter into the common bile duct to relieve obstruction. The gallbladder should be healthy and have a good blood supply to ensure satisfactory healing. If the gallbladder is infected, inflamed, or necrotic, perform cholecystectomy.

Objectives

- Open and inspect the gallbladder and its contents.
- Avoid spillage of bile into the peritoneal cavity.
- Provide a watertight seal of the cholecystotomy incision using absorbable suture material.
- Submit samples of tissue, calculi, and/or bile for analysis and culture.
- Thoroughly flush the gallbladder and biliary ducts to remove stones and infected material.

Equipment

Equipment is the same as for cholecystectomy plus the following:

- Fine absorbable suture with taper or taper-cut needle (4-0, 5-0 polydioxanone or polyglactin 910).
- Infant feeding tube or small (5-French) Brunswick rubber catheter.

Technique

1. Prepare and position the animal as previously described for liver biopsy and hepatic surgery. The surgical approach is the same as for a cholecystectomy.
2. Isolate the gallbladder from the remainder of the peritoneal cavity with laparotomy sponges.
3. Use stay sutures (5-0 silk) on the gallbladder on each side of the proposed incision.
4. Incise the gallbladder fundus, using a #11 scalpel blade and Metzenbaum or tenotomy scissors. Evacuate the contents and save samples of bile or calculi for analysis and culture.

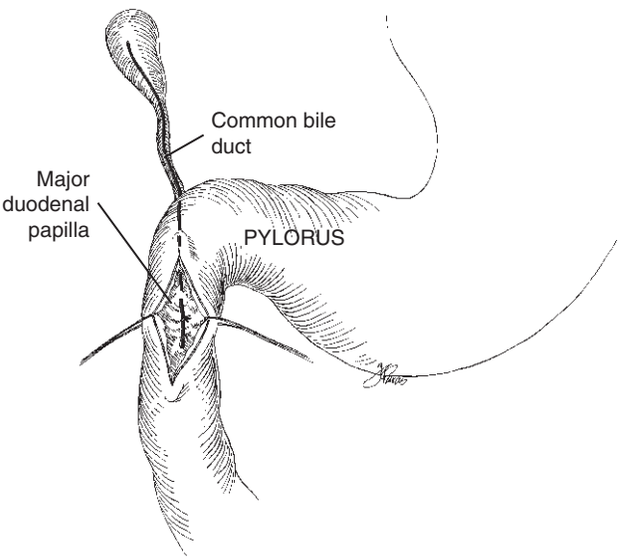

Figure 72-5. Placement of an indwelling stent catheter in the common bile duct. The catheter is placed via a duodenotomy. Insert the catheter retrograde through the major duodenal papilla and into the gallbladder. Leave the end of the catheter in the duodenal lumen and ligate in place with 4-0 or 5-0 catgut; close the duodenotomy incision.

5. Flush the gallbladder with warm, sterile saline.
6. To ensure patency, cannulate and flush the cystic and common bile ducts with an infant feeding tube or 5-French Brunswick catheter.
7. If necessary, perform a duodenotomy approximately 2 to 4 cm distal to the pylorus to pass a catheter retrograde into the common bile duct through the major duodenal papilla. Place a stent catheter if recurrent bile duct obstruction is expected or to stent a ruptured biliary duct (Fig. 72-5) (see more detailed description of stent catheter placement under "Surgical Repair of Traumatic Biliary Rupture").
8. Close the gallbladder incision in a one- or two-layer inverting pattern (e.g., Cushing and/or Lembert), using 4-0 or 5-0 absorbable suture and a taper needle.
9. Close the abdominal incision in a routine manner.

Cholecystoenterostomy—Surgical Procedure

Cholecystoenterostomy is surgical anastomosis of the gallbladder to the intestinal tract. The major objective is to bypass the cystic and common bile ducts when these ducts are irreversibly obstructed. Examples of indications are severe scar tissue in the bile ducts (sequela of cholangitis), non-resectable neoplasia, severe cholangiohepatitis with sludged bile (in cats), and large bile duct calculi that cannot be removed. The gallbladder can be anastomosed to the duodenum (cholecystoduodenostomy) or to the jejunum (cholecystojejunostomy).

Objectives

- Establish flow of bile from the gallbladder directly to the duodenum or jejunum to bypass the cystic and common bile duct.
- Maintain sufficient lumen size to allow free flow of bile from the gallbladder to the intestine.
- Prevent bile or intestinal leakage.
- Provide a tension-free anastomosis.

Equipment

- Equipment is the same as for cholecystotomy.

Technique

1. Prepare and position the animal as previously described for liver biopsy and hepatic surgery. The surgical approach is identical to that for cholecystectomy.
2. Using blunt dissection, gently free the gallbladder from the surrounding liver tissue.
3. Bring a loop of duodenum or jejunum close to the gallbladder and place stay sutures in both structures.
4. Incise the gallbladder along the fundus and the intestine on its antimesenteric surface.
5. Perform a two-layered anastomosis, using absorbable suture (e.g., 4-0 PDS). The inner layer is a simple continuous, full-thickness closure; the outer layer is a Cushing pattern. Make sure the anastomosis is at least 2.5 cm in diameter. This large opening helps prevent sequestration of intestinal contents in the gallbladder that could result in severe cholecystitis and cholangitis.
6. Close the abdominal incision in a routine manner.

Surgical Repair of Traumatic Biliary Rupture

Rupture of the biliary tract causes severe chemical and possibly septic peritonitis. Diagnosis and initial management of animals with bile peritonitis is discussed in Chapter 76. Perform surgical correction of bile leakage promptly because metabolic consequences are serious and life-threatening.

Objectives

- Evaluate the entire liver and biliary tract for evidence of damage.
- Identify the source of bile leakage and control it.
- Treat the peritonitis with copious lavage and abdominal drainage.
- Maintain patency of major biliary pathways.
- Provide nutritional access for hyperalimentation in patients in critical condition.

Equipment

Equipment is the same as for cholecystotomy plus the following:

- Stent tubing (e.g., 5-French Brunswick catheter, infant feeding tube, or Silastic tubing)

Technique

1. The preparation of the animal and surgical approach are the same as for cholecystectomy.
2. Evacuate fluid from the peritoneal cavity.
3. Examine the entire liver and biliary system for evidence of trauma and injury. Examine the remainder of the abdominal organs for abnormalities.
4. Find the source of bile leakage:
   a. If the gallbladder is intact, express it and look for leakage.
   b. If the above is unsuccessful, perform a duodenotomy over the major duodenal papilla and catheterize the common bile duct, using a 5-French Brunswick catheter or infant feeding tube. Flush the bile duct with sterile saline and look for leakage.
5. Correct the leakage.
   a. If the rent is in the gallbladder, perform cholecystectomy. Suture the rent if in a large bile duct. Use fine absorbable suture material (4-0 or 5-0 polydioxanone).
   b. If primary closure is not possible, stent the torn duct by passing a soft catheter up the common bile duct via the major duodenal papilla. Make sure that the end of the catheter is at least 2 to 3 cm proximal to the rent. Secure the catheter to the duodenal mucosa by placing one or two ligatures of 5-0 catgut. Cut the catheter, leaving 2 to 3 cm in the lumen of the duodenum, and close the duodenal incision in a routine manner. In 1 to 2 weeks, the catheter will dislodge and be passed through the intestinal tract. If the catheter has not passed in 3 weeks, remove via endoscopy.
   c. Rupture of small hepatic ducts can be treated by simple ligation of the duct. Collateral biliary ducts should allow for continued flow of bile from that liver lobe.
6. Lavage the abdomen with copious amounts of warm, sterile saline.
7. Close the abdomen routinely.

Postoperative Care and Complications

- Maintain IV fluid therapy until oral intake resumes.
- Monitor for evidence of bile peritonitis: painful abdomen, fever, leukocytosis, icterus, and bile-stained fluid on abdominal tap.
- If cultures from the biliary tract are positive, administer long-term (6 weeks) antibiotic therapy.

▼ ***Key Point*** Mortality associated with bile peritonitis is significantly higher if bacterial contamination is also present.

- Monitor for evidence of pancreatitis; withhold food and water if it occurs (maintain the animal on IV fluids).
- Reevaluate every 3 to 6 months for recurrence of biliary obstruction or ascending infection of the biliary tract after cholecystoenterostomy.

Chapter

73 Diseases and Surgery of the Exocrine Pancreas

Robert G. Sherding / Stephen J. Birchard / Susan E. Johnson

The pancreas is a V-shaped gland in the cranial abdomen composed of an exocrine portion (the acinar cells) and an endocrine portion (the islets of Langerhans). The normal functions of the exocrine pancreas are summarized in Table 73-1. The clinically important disorders of the exocrine pancreas include pancreatitis, exocrine pancreatic insufficiency, and neoplasia. Diseases of the endocrine pancreas are discussed in Chapters 34 and 35.

PANCREATITIS

Pancreatitis is an acute or chronic inflammatory condition of the pancreas that develops when premature intrapancreatic activation of digestive enzymes results in progressive autodigestion of the pancreas. Clinically, pancreatitis can be acute or chronic and mild or severe. The clinical forms of pancreatitis are categorized in Table 73-2.

▼ ***Key Point*** Dogs most frequently develop acute pancreatitis. Cats are more likely to develop chronic pancreatitis.

Etiology and Risk Factors

In most animals with spontaneous pancreatitis, an etiology is not identified and the pathogenesis is poorly defined. Based on clinical associations found in naturally occurring cases and on various experimental models for producing pancreatitis, the following have been implicated as etiologic or predisposing factors:

- ***Nutrition***—Obesity (dogs), long-term intake of high-fat low-protein diet
- ***Hyperlipidemia***—As a result of recent ingestion of a fatty meal, miniature schnauzer hyperlipidemia, lipodystrophy, or endocrinopathy (e.g., hyperadrenocorticism, diabetes mellitus, or hypothyroidism)
- ***Reflux of duodenal contents***—Into the pancreatic duct as bile, fatty acids, activated enzymes, or bacteria
- ***Obstruction of the pancreatic duct or papilla***—As a result of duodenitis, edema, spasm, calculi, neoplasia, metaplasia, or aberrant intestinal parasite migration
- ***Biliary tract disease***—Especially cholangitis in cats
- ***Gastrointestinal disease***—Especially inflammatory bowel disease in cats
- ***Infection***—For example, ascending enteric bacteria, parvovirus, feline infectious peritonitis, *Toxoplasma gondii, Babesia canis,* pancreatic flukes *(Eurytrema procyonis),* or liver flukes *(Amphimerus pseudofelineus)*
- ***Hypercalcemia***—When total serum calcium exceeds 15 mg/dl, as can occur in hypercalcemia of malignancy, hyperparathyroidism, and vitamin D intoxication
- ***Hyperstimulation***—By organophosphate toxicity, cholinergic agonists, scorpion venom, and caerulein (an analogue of cholecystokinin)
- ***Idiosyncratic drug reactions***—Corticosteroids, potassium bromide, L-asparaginase, azathioprine, sulfonamides, etc.
- ***Zinc toxicosis***
- ***Pancreatic trauma***—Abdominal injury, surgery, or lithotripsy
- ***Pancreatic ischemia***—For example, hypovolemia, thrombosis, and gastric dilatation-volvulus
- ***Genetic predisposition***—Miniature schnauzers, etc.

Pathogenesis

Pancreatitis results from the premature intrapancreatic activation of trypsin and other digestive enzymes, resulting in acinar cell necrosis and pancreatic autodigestion.

- Once initiated, amplification and progression of pancreatitis involves factors such as nitric oxide, oxygen-derived free radicals, and various inflammatory mediators, cytokines, and interleukins.
- Severity is enhanced by pancreatic microvascular injury, pancreatic ischemia, systemic inflammatory response, disseminated intravascular coagulation (DIC), and intestinal bacterial translocation (Table 73-3).

▼ ***Key Point*** Intrapancreatic activation of trypsin and other digestive enzymes leads to autodigestion of the pancreas. Impaired pancreatic microcirculation is a key factor in the progression from mild self-limiting pancreatitis to severe necrotizing pancreatitis.

Table 73-1. FUNCTIONS OF THE EXOCRINE PANCREAS

Secretory Products	Functions
Digestive enzymes*	
Trypsins	Protein digestion
Chymotrypsins	Protein digestion
Elastases	Protein digestion
Carboxypeptidases	Protein digestion
Amylase	Polysaccharide digestion
Phospholipase	Lipid digestion
Lipase	Lipid digestion
Colipase	Coenzyme facilitator of lipase
Bicarbonate and water†	Neutralization of gastric acid entering duodenum
Pancreatic trypsin inhibitor	Protection against autodigestion
Pancreatic intrinsic factor	Facilitation of cobalamin (vitamin B_{12}) absorption
Antibacterial proteins	Antibacterial (regulation of small intestinal microflora)
Miscellaneous	Facilitation of zinc absorption
	Trophic effect on intestinal mucosa

*Acinar cells secrete enzymes in response to cholecystokinin, which is released into the blood from the proximal intestine when partially digested food enters the duodenum from the stomach. Proteolytic enzymes are secreted as inactive precursors (zymogens) that are not activated until they enter the intestinal tract. Enteropeptidase from the duodenal mucosa activates trypsinogen to active trypsin; trypsin then activates the other proteases and phospholipase.

†Centroacinar and duct cells produce bicarbonate-rich secretion in response to secretin released into the blood from the proximal intestine when acid enters the duodenum from the stomach.

Table 73-2. CATEGORIES OF PANCREATITIS

Acute Pancreatitis
(abrupt onset, acute episodes may recur)

Mild (Edematous)
Self-limiting
Minimal necrosis and vascular compromise
No multisystemic effects or complications
Uncomplicated recovery

Severe (Hemorrhagic)
Self-perpetuating (progressive)
Extensive necrosis and vascular compromise
Severe complications
Multisystem failure
Guarded prognosis

Chronic Pancreatitis
(may be continuous and "smoldering" or recurrent and episodic)

Mild
Minimal morphologic damage
Absence of complications

Severe
Progressive irreversible destruction of acinar and islet cells
Severe pancreatic fibrosis and atrophy
Complications:
- Exocrine pancreatic insufficiency
- Diabetes mellitus
- Extrahepatic bile duct obstruction

- Natural protective mechanisms against autodigestion involve pancreatic secretory trypsin inhibitor, $alpha_1$-proteinase inhibitor, and alpha-macroglobulins. These become overwhelmed as pancreatitis develops.
- Pathologically, pancreatitis can be categorized as acute edematous, acute necrotizing, acute suppurative, or chronic nonsuppurative. Sequelae include pseudocyst, abscess, fibrosis, and atrophy.

Clinical Signs and Manifestations

Clinical signs of acute pancreatitis are extremely variable, ranging from inapparent to mild to fulminant "acute abdomen" crisis. Signs may be vague, especially in cats. In chronic pancreatitis, episodic signs may correspond to periodic flare-ups of inflammation. In some cases, clinical signs are dominated by secondary complications (e.g., DIC) or sequelae (e.g., diabetes mellitus).

▼ ***Key Point*** The "classic" signs of vomiting and abdominal pain are frequent in dogs with acute pancreatitis but are relatively uncommon in affected cats.

Canine Pancreatitis

Pancreatitis most frequently occurs in middle-aged and older dogs that are overweight. A recent history of dietary indiscretion or a high-fat meal is common.

- Vomiting (90% of severe cases), anorexia (91%), and depression are the most consistent signs.
- Cranial abdominal pain is found in 58% of dogs, varying from mild to intense (manifested as restlessness, panting, trembling, hunched-up abdomen, praying position of relief, seeking of cool surfaces, and pain on palpation).
- Cranial abdominal mass may be palpable in some dogs.
- Dehydration is detected in 50% of dogs.
- Diarrhea (sometimes hemorrhagic) is reported in 33% of dogs.
- Fever is seen in 32% of dogs, usually attributable to the inflammatory response. It does not necessarily imply infection.
- Weakness or, in severe cases, acute collapse from shock may be observed.

Feline Pancreatitis

Cats are more likely to have chronic "smoldering" pancreatitis, manifested by nonspecific signs of lethargy, anorexia, and weight loss, with or without vomiting. Cats with severe acute pancreatitis can have any of the clinical sign seen in dogs, but less consistently.

The reported frequency of clinical signs and physical findings in cats with severe pancreatitis is as follows:

- Lethargy (100% of cases)
- Inappetence (97%)

Table 73-3. FACTORS IN THE PATHOGENESIS OF PANCREATITIS

Factor	Proposed Role in Pathogenesis
Pancreatic Enzymes	
Trypsin	Perpetuation of proteolytic damage of pancreatic tissue (autodigestion)
	Perpetuation of activation of more trypsin and other proteases
	Consumption of plasma protease inhibitors
	Coagulation/fibrinolysis (DIC)
	Activation of kinin system and release of histamine from mast cells, contributing to edema and hemorrhage
Phospholipase A	Cell membrane damage (necrosis, non-cardiogenic pulmonary edema)
	Liberation of toxins (e.g., myocardial effects)
Elastase	Vascular damage (progression of edematous to hemorrhagic pancreatitis)
Chymotrypsin	Activation of xanthine oxidase (generation of oxygen-derived free radicals; see below)
Lipase	Local fat necrosis (peritonitis, "calcium soaps," hypocalcemia)
Inflammatory Mediators	Systemic inflammatory response syndrome
	Vasodilation, hypotension, shock
	Local inflammation and aggregation of leukocytes; peritonitis
Oxygen-Derived Free Radicals	Damage of tissues by disrupting cell membranes through peroxidation of lipids in the membrane
	Endothelial cell injury (pancreatic edema and hemorrhage, DIC)
Coagulation/Fibrinolysis	Disseminated intravascular coagulopathy
	Thrombosis of pancreatic blood vessels
	Ischemic pancreatic necrosis

DIC, disseminated intravascular coagulation.

- Dehydration (92%)
- Hypothermia (68%)
- Icterus (64%)
- Vomiting (35%)
- Abdominal pain (25%)
- Palpable abdominal mass (23%)
- Dyspnea (20%)
- Diarrhea (15%)
- Ataxia (15%)
- Fever (7%)

▼ ***Key Point*** Concurrent inflammatory bowel disease and cholangitis are frequent in cats with pancreatitis. This may be related to the anatomic arrangement of the bile and pancreatic ducts that join and have a common opening into the duodenum in cats.

Acute Complications

Most of the following complications seriously worsen the prognosis in pancreatitis:

- Shock, collapse, and hypothermia (due to hypovolemia and endotoxemia)
- Peritonitis (sterile exudate) and intra-abdominal fat necrosis
- Jaundice (intrahepatic cholestasis, hepatocellular necrosis, biliary obstruction, lipidosis in cats)
- Hepatic lipidosis (in cats)
- Sepsis
- DIC (bleeding, thrombosis, infarction)
- Acute oliguric renal failure
- Intestinal hypomotility (ileus)
- Hypocalcemia (rarely, overt tetany)
- Hyperglycemia (due to hyperglucagonemia and hypoinsulinemia)
- Cardiac arrhythmias (myocardial depressant factors, myocardial ischemia or necrosis)
- Respiratory distress (rarely, non-cardiogenic pulmonary edema or pleural effusion)

Chronic Complications and Sequelae

- ***Pancreatic pseudocysts and abscesses***—Characterized by persistence or recurrence of signs associated with a cavitated pancreatic mass that contains liquefied necrotic debris, which can be sterile (pseudocyst) or infected (abscess)
- ***Chronic relapsing pancreatitis***—Characterized by chronic smoldering disease with periodic flare-ups
- ***End-stage pancreatic fibrosis and atrophy***—Manifested as diabetes mellitus, exocrine pancreatic insufficiency, or both
- ***Liver disease***—Resulting from common bile duct obstruction or concurrent cholangiohepatitis

Diagnosis

The diagnosis of pancreatitis is based on the combination of clinical signs, physical examination, routine laboratory findings, assays for circulating pancreatic enzymes, radiography, ultrasonography, and in some cases, pancreatic biopsy.

Clinical Signs and Physical Findings

- Suspect pancreatitis in animals presented for vomiting, depression, anorexia, and abdominal pain. Most dogs have vomiting, abdominal pain, or both; how-

ever, only 33% of cats have vomiting as a sign and only 25% are painful.
- Nearly 33% of dogs are febrile, compared with only 7% of cats. More than 66% of cats with severe acute pancreatitis are hypothermic.
- Identifiable risk factors increase the index of suspicion (e.g., obesity, recent fatty meal, miniature schnauzer breed, and endocrinopathy).
- A palpable right cranial abdominal mass or fluid suggests a pancreatic lesion.

Hematologic Findings

Dogs

- In dogs with severe pancreatitis, the most frequent findings are neutrophilic leukocytosis (55% of cases), with or without a left shift; thrombocytopenia (59%); and hemoconcentration (dehydration) or anemia (29%).
- Neutropenia with a degenerative left shift occurs occasionally with severe necrosis, peritonitis, sepsis, or endotoxemia.
- Red blood cell (RBC) fragments and macroplatelets are consistent with subclinical DIC.

▼ ***Key Point*** Evaluate hemostasis in pancreatitis dogs with thrombocytopenia that may be developing DIC.

Cats

- In cats with severe pancreatitis, the most frequent findings are anemia (55% of cases) or hemoconcentration (30%) and leukocytosis (30%) or leukopenia (15%).

Routine Serum Chemistries and Urinalysis

Several nonspecific abnormalities may be found on routine serum chemistries:

- Azotemia (increased blood urea nitrogen and creatinine), resulting frequently from dehydration and hypovolemia (prerenal) or occasionally from renal damage and acute oliguric renal failure
- Metabolic acidosis and hypokalemia
- Hypocalcemia (usually subclinical; tetany is rare)

▼ ***Key Point*** Hypokalemia is more common in cats with pancreatitis (50% of cases) than in dogs (5%) and is a negative prognostic indicator.

- Elevated serum liver enzymes (ALT, AST, ALP, GGT) and hyperbilirubinemia, can result from hepatocellular injury (due to ischemia, sepsis, or toxins from the pancreas), biliary obstruction, or concurrent cholangitis (cats).
- Hyperglycemia (usually transient, but some animals are diabetic after recovery)
- Fasting hyperlipemia (hypertriglyceridemia and hypercholesterolemia)
- Urinalysis is usually normal with concentrated specific gravity except in cases complicated by diabetes mellitus (glucosuria) or renal failure (isosthenuria).

▼ ***Key Point*** Because elevated levels of amylase, lipase, blood urea nitrogen, and creatinine are common in both renal failure and pancreatitis, assess urine specific gravity (USG) as a reflection of renal concentrating ability; USG > 1.025 indicates adequate renal function.

Serum Amylase and Lipase

Dogs

Serum amylase and lipase concentrations have traditionally been used as indicators of pancreatic inflammation, but these enzymes lack sensitivity and specificity and thus are only appropriate as aids for the diagnosis of canine pancreatitis. Amylase and lipase are normal in one-third to one-half of dogs with histologically confirmed pancreatitis, and up to one-half of dogs with elevation of one or both enzymes do not actually have pancreatitis. Serum amylase and lipase are frequently increased in non-pancreatic diseases.

- Serum amylase and lipase also originate from non-pancreatic sources and may be increased in many renal, gastrointestinal, liver, and neoplastic diseases.
- Delayed renal clearance of enzymes combined with increased secretion due to hypergastrinemia can cause elevations in azotemic patients.
- Corticosteroids in high doses can cause a significant increase (up to fivefold) in serum lipase in the absence of pancreatitis.
- The magnitude of amylase or lipase elevation does not correlate with the severity of the pancreatitis or the prognosis.

Cats

Serum amylase and lipase do not appear to be diagnostically useful in the cat. Most cats with pancreatitis often have minimal or no increase in amylase or lipase.

Serum Trypsin-Like Immunoreactivity Assay

The serum trypsin-like immunoreactivity (TLI) assay is an exocrine pancreatic function test that detects circulating trypsinogen and trypsin. For normal reference ranges see under "Exocrine Pancreatic Insufficiency."

- Serum TLI may be increased in pancreatitis (>50 µg/L in dogs; >100 µg/L in cats) associated with enzyme leakage from the inflamed pancreas.
- Increased serum TLI has good specificity, but its diagnostic usefulness is limited by its low sensitivity (30–60%). TLI has some value as a diagnostic aid in cats. For the diagnosis of canine pancreatitis, TLI

offers minimal advantage over conventional serum lipase and amylase.

Serum Pancreatic Lipase Immunoreactivity Assay

The serum pancreatic lipase immunoreactivity (PLI) assay is an exocrine pancreatic function test that detects circulating pancreas-specific lipase. For normal reference ranges, see under "Exocrine Pancreatic Insufficiency."

- Increased serum PLI (>200 µg/L in dogs; >12 µg/L in cats) appears to be a sensitive indicator of pancreatitis (82% in dogs; nearly 100% in cats) with specificity of approximately 90%.
- Studies suggest that PLI is not increased by gastritis, chronic renal failure, or corticosteroid therapy.
- PLI requires a 0.5-ml fasting serum sample and is commercially available at the Gastrointestinal Laboratory, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, Texas A&M University, College Station, TX 77843-4474 (website: www.cvm.tamu.edu/gilab).

▼ ***Key Point*** Preliminary studies suggest that the serum pancreatic lipase immunoassay may be the most accurate and reliable diagnostic test available for pancreatitis in dogs and cats.

C-Reactive Protein Assay

C-reactive protein (CRP) concentration is an acute phase reactant produced by the liver in response to inflammation, necrosis, and infection, and is a useful serum marker of systemic inflammation associated with pancreatitis. Canine CRP assays are commercially available (e.g., the gastrointestinal laboratory at Texas A&M; see preceeding section).

- CRP serum level may be an indicator of the severity of pancreatitis.
- CRP may be useful for monitoring response to therapy in dogs with pancreatitis.

Other Pancreatic Function Tests

The following tests have been evaluated as potential indicators of pancreatic inflammation; however, they do not appear to be clinically useful for the diagnosis of pancreatitis in dogs and cats:

- Assay for urine or plasma trypsin activation peptide (TAP)
- Assay for trypsin-alpha$_1$-proteinase inhibitor complexes in plasma
- Plasma protease inhibitor consumption (alpha$_1$-proteinase inhibitor, alpha$_2$-macroglobulin)
- Amylase isoenzyme analysis (for pancreas-specific isoenzyme)
- Assay for serum phospholipase A$_2$

Radiography

Radiography is a useful diagnostic aid for canine pancreatitis and for ruling out other conditions with similar presenting signs.

Dogs

The following radiographic findings are subjective indicators of pancreatitis in dogs but are not present in all cases:

- Increased density and loss of abdominal contrast and detail in the right cranial abdomen (localized peritonitis, ground-glass appearance)
- Displacement of the descending duodenum ventrally and to the right and the pyloric antrum to the left, producing a widened angle or mass effect between the antrum and the duodenum on ventrodorsal radiographs
- Gastric distention and static gas pattern (ileus) in the duodenum and transverse colon
- Delayed passage of barium from the stomach and through the duodenum; also, thickening, corrugation, or spasticity of the duodenum

Thoracic radiography may identify complicating pulmonary edema, pleural effusion, or aspiration pneumonia.

Cats

The abdominal radiographic abnormalities described for dogs are rarely seen in cats with acute pancreatitis. Hepatomegaly and abdominal effusion may be identified in some cats. Thoracic radiography is the same as for dogs.

Ultrasonography

Ultrasonography has high specificity (>85%) but moderate sensitivity (<70%). Detection rates are highest for moderate to severe pancreatitis. The sonographic findings in dogs and cats are similar.

- Pancreatitis is suggested by irregular pancreatic enlargement, decreased or mottled echogenicity of the pancreas, hyperechoic peripancreatic mesentery, and peripancreatic effusion.
- Dilatation of the pancreatic duct, bile ducts, or gallbladder are seen occasionally.

▼ ***Key Point*** Normal radiographic and ultrasonographic evaluations do not rule out pancreatitis, especially in cats.

- Pancreatic pseudocysts and abscesses appear as poorly defined, cavitated pancreatic masses. Consider ultrasound-guided needle aspiration of pseudocysts for diagnosis and therapeutic drainage. Pseudocysts

are more common than abscesses, and serial ultrasound examinations have shown that many pseudocysts resolve spontaneously without complications.

Computed Tomography

Abdominal computed tomography (CT) scanning is not a reliable diagnostic test for pancreatitis in dogs and cats.

Pancreatic Biopsy

Biopsy of the pancreas by laparoscopy or laparotomy can be used for confirming pancreatitis when less invasive diagnostics are equivocal and for staging the histopathologic category (i.e., necrotizing, suppurative, chronic mononuclear with fibrosis, or neoplastic). The pancreas may grossly appear normal in some cases. Take multiple biopsies as the lesions can be patchy in distribution, especially in mild or chronic cases.

Medical Treatment

Mild acute pancreatitis often is self-limiting and may resolve spontaneously in a few days. Severe acute pancreatitis is a life-threatening multisystemic crisis that requires intensive therapy. The goal of treatment is to rest the pancreas, provide supportive care, and control complications as they arise to allow time for the pancreatic inflammation to subside. In addition, identify and correct potential causative factors (see under "Etiology and Risk Factors"). Surgical intervention may be required for pancreatic abscessation or biliary obstruction.

Fluid and Electrolyte Therapy

Use IV fluid therapy to correct dehydration, control hypovolemia, maintain electrolyte balance, and support perfusion of the pancreatic microcirculation.

- For fluid volume replacement and maintenance, administer an IV, balanced crystalloid solution (e.g., lactated Ringer's) in sufficient volume to replace deficits, replace ongoing losses, and meet maintenance requirements (see Chapter 5). To treat shock, give up to 60 to 90 ml/kg IV in the first hour and consider other therapy described in Chapter 156.
- Supplement potassium with 20 to 30 mEq of KCl per liter of maintenance fluids, and adjust according to monitoring of serum potassium.
- Treat hypocalcemia as needed with calcium gluconate IV.
- Acid-base status is unpredictable in pancreatitis. Avoid unnecessary bicarbonate administration that can worsen hypocalcemia.
- Monitor urine output (for oliguria) and respiratory function (for pulmonary edema).
- In hypoproteinemic patients (serum albumin is <2.0 g/dl), consider infusion of colloid solution (hetastarch at a dosage of 10–20 ml/kg q24h IV), plasma, or whole blood (10–20 ml/kg) for maintenance of plasma oncotic pressure (see Chapter 5). Colloid may also enhance pancreatic microcirculation, reduce pancreatic edema, and help prevent secondary renal failure, pulmonary edema, and pleural effusion. Fresh plasma or whole blood also can replace circulating proteinase inhibitors (alpha-macroglobulins) that are consumed in pancreatitis.
- Use glucocorticoids only in patients presented in shock and only short term (one or two doses, as described for treatment of shock in Chapter 156). Glucocorticoids may impair clearance of circulating proteinase-macroglobulin complexes.

Control of Vomiting

For vomiting animals, restrict oral intake until vomiting is controlled.

- Use metoclopramide, chlorpromazine, or ondansetron to control vomiting (see Chapter 67, Table 67-3)
- Control gastric acid secretion with a drug such as famotidine (see Chapter 67, Table 67-3).
- Avoid anticholinergics because they potentiate ileus of the gastrointestinal tract.

Control of Abdominal Pain

- Use rest and confinement to help minimize pain.
- For initial pain relief, use buprenorphine (Buprenex at a dosage of 0.005–0.010 mg/kg SC, IM, or IV q6–12h) or oxymorphone (0.05–0.20 mg/kg SC, IM, or IV q2–6h), beginning at the lower dosage range in cats or with IV use and titrating higher as needed. Transdermal fentanyl patches and other analgesic options can also be used (see Chapter 6 for additional options for pain control).
- Avoid nonsteroidal anti-inflammatory drugs in pancreatitis because of risks of gastrointestinal ulceration and the potential for adverse renal and hepatic effects.
- Oral pancreatic enzyme supplements and insulin have been beneficial for pain relief in humans with chronic pancreatitis, but this effect has not been evaluated in animal patients.

Control of Bacterial Complications

Most animals with pancreatitis do not have bacterial infection, but translocation of enteric bacteria is possible. Potential indications for antibiotics include persistent fever, leukocytosis with left shift, systemic sepsis, aspiration pneumonia, septic peritonitis, pancreatic abscess, or failure to improve with therapy.

- The use of prophylactic antibiotics in pancreatitis is controversial and requires good clinical judgement. For initial routine prevention, administer ampicil-

lin (20 mg/kg q8h IV) or a cephalosporin (e.g., cephalothin or cephazolin) (20 mg/kg q6–8h IV).
- For treatment of suspected or confirmed infections, use ampicillin combined with enrofloxacin (Baytril at 5 mg/kg SC, IM, or PO q12h) or amikacin (Amikin at 5 mg/kg q8h IM or IV). If renal failure is present, adjust the aminoglycoside dosage or choose an alternative antibiotic.

Nutritional Support

- For dogs with pancreatitis, only restrict food intake for as brief a period as possible while vomiting is brought under control (i.e., 48 hours or less). As soon as food is tolerated orally, resume feeding. Use a diet that is moderately restricted in fat and protein.
- Feed cats with pancreatitis whenever possible to prevent hepatic lipidosis.
- Alternatively, use an endoscopically placed jejunostomy tube or other tube feeding strategy (see Chapter 3). Constant-rate infusion of a tube-fed diet may be tolerated even in vomiting animals.
- Use partial parenteral nutrition or total parenteral nutrition only when enteral nutrition fails or when necessary for animals with persistent vomiting.

Inhibition of Pancreatic Secretion

- Pancreatic enzyme secretion is normally stimulated by ingestion of food, particularly fats and proteins. The traditional approach to treating pancreatitis has been to restrict oral intake (nothing per os) to place the pancreas at "physiologic rest." However, this has not been proven to be effective, and evidence suggests that enteral nutrition enhances the speed and rate of recovery from pancreatitis (see under "Nutritional Support").
- The benefits are doubtful for experimental treatments such as glucagon, somatostatin, cholecystokinin inhibitors, and enzyme inhibitors that are intended to suppress pancreatic secretion.

Removal of Activated Enzymes

These measures promote natural plasma antiprotease activity or removal of activated proteases.

- Alpha$_2$-macroglobulin binds circulating activated enzymes for removal by the mononuclear phagocyte system. Fresh frozen plasma (10–20 ml/kg) or whole blood transfusion may benefit patients with fulminant pancreatitis by supplying macroglobulin. It also benefits hypoalbuminemia.
- Avoid glucocorticoids because they may have a detrimental effect on removal of macroglobulin-enzyme complexes.
- Peritoneal lavage using a dialysis catheter can help remove intraperitoneal enzymes, inflammatory mediators, and toxins. Although it is not practical to recommend as a routine method of treatment, it can be beneficial in cases of pancreatitis with abdominal effusion.

Treatment of Acute Complications

Disseminated Intravascular Coagulation

- Prevent by IV fluid therapy to promote perfusion of the microcirculation.
- Treat DIC with heparin (75–150 IU/kg q8h SC) (see Chapter 23).
- Give fresh frozen plasma or whole blood.

Oliguric Renal Failure

- Prevent by vigorous IV fluid therapy to control hypovolemia.
- If oliguria occurs (<1 ml of urine per kilogram per hour), ensure adequate circulatory volume expansion with IV fluids and give furosemide (Lasix at 2 mg/kg IV; repeat once or twice up to 4–6 mg/kg, if necessary). For refractory oliguria, give a constant-rate infusion of dopamine and other measures as described in Chapter 77.

Other Acute Complications

- Control hyperglycemia (if glucose exceeds 300 mg/dl) with short-acting regular crystalline zinc insulin (see Chapter 34).
- Control cardiac arrhythmias if they occur (see Chapters 145 and 146).
- Control non-cardiogenic pulmonary edema if it occurs (see Chapter 162).

Treatment of Chronic Complications and Sequelae

- Surgical intervention is indicated for management of septic peritonitis (see Chapter 76), for drainage or excision of pancreatic abscesses, and for cholecystoduodenostomy (after active pancreatitis is resolved) to relieve persistent biliary obstruction (see Chapter 72).
- Insulin is indicated if persistent hyperglycemia consistent with diabetes mellitus occurs (see Chapter 34).
- Pancreatic enzyme supplementation is indicated for exocrine pancreatic insufficiency (see discussion later in this chapter).
- In cats in endemic areas, diagnose infections caused by pancreatic flukes *(Eurytrema procyonis)* or liver flukes *(Amphimerus pseudofelineus)* by identifying the characteristic single-operculated fluke ova in the feces. Treat with praziquantel (Droncit at 40 mg/kg PO q24h for 3 days), or fenbendazole (Panacur at 50 mg/kg PO q24h for 10–14 days).

Prevention of Recurrences

- Identify and control underlying risk factors (see previous discussion under "Etiology and Risk Factors").
- Feed a fat-restricted diet and avoid fatty "treats."

Surgical Treatment of Pancreatitis

Medical treatment, as outlined in this chapter, is preferred for most animals with pancreatitis. However, surgery may be appropriate in certain patients. The decision to operate on an animal with pancreatitis is very difficult because such patients frequently are poor anesthetic and surgical risks. The surgical procedure may cause the animal's overall condition to worsen. Consider all options and thoroughly discuss the prognosis and potential complications with the owner prior to surgery.

Indications for Surgery

- *Failure to respond to appropriate medical therapy:* Assuming an accurate diagnosis, consider an exploratory laparotomy if the patient's condition deteriorates or does not improve with medical treatment.
- *Presence of a pancreatic abscess or other mass:* Consider surgery if repeated ultrasonographic examinations reveal persistence or enlargement of a pancreatic abscess, pseudocyst, or other mass and if the patient's condition dictates aggressive action.
- *Severe icterus due to extrahepatic biliary obstruction:* As previously discussed, inflammation and tissue swelling associated with pancreatitis can cause biliary obstruction (see Chapter 71). Serial serum chemistries and repeated ultrasonographic examinations are helpful in making this diagnosis and determining trends. If the obstruction and associated icterus do not improve with medical therapy, consider surgical exploration and biliary decompression.
- *Severe pancreatitis and septic peritonitis:* Severe peritonitis may occur with pancreatitis (see Chapter 76). Surgical lavage and drainage may be necessary.

Preoperative Considerations

- Thoroughly assess the animal and review the history and clinical course of events.
- Consider patient factors that may increase the complication rate, such as age, debilitation, sepsis, hypoproteinemia, DIC, diabetes mellitus, and disorders of other organ systems.
- Determine the coagulation status in animals with severe pancreatitis, biliary obstruction, or possible DIC.
- If the animal is not already receiving antibiotics, administer IV antibiotics at or before induction of anesthesia and continue postoperatively if necessary.

Surgical Procedure

Objectives

- Surgically expose the pancreas and determine the type and extent of the disease; remove devitalized tissue.
- Obtain fluid and tissue samples for culture, sensitivity, and histopathology.
- Open, drain, and omentalize pancreatic abscesses or pseudocysts.
- Thoroughly explore the abdominal cavity for evidence of associated lesions or other problems, such as obstruction of the common bile duct.
- Lavage the peritoneal cavity to remove necrotic tissue debris, toxins, enzymes, and exudate.
- Provide abdominal drainage in cases of severe peritonitis.

Equipment

- Standard general surgery pack and suture
- 5 Fr. infant feeding tube or red rubber catheter

Technique

1. Aseptically prepare the ventral abdomen.
2. Perform a standard ventral midline abdominal approach from the xiphoid to the pubis.
3. Expose the right limb of the pancreas by exteriorizing the small intestine and retracting the duodenum ventrally. Expose the left limb of the pancreas by retracting the transverse colon caudally.
4. Carefully and gently examine the pancreas for masses, abscesses, inflammation, and necrosis.
5. Gently break down adhesions and open areas of abscessation digitally to establish ventral drainage. Obtain samples of fluid or tissue for bacterial culture and histopathology. Carefully and judiciously debride necrotic pancreatic tissue and fat. Do not disrupt the pancreatic blood supply during dissection (see Chapter 35 under description of partial pancreatectomy). Minimize trauma to normal or non-necrotic pancreatic tissues. Submit all tissues for histopathology.
6. After draining, flushing, and debriding necrotic tissue, consider omentalization of large pancreatic abscesses or pseudocysts. Grasp the caudal edge of the greater omentum and place it into the abscess cavity. Place several tacking sutures (synthetic absorbable) from the omentum to the edges of the abscess cavity. As in omentalization of prostatic abscesses (see Chapter 85), the omentum will provide increased blood flow and lymphatic drainage and will fill dead space.
7. Carefully examine the gallbladder and biliary ducts for evidence of obstruction.
   a. Gently squeeze the gallbladder to determine if bile is expressible through the common bile duct.
   b. Consider retrograde catheterization of the common bile duct, using an infant feeding tube or red rubber catheter, if complete obstruction is suspected. A stent catheter can be left in the common bile duct if necessary (see Chapter 72). This procedure is somewhat risky because a duodenotomy is necessary and duodenal healing may be impaired by the severe local inflammation created by the pancreatitis. Close the duodenal

incision routinely, and place an omental patch over the incision.
8. Thoroughly lavage the peritoneal cavity with warm sterile saline.
9. Establish abdominal drainage by placing closed suction drains (e.g., Jackson-Pratt) or, in animals with severe peritonitis, by leaving the abdomen open (see Chapter 76). Otherwise, close the abdomen routinely.

Postoperative Care and Complications

- Maintain all aspects of medical therapy for pancreatitis (see previous discussion in this chapter). Consider plasma transfusions or IV colloids for hypoproteinemia (see Chapter 5) and whole blood transfusions for postoperative anemia (packed cell volume < 20%).
- See Chapter 35 for postoperative care of the partial pancreatectomy patient.
- See Chapter 76 for postoperative care of peritonitis.
- Consider total parenteral nutrition for animals with severe pancreatitis and open abdominal drainage (see Chapter 3).
- See under "Medical Treatment" in this chapter for dietary recommendations.
- Complications include septic shock, hypoproteinemia, worsening of pancreatitis and peritonitis, abdominal pain, and dehiscence of intestinal incisions.

Prognosis

Although most patients recover, pancreatitis is a life-threatening disease that frequently has a prolonged and unpredictable clinical course; thus, a guarded prognosis is warranted. The prognosis is poor when pancreatitis is complicated by septic shock, DIC, acute renal failure, or bowel infarction.

EXOCRINE PANCREATIC INSUFFICIENCY

Exocrine pancreatic insufficiency (EPI) occurs when 90% or more of pancreatic secretory capacity is lost. The key functions of the exocrine pancreas (see Table 73-1) that fail in EPI include the following:

- Secretion of enzymes for digestion of carbohydrate, protein, and fat
- Secretion of bicarbonate for neutralization of gastric acid entering the duodenum
- Secretion of pancreatic intrinsic factor for facilitating the intestinal absorption of cobalamin in the ileum
- Secretion of antibacterial proteins for regulation of the intestinal microflora

The results are maldigestion of nutrients, acid injury to the duodenal mucosa, deficiency of cobalamin and fat-soluble vitamins, and overgrowth of small intestinal bacterial flora. Clinically, these are manifested as chronic diarrhea, weight loss, and malnutrition.

Etiology

EPI results from severe irreversible loss of pancreatic acinar cells caused by atrophy, inflammation, hypoplasia, or neoplasia. Canine pancreatic acinar cell atrophy is by far most common. Chronic pancreatitis occasionally causes EPI in both dogs and cats. Rarely, EPI is associated with pancreatic hypoplasia in puppies or pancreatic adenocarcinoma in older dogs and cats (see the next section).

Pancreatic Acinar Atrophy

The most common cause of EPI is degenerative pancreatic acinar atrophy (PAA) of young dogs. The progressive loss of acinar tissue results in nearly total absence of digestive enzyme secretion. The endocrine part of the pancreas is spared.

- Many breeds can be affected, especially large breeds. The highest prevalence is in the German shepherd and rough-coated collie, breeds in which the predisposition to PAA appears to be inherited as an autosomal recessive trait.
- Studies in German shepherds suggest that PAA may be the end stage of autoimmune-mediated atrophic lymphocytic pancreatitis. Infiltration of cytotoxic T lymphocytes in the early preclinical stages has been demonstrated.

Chronic Pancreatitis

The end stage of progressive inflammatory destruction of the pancreas is fibrosis and atrophy, which can result in EPI. In addition to exocrine failure, substantial islet destruction can affect endocrine function, resulting in concurrent diabetes mellitus.

- Any breed of dog can be affected, but most are smaller breeds and are middle age or older.
- Chronic pancreatitis is the most common cause of EPI in cats.

Clinical Signs

Chronic small bowel diarrhea and weight loss are the most consistent clinical signs.

- PAA can occur at any age, but typically the onset of signs is prior to 4 years of age. Pancreatitis-associated EPI can occur at any age but most often is recognized in middle-aged and older dogs.
- Diarrhea in EPI is related to nutrient maldigestion and malabsorption and is characterized by large volumes of soft, semiformed, or unformed feces. The soft voluminous feces are also pale, fatty, and rancid-smelling. The owner may describe improvement with fasting or feeding of a highly digestible or fat-restricted diet, suggesting a malabsorptive process.

Table 73-4. NORMAL VALUES FOR PANCREATIC FUNCTION TESTS

Function Test	Canine	Feline
Serum TLI assay*	5–35 µg/L	12–82 µg/L
Serum PLI assay*	2.2–102 µg/L	2.0–6.8 µg/L
Fecal proteolytic activity (radial enzyme diffusion)* (3-day mean)	6–24 mm	6–17 mm
Fecal proteolytic activity (azocasein hydrolysis) (3-day mean)	19–200 ACU/g	29–207 ACU/g
Fecal elastase activity (ELISA)	>20 µg/g	
Serum cobalamin*	249–733 ng/L	290–1500 ng/L

*Available as mail-in test through Gastrointestinal Laboratory, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, Texas A&M University, College Station, TX, www.cvm.tamu.edu/gilab.
ACU, azocasein unit; ELISA, enzyme-linked immunosorbent assay; PABA, para-aminobenzoic acid; PLI, pancreatic lipase immunoreactivity; TLI, trypsin-like immunoreactivity.

- Weight loss or failure to gain weight occur despite a ravenous appetite and increased food intake. Intense hunger may cause pica and coprophagia in some dogs.
- Borborygmus and severe flatulence are common.
- The haircoat is often dull and poor in quality, with excessive shedding. Greasy soiling of hair around the perineum is often noted.
- There may be a history of recurring signs of pancreatitis when this is the underlying cause of EPI (see the prior section).

Diagnosis

The presenting signs of diarrhea and weight loss are nonspecific; thus, EPI must be differentiated from other causes of intestinal malabsorption and chronic small bowel diarrhea (see Chapter 69).

In EPI, routine hematology, serum chemistries, urinalysis, and radiographs are generally unremarkable. Serum amylase and lipase remain in the normal range because of non-pancreatic sources of these enzymes. The diagnosis of EPI is based on pancreatic function tests.

Serum Trypsin-Like Immunoreactivity Assay

The species-specific serum TLI assays are highly sensitive and specific pancreatic function tests for the diagnosis of EPI in both dogs and cats. The TLI measures total circulating trypsinogen and trypsin in a single fasted (8–12 hours) serum sample. TLI is readily available on a mail-out basis at reference veterinary laboratories (see Table 73-4).

▼ ***Key Point*** The serum TLI assay is the diagnostic test of choice for confirmation of EPI.

- In dogs with EPI, serum canine TLI is <2.5 µg/L (normal, 5–35 µg/L).
- In dogs with partial or early EPI, canine TLI is 2.5 to 5 µg/L.
- In cats with EPI, serum feline TLI is <8 µg/L (normal, 12–49 µg/L).
- The TLI assay is not affected by intestinal disease.
- Impaired renal elimination of trypsinogen may elevate TLI in renal failure patients.

Serum Pancreatic Lipase Immunoreactivity

The serum PLI assay is an exocrine pancreatic function test that detects circulating pancreas-specific lipase (see Table 73-4). The PLI test is more sensitive and specific than the TLI assay for diagnosing acute pancreatitis (see under "Pancreatitis"); however, the TLI test is more accurate and is preferred over PLI for the diagnosis of EPI.

Fecal Proteolytic Activity

Semiquantitative assays of fecal proteolytic activity by azocasein hydrolysis or radial enzyme diffusion are indirect methods of evaluating pancreatic function.

- Because the serum TLI assay is more accurate, reliable, and practical, TLI has replaced fecal proteolytic assays for diagnosis of EPI in both dogs and cats.
- Collect fecal specimens on each of 3 consecutive days because of daily variation. Freeze samples immediately for shipment to the laboratory. Fecal proteolytic activity is abnormally low in EPI (see Table 73-4).

Fecal Elastase Activity

Pancreas-specific elastase has been measured by fecal enzyme-linked immunosorbent assay as an indicator of exocrine pancreatic function in dogs.

- A single fecal sample is usually adequate, although low activity is occasionally found in normal dogs, as well as EPI dogs (see Table 73-4).
- Fecal elastase <10 µg/g is consistent with EPI and >20 µg/g has good predictive value for ruling out EPI. This test is not widely available.

Serum Cobalamin

Serum cobalamin (vitamin B_{12}) reflects pancreatic secretion of intrinsic factor, intestinal absorptive function, and status of the intestinal microflora.

- Serum cobalamin is frequently decreased in both dogs and cats with EPI, presumably due to the lack of pancreatic intrinsic factor combined with increased uptake by the overabundant intestinal bacterial flora. For normal values, see Table 73-4.
- Cobalamin deficiency is a nonspecific finding that also is common in chronic intestinal disease.

Treatment

Successful treatment of EPI requires lifelong pancreatic enzyme replacement. Dietary modification and adjunctive treatment with cobalamin, fat-soluble vitamins, antibiotics, and antacids are beneficial in some cases.

Immunosuppressive therapy directed toward the autoimmune pathogenesis of PAA in German shepherds has shown questionable benefit and is not recommended.

Pancreatic Enzyme Replacement

For best results, use dried, powdered porcine pancreatic extracts (e.g., Viokase-V [Fort Dodge], Pancrezyme [Virbac], or PancreVed [Vedco]). Bioavailability of other commercially available forms varies widely. Tablets, capsules, and enteric-coated formulations are less effective.

- For dogs, add 1 to 2 tsp of powdered pancreatic extract per meal to the food just prior to feeding and divide the daily food intake into two to three meals per day. For cats, give 0.5 tsp per meal. Moisten dry food with water.
- When the diarrhea is in remission and the animal is gaining weight, titrate to the minimum effective maintenance dose (1 tsp added to each of two meals daily is adequate for most dogs).
- Rarely, oral bleeding and irritation results from powdered enzyme supplementation. This adverse effect is dose dependent and resolves with a decrease in dosage.
- Chopped raw beef or pork pancreas (50–100 g per meal) has been used successfully to treat dogs with EPI, as an alternative to pharmaceutical extracts; however, this should be a last resort because of the risks of transmitting food-borne and zoonotic diseases (campylobacteriosis, salmonellosis, etc.).
- In cats that refuse food with commercial pancreatic extracts, chopped raw bovine pancreas (1–2 oz with each meal) has been used. A supply of raw pancreas can be stored frozen and can retain enzyme activity for several months.

▼ ***Key Point*** The effectiveness of enzyme supplementation is not increased by concurrent use of sodium bicarbonate, bile acids, or preincubation of enzymes with the food prior to feeding. Enteric-coated enzymes, capsules, and uncrushed tablets are less effective than powdered pancreatic extracts.

Diet Modification and Vitamins

- Most dogs with EPI can be fed an ordinary maintenance diet; however, if the response to enzyme supplementation is incomplete, consider substituting a diet that is highly digestible, low in fiber, and mildly restricted in fat.
- Consider daily use of a multivitamin supplement that contains the fat-soluble vitamins (A, D, E, and K). In dogs, vitamin E (tocopherol) may be severely depleted; thus, give vitamin E at 400 units PO daily for the first month.
- Cobalamin (vitamin B_{12}) deficiency is common in dogs and cats with EPI; thus, determine serum cobalamin levels at the start of treatment (see Table 73-4). Give deficient dogs cobalamin at a dosage of 250 to 500 µg SC weekly for 6 to 8 weeks, and give cats cobalamin at a dosage of 100 to 250 µg SC weekly for 6 to 8 weeks.
- Folate deficiency and vitamin K–responsive coagulopathies have been reported in cats with EPI.

What to Do if There Is Failure to Respond

1. Evaluate serum cobalamin and treat if too low. Severe cobalamin deficiency can cause intestinal malabsorption and may explain persistent diarrhea. Also evaluate serum folate.
2. Modify the diet and the enzyme brand, form, and dosage according to the above recommendations; if there is no response, go to step 3.
3. Administer antibiotics (e.g., doxycycline, metronidazole, or tylosin) for small intestinal bacterial overgrowth (see Chapter 69). If there is no response, go to step 4.
4. Administer an oral H_2 receptor blocker with meals, such as famotidine (Pepcid) (0.5–1 mg/kg PO q12h), to reduce acidic inactivation of enzymes. These reduce activity of gastric lipase and may not be effective for improving overall digestion. If there is no response, go to step 5.
5. Reassess the diagnosis and evaluate for intestinal mucosal disease via endoscopic biopsy.

PANCREATIC NEOPLASIA

Pancreatic neoplasms can be hormone-secreting tumors that arise from islet cells (insulinoma and gastrinoma are discussed in Chapter 35), or they can arise from the exocrine pancreas as adenomas or adenocarcinomas of acinar or duct cell origin. Pancreatic tumors occur most frequently in older dogs and cats (>9 years of age).

- Benign exocrine pancreatic adenomas are rare, well-encapsulated tumors that are usually incidental findings and are not associated with clinical signs.
- Exocrine pancreatic adenocarcinomas are more common and are discussed here. These are highly aggressive malignancies that metastasize early to the liver, regional lymph nodes, mesentery, duodenum, stomach, and occasionally lungs, often prior to the onset of clinical signs.

▼ ***Key Point*** Multifocal nodular hyperplasia of the pancreas is a common incidental finding in older dogs and cats. It does not affect pancreatic function or cause clinical signs. No treatment is necessary.

Clinical Signs

Pancreatic adenocarcinoma is usually in the advanced stages by the time presenting clinical signs develop.

- Clinical signs are usually insidious and nonspecific, often resembling chronic pancreatitis. Vomiting, anorexia, weight loss, depression, and abdominal pain are usually noted first.
- Bile duct obstruction or extensive liver metastases may lead to obstructive jaundice.
- Duodenal invasion and obstruction may lead to persistent intractable vomiting.
- Peritoneal carcinomatosis may lead to abdominal effusion.
- Pancreatic carcinoma in cats has been associated with paraneoplastic alopecia primarily involving the ventrum and legs, with hyperkeratosis, exfoliation, and painful footpad lesions.

Diagnosis

Suspect pancreatic adenocarcinoma in animals with progressive signs resembling chronic pancreatitis or obstructive jaundice, especially when a right cranial abdominal mass is identified by palpation or abdominal radiography or ultrasonography.

- Serum bilirubin and liver enzymes usually are elevated. Serum pancreatic enzymes may be increased. Tumor production of lipase and extreme hyperlipasemia have been associated with pancreatic and hepatic neoplasia in dogs.
- Cytology of abdominal effusion or fine-needle aspirates of the tumor mass are diagnostic in about 25% of cases but more often are inconclusive.
- In most cases, use exploratory laparotomy and surgical biopsy for definitive diagnosis and staging. Alternatively, use laparoscopic or ultrasound-guided needle biopsies. Because chronic pancreatitis and pancreatic adenocarcinoma can have a similar gross appearance, histopathologic evaluation is necessary.

Treatment and Prognosis

Attempted surgical resection (pancreatectomy) (see Chapter 35) is sometimes palliative (e.g., for relief of bile duct or duodenal obstruction); however, in most cases surgery is not beneficial and is virtually never curative. Adjunctive chemotherapy has little or no benefit. The prognosis is grave.

Chapter

74 Constipation and Anorectal Diseases

Robert G. Sherding

The presenting signs of anorectal disease can include any of the following: dyschezia, hematochezia, constipation, anal discomfort (licking, scooting), ribbon-like feces, fecal incontinence, anal discharge, malodorous perineum, matting of perianal hair, and perianal dermatitis. Physical examination establishes the diagnosis of anorectal disease in most cases. In many anorectal diseases, surgery is required for effective treatment (see Chapter 75).

CONSTIPATION

Constipation is a clinical sign characterized by absent, infrequent, or difficult defecation associated with retention of feces within the colon and rectum. When feces are retained for a prolonged period of time, they become progressively harder and drier and, eventually, become impacted as the mucosa continues to absorb water from the fecal mass. Terms associated with constipation are defined below:

- ***Obstipation***—A condition of intractable constipation in which the colon and rectum become so impacted with excessively hard feces that defecation cannot occur.
- ***Megacolon***—A condition in which the colon becomes extremely and irreversibly dilated and hypomotile. Megacolon occurs most frequently in cats with idiopathic smooth muscle dysfunction that leads to severe colonic dilation, recurrent constipation, and obstipation. Megacolon also can occur in both dogs and cats secondary to chronic colorectal obstruction.
- ***Dyschezia***—A clinical sign often associated with constipation, characterized by difficult or painful evacuation of feces from the rectum and usually associated with lesions in or near the anal region.
- ***Tenesmus***—A clinical sign characterized by straining to defecate, usually ineffectively or painfully; thus, it often accompanies dyschezia.

Etiology

Underlying causes and predisposing factors for constipation are listed in Table 74-1 and include dietary factors, environmental factors, painful defecation, anorectal or colonic obstruction, neuromuscular diseases, fluid and electrolyte disturbances, and drug-related effects.

Ingestion of Foreign Material

Ingested foreign material, such as indigestible fibrous material (especially hair in cats from their grooming behavior) and abrasives (especially bones in dogs), may become incorporated in the fecal mass and result in the formation of hard fecal impactions that are difficult and painful to evacuate from the colon.

Environmental Conditions

Environmental conditions that are not conducive to defecation or that vary from the daily routine to which a pet is accustomed may cause the pet to inhibit the urge to defecate, leading to constipation. This occurs, for example, when the pet is kept in strange surroundings, such as in a kennel or veterinary hospital, or when its daily outdoor exercise routine is changed. Indoor cats may suppress the urge to defecate when their litter box is too dirty or there is territorial competition with other cats in the household.

Painful Defecation

Painful anorectal diseases (anal sacculitis, perianal fistulas) and painful orthopedic disorders that limit positioning for defecation (diseases of the pelvis, spine, or hips) may result in voluntary inhibition of defecation and lead to constipation.

Rectocolonic Obstruction

Anorectal or colonic obstruction that mechanically impedes the passage of feces may result from intraluminal causes, such as foreign bodies, perineal hernia, and stenosing neoplastic or inflammatory lesions, or from extraluminal causes, such as prostatic enlargement, paraprostatic cysts, compressive pelvic fractures, perianal tumors, and pseudocoprostasis (feces matted in perianal hair).

Neuromuscular Disease

Neuromuscular disorders may lead to constipation by interfering with colonic innervation or smooth muscle

Table 74-1. CLASSIFICATION AND CAUSES OF CONSTIPATION

Category	Cause
Dietary factors	Ingested foreign material mixed with feces (hair, bones, cloth, garbage, cat litter, stones, wood, plant material) Inadequate water intake
Environmental/psychological factors	Dirty litter box Prolonged inactivity Confinement (hospitalization, boarding) Change in habitat or daily routine
Painful defecation	Anorectal disorders Anal sac impaction, infection, or abscess Anorectal stricture, tumor, or foreign body Myiasis Perianal fistulae Perianal bite wound cellulitis or abscess Pseudocoprostasis Orthopedic disorders Spinal disease or injury Injuries of the pelvis, hip joints, or pelvic limbs
Rectocolonic obstruction	Extramural Prostatic hypertrophy, tumor, abscess, or prostatitis Paraprostatic cyst Pelvic fracture (malunion) Pelvic collapse due to nutritional bone disease Perianal tumor Pseudocoprostasis Intramural or intraluminal Rectocolonic stricture, tumor, or foreign body Perineal hernia or rectal diverticulum Rectal prolapse Fecalith
Neuromuscular dysfunction	Lumbosacral spinal cord disease (injury, deformity, degeneration, neoplasia) Bilateral pelvic nerve injury Dysautonomia (Key-Gaskell syndrome) Hypothyroidism Idiopathic megacolon
Fluid and electrolyte abnormalities	Dehydration (e.g., chronic renal disease) Hypokalemia Hypercalcemia (hyperparathyroidism, etc.)
Drug-induced effects	Anticholinergics Adrenergic antagonists Calcium channel blockers Phenothiazines and benzodiazepines Opiates and opioids Diuretics Antihistamines Aluminum hydroxide antacids Sucralfate Kaolin-pectin Barium sulfate Iron Laxatives (abuse or chronic overuse)

function or with the ability of the animal to assume the normal defecation stance. For example, this may occur in association with disease or injury of the lumbosacral spinal cord (canine intervertebral disc disease), spinal deformity (e.g., Manx cats), endocrine disease (hypothyroidism), and dysautonomia, a progressive fatal autonomic polyneuropathy. When innervation of the anus is also impaired, fecal incontinence may be an associated clinical sign.

The pathogenesis of idiopathic megacolon involves a primary or secondary dysfunction of colonic smooth muscle (see later under "Megacolon").

Fluid and Electrolyte Disorders

Dehydration can cause the feces to become excessively dry and hard, predisposing the animal to constipation. Hypokalemia and hypercalcemia can impair colonic

smooth muscle function. A combination of these may explain the frequent constipation seen in chronic renal failure, especially in cats.

Drug-Related Constipation

Drug-induced constipation may be a side effect of motility-modifying drugs (anticholinergics, opiates, loperamide), antihistamines, barium sulfate, aluminum hydroxide, and diuretics.

Clinical Signs

- ***Reduced or absent defecation:*** Constipated animals are usually presented because of failure to defecate over a period of days. The owner may notice tenesmus or frequent attempts to defecate with little or no passage of feces. Constipation tends to be a recurrent problem in some patients, especially in cats.
- ***Dyschezia:*** Difficult or painful defecation usually indicates anorectal disease. The animal first may cry out as it attempts to defecate, usually with straining (tenesmus) during the attempt; then it may cease the effort, walk around anxiously, and repeatedly try again.
- ***Abdominal discomfort:*** Constipated animals may develop a hunched-up appearance.
- ***Paradoxical diarrhea:*** Mucosal irritation caused by impacted feces may provoke a secretion of fluid and mucus, which passes around the retained fecal mass and is expelled paradoxically as diarrhea during attempts to defecate.
- ***Other signs:*** Prolonged constipation may lead to anorexia, weight loss, lethargy, vomiting, and dehydration.

Diagnosis

▼ ***Key Point*** The presence of constipation usually is determined from the history and confirmed by rectal and abdominal palpation of colonic distention with hard, impacted feces. The goal of diagnosis is to identify predisposing factors (see Table 74-1).

- Use abdominal radiography to confirm constipation, assess the degree of colonic impaction with feces, and identify megacolon.
- Depending on severity and clinical signs, consider serum chemistries, neurologic examination, neurodiagnostics, abdominal ultrasonography, contrast barium enema radiography, and colonoscopy to identify underlying causes of constipation or predisposing factors. Diagnostics are indicated when constipation is recurrent.

History

Question the owner to identify the potential dietary, environmental, behavioral, psychological, and medication-related factors or predispositions listed in Table 74-1.

Physical Examination

- Perform a digital anorectal examination to detect painful or obstructive lesions of the anorectal area and pelvic canal. Sedation may be required.
- Evaluate the pelvic limbs, coxofemoral joints, pelvis, and lumbosacral spine for orthopedic problems that could cause painful defecation or difficulty maneuvering into position for defecation.
- Perform a neurologic examination (see Chapter 125) to identify underlying neurologic deficits that may be involved in causing constipation.
- In cats with constipation caused by dysautonomia (Key-Gaskell syndrome), additional manifestations of progressive autonomic failure that may be seen include urinary and fecal incontinence, megaesophagus, bradycardia, mydriasis, decreased lacrimation, and prolapse of the nictitating membranes.

Routine Laboratory Evaluations

Perform a serum biochemical profile, urinalysis, and complete blood count (CBC) in animals with recurrent constipation or during an episode of severe obstipation.

- This may identify underlying systemic disease that could cause constipation related to dehydration or electrolyte disturbances (e.g., chronic renal failure).
- In severely obstipated animals, especially those that are vomiting and depressed, this detects the metabolic consequences of prolonged fecal retention (e.g., fluid and electrolyte imbalances, endotoxemia, and azotemia) and guides supportive treatment.

Abdominal Radiography

Perform abdominal radiography to determine the following:

- Confirm the extent of colonic impaction with densely packed feces
- Identify the extreme dilation of the colon that indicates megacolon
- Identify radiopaque foreign material (e.g., bone chips) in the retained feces that indicates a dietary cause of constipation
- Identify pelvic, coxofemoral, or spinal lesions that can cause constipation
- Identify underlying prostatic enlargement that might cause constipation

Other Diagnostic Evaluations

These diagnostics may be warranted in selected patients with recurrent constipation:

- ***Thyroid function testing***—Evaluate thyroid function in dogs with recurrent constipation and other signs compatible with hypothyroidism (see Chapter 31).

- ***Abdominal ultrasonography***—Use this to evaluate the urogenital tract when prostatic disease, paraprostatic cyst, or pelvic canal neoplasia is suspected.
- ***Barium enema contrast radiography***—Use this to evaluate the lumen of the colon when an intraluminal obstructive lesion is suspected (e.g., rectal stricture or neoplasia).
- ***Colonoscopy***—Use this to evaluate the lumen of the colon after all retained feces have been removed.
- ***Neurodiagnostic evaluations***—Use myelography, magnetic resonance imaging (MRI), electromyography, and nerve conduction studies to evaluate the lumbosacral spinal cord and spinal nerves in selected patients in which impaired anorectal innervation is suspected (see Chapter 125).

Treatment Overview

Simple constipation with mild to moderate impaction of feces and without systemic signs (depression, vomiting, dehydration) can be managed on an outpatient basis using rectal suppositories or oral laxatives combined with dietary modification and measures to enhance water intake. Oral laxatives can be prescribed (see a later section) and the patient can be reevaluated after 48 hours.

Severe constipation and obstipation may initially require evacuation of impacted feces from the colon (using enemas, manual extraction, or both) with correction of complicating dehydration and electrolyte imbalances.

- The subsequent goals of therapy are to eliminate or control any of the underlying causes of constipation (see Table 74-1) that are identified and to prevent recurrences using dietary modification, laxatives, and promotility agents as needed.
- Surgical correction is required for obstructing neoplasms, strictures, pelvic malunions, and anorectal diseases.
- Subtotal colectomy is often the most effective way to manage cats with advanced megacolon and recurrent obstipation that are unresponsive to medical therapy (see Chapter 70).

Initial Relief of Constipation

Use rectal suppositories, enemas, or manual extraction under anesthesia to initially relieve constipation.

Rectal Suppositories

To promote defecation in patients with mild constipation, give one to three pediatric rectal suppositories of docusate, glycerin, or bisacodyl. Rectal suppositories can be used alone or in combination with an oral laxative (Table 74-2). Pet and owner compliance are often limiting factors with suppositories.

- Docusate rectal suppository: An emollient (stool softener) laxative
- Glycerin: A lubricant laxative
- Bisacodyl: A stimulant laxative

Enema Therapy

Enema solutions are used to soften hard, impacted feces and promote evacuation. Warm the enema solution prior to instillation and use a lubricated rubber catheter or feeding tube to administer the calculated dose slowly so as not to induce vomiting. Commonly used enema solutions (see Table 74-2) include the following:

- Warm isotonic saline or tap water (5–10 ml/kg of body weight)
- Lactulose as an osmotic stool softener
- Docusate as an emollient (stool softener)
- Mineral oil as a lubricant

▼ ***Key Point*** Do not mix mineral oil and docusate. Docusate promotes mucosal absorption of mineral oil, and mineral oil coats the feces, preventing the emollient effect of docusate.

- Sodium phosphate solution, which has softening, bulk-producing, and irritant effects, can only be used in medium-sized and large dogs with normal hydration and renal function

▼ ***Key Point*** Caution! Never use phosphate enemas in cats or small dogs because of life-threatening hypernatremia, hyperosmolality, hyperphosphatemia, and hypocalcemia.

Manual Extraction of Impacted Feces

In severe constipation or obstipation, restore fluid and electrolyte balance parenterally and evacuate the colon manually under general anesthesia with endotracheal tube in place.

- Use colonic irrigation with warm isotonic saline as an enema solution to soften the impacted feces.
- Extract retained fecal masses by gentle transabdominal manipulation to milk the feces into the distal rectum for digital or forceps removal (using a sponge or whelping forceps).
- To avoid excessive bowel trauma in animals with extensive fecal impaction, it may be advisable to evacuate the colon manually in stages over 2 to 3 days.

Oral Laxative Therapy

Oral laxative medications and dietary supplements can be prescribed as needed for control of constipation and to prevent recurrences (Table 74-2). Laxatives lubricate feces, promote water penetration to soften feces, enhance intestinal mucosal fluid and electrolyte transport, or stimulate colonic propulsive motility. They are classified by their properties and mechanisms of action as bulk forming, lubricant, emollient, osmotic, stimulant, or promotility.

Table 74-2. LAXATIVE THERAPY FOR CONSTIPATION

Treatment	Product (Manufacturer)	Dosage Regimen
Oral Laxatives		
Bulk-Forming Laxatives		
Psyllium	Metamucil (Searle)	1–5 tsp daily with food
Unprocessed whole grain and bran cereal	Fiber One (General Mills) and others	1–5 tbsp daily with food
Canned pumpkin	Pie filling (Libby)	1–5 tbsp daily with food
Commercial high-fiber diet	Many	Use as daily food source
Lubricant Laxatives		
White petrolatum	Laxatone (Evsco)	1–5 ml daily PO
Mineral oil*	Many	Not recommended
Emollient Laxatives		
Docusate sodium	Colace (Shire)	Cat: 50 mg daily PO Dog: 50–200 mg daily PO
Docusate calcium	Surfak (Geneva)	Cat: 50–100 mg daily PO Dog: 100–240 mg daily PO
Osmotic Laxatives		
Lactulose	Duphalac Syrup (Reid-Powell), Cephulac (Marion Merrell Dow)	0.5–1.0 ml/kg q8–12h PO
Magnesium hydroxide	Phillips Milk of Magnesia (Glenbrook)	2–8 tablets daily PO
Polyethylene glycol and electrolytes†	Colyte (Schwarz), GoLytely (Braintree)	25–40 ml/kg PO, repeat in 2–4 hours (for bowel prep)
Stimulant Laxatives		
Bisacodyl	Dulcolax (Boehringer Ingelheim)	Cat: 5 mg daily PO Dog: 5–20 mg daily PO
Senna	Senokot (Purdue Frederick)	1–4 tablets q12–24h PO
Castor oil†	Many	5–30 ml PO (bowel prep)
Promotility Drugs		
Cisapride	Compounded pharmaceutical	Cat: 1.0 mg/kg q8h or 1.5 mg/kg q12h PO Dog: 0.25–0.5 mg/kg q8–12h PO
Tegaserod	Zelnorm (Novartis)	0.05–0.1 mg/kg q12h PO
Ranitidine	Zantac (Glaxo)	Cat: 3.5 mg/kg q12h PO Dog: 2.0 mg/kg q12h PO
Nizatidine	Axid (Eli Lilly)	2.5 mg/kg q24h PO
Rectal Suppositories		
Glycerin	Many	1–3 pediatric
Docusate sodium	Colace (Shire)	1–3 pediatric
Bisacodyl	Dulcolax (Boehringer Ingelheim)	1–3 pediatric
Enemas		
Isotonic saline solution (or tap water)		5–10 ml/kg
Lactulose	Duphaloc, Cephulac (see above)	5–30 ml
Docusate sodium	Colace (Shire)	5–30 ml
Mineral oil	Many	5–30 ml or 1–2 ml/kg
Sodium phosphate‡	Fleet Children's Enema (Fleet)	1–2 ml/kg or 1 enema unit
Bisacodyl	Fleet Bisacodyl Enema (Fleet)	1–2 ml/kg or 1 enema unit

**Caution:* May cause lipid aspiration pneumonia and may interfere with absorption of fat-soluble vitamins; combination with docusate may cause undesirable absorption of mineral oil.
†Used mainly to prepare the colon for radiography or endoscopy.
‡Do *not* use in cats or small dogs.

▼ ***Key Point*** Many oral laxatives require normal water intake and patient hydration for optimal activity.

The use of an oral laxative often must be individualized by adjusting the dose until the desired frequency of defecation and fecal consistency is obtained.

▼ ***Key Point*** The most clinically effective and useful laxatives are dietary fiber, lactulose, and promotility drugs such as cisapride.

High-Fiber Bulk-Forming Laxatives

Fiber-based laxatives are added to food to promote soft feces and normal colonic motility as an initial approach for long-term control of mild constipation, especially in dogs. These bulk-forming agents are non-absorbable polysaccharide and cellulose derivatives that exhibit hydrophilic properties within the bowel. This method of treatment is available as commercial high-fiber diets or as fiber additives for the regular diet, such as unprocessed cereal grains, wheat bran, or psyllium (see

Table 74-2). Efficacy depends on normal hydration and vigorous water intake.

▼ ***Key Point*** High-fiber diets may worsen obstipation in cats with megacolon or dehydration. Highly digestible low-residue diets may be preferable.

Lubricant Laxatives

Laxatives such as mineral oil and white petrolatum are used to soften and lubricate the feces to facilitate evacuation (see Table 74-2).

- *Flavored petrolatum* is the preferred oral lubricant laxative; however, it is only effective for treatment or prevention of mild constipation. Administer it between meals so that it does not interfere with the absorption of fat-soluble vitamins.
- *Mineral oil enemas* are sometimes useful for assisting manual extraction of feces, but do not give mineral oil orally because it can lead to inhalation lipid pneumonia.

Emollient Laxatives

Docusate sodium, docusate calcium, and *docusate potassium* are mild laxatives available in enema and oral forms that promote water penetration into the feces, thereby softening the feces (see Table 74-2).

- Do not mix docusate and mineral oil.
- Efficacy requires normal patient hydration.

Osmotic Laxatives

These laxatives consist of poorly absorbed disaccharides (e.g., lactose or lactulose), ions (e.g., magnesium hydroxide or magnesium citrate), or inert osmotic agents (e.g., polyethylene glycol) that osmotically retain water in the bowel lumen to produce soft or fluid feces.

- A mild osmotic laxative effect can be produced in some animals by the addition of milk (lactose) to the diet in a quantity that exceeds the digestive capacity of small intestinal lactase.
- *Lactulose* is a non-absorbable disaccharide (see Table 74-2) that is fermented by colonic bacteria to lactic acid and other organic acids that exert an osmotic effect and stimulate colonic fluid secretion and propulsive motility. Lactulose is a very safe laxative for long-term use. An excessive dosage can cause abdominal discomfort, diarrhea, and flatulence.

▼ ***Key Point*** Lactulose is the most clinically useful and effective osmotic laxative. It is an excellent all-purpose laxative for both dogs and cats.

- *Magnesium hydroxide* (Milk of Magnesia) is an over-the-counter product for people; it is generally not recommended for dogs and cats (see Table 74-2). Magnesium is contraindicated in patients with renal failure.
- *Magnesium citrate* and *polyethylene glycol-electrolyte* solutions (see Table 74-2) are used primarily for bowel preparation for colonoscopy. The large doses required are given by orogastric intubation, which limits their usefulness for routine treatment of constipation.

Stimulant Laxatives

Stimulant laxatives are over-the-counter agents that increase propulsive motility of the bowel. Bisacodyl is the most effective drug in the group; others are senna, castor oil, and cascara (see Table 74-2). They are contraindicated in the presence of an obstructive lesion.

- *Bisacodyl* is available for oral, rectal suppository, and enema administration. It works by stimulating colonic smooth muscle and the myenteric plexus. Although beneficial on a short-term basis in conjunction with measures to soften the feces, long-term use may damage the myenteric plexus.
- *Senna* (Senokot) is a natural vegetable-based laxative.
- *Castor oil* is hydrolyzed in the intestines to ricinoleic acid, which stimulates colonic motility and secretion. Castor oil is not useful for outpatient treatment because of poor patient acceptance. Some clinicians use a dose of castor oil to stimulate defecation in hospitalized patients prior to abdominal imaging and other procedures.

Promotility Drugs

Promotility drugs have a prokinetic effect on the gastrointestinal tract, including propulsive motility of the colon. They are contraindicated in the presence of an obstructive lesion.

- *Cisapride* is a 5-HT_4 serotonergic agonist that is highly effective for stimulating colonic propulsive motility (see Table 74-2). Anecdotal experience suggests it may be the most effective drug for medical therapy of megacolon in cats, although many cats become refractory after several months and require colectomy. The current availability of cisapride in the United States is limited to compounding pharmacies. Cisapride was taken off the market because of fatal ventricular arrhythmias that occurred in people, but these have not been documented in dogs and cats.
- *Tegaserod* and *prucalopride* are new serotonergic (5-HT_4) agonist promotility drugs that may have application in animal patients.
- *Ranitidine* and *nizatidine* are H_2 blockers that stimulate gastrointestinal and colonic motility through inhibition of synaptic acetylcholinesterase, which increases acetylcholine (see Table 74-2). These drugs have less potent prokinetic effects than cisapride.

Adjunctive Treatment and Preventive Measures

Following evacuation of retained feces from the colon, institute measures to prevent and control recurrences

of constipation. Identify and eliminate or correct underlying causes or predisposing factors (see Table 74-1).

- Prevent ingestion of constipating or abrasive materials such as bones.
- Prevent loose hair ingestion by adopting a routine of regular grooming, especially in cats.
- Provide dogs with a daily exercise routine and frequent opportunities to defecate.
- Provide cats with clean litter daily to encourage regular defecation.
- Provide access to fresh water at all times to encourage water intake.
- Adjust or discontinue the use of any medications that promote constipation.
- Treat predisposing prostatic, endocrine (hypothyroidism), spinal, and orthopedic disorders.
- Correct painful or obstructing anorectal lesions, by surgery if necessary (see Chapter 75).

MEGACOLON

Megacolon, which occurs most frequently in cats, is characterized by a colon that becomes severely and irreversibly dilated and hypomotile.

Etiology

- ***Idiopathic:*** In 70% of cases, feline megacolon is an idiopathic hypomotility disorder involving colonic smooth muscle. This *dilated megacolon* is usually irreversible. In vitro studies have demonstrated decreased active contraction of megacolonic smooth muscle in response to neurotransmitters (acetylcholine, substance P, cholecystokinin), membrane depolarization (potassium), and electrical stimulation. Innervation of the colon is intact, and histopathology of the muscle and nerves is unremarkable.
- ***Obstructive:*** In up to 25% of cases, megacolon is secondary to an underlying cause of persistent rectocolonic obstruction, such as perineal hernia, anorectal stricture, anorectal neoplasia, or pelvic canal stenosis caused by fracture malunion. This *hypertrophic megacolon* is potentially reversible with early removal of the obstruction.
- ***Neurologic:*** Neurologic dysfunction may account for 5% of megacolon cases, for example, lumbosacral spinal cord disease, Manx cat deformity, or dysautonomia.

Clinical Signs

- Megacolon occurs mostly in middle-aged and older cats with a 2:1 predilection for male cats. It is most prevalent in domestic shorthair (46%), domestic longhair (15%), and Siamese (12%) cats.
- Recurrent constipation and obstipation are the primary signs (see under "Constipation"). Episodes of constipation usually become more frequent and severe with progressive decline in motor function of the colon.

Diagnosis

Severe irreversible dilation of the colon is the hallmark of megacolon.

- Severe colonic impaction with feces is evident by abdominal palpation and abdominal radiography.
- Perform rectal palpation to rule out anorectal obstructive disease.
- Evaluate for evidence of neurologic disease that could result in secondary megacolon.

Treatment

Treatment is based on evacuation of impacted feces, correction of predisposing causes, and prevention of constipation episodes by the use of laxatives such as lactulose (osmotic) and cisapride (prokinetic) as described previously under "Constipation" (see Table 74-2 for dosages). Dietary adjustments alone are not usually sufficient to control constipation in cats with megacolon.

▼ ***Key Point*** In cats, use subtotal colectomy for severe recurrent constipation, obstipation, or megacolon that is unresponsive to medical management (see Chapter 70).

- Eventually most cats with idiopathic megacolon become refractory to medical management and require subtotal colectomy that removes 95% of the colon (see Chapter 70). Results are satisfactory to excellent with this palliative procedure in most cats. Diarrhea and increased frequency of defecation are common postoperatively but resolve after 2 to 4 weeks.
- In cats with obstipation from pelvic fracture malunion, pelvic osteotomy and reconstructive surgery can allow return of normal colonic function if obstipation has been present for less than 6 months; otherwise, perform subtotal colectomy.

PROCTITIS

Proctitis, or inflammation of the rectum, can cause tenesmus, diarrhea, and hematochezia. Therefore, it must be differentiated from other anorectal diseases. Proctitis usually is a manifestation of colitis or inflammatory bowel disease, which are discussed in Chapter 69.

ANORECTAL PROLAPSE

Etiology

Anorectal prolapse is seen most frequently in puppies and kittens as a consequence of an underlying disorder

that produces persistent straining to defecate, especially endoparasitism. It also can be associated with straining caused by urogenital conditions. Predisposing causes include the following:

- Intestinal diseases that cause diarrhea and tenesmus (e.g., proctitis, colitis, and parasites)
- Anorectal diseases that cause dyschezia
- Anal sphincter incompetence in Manx cats
- Dystocia
- Lower urinary tract diseases (e.g., cystitis, urethral obstruction, and calculi) and prostatic diseases that cause stranguria

Clinical Signs

- *Partial prolapse* involves only the rectal mucosa and appears as a red, swollen, doughnut-shaped ring of prolapsed mucosa.
- *Complete prolapse* involves all layers of the rectal wall and appears as an edematous, cylindrical-shaped mass. The prolapsed tissue may be viable (pink or red and moist) or necrotic (blackened and dry).

Diagnosis

Insert a thermometer, blunt instrument, or finger in the space between the prolapsed tissue and the anal sphincter to probe for a cul-de-sac. If there is none and resistance is not met, the prolapsed tissue is an intussusception of ileum or colon (see Chapter 69) rather than an anorectal prolapse.

Conservative Treatment

Successful management of anorectal prolapse includes repair of the prolapse and identification and treatment of the underlying cause. Evaluate the anus, rectum, intestines, and urogenital tract by palpation, urinalysis, fecal examinations, proctoscopy, and diagnostic imaging studies, as appropriate.

▼ ***Key Point*** Effective treatment of anorectal prolapse requires reduction of the prolapse and medical therapy to reduce tenesmus and prevent recurrence.

- To treat minor prolapse in which the tissue is viable, lubricate and manually reduce the prolapse.
- Place a temporary (2–3 days) anal purse-string suture to prevent recurrence, especially in animals with persistent straining. Leave the purse-string suture loose enough to allow passage of feces. Feed a digestible low-fiber diet while the purse-string suture is in place.
- To enhance anal tone in animals with diarrhea, give loperamide (Imodium AD) (0.1–0.2 mg/kg PO q6–8h).
- To relieve persistent straining and spasm refractory to loperamide, use anticholinergic-antispasmodic drugs such as dicyclomine (Bentyl, Marion Merrell Dow), 0.15 to 0.20 mg/kg q8–12h PO or SC.
- For proctitis, consider an anti-inflammatory retention enema:
  - Hydrocortisone retention enema (Cortenema, Reid-Rowell), 10 to 60 ml q12–24h
  - Mesalamine retention enema (Rowasa, Reid-Rowell) for dogs only, 10 to 60 ml q12–24h

Surgery

- Perform colopexy if conservative management fails and to prevent recurrent prolapse (see Chapter 70).
- Perform resection and anastomosis (i.e., "prolapse amputation") if the prolapsed tissue is necrotic and non-viable (see Chapter 75).

PERINEAL HERNIA

Etiology

Perineal hernia occurs when weakened perineal musculature (levator ani and lateral coccygeus), also called the pelvic diaphragm, fails to support the rectal wall, resulting in persistent rectal distention and impaired defecation. Aged, intact male dogs are most frequently affected, but perineal hernia also occurs in female dogs and in cats. The pathogenesis of the muscle weakening is poorly understood. Persistent straining related to constipation or prostatic disease may play a role in some animals. Neurogenic atrophy of the perineal musculature may play a role in dogs. Male hormones have been implicated because the disease is extremely rare in neutered and female dogs. Chronic constipation and megacolon are predispositions in cats.

The hernia usually contains an outpouched rectum and can be unilateral or bilateral; unilateral hernias are predominantly right-sided. The hernia sac may also contain retroperitoneal fat, the prostate gland, and rarely abdominal organs such as the urinary bladder or intestines. The rectal defects associated with perineal hernia have been classified as follows:

- ***Sacculation***—Unilateral loss of support that allows expansion of the rectal wall to one side.
- ***Dilation***—Bilateral loss of support that allows generalized distention of the rectum.
- ***Deviation or flexure***—The rectum curves or bends to one side within the hernia sac.
- ***Diverticulum***—An outpouching of mucosa that occurs through a defect in the rectal wall.

Clinical Signs

Perineal hernia causes a perineal swelling or bulge in association with signs of constipation, obstipation, dyschezia, and tenesmus.

- Dysuria may occur when the urinary bladder is retroflexed into the hernia, causing urethral obstruction.

- Perineal hernia in cats may be a complication of megacolon.

Diagnosis

Diagnosis is based on palpation of a reducible perineal bulge ventrolateral to the anus and rectal palpation of the weakened pelvic diaphragm with dilatation or deviation of the rectum.

Treatment

The goal of initial treatment is evacuation of retained feces from the rectum (see under "Constipation"). Urethral catheterization or cystocentesis also may be necessary initially to relieve urinary obstruction.

- In a mild perineal hernia, normal defecations can be maintained by laxative therapy and stool-softening diets (see under "Constipation").
- Castration of male dogs with a mild perineal hernia may prevent progression of the disorder.
- Corrective perineal herniorrhaphy surgery combined with castration provides the best long-lasting results in most cases (see Chapter 75).

▼ ***Key Point*** Perform castration as an adjunct to perineal hernia repair in male dogs.

- Surgery may not resolve clinical signs in cats with perineal hernia secondary to megacolon.

ANORECTAL FOREIGN BODIES AND FECALITHS

Etiology

- Ingested foreign bodies such as bones, toys, sticks, and sewing needles can sometimes pass unobtrusively through the gastrointestinal tract and become lodged transversely within the rectum or at the anal sphincter.
- Foreign objects occasionally are inserted into the anus of an animal by malicious or abusive people.
- Aged cats sometimes present because of inability to pass a firm lump of feces (fecalith) that is lodged in the anal canal between the internal and the external sphincters.

Clinical Signs and Diagnosis

When a foreign body or fecalith is lodged in the anal canal or rectum, defecation becomes painful or impossible and dyschezia, tenesmus, and secondary fecal impaction occur. Diagnosis is usually confirmed by rectal examination. Radiography is occasionally required.

Treatment

Most anorectal foreign bodies and fecaliths can be detected and removed by rectal palpation; sedation or anesthesia is often necessary. In some cases a proctoscope may facilitate foreign body extraction. There are two potentially serious complications of anorectal foreign bodies:

- Rectal laceration resulting in retroperitoneal cellulitis
- Anorectal stricture (see the next section)

ANORECTAL STRICTURE (STENOSIS)

Etiology

Strictures of the anus or rectum can result from the following causes:

- Trauma caused by passage of sharp foreign bodies (especially bones)
- Postsurgical scarring after anorectal surgery
- Iatrogenic instrument trauma during treatment of obstipation
- Chronic inflammation associated with anal sac disease, perianal fistulae, or proctitis
- Annular stenosing anorectal adenocarcinoma

Clinical Signs and Diagnosis

Anorectal strictures cause dyschezia, tenesmus, hematochezia, and secondary constipation. The onset of signs is usually 2 to 3 weeks following rectal injury. The stricture can usually be identified by digital rectal palpation, proctoscopy, or barium enema contrast radiography.

Treatment

- Most anorectal strictures are successfully managed by a series of bougienage or balloon dilations under anesthesia. The balloon diameter is 10 to 20 mm in cats and small dogs, 20 to 30 mm in medium dogs, and 30 to 40 mm in large dogs. Dilate to 40 to 60 psi for 1 minute, 3 times in succession, and repeat the dilation procedure every 7 to 10 days for three treatments or until defecation is normal.
- Concurrently, give triamcinolone (5–10 mg by intralesional injection just prior to dilation), or prednisolone (1 mg/kg PO q12h) for 2 weeks and taper.
- If conservative dilation therapy fails, perform surgical correction (see Chapter 75).
- Severe and neoplastic strictures require resection and anastomosis by rectal pull-through (see Chapter 75).

ANAL SPASM

Etiology

This rare idiopathic form of severe dyschezia occurs when the anal sphincter contracts in spasm when the animal attempts to defecate.

Clinical Signs

When attempting to defecate, the animal may cry out in pain, move about frantically before stopping to make another attempt to defecate, turn and stare at its hindquarters, and appear extremely anxious. There appears to be a cycle of painful defecation, leading to defensive contraction of the anal sphincter, leading to more pain.

Diagnosis

- Most affected dogs are German shepherds of temperamental disposition.
- Digital palpation of the rectum is vigorously resented, and the anal sphincter muscle feels hypertrophied and tightly contracted in spasm. Visually, the external sphincter muscle appears hypertrophied.
- To attribute dyschezia to anal spasm, it is important to rule out other identifiable causes of dyschezia (e.g., anal sac disease, perianal fistulae, and anal stricture) by thorough anorectal examination under anesthesia, including proctoscopy.

Treatment

- Conservative treatment using anal sac evacuation, topical analgesics, antispasmodics, sedatives, or stool softeners is usually unsuccessful.
- Pin hole–sized perianal fistulae can be easily overlooked and cause identical clinical signs; thus, consider trial medical therapy for perianal fistula (see a later section) to see if the dyschezia subsides, especially in high-risk breeds such as German shepherds.
- Diffuse fibrosis of the anal ring can be less apparent than well-developed strictures and can cause dyschezia that resembles anal spasm; thus, consider empirical bougienage or balloon dilation of the anal ring under anesthesia followed by prednisolone (see under "Anorectal Stricture").
- As a last resort for palliation of anal pain and spasm, resection of one or both anal branches of the pudendal nerve may be required. Fecal incontinence is a frequent postoperative complication of this procedure.

ANAL AND RECTAL ATRESIA

Etiology

Imperforate anus (atresia ani) and rectal agenesis (rectal atresia) are rare congenital malformations of cloacal development that result in an absence of a patent anal opening for defecation.

Clinical Signs

Complete obstruction of feces produces clinical signs within the first several days of birth. The affected neonatal puppy or kitten develops abdominal distention and discomfort, bulging of the perineum, tenesmus, restlessness, vomiting, and loss of appetite. Without treatment the neonate becomes obtunded and dies.

Diagnosis

- The diagnosis is established by failure to defecate and absence of an anal opening. Variations in the malformation range from an imperforate anal membrane covering the anal opening (atresia ani) to varying degrees of rectal agenesis (rectal atresia) in which the rectum ends in a blind pouch at some distance cranial to the anus.
- The terminal end of the rectum can be delineated radiographically by the intraluminal air when a lateral radiograph is exposed with the animal's hind end slightly elevated.
- In some animals, imperforate anus is associated with genitourinary defects such as rectovaginal fistula.

Treatment

The treatment for atresia ani is surgical opening and removal of the retained anal membrane, usually producing favorable results (see Chapter 75). For rectal atresia, surgical correction is more difficult and may require combined abdominal surgery and rectal pull-through. The prognosis is guarded because of postoperative complications of fecal incontinence, anal stricture, or megacolon.

RECTOVAGINAL FISTULA

Rectovaginal fistula is a rare congenital malformation of females characterized by passage of fecal material through the vaginal opening. In many cases there also is an imperforate anus.

- Persistent fecal incontinence through the vagina leads to perivulvar dermatitis.
- Colonic distension usually occurs when the puppy or kitten begins eating solid food.
- The defect can be surgically corrected, but the prognosis is guarded (see Chapter 93).
- Other related, rare anorectal anomalies include rectovestibular fistula, anovaginal cleft, and rectourethral fistula.

ANAL SAC DISEASE

Anal sac disorders are the most common problem of the anal area in small animals, especially dogs. Anal sac

disease has been classified as impaction, inflammation (sacculitis), infection, abscess, and rupture:

- ***Impaction***—This is usually bilateral and indicated by a sac that is distended, mildly painful on palpation, and not readily expressed. The impacted contents are thick, pasty, and dark brown or grayish brown.
- ***Anal sacculitis***—This may be unilateral or bilateral and is associated with moderate to severe pain on palpation; the sacs contain a thinner-than-normal, yellowish or blood-tinged purulent fluid.
- ***Anal sac abscess***—This is usually unilateral and characterized by marked distention of the sac with pus, cellulitis of surrounding tissues, erythema of the overlying skin, and fever.
- ***Rupture***—Abscessed anal sacs may rupture through the adjacent skin, producing a draining fistulous tract.

These probably represent a continuum in that impacted anal sacs tend to become inflamed and secondarily infected, and the infection may lead to abscessation and, finally, to rupture or fistulation.

All breeds of dogs can be affected. Anal sac disease is uncommon in cats and usually involves only impaction.

Etiology

The specific cause of anal sac disease is poorly understood. It is believed to be associated with conditions that promote inadequate emptying of the sacs, which should normally occur during defecation when feces of normal consistency are forced through a normally functioning anal sphincter. Abnormal retention of anal sac secretions initiates the impaction–inflammation–infection cycle.

▼ ***Key Point*** Always consider the possibility that anal sac disease might be secondary to a generalized dermatologic disease or endocrinopathy (e.g., hypothyroidism).

Clinical Signs

- The most frequent clinical signs of anal sac disease are related to anal discomfort and include scooting the hind end on the floor, tenesmus, and licking and biting the anal area, perineum, or base of the tail.
- Chewing and licking may result in areas of self-inflicted (pyotraumatic) dermatitis.
- Tail chasing, malodorous perianal drainage, and change in temperament may be noted.

Diagnosis

The diagnosis of anal sac disease is based on the clinical signs and examination of the anal sacs. Examine and evacuate the anal sacs by palpation with a gloved index finger inserted in the rectum and a thumb compressed against the skin ventrolateral to the anus.

Treatment

▼ ***Key Point*** Anal sacculectomy as described in Chapter 75 is the treatment of choice for animals with recurrent anal sac disease.

Anal Sac Impaction and Sacculitis

- Manual evacuation of the sac contents to reestablish drainage is all that is required in many animals.
- Follow-up examination and expression of the anal sacs again in 1 to 2 weeks is advisable.
- A high-fiber diet (see Table 74-2) may help prevent recurrence.

Recurrence of Impaction or Sacculitis

- Irrigation with povidone-iodine solution using a tomcat urinary catheter or lacrimal needle and instillation of an antibiotic (e.g., otic or ophthalmic antibiotic ointment) into the sac may be helpful, along with expression of the sacs every 3 to 4 days.
- Consider systemic antibiotics based on culture and sensitivity testing of the sac contents for animals with troublesome recurrences.

Anal Sac Abscesses

- Drain, irrigate with povidone-iodine solution, and treat with systemic antibiotics.
- Treat recurrent anal sacculitis or abscess by surgical excision of the sacs (see under "Anal Sacculectomy" in Chapter 75). Delay anal sacculectomy until the severe inflammation associated with abscessation has resolved.

PERIANAL FISTULA

Perianal fistula (anal furunculosis) is a chronic progressive disease characterized by deep ulcerating sinuses and fistulous tracts in the perianal tissues. The disease occurs most frequently in German shepherds and Irish setters more than 5 years of age, but it occurs sporadically in Labrador retrievers and various other large-breed dogs.

Etiology

The pathogenesis is not well understood. It may involve infection and abscessation of the apocrine glands and other glandular elements in and around the anus, promoted by the moist, contaminated environment of the area and the broad-based tail with low tail carriage typical for many German shepherds. The pathogenesis appears to involve cell-mediated immune mechanisms, supported by the effectiveness of immunosuppressive therapy in many cases.

Clinical Signs

- Dogs with perianal fistulas usually present with signs of dyschezia, tenesmus, and severe anal discomfort (constant licking of the anal area and scooting).
- Hematochezia, constipation, fecal incontinence, and foul-smelling purulent perianal discharge may be present.

Diagnosis

Visual examination of the perianal area establishes the diagnosis. Because of severe pain, sedation or anesthesia is required for thorough examination of the area.

- The sinus tracts and fistulae first appear as small, draining puncture holes in the perianal skin; there is inflammation and hyperpigmentation of the surrounding skin.
- These small tracts enlarge and coalesce to form large, interconnecting sinuses and areas of ulceration and granulation tissue. The fistulous tracts may extend deep into the perirectal tissues, and the anal sacs may be infected or ruptured.
- Fibrosis may lead to anorectal stricture in chronic cases.
- Histopathologic findings include hidradenitis, chronic necrotizing pyogranulomatous inflammation of skin and hair follicles, cellulitis, necrosis, and fibrosis.

Treatment

Medical therapy can be used alone or can be combined with surgical therapy. Medical approaches include hair removal and cleansing of the perianal area, systemic antibacterial therapy, dietary therapy using novel protein diets, and immunosuppressive therapy using cyclosporine, tacrolimus, or azathioprine.

Medical Therapy

Clip hair from around the anal region and base of the tail and cleanse the area with chlorhexidine scrub. Use one of the following treatment approaches:

- *Cyclosporine* (Atopica, Novartis) (5 mg/kg PO q24h) produces improvement in nearly all dogs within 2 to 4 weeks and a full remission and healing in 85% of dogs within 16 weeks. The recurrence rate is 40%, necessitating additional medical treatment or surgery.
- *Tacrolimus* (0.1% topical ointment) is applied once daily to the perianal area after cleansing as a cost-effective alternative to systemic cyclosporine with similar actions, fewer side effects, and a 50% remission rate.
- *Azathioprine combined with metronidazole* is an alternate, less expensive form of immunotherapy that usually produces improvement, but the rate of complete healing may not be as high as with cyclosporine or tacrolimus. Azathioprine (Imuran) is dosed at 2 mg/kg PO q24h.
- *Novel protein diets combined with immunotherapy* is an alternative approach that has benefited some dogs.
- *Broad-spectrum antibiotics* (a cephalosporin or fluoroquinolone such as enrofloxacin, combined with amoxicillin-clavulanate or metronidazole) may be palliative and can be used in conjunction with other medical treatments.

Surgery

Numerous surgical techniques have been advocated (see Chapter 75), including varying degrees of excision and debridement of diseased tissue, chemical ablation, laser excision, electrocautery, cryosurgery, and tail amputation. It is advisable to tailor the aggressiveness of the technique to the extensiveness of the lesions and to preserve as much normal tissue and anal function as possible.

Prognosis

- Early diagnosis and medical or surgical intervention avoids radical surgical excision, which in turn means less risk of postoperative complications and a better prognosis.
- Complications such as fecal incontinence, anal stenosis, and recurrence of the lesions can lead to an unacceptable outcome.

PSEUDOCOPROSTASIS

Etiology

Pseudocoprostasis is a condition of obstruction of the anal opening in which the surrounding hair becomes densely matted with feces. It occurs most often in long-haired breeds of dogs and cats, especially during bouts of diarrhea. Obesity is a contributing factor in some animals.

Clinical Signs

The anal obstruction leads to anal irritation, inability to pass feces, and constipation.

- The animal usually is restless and attempts to bite or lick the anal region.
- The owner may complain of an unexplained foul odor from the animal.
- The matted hair often results in an underlying dermatitis that may attract flies and lead to a maggot infestation (myiasis) of the perianal area.

Diagnosis

Visual examination of the anal region is sufficient for diagnosis.

Treatment

- Clip hair mats, cleanse the underlying irritated skin, and apply a topical antibacterial ointment. When the obstructing hair mats are removed, defecation should occur normally.
- If the animal has secondary colonic impaction of feces, measures to evacuate the colon may also be required (see under "Constipation").
- Diagnose and treat underlying diarrheal disease that may have predisposed the animal to matting of perianal hair with feces.
- Correct obesity that may be a contributing factor.

MUCOCUTANEOUS AND PERIANAL DERMATITIS

- Anal irritation often causes licking, biting, and rubbing at the anal area that leads to perianal dermatitis.
- Generalized pruritic skin conditions may cause perianal dermatitis (e.g., allergic dermatitis), fleas, etc.
- Eosinophilic granuloma complex of cats may involve the perianal region (see Chapter 53).
- The mucocutaneous junction where the perianal skin meets the anal mucosa may be severely inflamed and ulcerated in conjunction with other mucocutaneous areas in animals with immune-mediated skin disease (e.g., pemphigus complex, pemphigoid diseases, or lupus erythematosus complex; see Chapter 48), cutaneous drug eruption, cutaneous vasculitis, or various necrotizing dermatoses (see Chapter 49).

Perianal dermatitis often can be treated topically; however, the key is to recognize that it is usually secondary to an underlying anorectal or dermatologic disorder that must be identified and treated. For information regarding specific dermatologic disorders, see the respective chapters.

RECTAL, ANAL, AND PERIANAL TUMORS

The most common rectal tumor in the dog is the benign adenomatous polyp. Malignant tumors of the rectum (adenocarcinoma, lymphoma) can occur anywhere in the colon and rectum of dogs and cats. These are discussed with intestinal neoplasia in Chapter 69.

The most common tumor of the anal region is benign perianal (circumanal) gland adenoma of dogs. Other benign tumors of the anal area are rare and include lipoma and leiomyoma. The two most common anal malignancies are perianal (circumanal) gland adenocarcinoma and apocrine gland (anal sac, anal gland) adenocarcinoma. Perianal tumors are also discussed in Chapter 30.

Other malignant tumors of the anal region include squamous cell carcinoma, melanoma, lymphoma, and mast cell neoplasia.

Benign Rectal Polyps

Benign adenomatous polyps of the rectum are common in middle-aged and older dogs. They are usually solitary, focal, pedunculated or sessile masses in the rectal mucosa. Rectal polyps may cause clinical signs of rectal bleeding, hematochezia, dyschezia, tenesmus, or excessive licking of the anal region. The clinical signs are often mistaken for chronic colitis. Polyps also may be inapparent or incidental findings.

Diagnosis

Polypoid rectal masses can usually be detected by rectal palpation. Many rectal polyps can be exteriorized through the anus by everting the rectal mucosa with gentle traction to allow visual inspection.

- Rectal polyps appear dark red and lobulated (raspberry-like appearance). They are friable and bleed easily.
- Proctoscopy is beneficial for identifying more proximal lesions.
- Biopsy is required for definitive diagnosis.

Treatment

Complete surgical excision is the treatment of choice for rectal polyps. Techniques include endoscopic polypectomy, surgical resection by rectal pull-through, or cryosurgery.

- Always submit excised tissue for histopathologic evaluation, because the visual appearance of polyps and adenocarcinomas can be identical.
- The prognosis is excellent. Recurrence is uncommon, and malignant transformation is very rare in animals.

Perianal (Circumanal) Gland Adenoma

These androgen-dependent tumors occur most often in older, intact male dogs and they usually appear as small, firm, well-circumscribed nodules in the skin surrounding the anus.

Clinical Signs

Perianal gland adenomas may be incidental findings unassociated with clinical signs or they may cause anal irritation with scooting and licking at the anal area. In addition, they sometimes ulcerate and periodically bleed.

Treatment

The treatment of choice is excision (see Chapter 75) and adjunctive castration because of their hormone dependency.

- Castration alone can produce regression of these tumors; however, excisional biopsy at the time of castration is necessary to rule out malignancy.

- Estrogens are inhibitory for perianal gland adenomas; however, they cannot be recommended for prolonged use because of their myelotoxic effects.

Perianal Gland Adenocarcinoma

These tumors occur most often in aged female dogs and may resemble an ulcerated perianal gland adenoma, except that they are locally invasive and may cause diffuse infiltration and thickening of surrounding tissues.

Clinical Signs

- Their appearance can be confused with a perianal fistula lesion or a ruptured anal sac.
- These tumors eventually metastasize to regional lymph nodes (sublumbar) and beyond.

Diagnosis and Treatment

For potentially malignant lesions of the perianal area, excisional biopsy is the diagnostic procedure of choice (see Chapter 75).

- First perform thoracic and abdominal radiography and abdominal ultrasonography to evaluate for lung or lymph node metastasis.
- Early excision of malignant tumors of the anal region can be effective; however, when extensive local invasion or regional lymph node metastasis has occurred, the prognosis for a cure is poor.
- Repeated partial excisions, radiation therapy, cryosurgery, and chemotherapy have been used for palliative therapy in patients with inoperative malignancies of the anal region.

Apocrine Gland Adenocarcinoma

Apocrine gland adenocarcinoma arises in the anal sac and affects middle-aged and older dogs (median age, 10 years). A recent large case series found equal gender distribution, although other studies have found higher prevalence in spayed females.

Clinical Signs

These small perianal tumors are often incidental findings on palpation of the anal sacs, or they cause signs referable to perianal irritation or obstructive constipation. However, 25% to 50% of affected dogs present with paraneoplastic hypercalcemia, with or without polyuria-polydipsia and anorexia.

- More than 50% of these tumors can produce parathyroid hormone-related protein (PTHrP) that causes a paraneoplastic humoral hypercalcemia of malignancy (see Chapter 32). Even very small tumor nodules can produce this syndrome.
- These tumors are malignant and metastasize to sublumbar lymph nodes and distant sites, such as the lungs.

Treatment

Surgical excision is the treatment of choice. The reported median survival has varied from 6 months to 1.5 years. Hypercalcemic cases and animals with evidence of metastasis at the time of diagnosis have a shorter survival.

- For medical treatment of associated hypercalcemia, see Chapter 32.
- Adjunctive radiotherapy and/or chemotherapy may be appropriate, especially for incompletely excised or metastatic tumors (see Chapters 26 and 30).

Chapter

75 Anorectal Surgery

Ronald M. Bright

Surgery of the rectum and anus is associated with a high rate of complications. The high bacterial population of the rectum increases the risk of wound infection and dehiscence. Bowel preparation with multiple enemas can mechanically remove large numbers of bacteria; however, enemas should not be done within 8 hours of anorectal surgery to avoid leakage of rectal contents during surgery. Prophylactic antibiotics are indicated with surgery of this area due to high numbers of bacteria. Synthetic absorbable sutures or monofilament nonabsorbable sutures are recommended for surgery of the rectum and anus.

ANATOMY

The rectum begins at the brim of the pelvis and joins the anal canal just inside the anal opening. The anal canal is approximately 1 to 2 cm in length. The circumanal glands, anal glands, and anal sacs are associated with the anus.

The rectum receives its blood supply from the caudal mesenteric artery and its branch coursing caudally, the cranial rectal artery. This artery forms anastomoses with the middle and caudal rectal arteries, which arise, in the male, from the prostatic artery, and in the female, from the internal pudendal arteries. At the caudal demarcation of the rectum are two anal sphincters (internal and external). Fecal continence is maintained by these sphincters, and surgery in this area always threatens their integrity.

RECTAL PROLAPSE

Rectal prolapse is almost exclusively limited to young dogs and cats. The most common cause is straining to defecate, associated with severe colitis or proctitis due to endoparasites. Other causes include foreign bodies, rectal neoplasia, dystocia, and, in the cat, persistent straining related to urethral obstruction or cystic calculi.

Differentiate this condition from prolapsed intussusception. In the latter condition, a probe can be inserted and advanced cranially into a space between the cylindrical mass and the edge of the anus. This cannot be done with rectal prolapse.

Preoperative Considerations

- Treat underlying diseases (e.g., parasitism) while attempting conservative management of rectal prolapse.
- Initial management consists of cleaning and lubricating the prolapse, determining viability of the tissue, and then manually reducing the prolapsed tissue followed by a loose pursestring suture. The pursestring suture should be loose enough to allow passage of loose feces, but tight enough to keep the prolapsed tissue reduced.
- Feed a digestible low-fiber diet for 7 to 8 days while the pursestring suture is in place.
- Failure of conservative management may necessitate a surgical procedure.
- The preferred surgical procedure is colopexy (see Chapter 70), unless there is non-viable tissue within the prolapsed segment of rectum that requires resection and anastomosis.

Surgical Procedure: Resection and Anastomosis

Objectives

- Remove devitalized tissue involved in the rectal prolapse.
- Remove excessive rectal tissue that continues to prolapse in spite of manual reduction or use of the pursestring suture technique alone or in conjunction with a colopexy.

Equipment

- General surgery pack
- A 3-cc syringe case

Technique

1. Place the animal in sternal recumbency in a perineal stand.
2. Insert a well-lubricated 3-cc syringe case into the rectum.
3. Place three or four stay sutures around the circumference of the prolapsed tissue through all the layers

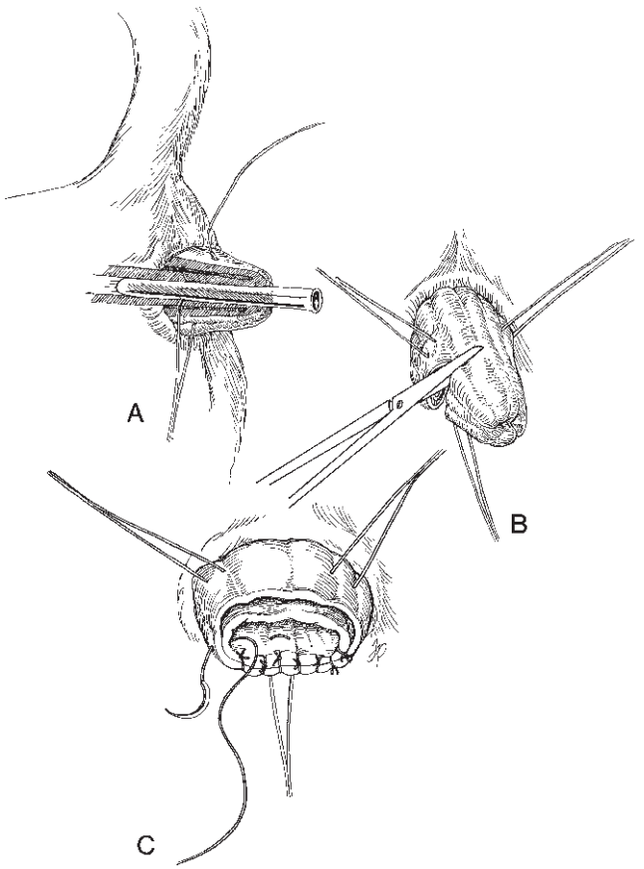

Figure 75-1. Resection and anastomosis of rectal prolapse.

of tissue. The needle should be against the syringe case at its deepest penetration (Fig. 75-1*A*).

4. Resect the prolapse around 180 degrees of the circumference, caudal to the stay sutures (Fig. 75-1*B*).
5. Place synthetic absorbable sutures (3-0 or 4-0) through the full thickness of the incised bowel, being sure to incorporate the serosal layers. A simple interrupted appositional pattern is preferred (Fig. 75-1*C*).
6. Incise the remaining 180 degrees and suture as described in Step 5. Push the rectum cranially into the pelvic canal.

Postoperative Care and Complications

Short T erm

- Give a stool softener (see Chapter 74) with food, which is offered the day after surgery. Continue giving the stool softener for 2 weeks.
- Closely monitor for leakage from the anastomotic site for at least 48 hours by observing the animal's temperature, level of activity, eating habits, and signs of excessive pain around the anorectal region. Be careful when placing a rectal thermometer.
- Recurrence of rectal prolapse may occur. A pursestring suture may have to be used again or a colopexy performed if it has not been done previously.

Long T erm

Long-term complications can include the following:

- Recurrence of rectal prolapse
- Fecal incontinence
- Anorectal stricture

ANORECTAL STRICTURE

Causes of anorectal stricture can be benign (e.g., inflammation) or malignant (e.g., adenocarcinoma):

- Inflammatory causes include perianal fistulas, prior anorectal surgery (including cryosurgery), and accidental trauma.
- Adenocarcinoma of the rectum and anus is the most common cause of stricture, resulting in a scirrhous, annular ring-type lesion.

Preoperative Considerations

Simple, annular non-neoplastic lesions that are not too cranial in location may respond to a series of bougienage or balloon dilations. During this therapy, give prednisolone for 10 to 14 days (1 mg/kg q12h).

- For other lesions (e.g., adenocarcinoma), resection/anastomosis (described below) is the treatment of choice.

Surgical Procedure: Resection/Anastomosis with Rectal Pull-Through

Objective

- Restore bowel lumen size that will accommodate the passage of feces with minimal resistance while preserving competence of the anorectal sphincter.

Equipment

- General surgery pack
- Senn retractors

Technique

1. Clip and aseptically prepare the perineal region.
2. Place a pursestring suture in the anus.
3. When the lesion is cranial to the anorectal junction, make an incision circumferentially around the anal ring.
4. Continue the perirectal dissection to normal tissue just cranial to the stricture ring. Avoid trauma to the sphincter muscles.
5. Place four stay sutures circumferentially through the normal rectal wall just ahead of the stricture.
6. Resect the diseased rectal tissue.

7. Pull the healthy tissue being held by the stay sutures caudally and appose to the anus. Avoid suturing under tension; mobilize more rectal tissue if necessary.
8. Close the tissues in two layers: subcutaneous tissue apposed to seromuscular layer of rectum (monofilament absorbable suture), and skin to rectal mucosa (monofilament non-absorbable suture).

Postoperative Care and Complications

Short Term

- Feed the animal the following day.
- Give stool softeners (see Chapter 74) for 2 weeks following surgery.
- Monitor for leakage from the anastomotic site, especially during the first 48 hours.
- Fecal incontinence may occur.

Long Term

- A pelvic abscess due to earlier leakage from the anastomosis can occur.
- Postoperative stricture can occur, especially if tension was present at the suture line.

Prognosis

The prognosis is poor if the stricture is due to an adenocarcinoma. It is poor to guarded if the stricture is related to an inflammatory process.

ANAL STRICTURE LIMITED TO THE ANAL RING

Causes, preoperative considerations, and objectives are similar to those for anorectal strictures, as described in the previous section.

Surgical Procedure

Technique

1. Cut the stricture in four places around the anal ring at 3, 6, 9, and 12 o'clock.
2. Make the incisions perpendicular to the ring. Extend one-half of each incision outward into the skin and the other half inward through the fibrotic mucosa.
3. Suture the incisions in the opposite direction to the edge of the anal ring with monofilament non-absorbable sutures.
4. Alternatively, excise the stricture and suture rectal mucosa to skin with monofilament non-absorbable sutures.

ATRESIA ANI

This condition exists in several forms, the most common being type I (imperforate anus) and type II, in which the rectal pouch is located cranial to the membrane overlying the anus. Regardless of the type, the main problem is loss of continuity between the rectum and anus during embryonal development of the cloacal membrane.

Preoperative Considerations

- Plain film radiography of the abdomen and pelvis with the animal standing helps to differentiate between type I and type II.
- Because the patient usually is only days or weeks old, there is a relatively high anesthetic risk.

Surgical Procedure

Objective

- Relieve the obstruction of feces in the rectum by opening the anus and reconstructing the anorectal junction.

Equipment

- General surgery pack
- Iris scissors
- Fine mouse-tooth thumb forceps or Simkin thumb forceps

Technique

Type I

1. Incise the skin overlying the anus in a cruciate pattern.
2. Protect the anal sphincter.
3. Incise the rectal pouch just under the incision in a cruciate pattern.
4. Suture the rectal circumference to the subcutaneous tissues and skin with 4-0 or 5-0 monofilament non-absorbable suture in a one-layer simple interrupted appositional pattern.

Type II

1. Incise the membrane overlying the anus in a cruciate pattern.
2. Continue the perirectal dissection cranially until the rectal pouch is identified.
3. Incise the blind pouch as described in Step 3 for type I.
4. Appose the rectocutaneous tissues as described in Step 4 for type I.

Postoperative Care and Complications

Short Term

- Monitor closely for suture line breakdown and infection of the surgical site.
- Because of the young age of these patients, give aggressive fluid therapy (including dextrose to prevent hypoglycemia) during surgery and well into the postoperative period.

- Initially, fecal incontinence often is a problem but resolves spontaneously in some animals.

Long Term

- Fecal incontinence may continue indefinitely.
- Stricture is a possible sequela to anorectal surgery.
- Megacolon that sometimes accompanies atresia ani may be permanent and constipation may be an ongoing problem.

PERIANAL FISTULAE

Perianal fistulae are multiple draining tracts that surround the anus and are chronic in nature. German shepherds and Irish setters are affected most commonly (see Chapter 74 for a complete description of this disease).

Preoperative Considerations

- Consider conservative therapy, consisting of perianal cleansing with an antiseptic solution and application of hot packs.
  - Antibiotic therapy for 2 to 3 weeks may ameliorate the pain associated with this condition. Medical therapy using cyclosporine or topical tacrolimus has reportedly been successful for many dogs with perianal fistulas (see Chapter 74)
- In some cases, surgical intervention will be necessary. Regardless of the procedure, surgical excision of diseased tissue is a compromise between complete excision and minimization of trauma to spare the external anal sphincter.
- An anal sacculectomy should accompany any excisional procedure.

Surgical Procedure

Objective

- Remove diseased tissue around a portion of the anus and, if necessary, around its entire circumference.

Equipment

- General surgery pack

Technique

1. Make a skin incision to incorporate all the diseased tissue surrounding the anus.
2. Dissect and continue into the deeper tissues until the cranial extent of the fistulous tracts is determined.
3. Take care to prevent damage to the external anal sphincter muscle or its innervation.
4. In some instances, a portion of the sphincter muscle may be removed coincidentally when attempting to excise the diseased tissue.
5. In severe cases, remove a doughnut-shaped piece of tissue, leaving healthy rectal tissue underneath.
6. Transversely incise the rectum to allow removal of the anus and diseased tissue.
7. Suture the subcutaneous tissue layer to the seromuscular layer of the rectum with 3-0 monofilament absorbable suture. Suture the rim of rectal mucosa directly to the skin, using 3-0 monofilament nonabsorbable suture.

Postoperative Care and Complications

- Keep the incision and underside of the tail clean, using hydrotherapy twice a day. A thin layer of petroleum jelly placed around, but not in, the incision is helpful for preventing fecal soiling and irritation.
- Give stool softeners for 1 to 2 weeks.
- Incisional dehiscence may occur but is usually treated conservatively (let heal by second intention).
- Fecal incontinence may occur after extensive resections.
- Recurrence of fistulas can occur. Treat by excision of affected tissues.

PERINEAL HERNIA

Perineal hernia results from weakening of the perineal muscles (i.e., the levator ani and lateral coccygeus) and external anal sphincter. Hernias may result in rectal sacculation and herniation of prostate, fat, urinary bladder, or bowel (see Chapter 74). The exact cause is uncertain but is thought to be related to any condition that causes chronic tenesmus (constipation, prostatomegaly). Other possible causes include hormonal imbalance and degenerative changes to the levator ani musculature.

Preoperative Considerations

- Castration usually accompanies a herniorrhaphy. It is thought to help prevent recurrence by decreasing tenesmus related to prostatomegaly.
- Urethral obstruction secondary to bladder entrapment requires emergency treatment (cystocentesis and placement of a urethral catheter).
- Administer an intravenous prophylactic broad-spectrum antibiotic immediately preoperatively.

Surgical Procedure: Herniorraphy

Objectives

- Replace contents of hernial sac into the peritoneal cavity.
- Reconstruct the pelvic diaphragm.
- Prevent deviation of the rectum and retroflexion of the bladder and prostate gland.

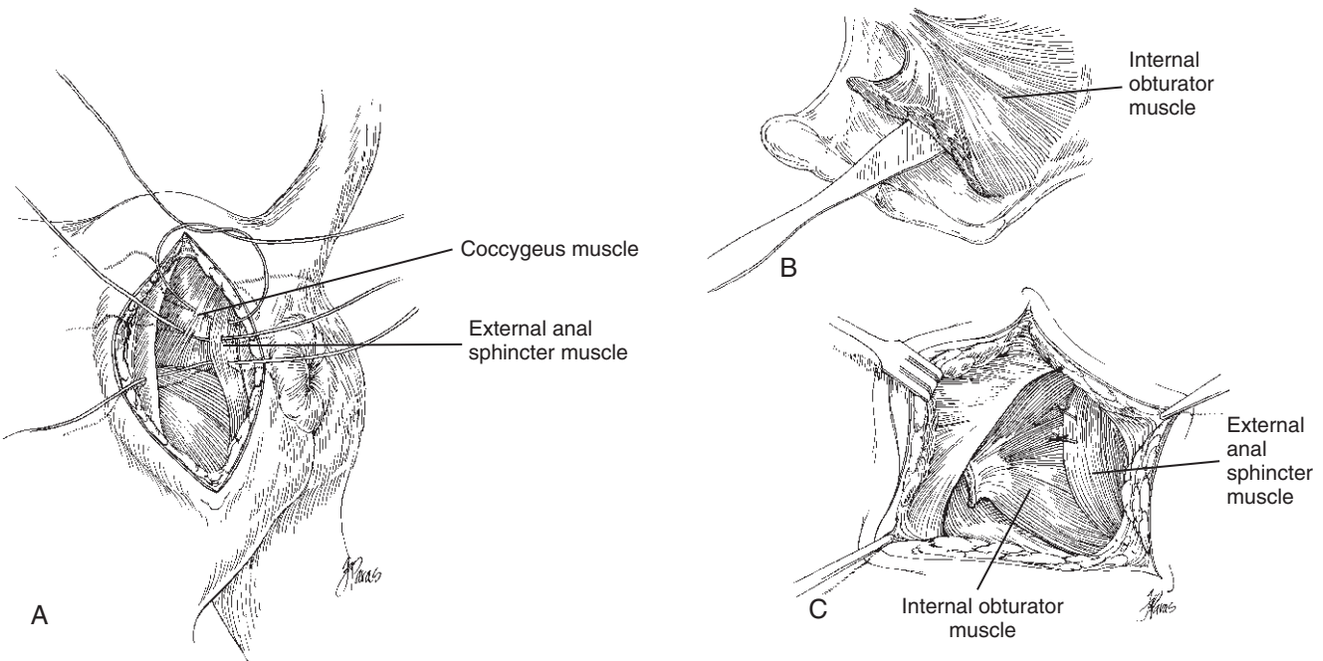

Figure 75-2. Repair of perineal hernia. Close the dorsal portion using the coccygeus and external anal sphincter muscles *(A)*. Close the remainder of the defect by elevating the internal obturator muscle *(B)* and suturing it to the external anal sphincter muscle *(C)*.

Equipment

- General surgery pack
- Self-retaining retractors
- $^1/_4$-inch Penrose drain

Technique

1. Place the animal in sternal recumbency and secure the tail forward over the back.
2. Place a pursestring suture around the anus.
3. Make a half-curved or a curvilinear incision, beginning just lateral to the base of the tail and extending ventrally below the perineal bulge.
4. Using blunt dissection, remove the tissue overlying the hernia sac; open the sac with scissors.
5. Gently replace the herniated viscera into the abdominal cavity.
6. Dissect the tissue overlying the external anal sphincter, exposing the muscle striations.
7. Identify dorsolaterally the levator ani and lateral coccygeal muscles.
8. Palpate the sacrotuberous ligament and use it as the lateral landmark.
9. Carefully isolate the neurovascular bundle containing the pudendal nerve and the internal pudendal vessels and place a $^1/_4$-inch Penrose drain around it to identify its presence as sutures are placed.
10. Repair the dorsal aspect of the hernia first by preplacing three or four sutures between the coccygeal musculature and the external anal sphincter. Monofilament non-absorbable sutures or synthetic absorbable sutures such as PDS or Maxon are preferred (Fig. 75-2*A*).
11. The sacrotuberous ligament may be incorporated with the coccygeal muscle when insufficient musculature is present. Tie the sutures.
12. Identify the obturator muscle and isolate by bluntly dissecting the overlying tissue.
13. Incise the caudal border of the internal obturator muscle and elevate the muscle with a periosteal elevator until the caudal border of the obturator foramen can be seen (Fig. 75-2*B*).
14. Partially or completely incise the tendon of the obturator muscle to allow the muscle to be drawn dorsomedially (Fig. 75-2*C*).
15. Preplace similar sutures between the obturator muscle and the external anal sphincter. Avoid penetrating the rectum. Tie the sutures after gently apposing the tissues.
16. Close the subcutaneous tissues (monofilament absorbable sutures) and skin (monofilament nonabsorbable sutures) routinely.

Alternative Techniques

- Porcine small intestinal submucosa has been used successfully as a primary means of repair in dogs or to augment the internal obturator muscle when it is too weak or thin to hold sutures securely. It can also be used as a last resort in those cases of failed herniorraphy.
- A staged approach has also been described in bilateral or complicated perineal hernias. This approach

uses a laparotomy as the initial step in the surgical treatment of bilateral or complicated perineal hernias in dogs.

1. Perform a ventral midline abdominal approach
2. Perform a colopexy (see Chapter 70) to reduce rectal sacculation or deviation of the rectum.
3. Perform either a vas deferens pexy, or cystopexy to prevent herniation of the urinary bladder. Vas deferens pexy involves fixing the vas deferens, after castration, to the interior abdominal musculature. Cystopexy involves creating a permanent adhesion between the apex of the urinary bladder and the peritoneum. Scarify the serosa of the urinary bladder with a scalpel, and then make an incision in the peritoneum and abdominal muscle adjacent to the bladder apex (similar to technique for colopexy). Suture the scarified bladder to the abdominal wall incision with 3 or 4 interrupted sutures (polydioxanone or monofilament non-absorbable)

- In those instances where there is a midline ventral component to the herniation, a semitendinosus muscle flap has been used as a salvage technique.

Postoperative Care and Complications

Short Term

- Administer postoperative analgesics (see Chapter 6).
- Straining to urinate or hematuria suggests iatrogenic trauma to the urethra by a misplaced suture.
- Rectal prolapse may occur, especially if a bilateral repair was done. Staging the repair of right and left sides several weeks apart usually eliminates this complication.
- Fecal incontinence may result from damage to the pudendal or caudal rectal nerves or to the sphincter muscle itself. If damage to innervation is bilateral, the animal usually will not regain continence.
- Urinary incontinence sometimes occurs postoperatively but is infrequent. It appears to be associated with bladder retroflexion before surgery.
- Wound infection may result because of improper suture placement through the rectal wall, penetration of the anal sac, or contamination. This usually is seen in the first 48 to 72 hours postoperatively.

Long Term

- Fecal or urinary incontinence may persist for weeks or months and sometimes indefinitely.
- Recurrence is directly correlated with the skill of the surgeon and the severity of the hernia. Castration may help to decrease recurrence regardless of the skill level of the surgeon.
- Colopexy and vas deferens pexy can be performed on recurrent hernias or if the initial hernia is severe. The colopexy procedure is described in Chapter 70. See "Supplemental Reading" for more information on the vas deferens pexy.

Prognosis

- If the surgery is performed by an experienced surgeon, the prognosis is good.
- Use of the obturator flap technique is believed to be associated with fewer problems postoperatively and with a lower recurrence rate.

ANAL SACCULECTOMY

The primary goal of anal sac surgery is correction of long-standing anal sac infection (see Chapter 74) that is refractory to conservative therapy.

Preoperative Considerations

- Do not perform anal sacculectomy during the acute inflammatory stage of infection.
- Administer antibacterial therapy, flush the anal sacs with antiseptic solutions, and use hot packs to control the sacculitis. (See Chapter 74 for a complete discussion of anal sac diseases.)
- Tumors of the apocrine glands of the anal sac are an indication for surgery (see Chapter 74). If neoplasia is suspected, obtain thoracic and abdominal radiographs (or abdominal ultrasound) to check for evidence of metastasis.
- A recent study suggests that complications associated with the standard open technique were greater than when using a closed technique.

Surgical Procedure

Objectives

- Remove the entire anal sac.
- Preserve anorectal function by carefully avoiding excessive trauma to the external anal sphincter muscle and its corresponding innervation.

Equipment

- General surgery pack
- Electrocautery
- Iris scissors (optional)

Technique

1. Place a scissors blade into the duct of each anal sac (Fig. 75-3*A*).
2. Use thumb forceps to place countertraction on the duct before cutting so that all structures can be exposed.
3. After incising the sac, identify the lining by its gray color.
4. Place mosquito forceps at opposite ends of the anal sac lining.

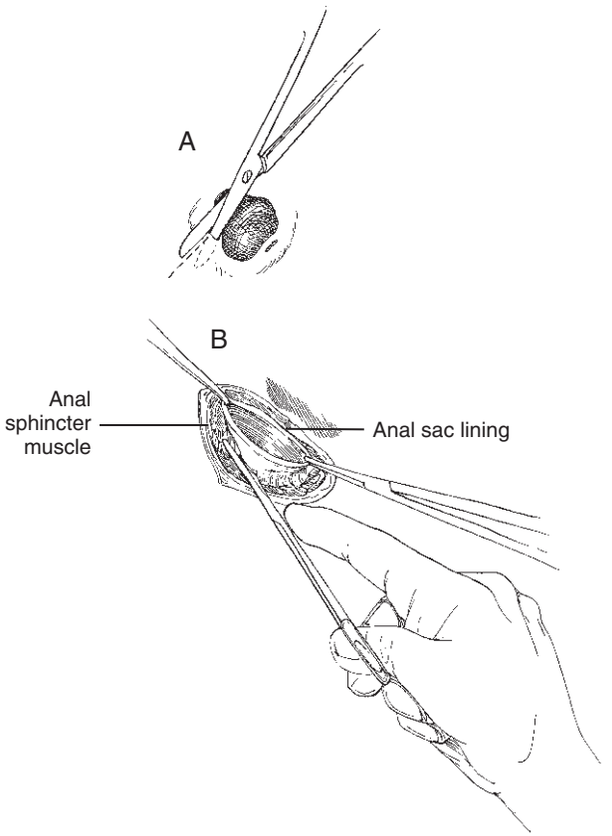

Figure 75-3. Surgical technique for resection of the anal sac.

5. Use small Metzenbaum or iris scissors to bluntly dissect the sac free of its attachments, including the fibers of the external anal sphincter (Fig. 75-3*B*).
6. When dissecting medial to the anal sac duct, preserve the caudal rectal artery.
7. Use fine, monofilament absorbable sutures to close defects in the anal sphincter and subcutaneous tissues after flushing thoroughly with saline. Close the skin with monofilament non-absorbable suture.

Alternative Technique

1. I now prefer a "closed" technique using a 6-French Foley catheter. Gently flush each anal sac to be removed with saline or a dilute antiseptic solution.
2. Place a 6-French silicone or latex catheter into the anal sac and fill the catheter bulb gently with saline until the anal sac can be easily palpated below the skin.
3. Occasionally, the inflated bulb will tend to migrate out of the anal sac as it is distended. Place a suture across the anal duct opening to prevent this.
4. The distended bulb makes identification and palpation of the gland simple. Gentle traction on the catheter by an assistant enhances the dissection of the sac from its surrounding attachments including the fibers of the external anal sphincter muscle. The wall of the sac is off-white or gray in appearance compared to the reddish color of the external anal sphincter.
5. Dissection with the inflated Foley catheter bulb allows the surgeon to stay close to the sac and minimize injury to the sphincter muscle fibers.
6. Once the sac is dissected free, excise the duct along its length toward the duct opening.
7. Flush the pocket that remains vigorously with saline. Repeat the flush three to four times as the subcutaneous tissues and skin are closed.
8. Close the deep tissues (including external anal sphincter muscle) and subcutaneous tissues with monofilament absorbable sutures.
9. Use 3-0 or 4-0 absorbable multifilament synthetic suture to appose the skin as it is softer and is less irritating to the tender perianal tissues. Remove sutures in approximately 10 to 14 days.

Postoperative Care and Complications

Short Term

- Hemorrhage due to inadequate hemostasis may continue after closure of the skin.
- Rarely, temporary or permanent fecal incontinence may result.
- Wound infection is more likely because of the location of the surgical site.
- Tenesmus or dyschezia may occur for a few days but usually resolves spontaneously.

Long Term

- Fistulous tracts may form after sacculectomy and are the result of incomplete excision of the anal sac lining.
- Wounds that do not heal after surgery may indicate a concurrent anal sac tumor.

Prognosis

- The prognosis is good with complete excision of the sac lining and preservation of the external anal sphincter.

Chapter

76 Peritonitis

Stephen J. Birchard

Peritonitis is a common problem in small animals. Primary peritonitis can occur in cats (feline infectious peritonitis; see Chapter 10), but other forms of peritonitis in dogs and cats are usually secondary to other diseases or injuries. Advances in the diagnosis and treatment of peritonitis have lowered mortality rates. However, peritonitis continues to be a serious and life-threatening condition that requires aggressive management.

In this chapter, the general topic of peritonitis is discussed. For more detailed information on the treatment of the specific causes of peritonitis, refer to appropriate chapters.

ANATOMY

The peritoneum is a serous membrane composed of mesothelial cells. It consists of the parietal peritoneum that lines the abdominal cavity and the visceral peritoneum that covers the abdominal viscera. The peritoneum has tremendous surface area (i.e., 50–100% of body surface area). The peritoneal cavity is closed in the male but open in the female through the reproductive tract. A small amount of fluid that lubricates the abdominal viscera is produced by the peritoneum.

ETIOLOGY

Viral

Feline infectious peritonitis is an example of primary peritonitis (see Chapter 10).

Bacterial

Gastrointestinal Perforation or Leakage

▼ ***Key Point*** Loss of bowel wall integrity accounts for the majority of cases of bacterial peritonitis in dogs and cats.

Leakage of bowel contents allows release of bacteria, predominantly anaerobes and gram-negative aerobes. Fluid and ingesta may also leak if gross bowel wall disruption occurs, resulting in a complex interaction of bacterial, chemical, and foreign body factors in the pathogenesis of peritonitis.

Bowel leakage can occur by a variety of mechanisms:

- *Perforation*—The bowel can be penetrated by external objects such as gunshot or a sharp object.
- *Neoplasia or granuloma*—Leakage from a necrotizing gastrointestinal (GI) neoplasm (carcinoma, lymphoma) or granuloma can occur.
- *Corticosteroids*—Colonic perforation can occur secondary to the administration of high doses of corticosteroids in animals with spinal compression.
- *Foreign bodies*—Sharp intestinal or linear foreign bodies frequently cause perforation (see Chapter 69). Also, intraluminal pressure on the intestinal wall by a foreign body can eventually lead to ischemic necrosis and leakage.
- *Blunt trauma*—Devitalization of the bowel can occur secondary to tearing of the mesenteric blood supply.
- *Strangulation*—Any process causing obstruction of the intestinal blood supply causes loss of mucosal integrity and eventually full-thickness necrosis (see Chapter 69). Loss of the so-called mucosal barrier can result in translocation of bacteria and/or endotoxins into the peritoneal cavity.
- *Dehiscence*—Unsatisfactory healing of a GI incision may result in leakage through the wound and subsequent peritonitis.

Pyometra

Bacterial infection of the uterus can lead to peritonitis by leakage through the fallopian tubes or overt rupture of a pus-filled uterus (see Chapter 90).

Prostatic or Liver Abscess

Abscesses of the prostate gland (see Chapter 84) or liver (see Chapter 71) may leak bacteria to the peritoneal cavity spontaneously or iatrogenically during surgical exploration.

Surgical Contamination

A breakdown in aseptic technique can result in contamination of the peritoneal cavity and peritonitis.

Chemical

Urinary Tract

Leakage of urine from any part of the urinary tract can cause chemical peritonitis.

- Causes of urinary tract disruption include trauma (blunt or penetrating), bladder or urethral rupture due to obstruction, and traumatic catheterization (see Chapters 77, 79, and 81). Urinary tract disruption due to blunt trauma frequently is associated with pelvic and sacral fractures or luxations.
- Bacterial peritonitis can complicate the chemical peritonitis from urine leakage if urinary tract infection was present before the leakage occurred.

Biliary Tract

- Trauma to the biliary tract can cause leakage of bile due to rupture of the gallbladder or one of the bile ducts.
- Spontaneous leakage of bile can occur with rupture of the gallbladder due to diseases like necrotizing cholecystitis and mucocele. Bacterial peritonitis may also complicate this situation.
- Bile is irritating to the peritoneum. However, several days may elapse before an affected animal is presented for clinical signs of peritonitis and biliary disease.

▼ ***Key Point*** A clinical study in dogs and cats found a grave prognosis for animals with combined bacterial and bile peritonitis.

Gastrointestinal Tract

- Gastric fluid contains hydrochloric acid and therefore is very irritating to the peritoneum. Proximal intestinal fluid contains bile and pancreatic enzymes that may cause a combination of chemical and bacterial peritonitis.
- Leakage of gastric fluid may occur due to trauma or any of the other causes of tissue breakdown listed under "Gastrointestinal Perforation or Leakage."
- Gastric fluid may leak secondary to perforating ulcers or necrotizing gastric neoplasms (see Chapter 67).
- Tissue necrosis secondary to gastric dilatation-volvulus can cause leakage of gastric contents.
- Gastric contents are not always sterile. Bacterial contamination associated with leakage of ingesta can complicate the peritonitis and result in a combination of chemical and septic peritonitis.

Chyle

- Disruption of the mesenteric lymphatics, lymph nodes, or cisterna chyli can cause leakage of chyle into the peritoneal cavity.
- Neoplasia or other diseases causing erosion or obstruction of the lymphatics are more likely causes than disruption due to trauma.
- Chyle is irritating to the peritoneum, although in some animals it is reabsorbed by the abdominal lymphatics.

Pancreatitis

- Leakage of pancreatic enzymes and various chemical mediators of inflammation from the inflamed pancreas causes peritonitis (see Chapter 73).
- Local peritonitis is very common with pancreatitis. Severe, necrotizing pancreatitis or pancreatic abscess may cause generalized peritonitis.

Traumatic

Penetrating trauma that involves the peritoneal cavity, such as a gunshot or knife wound, will cause peritonitis even if the viscera are not injured.

Iatrogenic (Surgical)

- Varying degrees of peritonitis result from surgical manipulation of the peritoneum or abdominal structures.
- Analysis of peritoneal fluid after routine abdominal surgery shows increased neutrophils and increased serum lipase concentrations, suggesting pancreatic inflammation.
- Typically, peritonitis from routine visceral manipulation is clinically insignificant. Poor surgical technique, such as rough handling of tissues, allowing tissues to become desiccated, and lack of aseptic technique, can result in more serious peritonitis.

Foreign Body

Sutures

- Implantation of excessive, large, or contaminated sutures can result in focal peritonitis.
- Non-absorbable braided sutures (e.g., Braunamid, B. Braun Melsungen) that are contaminated can cause chronic focal peritonitis and resultant sinus tracts and abscesses.

▼ ***Key Point*** Avoid placing non-absorbable, multifilament sutures in the peritoneal cavity or viscera.

Surgical Sponges

- Failure to remove surgical sponges can result in focal or diffuse peritonitis. Even sponges considered sterile can cause a significant foreign body reaction. Contaminated sponges cause abscesses and possibly severe, septic peritonitis.
- Prevention of this complication is essential.
- Count surgical sponges before and after surgery to be sure that none have been left in the abdomen.
- Use sponges that contain a radiopaque marker to allow diagnosis of a sponge foreign body with abdominal radiography.

Other Foreign Bodies

- Failure to remove surgical instruments can cause a foreign body reaction, irritation of viscera, and strangulation of blood supply to structures.
- Talc used on surgical gloves can cause a foreign body, granulomatous peritoneal reaction. After donning surgical gloves, rinse with sterile saline before opening the peritoneal cavity.
- Bacterial peritonitis is a potential complication of peritoneal dialysis caused by contamination during the procedure or ascending infection via the indwelling dialysis catheter.

DISTRIBUTION AND LETHAL FACTORS

Local Peritonitis

- Local peritonitis is common and usually does not require aggressive surgical management.
- The abdominal structures, such as the omentum and mesentery, are able to "wall off" inflammatory processes and prevent spread to the entire cavity.
- The production of fibrin by the peritoneum is also an important process in confining bacteria and debris to an isolated area of the peritoneal cavity.
- Permanent adhesions can be a sequela of local peritonitis, but they rarely cause a significant clinical problem in dogs and cats.

Diffuse Peritonitis

- Diffuse or generalized peritonitis occurs when the processes of confinement are overwhelmed and the entire cavity is affected.
- Diffuse peritonitis is a serious condition that requires aggressive medical and usually surgical therapy.
- Movement of the diaphragm, intestinal peristalsis, and gravity encourage dissemination of bacteria throughout the peritoneal cavity.
- Surgical manipulation of contaminated tissues can convert local to diffuse peritonitis.

Lethal Factors

Certain substances or combinations of substances have been shown to be especially devastating to the animal with peritonitis.

▼ ***Key Point*** The addition of blood, fluid, or barium (or other foreign material) to bacterial contamination of the peritoneum can cause severe, frequently fatal peritonitis.

- Hemoglobin and bacteria are a lethal combination in peritonitis. Hemoglobin tends to reduce the ability of the neutrophils to phagocytize bacteria.
- Barium sulfate, in addition to bacteria, has the same effect as hemoglobin.
- Excessive peritoneal fluid acts as an adjuvant in peritonitis. Fluid causes dissemination of bacteria and interferes with neutrophil migration along visceral and peritoneal surfaces.
- Contamination of the peritoneal cavity with multiple species of bacteria, such as occurs with bowel leakage, causes a more severe peritonitis than that due to one species.
- The combination of chemical and bacterial peritonitis is especially devastating. Proteolytic and lipolytic enzymes cause tissue necrosis, an ideal medium for bacterial growth.

CLINICAL SIGNS

Pain

The peritoneum is a very sensitive membrane. Irritation of the peritoneum can cause abdominal discomfort.

- The mildly affected animal is resistant to abdominal palpation.
- Signs of severe pain include reluctance to move and tachycardia and tachypnea.
- The animal may assume the "praying mantis" posture in an attempt to alleviate peritoneal pain.
- Peritoneal pain may cause the animal to contract the abdominal muscles, giving the abdomen a "tucked up" appearance.

Fever

- Pyrexia may or may not be present.
- Fever does not always imply sepsis but is more likely when bacterial contamination complicates peritoneal inflammation.
- An animal with overwhelming peritonitis, dehydration, and shock may have a subnormal temperature.

Vomiting

Vomiting may result from irritation of serosal surfaces, ileus, or the primary disease causing peritonitis.

Dehydration

- The peritoneum responds to inflammation by producing large amounts of protein-rich fluid.
- Loss of fluid from the peritoneum, inadequate intake of water and food, vomiting, and fever rapidly cause significant dehydration and hypovolemia.

Shock

- Hypovolemic shock can develop rapidly with peritonitis as a result of the processes described under "Dehydration," as well as the sequence of events described in Chapter 156 on shock.
- Septic shock also is possible with diffuse peritonitis owing to release of bacteria to the peritoneal cavity,

followed by absorption to the systemic circulation. Lysis of gram-negative bacteria that have leaked from the bowel causes endotoxemia. These endotoxins have a direct cytotoxic effect, as well as causing many systemic changes such as vasodilation and blood pooling, hypoglycemia, and acidosis.

DIAGNOSIS

History

- Thoroughly review the animal's history to gain clues to the presence of peritonitis and possible etiologies.
- Give special attention to any history of trauma or prior abdominal surgery.
- Determine if the animal recently ate any foreign bodies that could have caused bowel perforation.
- Determine if the animal has had any signs of gastric or colonic ulceration. A history of hematemesis, melena, or hematochezia is indicative of a more serious lesion of the GI tract and increases the suspicion of perforation.
- Determine if the signalment and history are typical of pancreatitis.

Physical Examination

- Look for the clinical signs listed previously.
- Carefully palpate the abdomen for evidence of pain, fluid, ileus, or masses. Perform a rectal examination to evaluate for evidence of pelvic trauma, prostate or urethral problems, or hematochezia.
- Evaluate for fever.

Diagnostic Tests

Fluid Analysis

Abdominocentesis

See Chapter 3 for a description of the technique for abdominocentesis.

- Animals with peritonitis will have many neutrophils (>500/μl) and may have bacteria on cytologic examination. Absence of bacteria suggests a sterile peritonitis, such as can occur with chemical peritonitis.
- The presence of bacteria within phagocytes confirms septic peritonitis. Bacteria within and outside phagocytes suggest that the infection is overwhelming the defense mechanisms. The presence of cocci and rods indicates mixed infection, such as can occur with GI perforation. Gram stain of the fluid can differentiate gram-negative rods (usually aerobes such as *Escherichia coli*) from gram-positive rods (usually anaerobes such as *Clostridium* spp.).
- Large numbers of red blood cells (RBCs) indicate hemorrhage associated with the peritonitis. This can occur with trauma, bleeding tumors, or disseminated intravascular coagulation.
- Recent studies indicate that animals with septic peritonitis have decreased abdominal fluid glucose compared with their serum.

Diagnostic Peritoneal Lavage

See Chapter 3 for a description of the technique for diagnostic peritoneal lavage (DPL).

- Observe the gross appearance of the fluid. Opaque fluid is likely from animals with peritonitis.
- Analyze the fluid for neutrophils (>500/μl is considered a positive finding), toxic neutrophils, bacteria, bilirubin, creatinine higher than serum concentration, amylase > 200 IU, and vegetable fibers.
- Animals that have had recent surgery normally have a high number of nucleated cells in the peritoneal cavity (>6000/μl).

Hematology

- Neutrophilia may be present with or without toxic neutrophils. A left shift (an increase in the number of band neutrophils) indicates more significant inflammation. A degenerative left shift (more bands than segmented neutrophils) indicates an overwhelming, life-threatening inflammatory process.
- Chronic blood loss or chronic infection may result in anemia.
- Hypoproteinemia due to loss or sequestration of albumin is very common in peritonitis.

Serum Chemistry Profile

- Many parameters may be altered, depending on the type of peritonitis and the associated clinical signs.
- Electrolytes (sodium, potassium, and chloride) may be depleted in animals that are vomiting. Acidotic animals may be hyperkalemic. Dehydration can artificially elevate electrolyte concentrations.
- Hypoglycemia may be present in animals with septic peritonitis.
- Serum urea nitrogen is elevated in animals with uroperitoneum and in animals suffering from prerenal azotemia due to dehydration or shock. Hyperkalemia may also be seen in animals with uroperitoneum.
- Serum pancreatic enzymes (amylase, lipase, trypsin) frequently are mildly elevated in all types of peritonitis, and they are moderately to markedly elevated when underlying pancreatitis is the cause of peritonitis.
- Serum liver enzymes and bilirubin are variably increased in all types of peritonitis and may be markedly increased in sepsis, biliary tract rupture, liver abscess, and pancreatitis.

Radiography

Plain Radiography

- Plain abdominal radiography usually reveals a loss of contrast and lack of soft tissue detail either focally or throughout the abdomen. Fluid may be present in the peritoneal cavity.
- Pneumoperitoneum may be seen if any portion of the GI tract has perforated or there has been penetrating abdominal trauma. Radiographs obtained using horizontal projection can confirm air in the peritoneal space, because it rises to the dorsum of the cavity (see Chapter 4).

Contrast Studies

- Perform positive-contrast urethrography, cystography, and/or intravenous (IV) pyelography if uroperitoneum is suspected (see Chapter 4).
- Perform positive-contrast GI studies to diagnose perforation (see Chapter 4). Avoid using barium as the contrast agent when perforation is suspected, because barium leakage into the peritoneal cavity can be devastating (treat with immediate laparotomy, peritoneal lavage, and drainage). Instead, use a water-soluble, non-ionic, iodinated contrast agent, such as iohexol (Omnipaque).

Ultrasonography

- Ultrasonography can confirm the presence of peritoneal fluid and can be used to assist in sampling the fluid for analysis. It is especially valuable for evaluating the pancreas as a potential cause of peritonitis.
- Soft tissue masses or abscesses may be detected (see Chapter 4).

TREATMENT

Management of peritonitis consists of supportive care and definitive measures to eliminate or correct the cause. The decision to treat the animal medically or surgically depends on the cause and the animal's response to treatment. If a surgical disease is not suspected and the peritonitis is mild, medical treatment alone may suffice. However, promptly initiate surgical treatment if the peritonitis is moderate or severe, is not improving with medical treatment, or is due to a surgical lesion such as a perforated intestine or biliary or urinary rupture.

Medical Management

Fluids

IV fluids are probably the most important supportive treatment. The type of fluids used depends on the type of peritonitis and the metabolic alterations present in the patient.

- In most cases, use lactated Ringer's solution supplemented with potassium to prevent or correct hypokalemia.
- After correcting the dehydration, give fluids at a maintenance rate, plus continuing losses, until the animal is able to maintain hydration with oral intake. (See Chapter 5 for fluid therapy details.)

Antibiotics

Systemic antibiotics are indicated in bacterial peritonitis. Choose antibiotics based on culture and sensitivity testing of peritoneal fluid.

- In the absence of culture results, use broad-spectrum bactericidal drugs. Results of Gram stain of abdominal fluid (see under "Diagnosis") can be used to guide antibiotic choice.
- Combinations of antibiotics may be necessary if a mixed population of bacteria is present. For example, combine ampicillin or one of the cephalosporins (e.g., cefazolin) with enrofloxacin for peritonitis due to a mixed bacterial population. Alternatively, if the animal has normal renal function, combine ampicillin with an aminoglycoside (e.g., amikacin or gentamicin). Other options include penicillins, clindamycin, or metronidazole for anaerobes and other fluoroquinolones for gram-negative rods.

Lavage and Drainage

▼ ***Key Point*** One of the most important treatments for peritonitis is drainage of fluid and debris from the peritoneal cavity.

Abdominal drains such as Penrose drains or sump drains (e.g., a fenestrated Brunswick catheter inside a fenestrated Penrose drain) are ineffective for draining the entire peritoneal cavity for any longer than a few hours. However, these types of drains can be effective for the initial drainage of the abdomen or for animals that are producing large amounts of abdominal fluid.

- Open abdominal drainage has been used successfully in experimental and clinical peritonitis and is described under "Surgical Management."

▼ ***Key Point*** Recent studies have found closed suction drains (e.g., Jackson Pratt drains) to be effective in the treatment of generalized peritonitis (see description under "Surgical Management").

- Lavage of the peritoneal cavity has been recommended but is controversial. Addition of fluid to the peritoneal cavity may potentiate generalized peritonitis and should only be used when all of the lavage fluid can be drained. Therefore, lavage should be reserved for those patients that undergo surgical treatment of the problem. Lavage consists of copious

amounts of warm, sterile saline. Continue lavage until the fluid removed from the peritoneal cavity appears clear.
- Addition of antibiotics or antiseptics to the lavage fluid has *not* been shown to have any benefit over the use of saline alone in conjunction with systemic antibiotics.
- Do not use aminoglycosides in peritoneal lavage during anesthesia, especially if systemic neuromuscular blocking agents are being used. Aminoglycosides can potentiate the effect of these agents. Also, aminoglycosides will be absorbed and can reach toxic blood levels if they also are being given parenterally.
- Avoid using povidone-iodine (Betadine) in lavage fluid in animals with peritonitis, because it can also be absorbed and cause severe toxicity, possibly due to absorption of large amounts of iodine.

Surgical Management

Correction of lesions resulting in peritonitis is covered in the appropriate chapters.

Preoperative Considerations

- As discussed under "Medical Management," correct fluid and electrolyte disorders, when possible, before surgery.
- Begin antibiotic treatment before surgery if contamination is present or is likely to occur during the surgery.

Closed versus Open Peritoneal Drainage

A key decision for the surgeon is whether to use closed or open drainage methods for peritonitis. Closed suction drains are reasonably effective for septic peritonitis. Complications with the use of these drains are less than with open drainage. Consider the following factors when deciding which type of peritoneal drainage to use:

- Type and severity of the peritonitis
  - If the source of the peritonitis can be definitively corrected at surgery, consider choosing closed peritoneal drainage.
- Ability of the patient to withstand the complications of open drainage
- Financial considerations (closed drainage patients tend to require less intensive therapy)
- Hospital facilities and personnel
- Personality of the patient
  - Open peritoneal drainage would be very difficult in a fractious animal.

Technique for Closed Peritoneal Drainage

1. After the laparotomy has been performed and the cause of the peritonitis has been corrected, lavage the abdominal cavity with warm, sterile saline. Use copious amounts of saline to flush bacteria and debris from the cavity. Discontinue flushing when the lavage solution appears clear on removal from the abdomen.
2. Place the drain(s) (e.g., Jackson Pratt drain) either directly adjacent to the source of the peritonitis or along the ventral midline to facilitate drainage of fluid from the entire abdomen.
3. If necessary, use absorbable sutures to tack the omentum to the peritoneum away from the drain to prevent occlusion.
4. Exit the drain from the abdominal cavity through separate stab incisions lateral to the ventral midline abdominal incision.
5. Close the abdominal incision routinely.
6. Frequently empty the drain reservoir, and characterize the type and amount of fluid.
7. Remove the drain when little or no fluid is being recovered and the patient's other clinical parameters are significantly improved (usually 3–5 days postoperatively).

Technique for Open Peritoneal Drainage

1. After the laparotomy has been performed and the cause of the peritonitis has been corrected, lavage the abdominal cavity with warm, sterile saline. Use copious amounts of saline to flush bacteria and debris from the cavity. Discontinue flushing when the lavage solution appears clear on removal from the abdomen.
2. Partially close the abdominal incision. Place large horizontal mattress or simple continuous sutures of monofilament polypropylene or nylon (1-0 or 2-0) in the linea alba to reduce the incisional gap to approximately 3 to 4 cm in width. Leave the remaining tissue layers open (Fig. 76-1*A*).
3. Cover the incision with a sterile dressing consisting of (from inside out) sterile petrolatum-impregnated gauze, sterile laparotomy sponges or towels, cotton, conforming gauze, and tape. Make the bandage large enough to extend several centimeters beyond the cranial and caudal aspect of the incision, and construct it so that slippage will not occur.
   a. Large monofilament polypropylene eyelet sutures can be placed, and umbilical tape "laces" used to hold the laparotomy pads or towels in place (Fig. 76-1*B*).
4. Change the bandage aseptically two or more times daily, depending on the quantity of fluid drainage. Sedate the patient if necessary for bandage changes. Gently break down omental or falciform ligament adhesions to the sutures with a sterile-gloved hand between bandage changes. If necessary, obtain samples of peritoneal fluid periodically for cytology and culture.
   a. Weigh the bandage before and after placement on the animal to estimate fluid loss (500 ml = 1 lb). Use this information to help

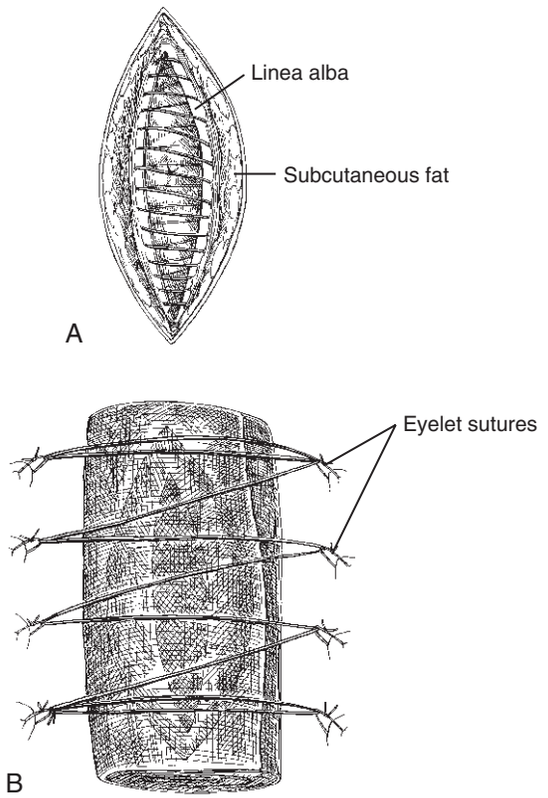

Figure 76-1. Partial closure technique for open abdominal drainage. *A,* Partially close the linea alba with a loosely placed, simple continuous suture using a monofilament non-absorbable material. *B,* To hold the primary layer of the abdominal bandage in place, put several eyelet sutures in the skin, then use umbilical tape to "lace" through the eyelets over the abdominal sponge.

calculate fluid requirements and to monitor the trend of abdominal fluid production.

5. In most patients, the abdomen can be closed within 5 to 7 days of the original surgery (see below). Perform abdominal closure by removing the original sutures in the fascia and proceeding with routine closure. Additional culture samples from the peritoneum may be obtained just before closure.

The decision on when to close the abdominal incision is subjective. Base this decision on several factors:

- Overall progress of the patient
- Quantity, character, and cytology of fluid drainage from the abdomen
- Resolution of fever and neutrophilia with a left shift

Postoperative Care and Complications

- Keep the bandage as clean as possible. Indwelling urinary catheterization may be necessary in a male dog, or the animal can be kept on an elevated grate to prevent urine soaking of the bandage.
- Open drainage of the abdomen can cause several complications:
  - *Loss of fluid and protein from the peritoneal cavity*—Supportive care with IV fluids and colloids is very important. Hyperalimentation (or total parenteral nutrition) also is necessary if the animal is not eating adequately (see Chapter 3 for nutritional management of the critical care patient).
  - *Electrolyte depletion, especially potassium*—Supplement IV fluids with potassium if necessary (see Chapter 5).
  - *Discomfort from the peritonitis and from the open abdomen*—Administer analgesics as necessary (e.g., morphine, butorphanol, buprenorphine, or oxymorphone) (see Chapter 6).
  - *Herniation of abdominal viscera or omentum*—This may occur if the bandage slips or is damaged by the animal. Gently lavage any tissue that becomes contaminated with sterile saline or remove surgically. Restrict exercise.

Chapter 77

Diseases of the Kidney and Ureter

David Grant / S. Dru Forrester

ACUTE RENAL FAILURE

Acute renal failure (ARF) is a syndrome caused by an abrupt decline in renal function that occurs over a period of hours to days. Clinical signs result from inability of the kidneys to excrete metabolic wastes and adequately regulate fluid, acid, base, and electrolyte balance. Consistent laboratory findings include azotemia with decreased urine concentrating ability (urine specific gravity usually <1.025).

▼ ***Key Point*** When azotemia is identified, it is important to distinguish among prerenal, renal, and postrenal causes.

- ***Prerenal azotemia*** can result from any disorder that decreases renal perfusion (e.g., dehydration, heart failure, or hypovolemia) or that results in increased production of urea (e.g., gastrointestinal hemorrhage). With few exceptions (Table 77-1), dogs and cats with purely prerenal causes of azotemia produce concentrated urine (i.e., specific gravity >1.035 in dogs and >1.040 in cats). In addition, prerenal azotemia quickly resolves when the cause of decreased renal perfusion is corrected (e.g., fluid therapy).
- ***Renal azotemia*** is caused by renal failure and occurs when 75% of nephrons are nonfunctional. Dogs and cats with renal failure have concomitant azotemia and inability to adequately concentrate urine. Isosthenuria (specific gravity of 1.008–1.012) often exists, and urine specific gravity (USG) is almost always <1.025, although some cats with renal failure maintain ability to concentrate urine up to 1.035. In contrast with prerenal causes, renal azotemia usually does not resolve quickly with treatment.
- ***Postrenal azotemia*** results from decreased elimination of urine from the body, most often due to urethral obstruction or a rupture in the urinary system. There usually is something in the history (e.g., trauma or stranguria) or physical examination (e.g., abdominal fluid, swelling or discoloration of the perineal area, or masses within the prostate, urethra, or urinary bladder) that suggests a postrenal cause of azotemia. Additional tests such as radiography (plain and contrast), ultrasonography, and abdominal fluid analysis are helpful in confirming postrenal azotemia. Postrenal azotemia also rapidly resolves after correction of the underlying cause.

Etiology

ARF in dogs or cats results from acute tubular necrosis (i.e., nephrosis) and less frequently from renal inflam-

NSAIDs, nonsteroidal anti-inflammatory drugs.

mation (i.e., nephritis). Acute tubular necrosis is caused by nephrotoxins or renal ischemia (Table 77-2). Nephritis usually is due to infectious diseases in small animals.

- *Toxins:* Renal tubular toxins are responsible for about 20% to 25% of cases of ARF. Ethylene glycol is responsible for the overwhelming majority of ARF cases due to toxins. Less commonly, drugs (e.g., aminoglycosides) are a cause of ARF.
- *Ischemia:* Renal ischemia probably causes ARF more often than was once considered. Approximately one-third of dogs with ARF have a condition that predisposes to renal ischemia. In general, renal ischemia is most likely to cause ARF in patients that have preexisting renal disease or that have multiple, concomitant disorders that cause renal injury.
- *Nephritis:* Nephritis causes ARF in a small number of cases, probably less than 10%. Leptospirosis is the most common infectious cause of ARF (see Chapter 19), but pyelonephritis also may cause ARF, especially if concomitant urinary obstruction exists. Rarely, ARF occurs in dogs with rickettsial infections such as Rocky Mountain spotted fever (see Chapter 17). Recently, Lyme disease has been associated with ARF in dogs (i.e., Lyme nephritis) (see Chapter 18).
- *Idiopathic:* Even after thorough evaluation, a cause for ARF cannot be identified in approximately 20% to 25% of patients.

Clinical Signs

Clinical findings in patients with ARF are nonspecific and include lethargy, depression, inappetence, vomiting, and diarrhea. Urine volume varies, and in most cases the patient is presented for other signs before the owner has a chance to observe a change in urinary habits. Most patients with ARF have normal to decreased urine output, although some have polyuria (e.g., aminoglycoside toxicosis).

Diagnosis

▼ ***Key Point*** Make sure to distinguish between ARF and chronic renal failure (CRF) because ARF is a potentially reversible condition that requires aggressive treatment initially.

Distinguish between ARF and CRF on the basis of findings from history, physical examination, and routine laboratory evaluation (Table 77-3). Evaluation of renal size by abdominal radiography or ultrasonography also is helpful. In some cases, a renal biopsy is necessary to make a definitive diagnosis of ARF or CRF.

History

- Carefully question owners about potential for exposure to nephrotoxins. Ethylene glycol toxicosis cannot be excluded in any patient that is allowed outdoors, especially in free-roaming pets. Ask the owner if the animal has been given any over-the-counter medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) (ibuprofen, aspirin).
- Ask about the patient's urine volume. Many dogs and cats with CRF have a history of polyuria/polydipsia (PU/PD), whereas oliguria or anuria usually indicates ARF.

Physical Examination

- Nonspecific findings on physical examination of patients with ARF include depression, dehydration, hypothermia, and oral ulcerations.

Table 77-3. DIFFERENTIATION BETWEEN ACUTE AND CHRONIC RENAL FAILURE

	Acute Renal Failure	Chronic Renal Failure
Clinical Findings	Acute onset of inappetence, depression, and vomiting (less than 1 week)	Chronic inappetence, vomiting, depression, weight loss (usually weeks to months)
	Usually moderate to severe depression	Often alert, responsive, and only slight depression
	Urine volume often decreased	Polyuria/polydipsia common
	Good body condition	May be thin
	Kidneys enlarged, painful but possibly normal	Kidneys small, irregular but possibly normal
	Bone density always normal	Bone density may be decreased
Lab Findings	Normal or increased hematocrit, but anemia may be present	Nonregenerative anemia, but hematocrit may be normal
	BUN and SCr previously normal but increasing progressively	BUN and SCr previously increased and typically stable
	Normal to increased serum potassium	Normal to decreased serum potassium
	Moderate to severe metabolic acidosis	Mild to moderate metabolic acidosis
	Urinary casts in some patients	Urinary casts usually absent
	Proteinuria or glucosuria may result from acute tubular necrosis	Proteinuria often present but usually due to glomerular disease

BUN, blood urea nitrogen; SCr, serum creatinine.

- Abdominal palpation may reveal enlarged, painful kidneys in patients with ARF, whereas finding small, irregularly shaped kidneys suggests CRF.
- Fever may be present in patients with ARF due to infectious diseases such as leptospirosis or pyelonephritis.
- Icterus in a patient with ARF suggests multisystemic disease such as leptospirosis, Rocky Mountain spotted fever, or disseminated intravascular coagulation.

Laboratory Evaluation

Hemogram

- Hemogram changes in patients with ARF usually are nonspecific and may include leukocytosis, with or without a left shift, and monocytosis. Increased hematocrit and plasma protein are consistent with dehydration. Mild anemia may occur secondary to gastrointestinal hemorrhage or hemodilution after fluid therapy. Finding a normocytic, normochromic, nonregenerative anemia (packed cell volume [PCV] <30%) is common in patients with CRF.

Biochemistries

- Serum chemistry abnormalities include azotemia and hyperphosphatemia. Hyperkalemia is very suggestive of ARF because patients with CRF usually have normal or low serum potassium. Some patients with ARF, especially due to ethylene glycol intoxication, may have hypocalcemia.
- Blood gas evaluation most often shows metabolic acidosis. Calculate the anion gap ([Na + K] − [Cl + HCO_3]) to help characterize metabolic acidosis; normal values for the anion gap are 12 to 18 mEq/L. An increased anion gap may occur with CRF, ARF, diabetic ketoacidosis, or lactic acidosis, but values >40 are almost always due to ethylene glycol intoxication or salicylate poisoning, which can be investigated by questioning the owner and performing an ethylene glycol test (measures blood levels of ethylene glycol).

Urinalysis

Analysis of urine, collected by cystocentesis where possible, should include evaluation of urine specific gravity, routine dipstick tests, and sediment examination.

- USG in patients with ARF is either isosthenuric (1.007–1.012) or minimally concentrated (usually <1.025).
- Dipstick analysis may reveal proteinuria or glucosuria, without concomitant hyperglycemia, due to renal tubular damage.
- Examine urine sediment for pyuria, bacteriuria, crystalluria, or cylindruria (renal casts).
  - Pyuria or bacteriuria suggests urinary tract inflammation or infection, respectively, and indicates the need for bacterial urine culture.
  - Hippurate or calcium oxalate crystals in patients with ARF suggest ethylene glycol intoxication.
  - White or red blood cell casts indicate renal inflammation or hemorrhage, respectively. However, most patients with pyelonephritis do not have white blood cell casts.
  - Renal epithelial cellular casts occur in patients with ARF due to acute tubular necrosis (i.e., nephrotoxicosis or ischemia).

Urine Culture

- Culture of urine collected by cystocentesis is indicated in patients with ARF to rule out urinary tract infection (UTI), a potentially reversible cause of renal injury.

Abdominal Radiography

- Plain radiographs of the abdomen help to objectively evaluate renal size and identify radiopaque uroliths that may be associated with urinary obstruction or infection.

Contrast Radiography

- Contrast radiography may be indicated to help identify urinary tract rupture or obstruction as a cause of postrenal azotemia (see Chapter 4).
- Excretory urography is indicated for evaluation of the kidneys and ureters. To avoid additional renal injury, establish adequate hydration prior to administration of IV contrast agents. Except for identifying rupture or obstruction of the upper urinary tract, excretory urography is of limited value in patients with renal failure because the kidneys cannot excrete contrast material well enough to produce useful images.
- Perform contrast urethrocystography when obstruction or rupture of the urinary bladder or urethra is suspected.

Ultrasonography

- Abdominal ultrasonography is helpful for evaluating renal size, changes in echogenicity, pyelectasia, perinephric effusions, and architecture and for identifying uroliths and signs of urinary tract obstruction (hydroureter, hydronephrosis). Ultrasonography is preferred over excretory urography for evaluation of the kidneys in patients with ARF (see Chapter 4).

Renal Biopsy

- Collection of renal tissue for histologic evaluation is unnecessary in most cases of well-defined ARF.
- Renal biopsy, however, may be helpful in the following situations:
  - When it is not possible to distinguish between ARF and CRF on the basis of clinical and laboratory findings
  - When the cause of ARF is not apparent and the mechanism of renal injury seems to be ongoing
  - When response to treatment is inadequate and expensive forms of treatment such as dialysis are being considered
- Renal biopsy is contraindicated in patients with coagulopathies (thrombocytopenia), renal cysts or abscesses, or hydronephrosis. Use caution in patients that have only one kidney.

Testing for Leptospirosis

- If leptospirosis is even a remote possibility, submit serum samples for determination of *Leptospira* titers (see Chapter 19 for guidelines on interpreting results of titers) as this is a potentially reversible cause of ARF.
- At minimum, evaluate *Leptospira* titers for serovars *L. pomona, L. grippotyphosa, L. bratislava, L. canicola,* and *L. icterohaemorrhagiae.*

Treatment

▼ ***Key Point*** Objectives of treating ARF are to minimize additional renal injury, promote diuresis if oliguria exists, and combat metabolic consequences of uremia.

- With time, renal injury in patients with ARF may be repaired so that there is adequate renal function to maintain homeostasis. This requires 2 to 4 weeks of aggressive medical treatment in many patients.
- Discontinue all potentially nephrotoxic drugs to avoid additional renal injury; if a potentially nephrotoxic drug must be administered, adjust the dosage appropriately. For drugs that undergo renal excretion, dividing the dose by the creatinine concentration or multiplying the dosing frequency (in hours) by the creatinine concentration provides a rough adjustment for the increased exposure to drugs in patients with renal failure.
- Rapidly correct all prerenal factors (dehydration, decreased cardiac output) so that renal perfusion is maintained.
- Administer treatment as necessary to control consequences of uremia such as vomiting, metabolic acidosis, hyperkalemia, and hyperphosphatemia.
- If an underlying cause of ARF or renal injury can be identified (pyelonephritis, leptospirosis), administer specific treatment to eliminate the disorder.

Initial Patient Management

- Determine baseline values for PCV, plasma or total protein, blood urea nitrogen (BUN), serum creatinine, phosphorus, potassium, calcium, sodium, and total carbon dioxide (CO_2).
- Record values for body weight and hydration status. Use body weight after rehydration as a reference for future comparisons.
- Aseptically place an indwelling IV catheter, preferably in a jugular vein. In addition to convenience for the patient, jugular catheters allow collection of blood, measurement of central venous pressure, and IV administration of hypertonic solutions (see Chapter 5).
- If oliguria (i.e., urine volume <1 ml/kg/hr) persists after apparent rehydration, place an indwelling urinary catheter so that urine volume can be objectively measured. Connect the urinary catheter to a closed collecting system. Unless absolutely necessary, avoid administering antimicrobials to patients with indwelling urinary catheters because it may predispose to development of resistant UTI.

Fluid Therapy

A comprehensive discussion of fluid therapy is provided in Chapter 5.

Initial Treatment

- Calculate the dehydration deficit using the following formula to determine volume of fluids (milliliters) to correct dehydration initially:

$$\% \text{ Dehydration} \times \text{Body Weight (kg)} \times 1000$$

- If cardiac function is normal, correct dehydration within 6 hours by administering fluids IV.
- Ideally, select the type of fluid on the basis of serum electrolyte concentrations and acid-base status. It usually is safe to use lactated Ringer's solution in most patients unless hyperkalemia exists. If serum potassium concentration is unknown, initial administration of 0.9% sodium chloride is more appropriate.
- Clinical dehydration may not be apparent in all patients with ARF; however, most of these patients have a history of inappetence, vomiting, and/or diarrhea. Therefore, it generally is safe to assume subclinical dehydration (3–5% of body weight) and treat accordingly. In most cases, it is better to cause slight overhydration than to risk persistent mild dehydration, which may contribute to prerenal azotemia and potentiate ischemic renal injury.

Maintenance Treatment

- After rehydration, the volume of fluids to administer IV for maintenance needs equals the sum of ongoing losses (e.g., vomiting or diarrhea), insensible losses, and urine volume ("in and outs"; see Chapter 5). The fluid rate/volume should be recalculated every 4 to 6 hours to prevent dehydration or hypervolemia.

▼ ***Key Point*** Select a fluid such as Plasma-Lyte M or Normosol-M to facilitate maintenance of normal serum electrolytes. Avoid lactated Ringer's solution and 0.9% sodium chloride because they contain too much sodium and too little potassium to be maintenance solutions. If a maintenance fluid is not available, alternate lactated Ringer's solution with 5% dextrose to avoid hypernatremia; add potassium to fluids as needed to maintain serum potassium concentration, especially during the recovery phase of ARF.

- Depending on the severity of renal injury, IV fluid therapy may be necessary for 1 to 3 weeks.

Discontinuing Fluids

- Gradually taper the volume of fluids administered to patients with ARF, once BUN and serum creatinine return to normal or oral intake of fluid is tolerated without vomiting.
- Provide unlimited access to water and decrease the patient's daily fluid volume administered IV by one-half every 24 hours.
- Monitor hydration (body weight, skin turgor, moistness of mucous membranes) closely while IV fluids are gradually discontinued.
- Monitor BUN, serum creatinine, and electrolytes every 1 to 2 days to detect need for additional treatment.

Reversing Oliguria

▼ ***Key Point*** Do not attempt to stimulate diuresis (increased production of urine) with diuretics in patients that are dehydrated or that have non-oliguric renal failure. This will worsen or cause dehydration and electrolyte disturbances, which adversely affect renal function.

If oliguria (<1 ml of urine per kilogram per hour) persists after correction of dehydration, additional treatment is indicated to increase urine production. Urine formation does not necessarily indicate improved renal function; however, it generally is easier to maintain serum electrolytes and acid-base balance in patients that are not oliguric. If there is any doubt whether oliguria exists, place an indwelling urinary catheter so that urine output can be measured.

IV Fluid Therapy

- IV administration of balanced electrolyte solutions promotes diuresis in normal patients and those with non-oliguric renal failure but usually is not effective in patients with ARF.
- Administer fluids to correct dehydration or cause slight volume expansion (3% to 5% of body weight) only and not 1.5 to 3 times maintenance volumes. Patients with ARF cannot adequately handle excessive IV fluids because of acute renal tubular dysfunction and are predisposed to overhydration, which may cause peripheral and pulmonary edema.

Mannitol (20% or 25%)

- Osmotic diuretics such as mannitol are often used initially to stimulate urine production in patients that remain oliguric after rehydration. In addition, mannitol may have beneficial free radical–scavenging properties.
- To avoid thrombophlebitis in peripheral veins it is preferable to administer hypertonic solutions (>10%) through a jugular vein.
- Initially, administer 0.25 to 0.5 g/kg IV over 5 to 10 minutes. If treatment is effective, increased urine production begins within 15 minutes. The goal is to produce 1 to 2 ml of urine per kilogram per hour.

- Continue mannitol every 6 to 8 hours as needed.
- If urine flow does not increase after initial treatment, repeat the dose every 15 minutes up to a total dose of 1.5 g/kg. Do not administer additional mannitol because vascular overload may occur.

Furosemide

- Loop diuretics, such as furosemide, may be administered to promote diuresis when an osmotic diuretic has been unsuccessful. Do not use furosemide in patients with aminoglycoside-induced ARF, because it can worsen renal injury.
- Administer furosemide at a dose of 2.2 mg/kg IV initially. If urine production increases, continue every 8 hours.
- If urine production does not increase within 30 to 60 minutes, administer a dose of 4.4 mg/kg IV. If there still is no response, administer furosemide 6.6 mg/kg IV. If the third attempt is unsuccessful, additional furosemide treatment is unlikely to be effective.

Dopamine

- Dopamine often is used to stimulate urine production when patients do not respond to other treatment. Infusion of low doses of dopamine causes dilation of renal vasculature and increased urine production.
- Dilute dopamine in 0.9% saline or 5% dextrose and infuse at a rate of 1 to 3 µg/kg/min using an infusion pump or pediatric infusion set.
- Ideally, a separate IV line should be used so that changes in rate of dopamine infusion can be made without interfering with administration of other IV fluids. However, patients with severe oliguria may need to receive dopamine mixed in a small volume of fluids to avoid overhydration.
- Monitor patients during infusion of dopamine, preferably by continuous electrocardiography, to detect tachycardia or cardiac arrhythmias, which indicate the need to slow the rate of infusion.
- If urine production increases, continue dopamine for 12 to 24 hours or until urine flow can be maintained with IV fluids.
- Continued infusion of dopamine after 6 hours is likely to be ineffective if urine production does not increase.

Furosemide and Dopamine Combination

- There is some evidence to suggest that concomitant treatment with furosemide and dopamine may be more effective than either drug used alone.
- We prefer to use both drugs simultaneously by administering dopamine as directed in the previous section and also giving furosemide at a dose of 1 mg/kg IV every hour.
- Treatment beyond 6 hours is unlikely to be beneficial.

Dialysis

Hemodialysis is the treatment of choice for ethylene glycol and salicylate toxicosis, life-threatening electrolyte disturbances, severe fluid overload, and cases in which oliguria persists despite measures to stimulate urine production. This requires an intensive care facility equipped for this procedure. For financial reasons, limited availability of hemodialysis, intense labor and complications of peritoneal dialysis, and guarded to grave prognosis for recovery in many cases of ARF, most owners elect euthanasia when dialysis is the only treatment that can maintain their pet.

Managing Electrolyte Disturbances

Hyperkalemia

Hyperkalemia is a potentially life-threatening electrolyte abnormality that occurs in patients with oliguria.

- Serum potassium concentrations between 6 and 8 mEq/L usually do not cause clinically important problems and are best treated by IV administration of 0.9% sodium chloride.
- If serum potassium concentration exceeds 8 mEq/L or if signs of cardiotoxicosis occur (bradycardia, prolonged P-R intervals, absent P waves, tall and peaked T waves, widened QRS complexes, ventricular arrhythmias), other treatment is indicated in addition to IV fluids. Administer sodium bicarbonate (0.5–1.0 mEq/kg) IV over 15 to 20 minutes. Sodium bicarbonate may be preferred in patients with ARF because they often have concomitant acidemia. Sodium bicarbonate causes potassium to move into cells, which lowers serum potassium concentration for several hours.
- Alternatively, administer 0.5 U/kg of regular insulin IV with 1 to 1.5 grams of dextrose for every unit of insulin. This also causes potassium to shift inside cells.
- If life-threatening cardiac arrhythmias exist, administer 10% calcium gluconate (0.5–1.0 ml/kg IV over 10 to 15 minutes) to effect. During treatment, monitor the electrocardiogram (ECG) for shortening of the QT interval and progressive bradycardia, and slow or discontinue calcium infusion if these occur. Calcium gluconate directly antagonizes effects of hyperkalemia on the myocardium for 10 to 15 minutes. It does not affect serum potassium; therefore, concurrent treatment with either bicarbonate or dextrose and insulin is indicated to lower serum potassium.

Hypokalemia

- Hypokalemia may occur during the recovery phase of ARF due to excessive urinary losses and decreased oral intake. Therefore, monitor serum potassium every 1 to 2 days to detect hypokalemia.

- Add potassium chloride to IV fluids as needed to correct hypokalemia (see Chapter 5 for specific guidelines).

Hyperphosphatemia

Hyperphosphatemia occurs secondary to decreased renal elimination of phosphorus in patients with ARF.

- IV administration of fluids helps lower serum phosphorus.
- Additional treatment to control hyperphosphatemia (i.e., feeding a phosphate-restricted diet and administering phosphate binders) can be instituted when the patient tolerates oral feeding.

Correction of Acid-Base Abnormalities

- Metabolic acidosis is the most common and clinically important acid-base disturbance that occurs in patients with ARF. Acidosis occurs because of the kidneys' inability to reabsorb bicarbonate and excrete hydrogen ions.
- Acidosis predisposes to cardiac arrhythmias, decreased cardiac output, decreased renal perfusion, hyperkalemia, and obtundation.
- Patients with blood pH values above 7.2 or a total CO_2 >12 mEq/L usually respond to IV administration of fluids alone.
- If blood pH is less than 7.2 or the total CO_2 is <12 mEq/L, administer sodium bicarbonate to help normalize acid-base status.
  - Calculate the initial bicarbonate dose (mEq) using the following formula: (base deficit) × (body weight in kg) × 0.3. If base deficit is unknown, substitute the value for (20 – total CO_2).
  - Administer one-quarter to one-half of the deficit over the first 1 to 2 hours, then add the remaining volume of bicarbonate to calcium-free IV fluids and administer over the next 12 hours.
  - Reassess blood gas data or total CO_2 to determine the need for additional bicarbonate therapy. If these values are not available, add bicarbonate at a dosage of 1 to 5 mEq/kg, depending on severity of initial acidemia, to IV calcium-free fluids to be administered over the next 12 to 24 hours.
- Refer to Chapter 5 for a detailed discussion of managing acid-base abnormalities.

Control Vomiting

Vomiting is a common complication of ARF due to effects of uremic toxins on the chemoreceptor trigger zone and emetic center and due to gastrointestinal ulceration, which results from decreased renal elimination of gastrin and subsequent gastric hyperacidity.

- Administer an H_2-receptor antagonist to help control uremic gastritis.
  - Administer cimetidine (Tagamet, SmithKline Beecham) IV initially at a dose of 10 mg/kg q12h. As uremia resolves, decrease the dose to 5 mg/kg IV q12h.
  - Alternatively, administer ranitidine (Zantac, Roche) at a dose of 2 mg/kg IV q8h in dogs and 2.5 mg/kg IV q12h in cats.
  - If vomiting persists, administer a centrally acting antiemetic.
  - Metoclopramide (Reglan, Robins) may be administered at a dose of 0.2 to 0.4 mg/kg IV q6–8h. Because it is a dopamine antagonist, do not use it concomitantly with dopamine.
  - Alternatively, administer chlorpromazine (Thorazine) at a dose of 0.25 to 0.5 mg/kg IV or IM q6–8h. Because chlorpromazine may cause hypotension and decrease renal perfusion, avoid using it in patients that are dehydrated. Do not combine chlorpromazine and metoclopramide as this can potentiate neurologic side effects.
  - Refer to Chapter 67 for other recommendations for treating gastritis and the control of vomiting.

Monitoring Patients

The objectives of monitoring patients are to evaluate response to treatment, avoid potential complications, and help establish a prognosis. Patients generally are monitored more frequently during initial treatment or when life-threatening complications such as severe metabolic acidosis, oliguria, or hyperkalemia exist and less often when there is improvement or stabilization of the patient's condition. Parameters that are evaluated include hydration status, body weight, urine volume, and laboratory values.

- Record body weight and hydration status 2 to 4 times daily. Clinical estimation of hydration status and fluid losses can be inaccurate. Once a patient is rehydrated, rapid changes in body weight generally reflect net fluid losses or gains and signal the need for a change in the rate of fluid administration.
- Measure hematocrit and total protein values at the end of rehydration and then at minimum daily to help evaluate hydration status.
- Measure serum chemistries and electrolytes at the end of rehydration and then at minimum daily for the first 4 to 7 days.
- Monitor blood gas values or total CO_2 and serum potassium several times daily if severe metabolic acidosis or hyperkalemia exists.
- To prevent overhydration, monitor changes in central venous pressure in patients with cardiac disease or persistent oliguria. In addition, a system of measuring "ins" and "outs" helps guide fluid therapy in these patients (see Chapter 5).
- Place an indwelling urinary catheter in patients that appear to have anuria or oliguria after rehydration. This helps determine the need for measures to stimulate urine production and guides fluid therapy to prevent overhydration.

Treatment of Underlying Causes of ARF

Leptospirosis

- Administer penicillin (20,000–40,000 U/kg IV q12h) or ampicillin (22 mg/kg IV q8h) initially. When vomiting resolves, administer doxycycline (5 mg/kg PO q12h) for 2 weeks to eliminate the carrier state of leptospirosis.

Ethylene Glycol (Antifreeze) Toxicosis

If a patient is presented within 6 hours of ingesting ethylene glycol, induce vomiting, lavage the stomach, and administer activated charcoal. If it has been less than 24 hours since ingestion, administer agents to slow conversion of ethylene glycol to its toxic metabolites. Unfortunately, most patients with ethylene glycol intoxication are presented after ARF develops and the following treatments are not effective. Remember, not all antifreeze products are ethylene glycol. Products containing propylene glycol are available and are less toxic. If in doubt as to which was consumed, treat for ethylene glycol exposure.

Ethanol

- Ethanol (20%) acts as a substrate for alcohol dehydrogenase and decreases metabolism of ethylene glycol. It remains the preferred treatment for ethylene glycol intoxication in cats.
- In dogs, administer 5.5 ml/kg IV q4h for five treatments, then q6h for four additional treatments.
- In cats, administer 5 ml/kg IV q6h for five treatments, then q8h for four additional treatments.

4-Methylpyrazole

- 4-Methylpyrazole (5%) inhibits alcohol dehydrogenase and does not cause central nervous system depression like ethanol. It is the preferred treatment for ethylene glycol intoxication in dogs.
- Administer 0.4 ml/kg IV initially, then 0.3 ml/kg IV at 12 and 24 hours after ingestion, and then a final dose of 0.1 ml/kg IV at 36 hours after ingestion.
- 4-Methylpyrazole is not effective for treatment of ethylene glycol intoxication in cats at dosages administered to dogs and therefore is not generally recommended. There is some evidence to suggest that when 4-methylpyrazole is administered 3 hours after ingestion of ethylene glycol it is safe and effective at preventing renal failure in cats. The dosing schedule is 125 mg/kg IV initially followed by 31.25 mg/kg at 12, 24, and 36 hours after ingestion.

Prevention

Because of expensive treatment and a guarded prognosis, make every effort to prevent ARF whenever possible.

- Warn owners about the danger of ethylene glycol if their pet lives outdoors.
- Do not use nephrotoxic drugs unless absolutely necessary (use enrofloxacin instead of aminoglycosides for severe gram-negative infections). If a nephrotoxic drug must be used, make sure the patient is well hydrated prior to treatment. Monitor serum drug concentrations, biochemical parameters, and urinalyses.
- Older patients often have chronic renal disease and are very susceptible to acute renal injury associated with dehydration or hypotension. Avoid stress and make sure the pet has access to fresh water at all times. Tell owners to avoid administering over-the-counter pain medications such as aspirin or ibuprofen. If general anesthesia is planned, administer IV fluids before and during anesthesia to maintain renal perfusion.

CHRONIC RENAL FAILURE

CRF is a syndrome characterized by inability of the kidneys to perform excretory, regulatory, and synthetic functions due to a loss of nephrons over a period of months to years. Loss of excretory function causes retention of urea nitrogen, creatinine, phosphorus, and other substances that are eliminated by glomerular filtration. Decreased ability of the kidneys to regulate fluid, electrolyte, and acid-base balance causes polyuria and/or polydipsia, hypokalemia, and metabolic acidosis, as well as other abnormalities. Failure of the kidneys to synthesize erythropoietin and calcitriol causes nonregenerative anemia and renal secondary hyperparathyroidism, respectively.

Etiology

Some breeds are predisposed to development of CRF due to congenital or familial renal disease; however, most dogs and cats with CRF are older and have acquired disease. Although many disorders may predispose to development of CRF in middle-aged to older patients, an underlying cause often is not identified. Regardless of the inciting cause, CRF tends to be a progressive and irreversible disorder.

- *Congenital and familial diseases* that cause CRF in dogs and cats are listed in Table 77-4.
- *Infectious and inflammatory disorders* may cause glomerular or tubulointerstitial damage that progress to CRF. Immune-mediated glomerular injury (e.g., glomerulonephritis) secondary to infectious or inflammatory diseases often progresses to cause CRF, especially in dogs. Tubulointerstitial inflammation associated with pyelonephritis, leptospirosis, or feline infectious peritonitis may progress to cause CRF.
- *Amyloidosis* may cause CRF secondary to deposition of amyloid in glomeruli or in the renal medulla.

Table 77-4. BREEDS WITH CONGENITAL OR FAMILIAL RENAL DISEASE

Breed	Renal Disease
Abyssinian cat	Renal amyloidosis
Basenji	Renal tubular dysfunction
Beagle	Unilateral renal agenesis, renal amyloidosis
Bernese mountain dog	Glomerulonephritis
Cairn terrier	Polycystic renal disease
Cocker spaniel	Hereditary nephritis
Doberman pinscher	Glomerulonephritis
Domestic longhaired and Persian cats	Idiopathic polycystic kidney disease
English foxhound	Renal amyloidosis
Lhasa apso	Renal dysplasia
Norwegian elkhound	Tubulointerstitial fibrosis
Pembroke Welsh corgi	Telangiectasia (idiopathic renal hematuria)
Samoyed	X-linked nephritis
Shih Tzu	Renal dysplasia
Soft-coated wheaten terrier	Renal dysplasia, protein-losing glomerulopathy

- *Neoplasia* of the kidneys infrequently causes CRF. Renal lymphoma in cats is the most common neoplastic cause of CRF.
- *Nephrotoxic substances* (drugs, toxins, hypercalcemia) usually cause ARF; however, CRF may persist after recovery from the acute insult.
- *Hyperthyroidism* in cats is often associated with CRF. Although the relationship is not yet fully understood, renal arteriolar hypertension is thought to play a role (see Chapter 31).
- *Idiopathic* glomerular or tubulointerstitial disease is the most common cause of CRF in dogs and cats. Despite thorough diagnostic evaluation, most patients do not have evidence of an inciting cause of renal injury.

Clinical Signs

Clinical signs in patients with CRF depend on the degree of renal insufficiency and the underlying cause.

- Lethargy, depression, and weight loss are frequent nonspecific signs.
- Gastrointestinal signs such as inappetence, vomiting, and diarrhea often occur in uremic patients; oral ulcerations also may be observed. Constipation is common in cats with CRF.
- Weakness and exercise intolerance may result from anemia.
- Polyuria and polydipsia often are reported by owners and may be the first abnormality noted.

Diagnosis

▼ ***Key Point*** Try to identify any concomitant disorders that may contribute to progression of CRF; these include pyelonephritis, hypertension, hyperthyroidism, hypercalcemia, renal neoplasia, and urinary obstruction.

History

- Ask owners about potential for exposure to nephrotoxic substances, including any over-the-counter medications.
- To help distinguish between CRF and ARF, ask how long clinical signs have been present. Most patients with CRF have changes in appetite, body weight, urine volume, and/or water consumption that have been present for several weeks to months, whereas clinical signs in patients with ARF have been present for <1 week.

Physical Examination

- Assess hydration status by evaluating skin turgor and moistness of mucous membranes.
- Examine the oral cavity for ulcerations that occur with uremia and pale mucous membranes that may be associated with anemia.
- Perform ophthalmic evaluation to detect changes consistent with hypertension, including retinal hemorrhages or detachments, or tortuous vessels.
- During abdominal palpation, try to evaluate renal size and consistency. Both kidneys usually can be palpated in cats, whereas in dogs only the left kidney can reliably be identified on physical examination. Small, firm, and/or "lumpy-bumpy" kidneys are typical of CRF, although kidneys in patients with CRF may be of normal size and consistency. Enlarged kidneys most often occur with ARF, especially in dogs. In cats, however, renomegaly may result from disorders that cause CRF such as hydronephrosis, feline infectious peritonitis, renal lymphoma, and polycystic kidney disease.
- Ascites, and less frequently peripheral edema, may be observed in patients with hypoalbuminemia due to severe glomerular disease.
- In cats, palpate the neck region for thyroid nodules.
- In dogs, perform a rectal examination to identify any potential causes of postrenal azotemia such as urinary bladder, urethral, or prostatic masses.

Laboratory Evaluation

- Hemogram often reveals nonregenerative anemia in patients with CRF. Infectious, inflammatory, or neoplastic diseases may cause hyperproteinemia.
- Serum chemistry abnormalities include azotemia and hyperphosphatemia.

▼ ***Key Point*** Approximately 75% of nephrons must be nonfunctional before azotemia occurs. This means that BUN and serum creatinine are insensitive indicators of renal function, and patients may have severe renal disease in the absence of azotemia.

- Hypokalemia often occurs in cats with CRF.
- Urinalysis shows decreased renal concentrating ability and isosthenuria (urine specific gravity of 1.008–1.013) in most patients. Some cats with CRF retain concentrating ability with values for urine specific gravity up to 1.035.

Urine Culture

- Culture urine obtained by cystocentesis to rule out UTI in all patients with CRF.

Leptospira Titers

- In addition to being a cause of ARF, leptospirosis can cause clinical signs related to decreased renal function for several weeks. If exposure is possible, measure serum microscopic agglutination titers (see Chapter 19).

Radiography

- Survey abdominal radiographs are helpful for evaluating renal size and identifying other abnormalities of the urinary tract such as radiopaque uroliths.
- Excretory urography may be indicated for evaluation of suspected pyelonephritis, hydronephrosis, and obstructive uropathy; however, reduced renal excretory function often limits usefulness of this technique (see Chapter 4).

Ultrasonography

- Ultrasonography is the preferred technique for identifying abnormalities in renal size and architecture.
- This can also be useful for diagnosing obstructive nephropathies, nephrolithiasis, neoplasia, polycystic kidneys, and renal dysplasia (see Chapter 4).

Renal Biopsy

- Consider collection of renal tissue for histologic evaluation when results could alter treatment or help give the owner a more accurate prognosis (biopsy techniques are described in Chapter 78).
- Disorders in which a renal biopsy may provide useful information include glomerular diseases (glomerulonephritis, amyloidosis) and renal neoplasia.

Systemic Blood Pressure

- Measure systemic blood pressure because 50% to 90% of dogs and cats with CRF are hypertensive.
- Indirect measurement of blood pressure using Doppler ultrasonic or oscillometric (e.g., Dinamap) techniques is most practical and convenient in the clinical setting.
- Collect three consecutive measurements of systolic, mean, and diastolic pressures and use the mean of these values.
- Hypertension is defined as systolic pressure greater than 180 mm Hg, mean pressure >150 mm Hg, or diastolic pressure > 100 to 120 mm Hg. Hypertension is also discussed in Chapter 153.

Treatment

Renal Transplantation

- Renal transplantation has become a legitimate option for treatment of cats with CRF. Postoperative survival is between 70% and 85% with some cats living many years. Cats must be free of concurrent diseases prior to consideration. Consider transplantation when medical management is failing and clinical signs are becoming apparent but are not advanced. Transplantation requires lifelong care of the recipient and the donor, frequent administration of medications, lifelong immunosuppression for the recipient, and significant time and financial commitment by the owner. Cost typically exceeds $5000 for the initial hospitalization and surgery followed by lifelong drug and monitoring costs. Numerous private and university clinics offer this service.
- Canine renal transplantation is not widely offered due to its relatively poor success compared with feline transplantation. On average, dogs do not live longer than a year following transplantation. Costs far exceed those of cats due to the number of immunosuppressants dogs require and their larger size.
- Because CRF is an irreversible disorder that usually has no identifiable underlying cause, and transplantation is rarely chosen or appropriate, the goals of treatment are to make the patient more comfortable and slow the progression of disease, if possible. This is accomplished by the following measures:
  - Control the clinical signs of uremia.
  - Maintain fluid, electrolyte, and acid-base balance.
  - Provide adequate nutrition.
  - Minimize the progression of renal failure by treating concomitant disorders such as UTI and hypertension.

Dietary Management

Dietary management of patients with CRF consists of feeding a diet that is moderately restricted in the amount of protein, phosphorus, and sodium while providing adequate amounts of non-protein calories, vitamins, and minerals. This approach has been shown to prolong survival and the time before uremic crisis.

Protein Restriction

- The primary beneficial effect of feeding a restricted amount of high-quality protein (which contains only essential amino acids) is to control clinical signs of uremia by reducing the amount of nitrogenous wastes that result from protein catabolism.

- Currently recommended protein levels for dogs (2.0–2.2 g/kg/day) and cats (3.3–3.5 g/kg/day) may be achieved by feeding commercial or homemade diets.
- Adjust protein intake to prevent malnutrition as evidenced by hypoalbuminemia, worsening anemia, or weight loss.
- Severely restricted protein diets (1.25 g/kg/day) that are used to treat patients with urolithiasis should be reserved for patients that continue to have signs of uremia after moderate protein restriction and even then should be used carefully because of potential for protein malnutrition.

Phosphorus Restriction

- Feeding a phosphate-restricted diet also may lessen signs of uremia and could prevent progression of CRF by blunting renal secondary hyperparathyroidism and decreasing renal mineralization. Most protein-restricted diets are also phosphate restricted.

Sodium Restriction

- Restriction of dietary sodium may help control hypertension in patients with CRF.
- Gradually restrict sodium intake by changing to the new diet over a 2- to 4-week period to allow the kidneys time to adapt to changes in sodium intake. A sudden decrease in dietary sodium could precipitate hypovolemia, which could worsen renal function.
- Avoid severely restricted sodium diets such as those used to treat patients with congestive heart failure because they may cause volume depletion and renal hypoperfusion.

Calcitriol Supplementation

- Calcitriol concentrations can become deficient in patients with CRF due to failure of renal metabolism. Calcitriol supplementation has been suggested for CRF patients because of its purported suppressive effects on parathyroid hormone secretion. Parathyroid hormone is considered by some to be a uremic toxin, and renal secondary hyperparathyroidism can certainly cause loss of bone density. In uncontrolled studies of veterinary patients with CRF, calcitriol has been associated with decreased uremic signs. Currently, controlled studies are under way to evaluate the efficacy of calcitriol in CRF patients. Until these results are available, we do not recommend routine use of calcitriol in dogs and cats with CRF.

Managing Fluid/Electrolyte/Acid-Base Disorders

Fluid Balance

Because of tubular dysfunction, patients with CRF cannot adequately produce concentrated urine and have primary polyuria. Fluid balance is maintained by increased water consumption.

▼ ***Key Point*** Be sure that patients with CRF have unlimited access to fresh water at all times.

- If water intake is not adequate to maintain hydration, as is often the case in cats, owners can administer supplemental fluids subcutaneously or via a gastrostomy tube at home.

Potassium Balance

Hypokalemia is the most common abnormality of serum potassium in patients with CRF; it is more common in cats than in dogs. Hypokalemia most likely results from decreased oral intake, as well as excessive urinary loss of potassium.

- If the patient is not vomiting, oral administration of potassium is preferred.
- Administer potassium gluconate (Tumil-K) at a dose of 2 to 6 mEq/cat once or twice daily, depending on severity of hypokalemia and the cat's size.
- Initially, monitor serum potassium weekly to determine the appropriate maintenance dose; 2 to 4 mEq/cat once daily often is adequate.
- If parenteral potassium is necessary due to vomiting or severe hypokalemia, administer potassium chloride with IV fluids (see Chapter 5 for details).

Metabolic Acidosis

Metabolic acidosis is the most common acid-base abnormality in patients with CRF. Treatment generally is indicated if blood pH is <7.2 or total CO_2 is <12 mEq/L.

- Administer sodium bicarbonate at a dose of 8 to 12 mg/kg PO q8–12h (1 teaspoon of baking soda = 2000 mg sodium bicarbonate); start at the lower dose and give several times daily to avoid fluctuations in blood pH.
- Alternatively, administer potassium citrate at a dose of 0.3 to 0.5 mEq of potassium per kilogram PO q12h. One advantage of potassium citrate is that it can be used to treat both hypokalemia and metabolic acidosis, which may be present together.
- Monitor total CO_2 in 10 to 14 days and try to maintain values within the normal range (e.g., 18–24 mEq/L).
- Avoid administering urinary acidifiers or feeding diets that are intended to acidify urine because they may worsen metabolic acidosis.

Controlling Hyperphosphatemia

Dietary phosphate restriction usually is successful for controlling hyperphosphatemia initially; however, as renal failure progresses, additional measures are necessary. Administer phosphate binders with a phosphate-restricted diet to provide additional control.

- Aluminum hydroxide, calcium carbonate, and calcium acetate are effective phosphate binders.

- Administer aluminum hydroxide at an initial dose of 100 mg/kg/day.
- Alternatively, administer calcium carbonate (100 mg/kg/day) or calcium acetate (60 mg/kg/day) if hypercalcemia does not exist.
- Phosphate binders are most effective when the daily dose is divided and administered 3 to 4 times daily with meals.
- Monitor serum phosphorus and calcium concentrations every 2 to 4 weeks initially and adjust the dose of phosphate binder as needed to maintain normophosphatemia.
- Side effects of phosphate binders include constipation with aluminum hydroxide and diarrhea or hypercalcemia with calcium-containing products.

Treatment of Anemia

Treatment of anemia may be indicated when hematocrit is <25% in cats and <30% in dogs or when clinical signs such as fatigue, depression, weakness, or respiratory distress occur. It is likely that anemia is responsible for many of the signs of CRF that have been attributed to uremia. This is supported by the observation that correction of anemia is associated with substantial clinical improvement and quality of life despite continued or worsening azotemia.

Transfusion

- Administration of whole blood or packed red cells generally is reserved for patients with severe clinical signs (dyspnea, extreme lethargy) due to anemia. Because of cost, limited availability of blood products, and inconvenience of repeated transfusions, this is not an option for long-term maintenance of hematocrit in dogs and cats with CRF.

Erythropoietin

- At this time, administration of recombinant human erythropoietin (Epogen) is the most reliable method for correcting anemia due to CRF in dogs and cats. It may be cost prohibitive for some owners and has potentially significant side effects; however, its beneficial effects exceed its disadvantages for patients with severe anemia due to CRF. Because erythropoietin is a human drug and is not approved for use in veterinary patients, obtain informed consent from owners before treatment.

Treatment Protocol

- Prior to using erythropoietin, measure blood pressure and control hypertension.
- Evaluate iron status by measuring serum iron and total iron-binding capacity (TIBC) and calculating the percentage of saturation (serum iron divided by TIBC). If iron deficiency is detected (see Chapter 22), it should be corrected before administration of erythropoietin.
- Administer erythropoietin (75–100 U/kg SC 3 times weekly) until hematocrit reaches 37% to 45% in dogs and 30% to 40% in cats; this usually requires 8 to 12 weeks of treatment, depending on severity of anemia and individual patient response.
- Because of the time required to reach a normal hematocrit, it may be more cost effective to administer a transfusion, especially in larger patients, and then begin treatment with erythropoietin.
- Once hematocrit reaches the low normal range, decrease frequency of treatment with erythropoietin to twice weekly. If anemia recurs during twice weekly treatment, administer erythropoietin 3 times weekly again. Most patients can be maintained with a dose of 75 to 100 U/kg 2 or 3 times per week.
- Because of tremendous demand for iron during treatment with erythropoietin, there is great potential for developing iron deficiency. Therefore, it may be best to administer iron to all patients receiving erythropoietin. Oral ferrous sulfate has been recommended for cats (50–100 mg/cat/day) and dogs (100–300 mg/dog/day); however, iron products often are unpalatable and cause gastric irritation. One over-the-counter ferrous sulfate product (Slow Fe) appears to be less likely to cause gastric irritation and may be suitable for veterinary patients.

Monitoring

- Monitor patients carefully during treatment with erythropoietin to determine efficacy and detect side effects.
- Measure hematocrit weekly until it reaches the normal range and remains stable for 4 weeks on a maintenance dosage and then every 1 to 2 months.
- Determine iron status 1 month after beginning treatment and every 2 to 3 months thereafter. Increase iron supplementation if serum iron is <84 µl/dl or the percentage of saturation is <20%.
- Measure blood pressure once monthly during initial treatment then every 1 to 2 months thereafter. If hypertension exists, monitor blood pressure more frequently and begin treatment.

Side Effects

- In addition to seizures and exacerbation of hypertension, the most clinically important side effect of treatment is development of antibodies against erythropoietin. This is reported to occur in 25% to 30% of veterinary patients. Development of antibodies is characterized by a precipitous drop of hematocrit that is preceded by erythroid hypoplasia of bone marrow. If this occurs, discontinue erythropoietin. These patients become transfusion dependent because the antibodies also form against endogenous

erythropoietin, and hematocrit often is lower than before treatment with erythropoietin.

Controlling Hypertension

Because of the potential for serious consequences (blindness, worsening of renal failure), treat hypertension whenever it is identified in a CRF patient. The goal is to maintain normal systemic blood pressures (systolic <160 mm Hg, diastolic <90 mm Hg).

- Feed a diet that is moderately restricted in sodium; most diets formulated for patients with CRF fit this criterion.
- Hypertension in patients with CRF usually does not respond to dietary sodium restriction alone and also requires administration of antihypertensive drugs. Avoid administering drugs to control hypertension if blood pressure cannot be adequately monitored. It is best to start with a single drug at the lowest dose and gradually increase the dose; however, it is not uncommon for hypertensive dogs and cats to require multiple drugs administered simultaneously to control hypertension (see Chapter 153 for additional treatment recommendations).
- To determine efficacy of treatment, monitor blood pressure every 1 to 2 weeks until pressures stabilize within the normal range and then every 1 to 3 months indefinitely.
- *Calcium channel blockers* cause vasodilation and decreased blood pressure and are effective antihypertensive agents. Amlodipine (Norvasc) is a long-acting calcium channel blocker and seems to be the most effective antihypertensive drug in cats (0.625 mg/cat PO q24h).
- *Angiotensin-converting enzyme* (ACE) inhibitors such as enalapril or benazepril (0.25–0.5 mg/kg q12–24h) also may be used initially to control hypertension. ACE inhibitors are commonly chosen as a first line antihypertensive in dogs. They prevent formation of angiotensin II, resulting in arteriolar dilation, vasodilation, and decreased blood pressure. Because ACE inhibitors can worsen renal function, it is important to start with a low dose and gradually increase while monitoring renal function. If azotemia develops or worsens, discontinue ACE inhibitors.
- *Beta-blockers* appear to decrease blood pressure by decreasing cardiac output, inhibiting renin release, or decreasing sympathetic activity. Atenolol (0.25–1.0 mg/kg PO q8–12h) is preferred in patients with respiratory disease because it is a cardioselective beta-blocker and does not cause bronchoconstriction like propranolol (0.25–1.0 mg/kg PO q12–24h).

Monitoring Patients

Monitor patients with CRF to determine efficacy of treatment and need for adjustments in therapy. Frequency of evaluation depends on severity of metabolic complications and the patient's overall condition. Those with severe abnormalities obviously need more frequent monitoring than stable patients.

- Evaluate stable patients (those that are eating, drinking, and maintaining body weight) every 2 to 4 months.
- Perform physical examination to detect changes in body weight, hydration status, and general condition.
- Perform laboratory evaluation including CBC, serum chemistries, electrolytes, and urinalysis to determine need for adjusting treatment.

PYELONEPHRITIS

Pyelonephritis implies inflammation of the renal pelvis and kidney; however, it usually is used to describe bacterial infection of the kidneys. Altered host defense mechanisms (diabetes mellitus, hyperadrenocorticism, hydroureter, ectopic ureters, nephrolithiasis) predispose to development of pyelonephritis, although not all patients have an identifiable cause. In general, UTIs, including pyelonephritis, occur more often in dogs than cats. For additional information on UTIs, see Chapter 79.

Etiology

▼ ***Key Point*** Ascending infection from the urinary bladder is the most common route of renal infection.

Organisms that most often cause UTI in dogs and cats include *Escherichia coli, Staphylococcus, Streptococcus, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus,* and *Enterobacter.*

Clinical Signs

- Acute pyelonephritis often is associated with lethargy, depression, dehydration, fever, and abdominal pain.
- Chronic pyelonephritis usually is subclinical or is characterized by vague signs such as weight loss, inappetence, and polyuria or polydipsia.
- Patients with pyelonephritis may have concomitant signs of lower UTI such as pollakiuria, stranguria, and dysuria.
- Discolored urine (hematuria) or malodorous urine also may be noted.

Diagnosis

Because there is no specific test that is diagnostic of pyelonephritis, a presumptive diagnosis usually is made on the basis of clinical findings and results of laboratory evaluation and diagnostic imaging.

History

- Clinical signs may be apparent from the history; however, many patients with pyelonephritis have no clinical signs.

Physical Examination

- Palpate the kidneys to detect enlargement or pain, which may occur with acute pyelonephritis.
- Physical examination usually is unremarkable in patients with chronic pyelonephritis.

Laboratory Evaluation

- *Serum chemistries* often are normal unless concomitant renal failure exists, causing azotemia and hyperphosphatemia.
- *Hemogram* changes may include leukocytosis characterized by mature neutrophilia with or without a left shift.
- *Urinalysis* may show decreased urine specific gravity, proteinuria, hematuria, pyuria, granular or smooth casts, and/or bacteriuria. Although white blood cell casts are diagnostic of renal inflammation, they often are not observed in patients with pyelonephritis.

Urine Culture

- Quantitative culture of urine collected by cystocentesis is indicated in patients with suspected pyelonephritis.
- A positive urine culture indicates UTI, but it must be interpreted with clinical findings and results of other diagnostic tests to make a presumptive diagnosis of pyelonephritis. For additional information on urine culture, see Chapter 79.
- Some patients with chronic pyelonephritis may have a negative urine culture because infection has been treated previously or resolved.

Radiography

- Results of excretory urography help support a diagnosis of pyelonephritis, but changes are neither sensitive nor specific (see Chapter 4).
- Dilation of ureters and renal pelves and blunted opacification of the collecting system may be observed in patients with pyelonephritis. Predisposing factors may also be identified (nephroliths, malformations).

Ultrasonography

- Ultrasonography is an excellent noninvasive method for evaluating patients with suspected pyelonephritis (see Chapter 4).
- Ultrasonographic findings of pyelonephritis include dilation of the renal pelvis and proximal ureter and generalized hyperechogenicity of renal cortices. Predisposing factors may also be identified (nephroliths, malformations).

Treatment

Treatment of patients with pyelonephritis includes correction of abnormal host defenses if possible and administration of appropriate antimicrobials.

- Ideally, select an antimicrobial based on results of urine culture and susceptibility.
  - Because treatment of patients with acute pyelonephritis must begin before culture results are available, select an antimicrobial such as ampicillin that is effective against many of the organisms that cause UTI and can be administered parenterally.
  - If life-threatening septicemia is suspected, administer a broad-spectrum combination such as ampicillin and enrofloxacin.
- Administer parenteral antimicrobials to patients with acute pyelonephritis until systemic signs such as fever, pain, and inappetence resolve (usually 2–3 days). Then administer oral antibiotics as for chronic pyelonephritis.
- Administer oral antimicrobials to patients with chronic pyelonephritis for a minimum of 6 to 8 weeks (Table 77-5).
- Monitor effectiveness of treatment by performing urine cultures 7 to 10 days after beginning treatment and 5 to 7 days after completing treatment.
- To detect relapsing or recurrent infections, repeat urine cultures every 4 to 8 weeks until negative findings are obtained from three consecutive cultures.

GLOMERULAR DISORDERS

Glomerular disorders are characterized by significant proteinuria that causes hypoalbuminemia. Glomerulonephritis and amyloidosis are the two most common disorders that cause glomerular disease in dogs and cats. In general, glomerular disorders are more commonly diagnosed in dogs than in cats.

Table 77-5. ANTIMICROBIAL DOSAGES FOR PYELONEPHRITIS

Drug	(mg/kg)	Frequency
Ampicillin/amoxicillin	25	q8h
Cephalexin	18	q8h
Tetracycline	18	q8h
Trimethoprim sulfa	15	q12h
Amoxicillin/clavulanic acid	16.5	q8h
Enrofloxacin	5 (dogs)	q12h
	2.5 (cats—maximum)	q12h

Etiology

- Many systemic infectious or inflammatory processes can cause production of immune complexes that adhere to glomeruli (i.e., glomerulonephritis) or that stimulate production of amyloid, which deposits in glomeruli (Table 77-6).
- Some breeds of dogs have a familial predisposition to development of glomerular disease (see Table 77-6).

Clinical Signs

- Signs that may result from hypoalbuminemia include weight loss, peripheral edema, and ascites. The combination of ascites or edema and hypoalbuminemia, proteinuria, and hypercholesterolemia is referred to as *nephrotic syndrome*. This syndrome is rare in dogs but relatively common in cats with glomerular disease.
- Inappetence, vomiting, and diarrhea may occur in patients that have developed CRF and azotemia secondary to glomerular disease.
- Some patients may have severe proteinuria and no clinical signs.

Table 77-6. CONDITIONS ASSOCIATED WITH GLOMERULONEPHRITIS IN DOGS AND CATS

	Cats	Dogs
Infectious	Feline infectious peritonitis	Heartworm disease
	Feline leukemia virus infection	Leishmaniasis
		Lyme disease
		Bacterial endocarditis
		Pyometra
		Ehrlichiosis
		Canine adenovirus-2 infection
Neoplastic	Lymphoma	Lymphocytic leukemia
	Myeloproliferative disorders	Transitional cell carcinoma
		Lymphoma
	Mast cell tumors	Bronchogenic adenocarcinoma
		Many others
Hereditary		Doberman pinscher
		Bernese mountain dog
		Beagle
		Soft-coated wheaten terrier
		Samoyed
		Bull terrier
		Standard poodle
		Golden retriever
		Cocker spaniel
Inflammatory	Systemic lupus erythematosus	Systemic lupus erythematosus
		Chronic dermatopathy
	Polyarthritis	Polyarthritis
		Immune-mediated hemolytic anemia
		Prostatitis
Endocrine		Hyperadrenocorticism
		Diabetes mellitus
Drugs		Corticosteroids
		Trimethoprim sulfadiazine

Diagnosis

▼ ***Key Point*** Look for historical, physical, and laboratory findings that might suggest the underlying cause of glomerular disease such as infectious, immune-mediated, parasitic, or neoplastic conditions.

History

- Try to determine potential for exposure to infectious diseases by asking owners about travel history, environment, and tick control. Certain infectious diseases are more common in some geographic areas and in pets that live outdoors or are housed in kennels or catteries.
- Ask owners about vaccination, heartworm preventive, and feline leukemia virus status.
- If the patient is an intact female, consider pyometra as a potential cause of glomerulonephritis and determine when the last heat cycle occurred.

Physical Examination

- Some patients with glomerular disease develop peripheral edema or ascites.
- Thin body condition, decreased muscle mass, and poor haircoat are common but nonspecific findings.
- Hypertension is common with glomerular disease. Perform a fundic examination to evaluate for tortuous vessels, hemorrhages, or detachments.
- Carefully examine patients for any signs of systemic infectious, inflammatory, or neoplastic disorders that may predispose to development of glomerular disease. These signs include the following:
  - Fever
  - Anterior uveitis or chorioretinitis
  - Dermatologic lesions such as chronic pyoderma or mucocutaneous ulcerations
  - Lymphadenopathy
  - Hepatomegaly or splenomegaly
  - Icterus
  - Abdominal pain
  - Enlarged uterus or other abdominal masses
  - Joint swelling, pain, or reluctance to walk
  - Signs consistent with hyperadrenocorticism such as thin skin, abdominal distention, and hyperpigmentation

Laboratory Evaluation

- *Hematologic abnormalities* are nonspecific and may include nonregenerative anemia, hypoproteinemia, and leukocytosis. Some infectious, inflammatory, or neoplastic disorders may be associated with thrombocytopenia. Occasionally, hyperproteinemia is observed because of increased globulins.
- *Serum chemistry abnormalities* may include hypoalbuminemia, hypercholesterolemia, and/or hyperglobu-

linemia. Azotemia and hyperphosphatemia are present in patients with CRF.

Urinalysis

▼ ***Key Point*** The hallmark of glomerular disease is the presence of significant proteinuria in the absence of hematuria, pyuria, and bacteriuria.

Urine specific gravity values are variable; most patients with glomerular disease retain the ability to concentrate urine unless CRF has developed.

Assessment of Proteinuria

- Dipstick analysis of urine protein is a semiquantitative test that is affected by urine concentration. Finding a 1+ protein in urine with a specific gravity >1.035 probably is not significant, but a 2 to 4+ proteinuria probably is significant at any urine specific gravity.
- Measurement of urine protein and creatinine for calculation of the protein-to-creatinine ratio is the most accepted test for confirming significance of proteinuria.
- In the absence of pyuria, hematuria, and bacteriuria, a urine protein-to-creatinine ratio of >1 indicates significant proteinuria.

Microalbuminuria

- Immunoassay kits are now available for determination of microalbuminuria (>1 mg/dl but <30 mg/dl) in dogs and cats. These tests detect concentrations of albumin smaller than would be considered abnormal by either the dipstick or the protein-to-creatinine ratio. Dipsticks designed to detect microalbuminuria in humans are unreliable in dogs.
- Microalbuminuria has been detected in numerous human diseases and is a predictor of sequelae and outcome for some of them. Positive tests have been found in dogs with such diseases as osteosarcoma, lymphoma, heartworm disease, hyperlipidemia, Samoyed nephropathy, and wheaten terrier nephropathy.
- The incidence of microalbuminuria increases with age in dogs. Administration of corticosteroids can induce microalbuminuria.
- Exercise and microscopic hematuria do not seem to cause microalbuminuria in dogs.
- Positive microalbuminuria has not been shown to resolve with treatment of underlying diseases. Correlation with development of progressive renal disease or with prognosis is uncertain at this time.
- At this point, microalbuminuria is probably best utilized as a monitoring and early detection tool in breeds with hereditary renal disease and in elderly patients. In these cases, microalbuminuria of increasing magnitude would seem to be an indication for evaluation of underlying causes of glomerular disease.

Ancillary Tests

▼ ***Key Point*** Because glomerular diseases may be associated with potentially treatable underlying disorders, perform diagnostic tests to help identify these conditions (Table 77-7).

- *Serologic tests* (as indicated by other clinical findings) to exclude occult heartworm disease, rickettsial diseases, feline leukemia and immunodeficiency virus infection, systemic mycotic infections, and systemic lupus erythematosus
- *Serum protein electrophoresis* to characterize hyperglobulinemia as polyclonal or monoclonal
- *Thoracic and abdominal radiographs* to detect signs of occult heartworm disease, systemic fungal infection, primary or metastatic neoplasia, and pancreatitis
- *Abdominal ultrasonography* to help identify pyometra and hepatic, splenic, or lymph node enlargement
- *Fine-needle aspiration cytology* to evaluate lymphadenopathy, splenomegaly, or hepatomegaly
- *Arthrocentesis* if there is lameness, joint swelling or pain, stiffness or reluctance to move, or no obvious cause for persistent fever

Renal Biopsy

- Perform renal biopsy if the results will influence treatment or provide additional prognostic information.

▼ ***Key Point*** The only method for distinguishing between glomerulonephritis and amyloidosis is microscopic examination of a renal biopsy.

Table 77-7. DIAGNOSTIC EVALUATIONS FOR GLOMERULONEPHRITIS

Cats	Dogs
Urine culture	Urine culture
CBC, chemistry panel	CBC, chemistry panel
FeLV/FIV ELISA	Heartworm antigen, ELISA
Thoracic/abdominal radiographs	Thoracic/abdominal radiographs
Abdominal ultrasound	Abdominal ultrasound
Heartworm Ag/Ab tests (in endemic areas)	Echocardiogram (if appropriate)
Blood pressure	Rickettsial and borrelia titers
Antinuclear antibody titer	ACTH stimulation test
	Blood pressure
	Antinuclear antibody titer
	Renal biopsy

ACTH, adrenocorticotropic hormone; Ag/Ab, antigen/antibody; CBC, complete blood count; ELISA, enzyme-linked immunosorbent assay; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus.

- The distinction between amyloidosis and glomerulonephritis is important because amyloidosis has no reliable treatment and rapidly progresses to terminal renal failure. In contrast, glomerulonephritis tends to progress more slowly and may even resolve if the underlying infectious, inflammatory, or neoplastic disease can be eliminated.
- The most reliable methods for obtaining samples of renal tissue are percutaneously by ultrasound guidance or keyhole technique or at exploratory laparotomy (see Chapter 78 for discussion of renal biopsy techniques).
- Contact the laboratory to determine the appropriate medium in which to submit samples. In most cases, it is appropriate to place samples for routine histologic evaluation in formalin and samples for immunofluorescence in Michel's solution.
- Findings on routine histologic evaluation usually are sufficient to diagnose either glomerulonephritis or amyloidosis. Special stains such as Congo red may be used to help identify amyloid.
- Immunofluorescent studies are done to identify glomerular immune complexes; however, their presence is not specific for glomerulonephritis. Findings must be interpreted with results of clinical signs, laboratory tests, and routine histologic studies of the kidney.

Treatment

Management of Glomerulonephritis

Predisposing Causes

Eliminate any disorders that may predispose to additional glomerular injury.

- Treatment of some diseases (e.g., pyometra, heartworm disease, and hyperadrenocorticism) may be associated with resolution of proteinuria.
- In many cases, however, a cause for glomerular disease cannot be identified or is not amenable to treatment (e.g., feline leukemia virus infection, neoplasia, and feline infectious peritonitis).

Immunosuppressive Therapy

- In general, avoid immunosuppressive treatment (e.g., prednisone, azathioprine, and cyclophosphamide) of patients with glomerular diseases. At present, no studies have documented the efficacy of immunosuppressive agents for treatment of dogs or cats with glomerular disease, and these agents may actually worsen proteinuria and signs of renal failure.
- However, use immunosuppressive drugs if they are significantly indicated to treat an underlying disorder (e.g., systemic lupus erythematosus, leukemia, and lymphoma).

Antiplatelet Therapy

- Because of the role of platelet aggregation in the pathogenesis of glomerulonephritis, antiplatelet drugs may be helpful.
- Consider administering a low dose of aspirin (for dogs: 0.5–5 mg/kg PO q12–24h) to inhibit cyclooxygenase and impair platelet aggregation.
- Although studies to document beneficial effects of aspirin or any other antiplatelet drugs in dogs or cats with glomerulonephritis are lacking, a low dose of aspirin is unlikely to produce serious side effects. Limited evaluation of the human platelet inhibitor clopidogrel has shown some promise in inhibiting aggregation in cats.
- Use caution when administering any nonsteroidal anti-inflammatory drugs such as aspirin to patients with CRF because they can cause acute worsening of renal function.

Angiotensin-Converting Enzyme Inhibition

- Consider ACE inhibitors in dogs and cats with glomerular disease when an underlying cause cannot be found or when there is concurrent hypertension.
- Enalapril (0.5 mg/kg PO q12–24h) decreases proteinuria, slows progression of azotemia, and prolongs the life of dogs with idiopathic glomerulonephritis. Benazepril (0.5 mg/kg PO q12–24h) undergoes less renal excretion and has had beneficial effects in cats. It may be an appropriate alternative for dogs. Monitor blood pressure and serum biochemistry as ACE inhibitors can exacerbate renal failure.

Management of Amyloidosis

▼ ***Key Point*** No reliable treatment exists for patients with amyloidosis and most progress rapidly to develop terminal renal failure.

Dimethyl Sulfoxide

- Treatment with dimethyl sulfoxide (DMSO) has been associated with improvement in some dogs with amyloidosis.
- Because the drug has few serious side effects and for lack of any other effective treatment, a therapeutic trial with DMSO may be warranted.
- Dosage regimens have included 125 mg/kg twice daily and 80 mg/kg 3 times weekly; DMSO can be administered either orally or subcutaneously.

Colchicine

- The efficacy of colchicine in dogs or cats with amyloidosis is unknown. Colchicine impairs the secretion of serum amyloid A. This would suggest that if used

it is best started in cases that have not progressed to CRF.
- Consider colchicine (0.02–0.04 mg/kg PO q24h) in these cases. Side effects can include nausea, vomiting, and diarrhea.

Immunosuppressive Drugs

- Avoid administering immunosuppressive agents to patients with amyloidosis because they may potentiate renal amyloid deposition.

Dietary Management

- The ideal diet for dogs and cats with glomerular disease is unknown at this time.
- Evidence in humans with hypoalbuminemia secondary to glomerular disease suggests dietary protein restriction is associated with increases in serum albumin and may lessen proteinuria.
- Restriction of sodium intake probably is beneficial because most patients with glomerular disease are also hypertensive.
- Avoid dietary protein supplementation because this may actually increase glomerular injury and worsen proteinuria.
- Omega-3-fatty acid supplementation may be renoprotective for patients with glomerular disease and CRF.
- Currently, diets formulated for dogs or cats with CRF (such as Hill's K/D) address these points and are appropriate for patients with glomerular disease.
- Carefully monitor patients for signs of protein malnutrition (continued weight loss, worsening hypoalbuminemia and proteinuria, anemia), worsening renal function, and increased proteinuria.
- Measure BUN, serum creatinine, serum albumin, and the protein-to-creatinine ratio 2 weeks after changing diets.
- Continue dietary protein restriction if the renal function has not deteriorated, the magnitude of proteinuria is reduced or unchanged, and the serum albumin has remained stable or has increased.

Managing Complications

Renal Failure

- Renal failure is a common complication of glomerular disease (see the previous section in this chapter for recommendations on treatment of patients with CRF).

Ascites and Edema

- Ascites and peripheral edema may occur in patients with glomerular disease secondary to hypoalbuminemia and renal retention of excessive sodium and water.
- Avoid removing fluid from body cavities unless it significantly interferes with respiration. Removing fluid potentiates hypovolemia, protein loss, and formation of additional edema or ascites.
- Enforce cage rest for 2 to 3 days until ascites or edema decreases or resolves.
- Administer loop diuretics such as furosemide (2–4 mg/kg PO q8–12h for dogs; 1–2 mg/kg PO q12–24h for cats) cautiously and only if edema or ascites interferes with vital functions. Gradually taper the dose and discontinue when edema resolves.

Hypertension

- Measure blood pressure and treat patients with hypertension to avoid additional worsening of renal function (see "Controlling Hypertension" in this chapter and Chapter 153 for guidelines on treatment of hypertension).

Thromboembolism

- Thromboembolism, especially of pulmonary vessels, is a potential complication of glomerular disease. Factors that contribute to a hypercoagulable state in glomerular disease include platelet hyperaggregability and glomerular loss of antithrombin.
- Because of the guarded to grave prognosis associated with thromboembolism, consider preventive measures to minimize its occurrence.
  - Reduce magnitude of proteinuria.
  - Treat any underlying inflammatory condition.
  - Avoid indwelling IV catheters.
  - Maintain adequate hydration.
  - Avoid excessive use of diuretics.
  - Avoid treatment with corticosteroids.
- For additional information on management of patients with thromboembolic disease, see Chapter 153.

RENAL TUBULAR DISORDERS

Renal tubular disorders are caused by functional tubular defects that produce altered urine, and in some instances abnormal plasma concentrations, of some substances.

Etiology

Renal Tubular Acidosis

- Renal tubular acidosis (RTA) may be acquired or congenital and rarely is observed in small animals.
- Proximal RTA (type II) is characterized by wasting of bicarbonate. It occurs as part of the Fanconi-like syndrome in certain breeds of dogs (see the next section). Type II RTA has been associated with gentamicin-induced nephrotoxicosis in dogs.
- Distal RTA (type I) is characterized by inability of the distal tubule to secrete hydrogen ions and produce acidic urine. Type I RTA has been reported in a cat

with pyelonephritis and in another cat with hepatic lipidosis. Distal RTA can be a component of hypoadrenocorticism.

Fanconi-like Syndrome

- Fanconi-like syndrome is characterized by multiple proximal tubular dysfunctions, which cause glucosuria, proteinuria, and phosphaturia.
- It is suspected to be an inherited disorder and has been observed in basenjis, Norwegian elkhounds, Shetland sheepdogs, and schnauzers.
- Acquired Fanconi-like syndrome has been reported in dogs treated with aminoglycoside antibiotics.

Renal Glucosuria

- Primary renal glucosuria is characterized by defective proximal tubular transport of glucose. It is an inherited defect in Norwegian elkhounds but has been observed in other breeds.

Cystinuria

- Cystinuria is characterized by defective tubular transport of the amino acid cystine and other amino acids.
- Dogs with cystinuria can have carnitinuria and resultant carnitine and taurine deficiency. Consider measurement of plasma concentration of these amino acids.
- It occurs most often in dachshunds but has been observed in other breeds such as English bulldogs, Tibetan spaniels, and basset hounds.
- Cystine is sparingly soluble in urine, and animals with cystinuria are predisposed to development of cystine urolithiasis (see Chapter 79 for discussion of urolithiasis).

Nephrogenic Diabetes Insipidus

- Nephrogenic diabetes insipidus is characterized by failure of the kidneys to concentrate urine because of inability of the renal tubules to respond to normal amounts of antidiuretic hormone.
- It usually is an acquired disorder that occurs secondary to disorders (pyometra, hyperadrenocorticism, pyelonephritis, hypercalcemia) that interfere with renal tubular response to antidiuretic hormone; however, it also is a rare congenital defect in dogs.

Clinical Signs

Clinical findings vary depending on the renal tubular defect that exists.

- Signs of lower urinary tract disease such as stranguria, dysuria, and pollakiuria may occur with urolithiasis (e.g., cystinuria).
- Polyuria or polydipsia may occur with glucosuria, Fanconi-like syndrome, or nephrogenic diabetes insipidus.
- Stunted growth and weight loss may be observed in patients with glucosuria, congenital nephrogenic diabetes insipidus, and RTA.
- Vomiting often occurs due to gastric distention with water associated with extreme polydipsia in animals with congenital nephrogenic diabetes insipidus.
- Some metabolic disorders (glucosuria, cystinuria) may not be associated with clinical signs.

Diagnosis

History

- History identifies breeds at risk, as well as clinical findings that occur with metabolic disorders.

Physical Examination

- Physical examination findings often are nonspecific but may include decreased muscle mass, muscle weakness, distended urinary bladder, and palpable urocystoliths.

Laboratory Evaluation

- Hemogram results usually are normal.

Serum Chemistries

- Hypokalemia may occur in RTA and Fanconi-like syndrome.
- Hyperchloremia may be observed in RTA.
- Hypophosphatemia may develop in patients with Fanconi-like syndrome.

Urinalysis

- Normoglycemic glucosuria occurs in patients with renal glucosuria and Fanconi-like syndrome.
- Proteinuria occurs in Fanconi-like syndrome.
- Urine specific gravity shows hyposthenuria (<1.008) in patients with congenital nephrogenic diabetes insipidus and ranges from 1.001 to 1.018 in dogs with Fanconi-like syndrome.
- Cystine crystals may be observed in urine of dogs with cystinuria; these crystals are colorless and hexagonal and are most likely to form in concentrated, acidic urine.
- Urine pH values > 6 often occur in patients with RTA. In the presence of metabolic acidosis, patients with proximal RTA can produce acidic urine (pH <6), whereas patients with distal RTA cannot.

Blood Gas Evaluation

- Hyperchloremic metabolic acidosis with a normal anion gap is found in patients with RTA.

Ancillary Tests

- Infuse sodium bicarbonate to help distinguish between proximal and distal RTA. Animals with proxi-

mal RTA respond with increased urine pH and fractional excretion of bicarbonate, whereas those with distal RTA do not.
- Confirm Fanconi-like syndrome by performing renal clearance studies that show excessive urinary losses of protein, amino acids, glucose, bicarbonate, phosphate, and potassium.
- Perform a modified water deprivation test to confirm nephrogenic diabetes insipidus (see Chapter 36 for details on performing water deprivation tests).

Treatment

Renal Tubular Acidosis

- Identify and eliminate any underlying causes.
- Administer sodium bicarbonate (1–2 mEq/kg PO) to control acidemia; higher doses may be needed for patients with proximal RTA. Adjust dosage on the basis of response to treatment.
- Administer supplemental potassium if hypokalemia exists (see previous discussion in this chapter).

Fanconi-like Syndrome

- Discontinue drugs that might cause acquired disease.
- Try to maintain a plasma bicarbonate of 12 to 18 mEq/L by administering sodium bicarbonate as needed.
- Administer supplemental potassium as needed to correct hypokalemia.
- Monitor patients for development of severe acidosis, hypokalemia, or decreased renal function.
- Allow unlimited access to fresh water at all times.

Primary Renal Glucosuria

- This condition does not require any treatment.

Cystinuria

- Monitor patients for development of cystine uroliths and remove them surgically or employ medical treatment to promote dissolution (see Chapters 78 and 79). Consider supplementation with taurine and carnitine if plasma levels are low or clinical signs of deficiency are present.

Nephrogenic Diabetes Insipidus

- Treat the underlying cause if acquired diabetes insipidus exists.
- For congenital diabetes insipidus, feed a low-sodium diet and administer chlorothiazide (Diuril) at a dosage of 20 to 40 mg/kg PO q12h. This diuretic enhances proximal tubular reabsorption of sodium, chloride, and water, which decreases urine volume.

CYSTIC RENAL DISEASE

Cysts are epithelium-lined cavities that contain fluid. Renal cysts are dilated nephron segments that may be single or multiple (i.e., polycystic). Pseudocysts are accumulations of fluid that collect outside the renal parenchyma. They are not lined by epithelium and, therefore, are not true cysts.

Etiology

- *Familial* polycystic disease has been reported in Cairn terriers and longhaired cats. This disease is inherited as an autosomal dominant trait in Persian cats.
- *Acquired* cystic disease may develop in animals with any type of chronic renal disease.
- *Perinephric pseudocyst* is an uncommon condition reported mainly in cats. Pathogenesis is unknown.

Clinical Signs

- Progressive abdominal enlargement is the most common clinical sign. This generally is the only sign in cats with perinephric pseudocysts.
- Vomiting, anorexia, weight loss, and polyuria or polydipsia occur secondary to renal failure in animals with familial polycystic renal disease.
- Solitary or multiple cysts that do not enlarge are usually of little clinical significance.

Diagnosis

History

- History identifies the clinical signs of cystic renal disease, especially in breeds with familial predispositions. Question the owner about an affected dam, sire, or sibling.

Physical Examination

- Physical examination findings include abdominal enlargement and non-painful renomegaly.

Laboratory Evaluations

- *Hemogram* may show increased erythropoiesis in longhaired cats with idiopathic polycystic renal disease, possibly due to hypoxia-induced release of erythropoietin. Anemia may be present if CRF is present.
- *Serum chemistry profile* abnormalities include increased BUN and serum creatinine concentrations and hyperphosphatemia in renal failure.
- *Urinalysis*
  - Isosthenuria occurs in renal failure.
  - Bacteriuria and pyuria occur if secondary UTI is present.

Urine Culture

- Culture the urine if UTI is suspected or CRF is present.

Excretory Urography

- Excretory urography (see Chapter 4) confirms renomegaly in animals with polycystic renal disease and may show the cysts as multiple radiolucent areas in the renal parenchyma. In animals with perinephric pseudocyst, the kidney is demonstrated within the fluid-filled structure.

Ultrasonography

- Ultrasonography (see Chapter 4) is quite useful for detection and characterization of fluid-filled renal lesions. Their number, size, and anatomic relationships can be assessed.

▼ ***Key Point*** Ultrasonography is the procedure of choice for reliable diagnosis of polycystic kidneys and perinephric pseudocyst. Hepatic cysts may also be noted in cats with polycystic disease.

Aspiration

- Aspirate the cyst if necessary to confirm that it is a fluid-filled structure.

Treatment

- No specific treatment of cystic renal disease now exists. Bilateral polycystic kidneys result in CRF. A unilateral polycystic kidney can be treated by unilateral nephrectomy or partial nephrectomy (see Chapter 78) if necessary, provided that normal renal function is documented in the unaffected kidney.
- If renal failure exists, treat it medically (see CRF).
- Treatment for perinephric pseudocyst is surgical drainage and resection of the cyst wall (renal capsule). (See Chapter 78 for a general discussion of renal surgery.)

Prognosis

- The prognosis for animals with perinephric pseudocysts is good after surgical treatment.
- The prognosis for progressive bilateral polycystic kidney disease is poor. Advise the owner of the potential genetic aspects (autosomal dominant in Persian cats) of the disease.

NEPHROLITHIASIS AND URETEROLITHIASIS

Uroliths are polycrystalline concretions that are composed mainly of organic or inorganic crystalloids (90–95%) and a smaller but essential amount of organic matrix (5–10%). Uroliths form in the urinary space within the excretory pathway, and they usually are classified according to mineral composition.

▼ ***Key Point*** In dogs and cats, the majority of uroliths are found in the urinary bladder or urethra (see Chapters 79 and 81). Fewer than 10% are found in the renal pelvis.

Occasionally, nephroliths pass from the kidney and become ureteroliths.

Etiology

Urinary Tract Infection

- UTI by bacteria that hydrolyze urea (e.g., *Staphylococcus* or *Proteus*) is the most common cause of magnesium ammonium phosphate (struvite) urolithiasis in dogs. UTI also may occur secondary to urolithiasis that initially developed in the absence of infection.

Idiopathic

- Idiopathic conditions often cause urolithiasis. The pathogenic mechanisms of urolith formation in animals with calcium oxalate, sterile struvite, and silica urolithiasis are poorly understood.

Metabolic

- Metabolic disorders that cause excessive urinary excretion of sparingly soluble compounds may predispose an animal to urolithiasis.
- Inborn errors of metabolism predispose Dalmatians to urate urolithiasis, dogs with cystinuria to cystine urolithiasis, and animals with RTA to calcium phosphate urolithiasis.
- Portal vascular anomalies predispose affected dogs and cats to the development of urate urolithiasis because of hepatic dysfunction (see Chapter 71).
- Acquired metabolic disorders that predispose animals to urolithiasis include hyperparathyroidism (see Chapter 32), which may lead to the formation of calcium phosphate uroliths.

Dietary Factors

- High-magnesium alkalinizing diets promote struvite urolithiasis in cats.
- Diets containing large amounts of corn gluten or soybean hulls have been associated with formation of silica uroliths.
- Excessive dietary calcium or phosphorus intake may promote formation of calcium phosphate uroliths.

Clinical Signs

- Clinical signs associated with renal and ureteral uroliths are diverse and primarily depend upon the following:
  - Size, number, and location of the stones

  - Presence (degree and duration) or absence of obstruction to urine flow
  - Presence or absence of UTI
- Hematuria and signs of sublumbar or abdominal discomfort may be observed.
- Bilateral obstruction or unilateral obstruction with inadequate renal function in the contralateral kidney causes vomiting, anorexia, and depression, owing to postrenal azotemia/uremia.
- Urine may have a foul odor if UTI exists.
- An affected animal may have subclinical disease.

Diagnosis

History

- History identifies the breed predispositions (see Chapter 79) and clinical signs associated with nephrolithiasis and ureterolithiasis.

Physical Examination

- Physical examination abnormalities may include sublumbar or abdominal pain and/or renomegaly. Fever may be found in a patient with UTI-causing nephritis, especially with concurrent obstruction.

Laboratory Evaluations

Hemogram

- Hemogram usually is normal. Leukocytosis may be found when UTI causes pyelonephritis, especially with concurrent obstruction.

Serum Chemistries

- Increased BUN, serum creatinine, and serum phosphorus concentrations accompany renal failure, bilateral ureteral obstruction, or unilateral obstruction of a single functioning kidney.
- Hypokalemia, hyperchloremia, and metabolic acidosis may occur in cases of urolithiasis associated with RTA (see previous discussion).
- Hypercalcemia occasionally is found in animals with calcium-containing uroliths; however, most of these animals are normocalcemic.

Urinalysis

- Hematuria is a common finding.
- Suspect UTI when pyuria or bacteriuria is found.
- Urine pH tends to be alkaline with struvite uroliths and acidic with cystine uroliths. Urate and calcium oxalate uroliths may be associated with either alkaline or acidic urine.
- Examine sediment for struvite, ammonium urate, cystine, or calcium oxalate crystals. Crystalluria represents a risk factor for urolithiasis; however, do not presumptively identify the mineral content of uroliths solely on the type of crystalluria.

Urine Culture

- Urine culture is indicated in all patients with uroliths.

Radiography

- Confirm the presence, location, density, size, and number of uroliths with abdominal radiography.
- Urolith density is quite variable; however, oxalate, struvite, calcium phosphate, and silica uroliths usually are more radiodense than urate and cystine uroliths.
- Confirm the presence of nephrolithiasis and ureterolithiasis and the degree of urinary obstruction by excretory urography (see Chapter 4). Consider cystourethrography to identify concomitant lower urinary tract uroliths (see Chapter 79).

Ultrasonography

- Ultrasonography helps confirm the presence and location of uroliths, identify radiolucent uroliths, and assess the degree of obstruction.

Urolith Analysis

- *Quantitative (crystallographic) urolith analysis* is required to accurately determine mineral composition of uroliths.

▼ ***Key Point*** A tentative diagnosis of urolith composition often can be made using information from the clinical, laboratory, and radiographic findings.

- Perform *urolith culture* because in some cases bacteria can be cultured from calculi even when urine culture has failed to identify bacteria.

Treatment

The goals of treatment are to correct any predisposing factors if possible, eliminate existing calculi by surgical or medical treatment, and prevent recurrence. Refer to Chapter 4 for discussion of treatment for urolithiasis.

Non-obstructing, sterile nephroliths that do not increase in size, do not cause significant hematuria, and do not produce deterioration in renal function can be monitored without treatment. However, even for seemingly innocuous nephroliths, consider medical dissolution therapy if the mineral composition (struvite, urate, cystine) can be estimated with confidence.

Correct Underlying Causes

- When concomitant UTI exists, administer an appropriate antimicrobial drug and continue for 2 to 3 weeks after dissolution or removal of uroliths.
- Correct portosystemic shunts surgically, when possible (see Chapter 72).
- Remove parathyroid adenomas in patients with primary hyperparathyroidism (see Chapter 32).

Medical Treatment

- This is not effective for calcium oxalate, calcium phosphate, or silica uroliths. Struvite, urate, and cystine uroliths may respond partially or completely to medical calculolytic therapy (see Chapter 79 for a description of protocols).
- Monitor the patient to determine efficacy of medical dissolution therapy efforts.
- Reassess the size and location of uroliths using radiography and/or ultrasonography every 4 to 6 weeks.
- Perform urinalysis periodically (every 4–6 weeks).
- Crystalluria must be absent for medical dissolution therapy to be effective.
- Perform urine culture periodically (every 4 to 6 weeks) to verify continuing control of UTI.
- If uroliths enlarge or fail to steadily decrease in size, verify compliance with intended treatment instructions, and based on that consider other treatment options. The original assessment of urolith mineral type might be incorrect, or the urolith might be composed of more than one mineral.
- As nephroliths decrease in size, they may move into the ureter, causing partial or complete obstruction.

Surgical Treatment

- Surgical treatment is required in some situations (see Chapter 78).

▼ ***Key Point*** Promptly remove nephroliths or ureteroliths that obstruct urine flow to any substantial degree.

- If treatment of uroliths composed of calcium oxalate, calcium phosphate, or silica is required, surgical removal is indicated.
- Uroliths that fail to dissolve when treated with appropriate medical strategies may also require surgical removal.

Prevention

Prevention of recurrent urolithiasis depends upon the mineral type involved (see Chapter 79).

RENAL PARASITISM

Etiology

Dioctophyma renale is the canine kidney worm. *D. renale* infection is rare. Dogs become infected by ingesting the larvae or by ingesting a paratenic host, usually a fish, that contains encysted larvae.

Clinical Signs

- Dogs often are asymptomatic. Signs of renal failure do not occur with unilateral involvement.
- Abdominal enlargement may occur if the worm migrates into the peritoneal cavity and causes peritonitis.
- Hematuria may be observed.

Diagnosis

History

- History identifies clinical findings and potential for exposure to a paratenic host.

Physical Examination

- Physical examination findings may be normal, or abdominal enlargement may be found.

Laboratory Evaluations

- *Hemogram:* Eosinophilia, basophilia, and hyperproteinemia may be observed.
- *Serum chemistries:* Azotemia does not occur unless both kidneys are affected or unless one kidney is affected and the other kidney is impaired owing to some other cause.

Urinalysis

- The diagnosis is confirmed by observing characteristic double operculated ova in urine sediment. Renal infestation is required for a patent infection.
- Hematuria, pyuria, and proteinuria may occur secondary to urinary tract inflammation.

Abdominal Fluid Analysis

- With peritoneal involvement, findings are consistent with peritonitis (see Chapter 76).
- Look for parasitic ova in abdominal fluid.

Treatment

- No medical therapy is effective.

Surgical Treatment

- Perform a nephrectomy if severe unilateral renal infection exists and a nephrotomy if bilateral renal infection exists. (Surgical techniques for nephrectomy and nephrotomy are described in Chapter 78.)
- If peritonitis is present, perform an exploratory procedure to identify and remove all parasites.

Prevention

Do not allow dogs to ingest paratenic hosts or infected water.

RENAL NEOPLASIA

Etiology

Primary Tumors

- Renal cell carcinoma, transitional cell carcinoma, and embryonal nephroblastoma are the most common primary renal tumors in dogs. A syndrome of dermatofibrosis and renal cystadenocarcinoma occurs primarily in female German shepherds and may be a heritable trait.
- Renal cell carcinoma is the most common primary renal tumor in cats.
- Renal tumors in dogs and cats are usually malignant.

Metastatic Tumors

- Metastatic neoplasia is more common than primary renal neoplasia.
- The kidneys are often involved in patients with lymphoma, especially cats.
- Hemangiosarcomas, melanomas, mast cell tumors, and carcinomas also may metastasize to the kidneys.

Clinical Signs

- Clinical signs usually are vague and nonspecific. Lethargy, anorexia, and progressive weight loss may occur.
- Anorexia, vomiting, and polyuria or polydipsia may occur in patients that develop renal failure.
- Hematuria of renal origin may be observed.

Diagnosis

History

- History identifies the clinical signs of renal neoplasia.

Physical Examination

- Palpate the kidneys for renomegaly.
- Examine for tumors or masses in other organ locations.

Laboratory Evaluations

- *Hematology:* Polycythemia may occur with some renal tumors (e.g., carcinoma and fibrosarcoma) presumably owing to inappropriate production of erythropoietin.
- *Serum chemistries:* Azotemia and hyperphosphatemia due to renal failure may occur with bilateral renal neoplasia, especially in cats with lymphoma.
- Hematuria and proteinuria may be observed.

▼ ***Key Point*** About 50% of cats with renal lymphoma are positive for feline leukemia virus by enzyme-linked immunosorbent assay (ELISA) test.

Radiography

- Survey abdominal radiographs may reveal unilateral or bilateral renomegaly. An abdominal mass that cannot be identified as kidney sometimes is seen.
- When a renal mass is suspected, perform excretory urography to confirm renal involvement (see Chapter 4).
- Radiography of the thorax is needed to look for possible metastasis. This finding is most likely with renal cell carcinoma.

Ultrasonography

Ultrasonography of the abdomen helps confirm renal mass lesions.

Renal Biopsy

- In cats with bilateral renomegaly, cytologic examination of a fine-needle aspirate sample from a kidney often is diagnostic of lymphoma and eliminates the need for renal biopsy.
- For other neoplasms, perform a renal biopsy. Tissue for histologic evaluation is submitted to determine definitive diagnosis. Surgical biopsy may be necessary to allow direct exposure of the neoplasm.

Treatment

Chemotherapy

- Treat lymphoma with combination chemotherapy (see Chapter 27).

Surgery

- Evaluate the function of the contralateral kidney prior to nephrectomy.
- With the exception of lymphoma, surgical excision of the neoplastic kidney and its ureter is the treatment of choice (see Chapter 78). Consider adjunctive treatment (see Chapters 26 and 27).

Prognosis

The prognosis is guarded to poor for patients with malignant renal neoplasms.

RENAL AND URETERAL TRAUMA

Because of their location in the abdominal cavity, traumatic injury to the kidneys and ureters is uncommon in small animal patients. See Chapters 79 and 81 for discussion of bladder and urethral trauma.

Etiology

- *Blunt trauma* may be caused by vehicular injuries and falls from heights.
- *Penetrating trauma* may result from fight wounds, gunshot injuries, and other objects.

Clinical Signs

- In most cases, renal and ureteral trauma is mild and self-limiting.
- Rupture of the renal capsule, pelvis, or mid- to upper ureter causes extravasation of urine into the retroperitoneal space, which is associated with vague signs including abdominal pain and fever.
- Rupture of the distal ureter causes leakage of urine into the abdominal cavity. Clinical findings result from peritonitis and uremia and may include abdominal enlargement and pain.
- Macroscopic hematuria occurs frequently.
- Severe bruising to the ventral abdominal wall is often, but not always, seen with traumatically induced uroabdomen.
- Normal urination may be seen with unilateral ureteral rupture.

Diagnosis

▼ ***Key Point*** Suspect renal or ureteral trauma when there are vague signs of abdominal discomfort; macroscopic hematuria; or fractures of the caudal ribs, vertebrae, or pelvis, particularly.

History

- Question the owner about the possibility of trauma.

Physical Examination

- Observe for any external signs of trauma.
- Palpate the abdomen to detect evidence of pain and fluid accumulation.

Laboratory Evaluations

- *Hemogram* is usually normal.
- *Serum chemistry panel* may reveal azotemia if the injury is not acute and significant urine leakage has occurred.
- *Urinalysis* may show hematuria.

Abdominal Fluid Analysis

Note: Urine leakage may remain confined to the retroperitoneal space and not result in uroabdomen.

- Perform cytologic evaluation. Non-septic inflammation occurs most often with uroabdomen.
- Determine creatinine and potassium concentration in abdominal fluid for comparison with serum.
- When urine leaks into the abdominal cavity, the creatinine and potassium concentrations of the peritoneal fluid are greater than that of the serum initially.

▼ ***Key Point*** A fluid to serum ratio of >2:1 for either creatinine or potassium is highly sensitive and specific for uroabdomen.

- Urea is a small molecule; therefore, its concentration rapidly equilibrates with that of serum, making its measurement less useful for diagnosis of uroabdomen.

Radiography

Radiography provides the most useful information regarding the location of ureteral rupture.

Survey Abdominal Radiography

- Survey abdominal radiographic findings are rarely diagnostic of renal or ureteral trauma.
- Signs suggestive of trauma include displacement, asymmetry, and inability to visualize one or both kidneys.
- Urine leakage into the retroperitoneal space causes increased opacity and streaky, hazy areas in the retroperitoneum.
- Loss of abdominal contrast occurs when urine leaks into the peritoneal space.

Contrast Radiography

▼ ***Key Point*** Excretory urography is the diagnostic test of choice for patients with renal and ureteral trauma.

- Look for an accumulation of contrast material in the area of suspected leakage.
- If a kidney is not visualized, perform renal arteriography to evaluate the kidney's vascular supply.
- Perform thoracic radiography in all trauma patients to evaluate for consequences of thoracic trauma.
- Ultrasonography may be helpful to delineate the kidneys and retroperitoneal space.

Treatment

Supportive

- Stabilize the patient by administering fluids and other treatment for shock as needed (see Chapter 156).
- Observe the animal for evidence of a ruptured urinary tract. Other injuries may be self-limiting (e.g., renal contusions and hematoma).
- Provide abdominal drainage in animals with uroabdomen to stabilize them prior to surgery (see Chapter 76).

Surgery

- After stabilization and diagnostic evaluation, consider surgical treatment (see Chapter 78).
- Indications for surgery include leakage of urine into the abdomen or retroperitoneal space and crushing injury to the kidney or its vascular supply.

ECTOPIC URETER

Etiology

- Ureteral ectopia is a congenital abnormality whereby one or both ureters do not terminate in the correct location in the trigone of the urinary bladder.
- In females, ectopic ureters may terminate in the bladder neck, vagina, urethra, or uterus. In males, ectopic ureters end in the bladder neck and prostatic urethra.

Clinical Signs

- Urinary incontinence is usually observed by the owner around the time of weaning. Incontinence can be continual or intermittent.
- Animals with ureteral ectopia usually retain the ability to urinate normally. (See Chapter 83 for discussion of micturition disorders.)
- Urine may have a foul odor if a concurrent UTI exists.
- Soiling of the perineal hair and skin with urine may cause dermatitis.

Diagnosis

History

- Identify urinary incontinence in a young animal. (For a discussion of diagnostic approach and differential diagnosis for incontinence, see Chapter 83.)
- Female dogs are affected most frequently; however, male dogs and cats may also have ectopic ureters.

Physical Examination

- Verify urinary incontinence by observing a urine-soaked perineal area or after observation during hospitalization.
- Look for other congenital defects.

Laboratory Evaluations

- These are usually normal with the exception of urinalysis. Pyuria and bacteriuria often occur secondary to UTI.

Urine Culture

- Perform urine culture to rule out UTI.

Contrast Radiography

- *Excretory urography* (see Chapter 4) usually confirms the diagnosis of ureteral ectopia.
  - Dilated ureters and hydronephrosis may occur secondary to UTI.
  - Inflating the bladder with room air or CO_2 helps improve visualization of terminal ureters, and oblique films may be indicated to outline individual ureters.
- *Retrograde contrast urethrography* or *vaginourethrography* may help localize the site of ureteral termination.

Vaginoscopy and Cytoscopy

- Vaginoscopy or cytoscopy may be helpful to locate the terminal ureteral orifice and to evaluate for ureteral abnormalities.
- Surgical exploration occasionally is required to achieve a definitive diagnosis if cytoscopy is not available. Cytoscopy allows evaluation of ureteral orifice location. Intramural ectopic ureter may enter the bladder in a normal trigonal position.

Treatment

Surgical Treatment

- Surgical correction is the treatment of choice (see Chapter 78 for description of techniques).

▼ ***Key Point*** Surgical correction cures about 50% of patients with ectopic ureter; incontinence continues in approximately 50%. One-third of these animals respond to medical treatment.

Medical Treatment

- Treatment of UTI is indicated.
  - Culture urine to determine the species of infecting organism.
  - If pyelonephritis is suspected, administer an antimicrobial agent for 6 to 8 weeks.
  - Reculture urine 3 to 5 days after beginning treatment and again 5 to 7 days after discontinuing treatment.
- Adrenergic stimulants (agonistic) may reduce incontinence following surgery (see Chapter 83).

Prevention

- Counsel the owners regarding possible inheritance of ectopic ureter.
- Consider neutering the animal.

URETERAL OBSTRUCTION

Etiology

- *Neoplasia*
  - Primary ureteral tumors include leiomyosarcoma and leiomyoma.
  - Any abdominal tumor may compress a ureter, causing extramural obstruction.
  - Extension of tumors from the bladder (e.g., transitional cell carcinoma and rhabdomyosarcoma) and prostate (e.g., adenocarcinoma) may obstruct the ureters.

- *Uroliths* formed in the kidney may enter a ureter, causing obstruction (see discussion of calculi of kidney and ureter).
- *Blood clots* may lodge in the ureter secondary to renal hematuria.
- *Strictures* may be congenital or occur secondary to inflammation or surgery.

Clinical Signs

- Partial and unilateral obstruction may be subclinical. Bilateral obstruction causes signs of renal failure (see previous discussion).
- Signs may result from the underlying disease.
  - Hematuria and stranguria may occur with urinary bladder neoplasia and prostatic disease.
  - Straining to defecate may be observed with prostatic disease.
  - Ureterolithiasis may cause pain and abdominal discomfort.

Diagnosis

History

- Look for clinical signs of ureteral obstruction.
- Determine the possible history of abdominal surgery or trauma, urolithiasis, and neoplasia.

Physical Examination

- Palpate the abdomen for evidence of pain and abdominal masses.
- Perform a rectal examination to evaluate the prostate gland, pelvic urethra, and sublumbar lymph nodes.
- Palpate the urinary bladder to detect a mass.

Laboratory Evaluations

- *Hemogram* may be normal or show an inflammatory response (e.g., pyelonephritis).
- *Serum chemistry panel* is usually normal. Azotemia may occur if both kidneys are affected.
- *Urinalysis* may show hematuria or pyuria associated with inflammation, neoplasia, or urolithiasis.

Radiography

- *Survey abdominal radiographs* may demonstrate radiopaque ureteroliths or compressing masses.
- *Excretory urography* confirms the presence and location of ureteral obstruction. Dilation of the ureter proximal to the obstruction and hydronephrosis often occur.

Ultrasonography

- Noninvasively detects changes (e.g., hydronephrosis) consistent with ureteral obstruction.
- Preferred over excretory urography in patients with compromised renal function.
- Normal findings do not rule out a diagnosis of obstruction.

Treatment

The goals of treatment are to provide supportive care and to remove the underlying cause, if possible.

Medical Treatment

- If the obstruction is partial, urine is sterile, and the cause of obstruction may resolve spontaneously (e.g., blood clot), monitor the animal for a period of weeks to months.
- If partial obstruction occurs because of urolithiasis (e.g., struvite or urate), attempt dissolution of the urolith.

Surgical Treatment

- Surgery is indicated with evidence of progressive renal damage, persistent UTI, and no response to medical therapy.
- If ureteral neoplasia or stricture exists, surgical excision (nephrectomy/ureterectomy) is the treatment of choice.
- If possible, remove extramural masses that compress the ureter. Severe renal damage from chronic obstruction and/or pyelonephritis with concurrent ureteral obstruction is treated by nephrectomy/ureterectomy, provided that the contralateral kidney is functioning adequately.

Chapter

78 Surgery of the Kidney and Ureter

Dale E. Bjorling / Támara M. Da Costa-Gómez

Biopsy of the kidney often gives the most reliable information regarding the presence of disease and the prognosis for improvement. When renal calculi are removed surgically, a nephrotomy is usually performed. When the renal pelvis and proximal ureter are dilated, a pyelolithotomy may be performed to remove calculi. Removal of the kidney (nephrectomy) is considered because of severe damage due to trauma, neoplasia, infection, or obstruction of the ureter. Reattachment of the ureter to the renal pelvis is extremely difficult without magnification and proper instrumentation and is infrequently attempted in veterinary practice. This disorder is more commonly treated by unilateral nephrectomy and ureterectomy. A ureterotomy may be performed to remove calculi from the lumen of the ureter. Ureteral anastomosis in small dogs and cats is a challenge for veterinarians. Magnification and microsurgical instrumentation are strongly encouraged during this procedure to improve outcome. Ureteroneocystostomy is a feasible treatment option for lesions of the middle and distal ureter and can also be used to treat some cases of ectopic ureter.

ANATOMY

Kidney

- The kidneys are normally found in the retroperitoneal space in a sublumbar location. The cranial pole of the right kidney may be in contact with the liver, and the left kidney is usually found several centimeters caudal to the liver. In dogs, the right kidney is relatively firmly attached by the renal fascia, but both kidneys are mobile in the cat.
- The renal arteries divide into dorsal and ventral branches after arising from the aorta. Each branch divides into five to seven interlobar arteries. The interlobar arteries branch into arcuate arteries at the corticomedullary junction and ultimately give rise to the radial interlobular arteries. Multiple renal arteries may occur on the left side in 13% of dogs and 10% of cats but are rare on the right side. The renal artery may give rise to the ovarian artery, and the left ovarian/testicular veins commonly drain into the renal vein. Multiple renal veins may be present in cats but are uncommon in dogs.

Ureter

- The ureter is a muscular tube that lies within the retroperitoneal space. The ureter carries urine to the bladder by coordinated peristaltic contractions and can dilate up to 17 times its resting diameter during diuresis or obstruction.
- The arterial blood supply of the ureter is longitudinal. Care must be taken not to disturb the arterial blood supply during dissection of the ureter.
- The ureter approaches the bladder at an oblique angle and passes submucosally within the bladder wall toward the neck of the bladder. A valve-like function is provided by the submucosal location of the ureters, which decreases vesicoureteral reflux of urine.

RENAL BIOPSY

Preoperative Considerations

- Platelet count and coagulation function must be normal prior to performing renal biopsy.

▼ ***Key Point*** Hemorrhage is a common complication after renal biopsy. Evaluate coagulation function before surgery. Apply pressure to the biopsy site until bleeding has stopped.

- If unilateral disease is present and a percutaneous biopsy is to be performed, identify the site of disease before performing the biopsy.

Surgical Procedure

Objectives

- Obtain a representative sample of renal tissue.
- Avoid damage to major vasculature or the renal pelvis.
- Control hemorrhage.

Equipment

- Standard surgical instruments and suture
- Vim-Silverman or Tru-Cut biopsy needle (or other biopsy needle of the surgeon's preference)
- Balfour self-retaining retractor for the celiotomy approach

Technique

Kidney biopsies can be performed through an ultrasound-guided percutaneous approach, through a "keyhole" approach, laparoscopically, or through a celiotomy. The celiotomy approach is described.

1. Place the patient in dorsal recumbency.
2. Aseptically prepare the ventral abdomen for a standard celiotomy incision.
3. Make a ventral midline approach to the abdominal cavity and extend the incision cranially to the xiphoid process to facilitate exposure of both kidneys.
4. Place a self-retaining Balfour retractor to maintain exposure of the abdominal cavity.
5. Examine and palpate the kidneys. If an isolated lesion is present, select an appropriate biopsy site.
6. Obtain single or multiple biopsy samples using a biopsy needle, or perform a nephrotomy to collect a wedge or slice of renal tissue. The technique for biopsy during nephrotomy is discussed in this chapter under Nephrotomy.
7. When a biopsy needle is used, direct the needle away from the pelvis through the cortical region to avoid damaging the pelvis and large vessels, and obtain at least two samples to be sure that a representative one has been taken. Apply pressure to the biopsy site for 5 minutes to promote hemostasis. If bleeding persists, tack the omentum onto the biopsy site with one or two sutures to act as a patch. Mattress or cruciate sutures can also be used in the renal capsule and superficial parenchyma. Tighten sutures just enough to stop bleeding, but avoid capsular tearing.

Postoperative Care and Complications

- Establish diuresis by IV administration of a balanced electrolyte solution at a rate of 90 ml/kg/24 hr for 8 to 12 hours. This helps prevent the formation of blood clots within the renal pelvis.
- Microscopic hematuria, gross hematuria, or both are often observed after renal biopsy and are usually self-limiting.
- Hemorrhage after renal biopsy can become life threatening. If this occurs during a limited approach procedure, surgically expose the kidneys via celiotomy, and place sutures in a mattress pattern through the renal capsule and superficial parenchyma to control hemorrhage. On rare occasions, uncontrollable hemorrhage necessitates nephrectomy.

NEPHROTOMY

Preoperative Considerations

- Nephrotomy is most often performed for removal of renal calculi. Investigate for other calculi within the urinary tract with excretory urography or ultrasonography before surgery.
- Remove large solitary calculi that result in extensive dilation of the renal pelvis by pyelolithotomy (described in other texts).
- Evaluate coagulation function before surgery. Abnormal coagulation may result in prolonged and possibly fatal hemorrhage after surgery. If possible, correct fluid deficits and serum electrolyte abnormalities before surgery.
- If bilateral renal calculi are present, perform nephrotomy as a staged procedure. Perform the second surgery 2 to 4 weeks after the first. Because transient decrease in renal function after nephrotomy is possible, absent or decreased function of the contralateral kidney may preclude nephrotomy. In these instances, pyelolithotomy is greatly preferred.

Surgical Procedure

Objectives

- Remove renal calculi.
- Obtain a renal biopsy or microbial culture specimen.
- Confirm patency of the ureter.

Equipment

- Standard surgical instruments and suture
- Balfour self-retaining retractor
- Catheters of appropriate diameter to pass into the ureter (3.5 Fr. or 5 Fr.)
- Vascular forceps or Rommel tourniquet

Technique

1–4. Refer to Renal Biopsy; Technique, Steps 1 to 4.

5. Examine and palpate the kidneys. Free the affected kidney of its peritoneal attachments, and identify and isolate the renal vasculature.
6. Apply a Rommel tourniquet or vascular forceps to the renal artery and vein. The time at which the vasculature is occluded is noted, and ischemia of the kidney is limited to 30 minutes or less.
7. Make a longitudinal incision through the renal capsule on the greater curvature of the kidney (Fig. 78-1*A*). Make the incision long enough to allow exposure of the renal pelvis after the renal parenchyma has been divided or incised. Sharply incise the renal parenchyma with a scalpel.
8. Remove calculi from the pelvis and diverticula of the kidney. Submit the calculi for analysis and culture.

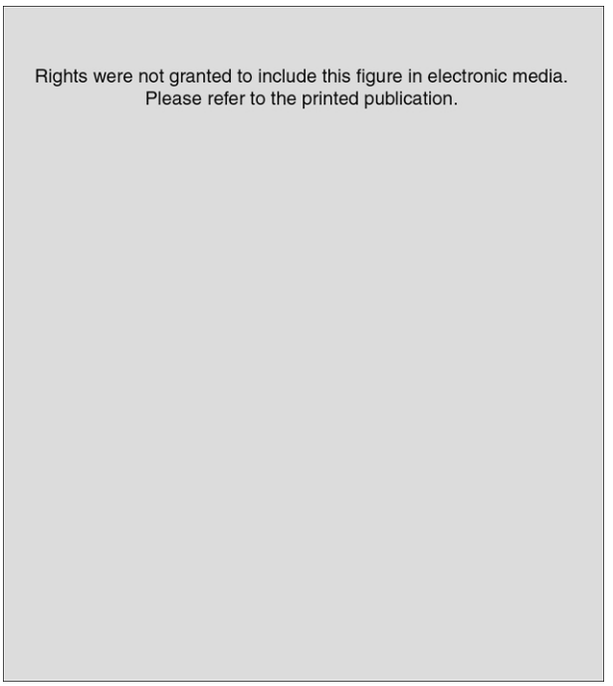

Figure 78-1. Nephrotomy. *A,* Make an incision through the renal capsule. Limit the length of the nephrotomy incision to the dimensions of the renal pelvis. *B,* Remove calculi from the renal pelvis, and pass a catheter through the ureter. *C,* Close the nephrotomy incision by placing sutures through the renal capsule and superficial parenchyma. (From Stone EA: Canine nephrotomy. Compend Contin Ed Pract Vet 9:883, 1987.)

▼ ***Key Point*** After removal of renal calculi, irrigate the renal pelvis and ensure that no calculi fragments are present in the ureter.

9. Pass a catheter through the ureter into the bladder to assess patency (Fig. 78-1*B*).
10. If a biopsy is to be done, remove a wedge or slice of parenchymal tissue 2 to 4 mm thick with a scalpel from the surface of the nephrotomy incision. Take care to avoid damaging the pelvis or diverticula.
11. Appose the exposed surfaces of the renal parenchyma, and hold them in this position with digital pressure as the tourniquet or vascular forceps is removed. Maintain pressure for 5 minutes to allow clotting to occur.
12. Close the nephrotomy incision by placing a single layer of absorbable suture in a simple continuous pattern through the renal capsule and superficial parenchyma (Fig. 78-1*C*).
13. If calculi are present in the bladder, perform a cystotomy to remove them.
14. Return the kidney to its normal position within the abdominal cavity. Close the body wall, subcutaneous tissues, and skin in a routine manner.

Postoperative Care and Complications

- Initiate and maintain diuresis by IV administration of a balanced electrolyte solution at a rate of 90 ml/kg/24 hr. Continue this for at least 12 to 24 hours. Monitor urine output to be sure that the kidneys are functioning satisfactorily.
- Hematuria is usually observed macroscopically for 1 to 3 days and microscopically for up to 1 week.
- Institute appropriate therapy to treat infection and prevent reformation of the calculi (see Chapters 77 and 79).

NEPHRECTOMY

Preoperative Considerations

▼ ***Key Point*** Function of the remaining kidney must be sufficient to support life.

- Preoperative evaluation of the function of a single kidney is often difficult. Common laboratory tests (determination of blood urea nitrogen, serum creatinine, serum potassium concentrations) are only relative indicators of renal function. Distinguish among prerenal, renal, and post-renal causes of azotemia. Concentration and excretion of a radiopaque dye (contrast agent) on excretory urography demonstrates that the vascular supply to the kidneys is intact and that the kidneys are capable of extracting the dye (contrast) from the blood and excreting it. This finding is only a relative indicator of renal function. Renal function is best evaluated by measuring the clearance of an indicator (e.g., creatinine, inulin, radioisotopes). Nuclear scintigraphy of the kidney allows determination of unilateral (differential) renal function, whereas determination of single kidney clearance of other indicators requires ureteral catheterization and collection of the urine from that kidney. See Chapter 77 for additional information on renal function testing. In general practice, excretory urography and standard clinical pathology testing are routinely done and usually provide adequate information.
- If possible, correct metabolic and hydration imbalances before performing surgery.

▼ ***Key Point*** If the kidney is functional, consider options for salvaging the kidney prior to performing a nephrectomy.

Surgical Procedure

- Indications for nephrectomy are listed in the introduction to this chapter.

Objectives

- Remove the diseased kidney and associated ureter.
- Control hemorrhage.

Equipment

- Standard surgical instruments and suture
- Balfour retractor
- Vascular forceps (optional)

Technique

1–4. Refer to Renal Biopsy; Technique, Steps 1 to 4.

5. Examine and palpate the kidneys. Obtain biopsy samples of the kidney to be preserved to be sure that it is free of disease.
6. Dissect the diseased kidney free of its attachments. Apply a vascular forceps or Rommel tourniquet to the renal vessels or ligate these vessels before dissection to minimize hemorrhage.
7. Ligate the renal vasculature with non-absorbable, monofilament (e.g., polypropylene) suture. Doubly ligate the renal vessels.
8. Ligate the ureter near the bladder with absorbable suture material, and remove the entire ureter. Leaving a segment of ureter may promote subsequent urinary tract infection by urine retention within the ureteral remnant.
9. Examine the renal bed for hemorrhage before closure of the abdominal wall.
10. Close the abdominal wall, subcutaneous tissues, and skin in a routine manner.
11. Submit the kidney and ureter for histopathology and culture if indicated.

Postoperative Care and Complications

- If the function of the remaining kidney is in doubt, initiate and maintain diuresis by IV administration of a balanced electrolyte solution at a rate of 90 ml/kg/24 hr until renal function and urine output appear satisfactory. (See Chapter 77 for more information on diuresis.)
- Observe the patient for 24 hours for hemorrhage due to displacement of ligatures.
- Warn the owner that continued renal disease in the patient may result in irreversible injury to the remaining kidney.

URETEROTOMY AND URETERAL ANASTOMOSIS

Preoperative Considerations

- Ureterotomy is most often performed for removal of calculi that have lodged within the ureter and cannot be dislodged by flushing and/or catheterization. Prolonged obstruction of the ureter by calculi results in necrosis of the ureteral wall and leakage of urine. Lesions of the distal ureter are best treated by ureteroneocystostomy.
- Ureteral obstruction or disruption most often is diagnosed by excretory urography, ultrasound evaluation, or contrast-enhanced computed tomography scan.
- When ureteral calculi are diagnosed, carefully examine the kidneys and bladder for additional calculi.
- Warn the owner of the potential for stricture formation after ureteral surgery.

Surgical Procedure

Objectives

- Relieve ureteral obstruction.
- Ensure patency and integrity of the ureter.

Equipment

- Standard surgical instruments and suture
- Balfour retractor
- Magnification loupes and microsurgical instrumentation (highly desirable); operating microscope (optional)
- Small (6-0 to 8-0) monofilament absorbable suture (polydioxanone [PDS], polyglyconate [Maxon], or poliglecaprone 25 [Monocryl])
- Catheters of appropriate size (3.5 or 5 Fr.)

Technique

1–4. Refer to Renal Biopsy; Technique, Steps 1 to 4. The incision is extended caudally to a few centimeters cranial to the pubis.

5. Examine and palpate the kidneys, ureters, and bladder.
6. Identify the site of the ureterotomy and make a longitudinal incision over the area of obstruction. Remove calculi, and pass a catheter through the ureterotomy site to the kidney and to the bladder to ensure patency of the ureter. In extremely small patients, use a large suture (1 or 0 polypropylene or nylon) instead of a catheter. Close the ureterotomy incision transversely with small (6-0 to 8-0) absorbable suture in an interrupted or continuous pattern. The transverse configuration of the closure increases the ureteral diameter at the site of the ureterotomy. This maneuver is achieved by initially opposing the midpoint of the proximal and distal ends of the ureterotomy incision with a single suture. To prevent misplacement of suture into the far wall of the ureter, close over a temporary stent.
7. If necessary, resect the devitalized portion of the ureter and identify the lumen of the proximal and distal remnants of the ureter. Make a linear incision 3 to 5 mm in length in the ends of the ureter to increase the circumference of the anastomosis. Perform the anastomosis with small, absorbable suture placed in an interrupted or a continuous pattern.

8. Pass a catheter through the urethra, bladder, and ureter to divert the flow of urine past the ureterotomy or anastomotic site for 10 to 14 days if leakage is considered a possibility. The placement of a catheter (stent) following surgery is controversial, and some believe this practice may predispose the patient to stricture formation in the ureter.
9. Close the abdominal wall, subcutaneous tissue, and skin in a routine manner.

Postoperative Care and Complications

- Stricture formation is common after ureteral surgery, particularly in cats and small dogs. Reevaluate the patient 3 to 4 weeks after surgery by excretory urography. If ureteral obstruction is observed, consider resecting the affected area of the ureter and performing an anastomosis or implanting the proximal portion of the ureter into the bladder (ureteroneocystostomy).

URETERONEOCYSTOSTOMY (URETERAL REIMPLANTATION)

Preoperative Considerations

- This procedure is performed most often for treatment of ectopic ureter (see Chapter 77 for diagnosis of ectopic ureter). Inform the owner that incontinence associated with an ectopic ureter may or may not resolve after ureteroneocystostomy. Incontinence that persists after this procedure may be the result of developmental abnormalities of the urethral sphincter or the presence of the remnant of the distal ureter within the sphincter mechanism.
- Ureteroneocystostomy may also be performed to treat disorders resulting in destruction or loss of function of the distal ureter and is preferable to resection and anastomosis of the distal ureter because a lower complication rate is observed after ureteroneocystostomy.

Surgical Procedure

Objectives

- Restore flow of urine from ureter into the bladder.
- Treat incontinence associated with ectopic ureter.

Equipment

- Standard surgical instruments and suture
- Balfour retractor
- Magnification—extremely helpful with small patients but optional with large patients
- Fine-gauge (5-0 to 7-0) absorbable suture

Technique

1–4. Refer to Renal Biopsy; Technique, Steps 1 to 4. Continue the incision caudally to the pubis.
5. Examine and palpate the kidneys, ureters, and bladder.
6. Identify the distal ureter and isolate it by dissection. Take care to preserve the longitudinal blood supply of the ureter. If the ureter is in an ectopic location, ligate and remove the distal continuation (Fig. 78-2*A*). Preserve a sufficient length of ureter to allow implantation into the bladder under minimal tension.
7. Perform a ventral cystotomy and create a circular defect 5 to 10 mm in diameter in the cranial aspect of the mucosa of the dorsal wall of the bladder (Fig. 78-2*B*). Pass a forceps from the lumen of the bladder at an oblique angle in a caudal-to-cranial direction. Grasp the distal end of the proximal

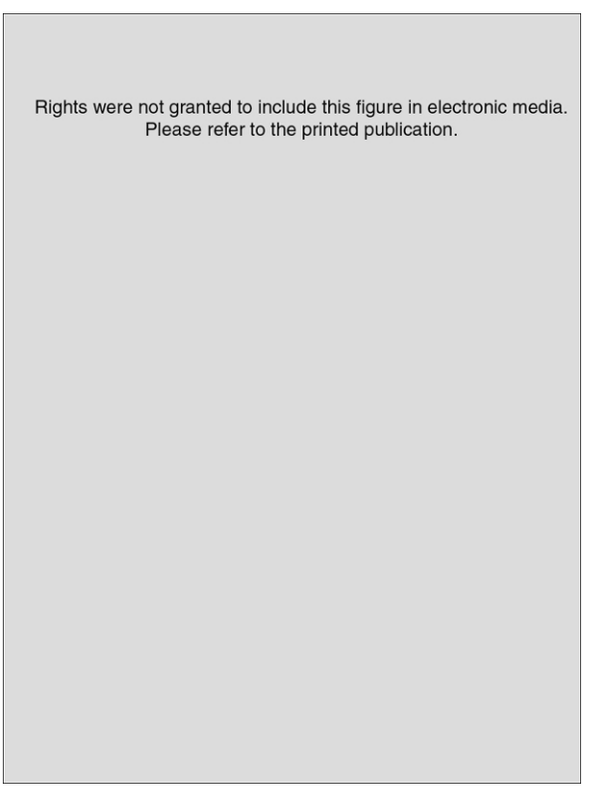

Figure 78-2. Ureteroneocystostomy. *A,* Isolate, ligate, and divide the distal ureter and perform a ventral cystotomy. *B,* Create a circular defect in the bladder mucosa, and pass forceps through the bladder wall to grasp the end of the ureter. *C,* Debride and spatulate the end of the ureter. *D,* Suture the ureter to the bladder mucosa. (From Rawlings CA: Repaired ectopic ureter. In Bojrab MJ [ed]: Current Techniques in Small Animal Surgery, 3rd ed. Philadelphia: Lea & Febiger, 1990, p 374.)

remnant of the ureter, or preferably a suture attached to this end of the ureter with the forceps, and draw the ureter through the bladder wall (Fig. 78-2*B*). As the ureter is drawn through the bladder wall, take care to avoid twisting the ureter, because this may obstruct the ureter or its blood supply.

8. Make a longitudinal incision 5 to 10 mm in length in the ventral aspect of the end of the ureter (Fig. 78-2*C*). Secure the ureter to the edge of the defect created in the bladder mucosa with small (5-0 to 7-0) synthetic absorbable sutures in an interrupted pattern (Fig. 78-2*D*). A ureteral catheter is not maintained after surgery.
9. Alternatively, create a new opening into the bladder by making an incision through the bladder mucosa overlying an intramural ectopic ureter into the lumen of the ureter (neoureterostomy). Suture the ureteral mucosa to the bladder mucosa with fine-gauge absorbable suture, and excise the distal ureter.
10. In addition to the above ureteral technique, some surgeons also prefer to remove the ectopic portion (remnant) of ureter that is present within the bladder neck and proximal urethra in dogs with ectopic ureter. This requires extension of the ventral cystotomy incision into the proximal urethra. From within the lumen, incise the bladder and urethral mucosa over the ureteral remnant, and carefully dissect the remnant from the urethral wall. Close the mucosal incision, and underlying urethral muscle layer, with 4-0 or 5-0 absorbable suture in a simple continuous pattern. Close the urethral and cystotomy incision with a simple continuous pattern of 4-0 absorbable suture. Consider placement of an indwelling urinary stent catheter in dogs undergoing this technique.
11. Close the cystotomy incision in a standard manner (see Chapter 80).
12. Close the abdominal wall, subcutaneous tissue, and skin in a routine manner.

Postoperative Care and Complications

- If an indwelling urinary catheter was placed, remove it 2 to 3 days postoperatively.
- Obstruction of the ureteroneocystostomy or leakage of urine from the site of ureteral reimplantation is uncommon.
- Treat urinary incontinence that persists after surgery with alpha-agonists in an attempt to increase urethral sphincter tone (see Chapter 83). If urinary incontinence persists with appropriate medical management, consider endoscopic submucosal implantation of collagen for urethral bulking to control urine outflow. Warn the owner that incontinence due to ectopic ureter may or may not improve in the patient after surgery and medical therapy.
- Perform excretory urography 4 weeks after surgery to assess the shape and function of the ureter.

Chapter 79

Diseases of the Urinary Bladder

Jennifer A. Gieg / Dennis J. Chew / Mary A. McLoughlin

The bladder has a limited manner in which it can respond to a variety of diseases and insults. This accounts for the similarity in clinical signs of lower urinary tract disease despite the diverse spectrum of underlying bladder disorders. Signs of inflammation (urgency, pollakiuria, dysuria, and hematuria) are common with most diseases of the bladder. Some of the disease processes listed in Table 79-1 can be associated with obstruction to the outflow of urine. In these instances, systemic signs of uremia (anorexia, lethargy, vomiting, and dehydration), as well as decreased or absent urination, may be recognized. Inability to evacuate urine can be a manifestation of obstruction, decreased ability to contract the detrusor, or inability to coordinate detrusor contraction with urethral relaxation.

PRINCIPLES OF DIAGNOSTIC EVALUATION

Blood Tests

Complete blood count (CBC) and serum biochemical analysis are essential in patients with clinical signs referable to bladder disease that are also systemically ill (anorexia, vomiting, lethargy, weight loss, polyuria and polydipsia, anuria).

Urinalysis and Culture

Although voided urine samples may be adequate for evaluation of urine concentrating ability or presence of hematuria, obtain urine by cystocentesis for evaluation of most bladder diseases. If cystocentesis is not possible or is undesirable (e.g., suspected neoplasia), obtain samples by urethral catheterization.

- Use the dipstick part of the urinalysis to identify blood, glucose, protein, and ketones in the urine. Also perform microscopic analysis of the urine sediment. Evaluation of the urine sediment may reveal inflammatory cells (red and white blood cells), bacteria, epithelial cells, and casts or crystals that may be important indicators of the disease process.
- Perform quantitative urine culture on freshly collected urine to determine what role, if any, uropathogens are playing in a particular bladder disease.

▼ ***Key Point*** While a negative culture on voided urine can reliably rule out infection, a positive culture may represent contamination rather than true urinary tract infection (UTI). For this reason, quantitative cultures are much more easily interpreted when urine is collected by cystocentesis.

Diagnostic Imaging

- Lower urinary tract imaging can be used both to include and to exclude the various bladder disorders. Some combination of plain abdominal radiography, contrast urography, abdominal ultrasonography, and urinary endoscopy are required to establish a definitive bladder disease process (see Chapter 4).
- CT with and without contrast is useful in selected cases to more definitively define bladder disease. Imaging of the upper urinary tract (kidneys and ureters) in addition to the bladder is important for any disease process that could affect the upper urinary tract, such as bladder infection leading to pyelonephritis, or proliferative bladder disease that has caused obstruction of the ureteral openings or urethral outflow (see Chapter 4).

Measurement of Residual Urine Volume

Measurement of post-voiding urine volume from the bladder (residual volume testing) is occasionally helpful in the evaluation of dogs with recurrent UTI or patients suspected of partial urinary obstruction or voiding disorders. Methods to estimate residual urine volume using ultrasonography have been attempted, but we recommend passing a urinary catheter following voiding and measuring the actual urine volume.

- Normal residual volume is estimated to be 0.2 to 0.4 ml/kg in dogs.
- Normal female dogs may have up to 5 to 10 ml and normal male dogs may have up to 10 to 20 ml of residual urine.
- Cats may have up to 2 or 3 ml of residual volume that is considered normal.

Table 79-1. CAUSES OF BLADDER DISEASE

Cystitis
Bacterial—Most common in dogs
Polypoid
Fungal—Rare
Parasitic—Rare
Chemical—Cyclophosphamide, ifosfamide
Idiopathic feline lower urinary tract disease
Suture reaction
Emphysematous

Neoplasia
Transitional cell carcinoma
Rhabdomyosarcoma (botryoid sarcoma)
Lymphoma
Adenocarcinoma
Single polyps

Congenital
Persistent urachus
Urachal diverticulum
Pelvic bladder positioning
Abnormal trigone

Trauma
Bladder contusion
Ruptured bladder

Cystoscopy

Cystoscopy can be a useful diagnostic tool for a variety of conditions such as urolithiasis, mass lesions such as polyps and neoplasms, cystic diverticula, and ectopic ureters.

Biopsy

The gross and endoscopic appearance of several proliferative or inflammatory diseases of the bladder can be similar. Biopsy of abnormal bladder tissue is essential to differentiate among neoplastic, polypoid, and granulomatous changes. Samples can be obtained via cystoscopy or surgically by laparotomy (see Chapter 80).

CONGENITAL DISEASES

Patent Urachus

Etiology

The urachus is the fetal conduit that allows urine to pass from the developing urinary bladder to the placenta. It usually atrophies completely and is nonfunctional at birth. The atrophied urachus is typically seen as a fibrous connective tissue remnant at the bladder apex. If the urachus does not close normally, urine leakage may occur from the bladder to the cutaneous opening of the urachus. At its most extreme, bladder exstrophy exists in which the bladder opens directly to the outside in the area of the umbilicus.

Clinical Signs

Urine leakage is seen in the area of the umbilicus. This can range from visible dripping of urine to damp fur or skin in the area of the urachus. These signs are typically present since birth. As a result, this condition is generally diagnosed in young animals.

Diagnosis

- *Physical examination:* Urine may be observed to collect or leak on the ventral abdominal wall around the umbilicus. Dermatitis or urine scald may be present in the urine-soaked area.
- *Urinalysis and urine culture:* There is an increased risk of UTI because of the leakage of urine. The urinalysis is typically normal unless a UTI is present.
- *CBC and serum biochemical analysis:* These tests are usually unremarkable.
- *Radiography and ultrasonography:* Plain radiography is usually normal. Abdominal ultrasound may be suggestive in some cases. Contrast cystography is the preferred imaging method to reveal the patent urachus (see Chapter 4). Options include a contrast cystourethrogram, or if an orifice is identified, contrast may be introduced at the umbilical opening. In either case, it is essential that an adequate volume of the contrast agent is used to distend the bladder and patent urachus.

Treatment

Surgical resection of the patent urachus (partial cystectomy) is the only definitive treatment option (see Chapter 80).

Urachal Diverticulum (Vesicourachal Diverticulum)

Etiology

- An urachal diverticulum is a small outpouching of tissue at the bladder apex resulting from incomplete closure of the fetal urachus.
- The lesion may be undetectable in a healthy bladder, but it can become more obvious in association with bladder disease, such as urolithiasis or infection.
- A recent study indicates that urachal diverticula are common in normal dogs.
- In cats, urachal diverticula can be acquired following severe urethral obstruction and, in some cases, is a component of non-obstructive sterile idiopathic cystitis.

Clinical Signs

- No clinical signs are observed in dogs with urachal diverticula if no other bladder disease is present.
- The diagnosis may be an incidental finding on radiographs or abdominal ultrasound performed in association with other bladder disease.

- Some diverticula provide a source of urine retention that can serve as a nidus for infection. The recess makes it difficult to eradicate bacterial UTI. Over time, microscopic abscesses commonly develop around the diverticulum. Many patients have a history of lower urinary tract disease that is refractory to treatment.
- In cats, the role of urachal diverticula in creating sterile inflammation and clinical signs is controversial.

Diagnosis

- *Physical examination:* The diverticulum itself causes no clinical signs, but clinical signs related to secondary infection or urolithiasis may be noted.
- *Urinalysis and urine culture:* In the absence of infection, the urinalysis may be normal. Because of urine retention, crystalluria and UTI may be seen more frequently than in normal animals.
- *CBC and serum chemistry profile:* These tests are unremarkable.
- *Diagnostic imaging:* Diverticula are rarely observed on survey radiographs and ultrasound; usually, they are diagnosed with contrast cystography (see Chapter 4). Look for a small pouch or outpocketing of the bladder apex.

▼ ***Key Point*** If a small diverticulum is suspected, gradual distention of the urinary bladder with contrast may better elucidate the extent of the abnormality. Note that maximal bladder filling may distort the architecture of the bladder, making the diverticulum more difficult to identify.

- Confirmation of equivocal diverticula at surgery can sometimes be made by simple inspection, or it may require forceps to probe the region from the interior of the bladder following cystotomy (see Chapter 80).

Treatment

- If lower urinary tract disease has not occurred, the diverticulum may be an incidental finding and treatment is not necessary.
- For a documented urachal diverticulum with recurrent disease such as infection, perform surgical resection (partial cystectomy) (see Chapter 80).
- Despite the tenuous association with inflammation in cats, reduction or resolution of clinical signs of lower urinary tract inflammation has been seen in some cats following diverticulectomy. This would only be recommended in cats that have failed attempts at medical management of their disease.

Other Bladder Anomalies

- *Complete agenesis of the urinary bladder* is extremely rare. Bladder hypoplasia or excessively small bladder size has been reported most frequently in patients with persistent urinary incontinence. This is more likely to represent a failure to distend the bladder as a result of urethral incompetence rather than a true inability to distend the bladder.
- *Malformations of the bladder wall*, trigone, and vesicourethral junction resulting in a poor distinction between the bladder neck and the proximal urethra are frequently identified in patients with ectopic ureters (see Chapter 77).
- *Urinary bladder duplication and colo-urocystic fistula* have also been rarely observed.
- These congenital conditions often become symptomatic in younger animals. It is necessary to rule out ureteral or urethral abnormalities that do not allow the bladder to store urine normally.
- *Pelvic bladder* refers to caudal positioning of the bladder within the pelvic canal. The bladder often appears elongated with a shortened urethra and an indistinct vesico-urethral junction. Pelvic positioning of the bladder can exert effects in some dogs so that urethral function is compromised, resulting in urinary incontinence. Pelvic bladder can be found as an incidental finding in dogs without urinary tract signs.

Clinical Signs

- Any abnormality leading to poor urethral tone or abnormal placement of ureters may lead to incontinence.
- Recurrent or persistent UTI and associated lower urinary tract signs may be additional findings.

▼ ***Key Point*** Pelvic bladders may be identified in normal dogs and, thus, should not always be considered a pathologic abnormality.

Diagnosis

- *Physical examination:* Abdominal palpation may reveal a small bladder or a bladder that is difficult to palpate because of its positioning.
- *Urinalysis and urine culture:* These are normal unless UTI is present.
- *CBC and serum biochemical analysis:* These tests are unremarkable.
- *Radiography and ultrasonography:* Radiography or ultrasonography may confirm a small bladder, an abnormal bladder shape or wall thickness, or a widened and indistinct junction between the bladder neck and the proximal urethra. Radiography is needed to diagnose a pelvic bladder (see Chapter 4).
- *Cystoscopy:* Cystoscopy can confirm an abnormal urethra-to-bladder transition.

Treatment

Treatment of the primary disease is not always possible. Control of UTI may be beneficial. Patients with bladder hypoplasia and ectopic ureters may show improvement in bladder capacity as continence is restored following

surgical management of ectopic ureters (see Chapter 78).

Ureteral Ectopia or Trigone Abnormalities

See Chapter 77 for discussion of this topic.

INFLAMMATORY BLADDER DISEASE

Urolithiasis (Bladder Calculi)

Etiology

- Uroliths (calculi in the urinary tract) are concretions of minerals with a small portion of matrix proteins that form in the urinary tract. The urinary bladder is the most common site of urolith formation.
- Uroliths form when urine is oversaturated with minerals in susceptible individuals. Supersaturation occurs when the concentration of calculogenic minerals is increased.
- Factors such as urine pH and promoters or inhibitors of crystal formation may affect the solubility of the calculogenic minerals.
- Some types of uroliths form because of metabolic disease such as urate-containing calculi in dalmatians and calcium-containing uroliths in animals with hypercalcemia.
- Additional risk factors for urolith formation include breed, gender, age, and diet (Table 79-2). Once initiation of urolith formation has occurred, the nidus must be retained within the urinary tract, and conditions must favor continued precipitation of minerals to promote growth of the urolith.

Struvite Uroliths

- Struvite (triple phosphate) uroliths are most likely to form in alkaline urine. Struvite is the most common urolith in dogs. Although struvite once was the most common urolith in cats, currently calcium oxalate is the most common.
- In dogs, UTI with urease-producing bacteria predisposes the animal to struvite stone formation in the vast majority of cases. Urease-producing bacteria cause alkaline urine, increased levels of ammonium ion in the urine, and increased trivalent phosphate ions.

Table 79-2. UROLITH BREED PREDISPOSITIONS

Predominant Mineral Type	Canine Uroliths	Feline Uroliths
Struvite	Miniature schnauzer Shih Tzu Bichon frisé Lhasa apso Miniature poodle Cocker spaniel (sterile)	Ragdoll Foreign, domestic, and Oriental shorthair Chartreux Himalayan
Calcium oxalate	Miniature schnauzer Shih Tzu Bichon frisé Lhasa apso Yorkshire terrier Miniature poodle	Persian Himalayan British, foreign, and Oriental shorthair Havana Brown Scottish Fold Ragdoll
Calcium phosphate	Miniature schnauzer Bichon frisé Shih Tzu Yorkshire terrier	No breed predisposition
Urate	Dalmatian English bulldog Any breed predisposed to portosystemic shunt	No breed predisposition
Cystine	Newfoundland Mastiff English bulldog Dachshund Tibetan spaniel Basset hound	Siamese Domestic shorthair
Silica	German shepherd Old English sheepdog	No breed predisposition
Xanthine	Cavalier King Charles spaniel Dachshund	

- A urine culture positive for a urease-producing organism (usually *Staphylococcus* or *Proteus* species, occasionally *Streptococcus, Klebsiella,* or *Ureaplasma* species) is necessary for infection-induced struvite uroliths to develop.
- Canine breeds predisposed to struvite formation include miniature schnauzers, Shih Tzus, bichon frisés, Lhasa apsos, and miniature poodles. Cocker spaniels have been reported to develop sterile struvite urolithiasis. Feline breeds at increased risk include the Ragdoll, foreign shorthair, domestic shorthair, Oriental shorthair, Chartreux, and Himalayan. The Rex, Burmese, Abyssinian, Russian Blue, Siamese, and Birman cats are reported to be at decreased risk.

▼ ***Key Point*** Unlike dogs, 95% of struvite uroliths in cats are sterile and considered metabolic in origin.

Calcium Oxalate Uroliths

- Calcium oxalate crystalluria is more likely to occur in acidic urine. This is due to systemic acid-base effects and not the effects of urine pH favoring precipitation.
- Factors that contribute to calcium oxalate urolithiasis include hypercalcemia, administration of calciuretic substances (e.g., saline diuresis, furosemide, and glucocorticoids), and hyperadrenocorticism.
- Calcium oxalate uroliths are recognized more commonly in male dogs with the following breeds being predisposed: miniature schnauzers, Shih Tzus, bichon frisés, Lhasa apsos, Yorkshire terriers, and miniature poodles. Persian, Himalayan, Ragdoll, British shorthair, foreign shorthair, exotic shorthair, Havana Brown, and Scottish Fold cats are predisposed. Birman, Abyssinian, and Siamese cats are at decreased risk.

Ammonium Urate Uroliths

- Ammonium urate uroliths form when increased amounts of uric acid build up in the urine. This can occur if there is increased intake of purines, the precursors of uric acid. It is also more likely to occur in acidic urine.
- These calculi can also occur with impaired ability to convert uric acid to allantoin, the more soluble end product of purine metabolism.
- Breed predisposition to ammonium urate uroliths has been reported most often in the dalmatian. This appears to be due to both impaired conversion of uric acid to allantoin and increased uric acid resorption by the kidneys. English bulldogs are also predisposed to these calculi.
- Formation of ammonium urate uroliths can also be associated with hepatic disease, most notably with portosystemic shunts (PSSs) or microvascular dysplasia. The breeds predisposed to PSS formation include Maltese dogs, Yorkshire terriers, miniature schnauzers, and papillons (see Chapter 71).

Calcium Phosphate Uroliths

- Pure calcium phosphate (hydroxyapatite) uroliths occur infrequently in dogs and cats. Calcium phosphate is more commonly found as a component of other stones (such as struvite uroliths).
- Canine breeds predisposed to these calculi include miniature schnauzers, bichon frisés, Shih Tzus, and Yorkshire terriers.
- Alkaline urine causes increased precipitation of hydroxyapatite in the urine. Hyperparathyroidism is the most common clinical disorder associated with calcium phosphate urolithiasis.

Cystine Uroliths

- Cystine uroliths are found in both dogs and cats, although they are much less common than the types of urolith discussed previously.
- Acidic urine decreases the solubility of cystine crystals, increasing the likelihood of stone formation.
- Breeds that are predisposed to cystine urolithiasis include the mastiff, Newfoundland, English bulldog, dachshund, Tibetan spaniel, and basset hound. Siamese cats also appear to be predisposed. Male dogs and cats are more likely to develop cystine uroliths than females.

Xanthine Uroliths

- Primary xanthine urolithiasis is uncommon in both dogs and cats.
- Xanthine uroliths occur most commonly secondary to allopurinol administration in the treatment of urate calculi. This is particularly true in patients still consuming a high purine diet.
- Cavalier King Charles spaniels and dachshunds are at increased risk for primary xanthine urolithiasis. Overall occurrence of xanthine uroliths is most frequent in breeds, such as dalmatians, that are likely to be placed on allopurinol.

Silica Uroliths

- Silica uroliths occur rarely in dogs and cats.
- German shepherds and Old English sheepdogs have an increased incidence of silica urolithiasis. Males appear to be affected more frequently than females. There is no reported feline predisposition.

Clinical Signs

- Animals affected with urolithiasis of any type typically present with signs of lower urinary tract disease including dysuria, stranguria, pollakiuria, and hematuria.
- Bacterial UTI associated with uroliths may magnify clinical signs.

- A surprising number of animals with cystic calculi display no signs for protracted periods of time. Animals may have a history of passing uroliths or of previous urolith episodes.
- If uroliths are small enough to move out of the urinary bladder but too large to pass through the urethra, urethral obstruction can occur.
- In some animals, uroliths may not be associated with any clinical signs and diagnosis may be incidental.

▼ ***Key Point*** Diseases that predispose an animal to urolithiasis or recurrent UTI should raise the index of suspicion for uroliths.

Diagnosis

Physical Examination

The exam is often normal unless urethral obstruction is present. Uroliths may be palpated in approximately 20% of the cases. It is more difficult to palpate uroliths in dogs, particularly large breeds, than in cats.

- Animals that form ammonium urate uroliths in association with PSS may be stunted in growth or exhibit signs of hepatic encephalopathy (see Chapter 71).
- Dogs and cats with infection-induced struvite uroliths may exhibit more severe signs of lower urinary tract disease due to the bacterial UTI.

Urinalysis

- Examination of urine may reveal hematuria, pyuria, bacteriuria, and/or crystalluria.
- Urine pH may aid in predicting the possible mineral composition of the uroliths. If a UTI with urease-producing bacteria is present, the urine pH will be alkaline.

▼ ***Key Point*** Crystalluria may or may not be present with uroliths. If present, the type of crystalluria may be different from that of the urolith.

Culture and Sensitivity

- Urine cultures may be positive with any urolith because, once present, they serve as a nidus for infection and damage to the bladder mucosa, increasing the risk of bacterial UTI.

▼ ***Key Point*** Although struvite urolith formation is caused by a UTI in most dogs, the presence of a UTI does not prove that uroliths are composed of struvite.

- Consider culture of the bladder mucosa or a portion of the removed stone at the time of surgery if urine culture was negative.

Complete Blood Count and Serum Biochemical Analysis

CBC and serum biochemical analysis are usually normal.

- Hypercalcemia may be observed in approximately 4% of dogs and 35% of cats with calcium oxalate uroliths.
- A low blood urea nitrogen (BUN) concentration or hyperammonemia may be observed in animals with ammonium urate uroliths that form in association with liver diseases such as portosystemic shunting or microvascular dysplasia.

Diagnostic Imaging

- Survey radiography may reveal radiodense uroliths (e.g., struvite, calcium oxalate, and calcium phosphate) if they are of adequate size. Typically uroliths must be greater than 3 mm to be identified radiographically. Urate uroliths and some cystine uroliths may not be observed on plain radiographs because of their poor mineral density. Double-contrast cystography will reveal these uroliths (see Chapter 4).
- Ultrasonography may demonstrate uroliths. It can be difficult to distinguish very small uroliths from aggregates of sediment, for even experienced ultrasonographers. Only the proximal urethra may be evaluated by ultrasonography.
- Consider intravenous pyelography in animals with nephroliths or ureteroliths or in animals with recurrent bacterial UTI.

▼ ***Key Point*** It is essential that the entire urethra be included on radiographs of male cats and dogs with suspected urolithiasis. If necessary, obtain a separate film of the caudal abdomen to be sure that the entire urethra is evaluated.

Additional Laboratory Testing

A bile acids test or other indicator of liver function is indicated in animals with ammonium urate uroliths (other than in dalmatians or English bulldogs) to determine if hepatic disease is present (see Chapter 71).

Urolith Composition

Submit all uroliths that are retrieved for quantitative analysis, even in animals with crystalluria or history of formation of a particular type of urolith. Also, submit stones for analysis for each episode of urolithiasis to be sure that stone composition has not changed.

Treatment

- Uroliths can be treated either medically or surgically.
- Surgically remove uroliths that cause repeated urethral obstruction, that cause unacceptable clinical signs, or in which the owners do not wish to attempt medical dissolution.

- Uroliths that are smaller than the smallest diameter of the urethra may be retrieved using voiding urohydropropulsion or catheter-assisted retrieval technique.
- For all stones being treated with medical dissolution, continue therapy for 1 month after radiographic resolution of the uroliths. If no improvement is seen in size after 4 to 6 weeks of therapy, consider surgical removal.

▼ ***Key Point*** Because many types of uroliths are recurrent, surgical removal or medical dissolution of uroliths is not the end point of therapy. Institute appropriate preventive measures and follow-up evaluations. Lack of adequate patient surveillance is often associated with recurrent stone formation.

Struvite Uroliths (Table 79-3)

- *Infection induced:* Medical dissolution of infection-induced struvite uroliths is possible using appropriate antimicrobial therapy based on culture and sensitivity and a diet designed for struvite dissolution. A diet for struvite dissolution should be protein and magnesium restricted and should induce an acid urine pH (e.g., Prescription Diet s/d; Hills). The average time for dissolution of canine uroliths is 12 weeks.
- *Sterile:* Dissolution of sterile struvite uroliths is accomplished in a manner similar to infection-induced struvite uroliths except that antimicrobial therapy is not necessary. Average dissolution time for dogs and cats is 4 to 6 weeks.

Calcium Oxalate Uroliths (Table 79-4)

- There is no medical therapy available for dissolution of calcium oxalate uroliths; however, use medical therapy to prevent recurrence after urolith removal.
- Surgical removal, urohydropropulsion, and lithotripsy are the treatment options for uroliths that are causing clinical problems.

Ammonium Urate Uroliths (Table 79-5)

- *Associated with PSS:* Medical dissolution of ammonium urate uroliths in animals with hepatic disease has not been documented to be successful; therefore, surgical removal remains the treatment of choice if uroliths are causing clinical problems. Uroliths may be removed at the time of surgical ligation of the PSS. Theoretically, uroliths may dissolve after the shunt is corrected, but this has not been evaluated in clinical studies.
- *Not associated with PSS:* Urate uroliths may be dissolved using allopurinol and a diet low in purines (e.g., Hill's u/d). The canine dosage for allopurinol is 30 mg/kg/day PO divided into two or three doses every 24 hours. Although a published dosage of 9 mg/kg PO q24h is reported in cats, there is limited data on the safety and efficacy of this treatment in cats. As a result, use allopurinol cautiously in cats. The average dissolution time is 4 weeks. Medical dissolution is successful in approximately 50% of cases.

Calcium Phosphate Uroliths

- Surgically remove these uroliths.

Cystine Uroliths

- Dissolution can be achieved using a combination of medical and dietary therapy. For dogs, 2-mercaptopropionol glycine (2-MPG) (tiopronin, Thiola) can be given at a dosage of 15 to 20 mg/kg PO q12h. No feline dosage has been established. Feeding a low-

Table 79-3. PROTOCOL FOR DISSOLUTION OF STRUVITE UROLITHS IN ADULT DOGS AND CATS

1. Confirm the mineral composition of uroliths when a stone is available. If no stone is available, make the best estimate of its mineral content using results from a combination of urine pH, radiodensity, breed, sex, and diet history.
2. If uroliths are obstructive, recommend surgical removal to the owner (see Chapter 80).
3. In infection-associated stones, begin therapy for urinary tract infection with antibiotics based on cystocentesis, culture, and susceptibility. Maintain antimicrobial therapy during, and for 3 to 4 weeks following, urolith dissolution.
4. Dietary therapy includes use of a phosphorus- and magnesium-restricted diet that is highly acidifying. Dissolution of struvite stones has been achieved following the feeding of Prescription Diet s/d (Hills) (usually canned) in both dogs and cats and IVD Dissolution Diet in cats. Compliance with dietary recommendations is suggested by reduction in blood urea nitrogen concentration (usually <15 mg/dl). Other dietary formulations designed to undersaturate urine for struvite in prevention protocols are not useful in dissolution protocols.
5. Monitor efficacy of therapy:
   a. Perform serial radiographs at monthly intervals to evaluate stone location(s), number, size, density, and shape.
   b. If urinary tract infection was present, perform a quantitative urine culture 5 to 7 days after initiation of therapy to document sterile urine while on antibiotic therapy.
   c. Repeat urine culture several days after completion of antibiotic therapy to document sterile urine.
   d. Continue all therapy for 1 month after radiographic resolution of uroliths.
   e. If uroliths increase in size or have not decreased in size within 4 to 6 weeks of appropriate medical management, consider the following:
      (1) The wrong mineral component was identified
      (2) The nucleus of the uroliths is of different mineral composition than other portions of the urolith.
      (3) Relapsing urinary tract infection or reinfection is interfering with dissolution of the stones.
      (4) The owner or the patient is not complying with medical recommendations.
6. In dogs and cats with persistent urinary tract infection or stones despite appropriate medical therapy, surgical removal of the stones is recommended.

Table 79-4. PROTOCOL FOR PREVENTION OF CALCIUM OXALATE UROLITHS

1. Calcium oxalate stones cannot be dissolved medically. Recommend surgical removal, lithotripsy, or, for small enough stones, urohydropulsion.
2. Although urinary tract infection is not a cause of calcium oxalate urolithiasis, treat secondary urinary tract infection with antibiotics based on culture and sensitivity.
3. Perform complete blood count and biochemical profile on all patients with calcium oxalate urolithiasis to rule out hypercalcemia or any other diseases (e.g., hyperadrenocorticism) that could predispose to stone formation. Identify and treat the underlying cause of hypercalcemia. Persistent hypercalcemia greatly increases the risk of recurrence.
4. For normocalcemic patients with confirmed calcium oxalate urolithiasis take the following actions:
   a. Lower the dose or, if possible, discontinue medications that promote calciuresis (e.g., glucocorticoids and furosemide).
   b. Discontinue supplementation with calcium, vitamin D, and vitamin C.
   c. As with any type of urolith, increasing water intake is a critical part of preventative therapy.
      (1) Recommend transitioning pets to canned food or adding water to dry food.
   d. Diets that may help prevent calcium oxalate uroliths are less acidifying than other diets. Most are sodium restricted but are not magnesium restricted. Diets that may be effective include Prescription Diet canine u/d (Hills), Prescription Diet feline x/d (Hills), Eukanuba Moderate pH/O (Iams), and SO Diet (Waltham).
   e. In cases in which dietary therapy and control of metabolic disease alone have not prevented recurrence of calcium oxalate uroliths, addition of potassium citrate to the diet may be considered. Potassium citrate will help alkalinize the urine and may reduce precipitation of calcium oxalate crystals. The canine dosage is 50 to 75 mg/kg PO q12h. Similar dosages have been reported for cats. Eukanuba Moderate pH/O (Iams) and Prescription Diet feline x/d (Hills) contain increased amounts of potassium citrate.

Table 79-5. PROTOCOL FOR DISSOLUTION OF AMMONIUM URATE UROLITHIASIS*

1. Evaluate urolith(s) location(s), number, size, density, and shape in approximately monthly intervals. Intravenous urography may be utilized for radiolucent uroliths located in the kidneys, ureters, or urinary bladder. Double-contrast cystography may be required for radiolucent uroliths.
2. If the uroliths are obstructive, recommend surgical removal (see Chapter 80).
3. Initiate therapy with a low-protein, alkalinizing diet. In particular, it is important that the diet be low in purines. Purines are found primarily in animal protein, so diets that are based on vegetable proteins or diets that are low in protein will reduce the purine load. Examples of diets that could aid in dissolution of urate stones include Prescription Diet u/d (Hills).
4. If dietary therapy alone does not result in dissolution of stones, initiate therapy with allopurinol. The recommended canine dosage is 30 mg/kg q24h divided into two or three doses. The feline dosage is approximately 9 mg/kg PO q24h, but use it with caution because the safety of allopurinol in cats has not been determined.
5. If urine remains acidic, diet may be supplemented with potassium citrate to achieve a more alkaline urine pH (close to 7.0). The canine and feline dosages are similar, 50 to 75 mg/kg PO q12h.
6. If necessary, eradicate or control urinary tract infections with appropriate antimicrobial agents. Maintain antimicrobial therapy during, and for an appropriate period following, urate urolith dissolution.
7. Regularly monitor urolith size and number to evaluate whether the dissolution therapy is effective. If the stones become larger or have not dissolved within 4 to 6 weeks, consider surgical removal.
8. Continue calculolytic diet, allopurinol, and alkalinizing therapy for approximately 1 month following radiograph disappearance of uroliths.

*This protocol is not effective for ammonium urate uroliths associated with portosystemic shunts.

protein, alkalinizing diet (e.g., Hill's canine u/d) may also decrease cystinuria.
- Time for stone dissolution ranges from 4 to 12 weeks.

Xanthine Uroliths

- Dissolution of xanthine urolithiasis may be achieved with the use of a low purine diet. These include diets that are low in total protein and those composed primarily of plant-based proteins.
- If allopurinol is being given for treatment of urate uroliths, discontinue the drug while stone dissolution is being attempted.

Silica Uroliths

- No proven therapy for dissolution of silica urolithiasis has been reported. Perform surgical removal.

Prevention

- Most types of uroliths can reoccur; therefore, institute patient monitoring and preventive measures.
- Production of dilute urine is beneficial for all urolith types except for infection-induced struvite. Therefore, diet and environmental changes aimed at increasing water intake may help prevent recurrence of uroliths.
  - These changes may include transition from dry to wet diet or addition of water to dry food, placement of additional water bowls or different types of water sources in the home, and attention to water bowl hygiene.
- Dilute urine is a predisposing risk factor for UTI. Therefore, it may predispose an animal to infection-induced struvite urolith formation, although this has not been proven.

- Many uroliths are recurrent. Therefore, reexamine affected animals frequently and assess urine specific gravity, urine sediment, and perform diagnostic imaging if indicated.

Infection-Induced Struvite Uroliths

Because this type of struvite urolith forms as a result of a UTI with urease-producing bacteria, prevention is dependent upon preventing recurrence of the infection.

- Treat any underlying causes of recurrent UTI, such as hyperadrenocorticism and diabetes mellitus (see Chapters 33 and 34, respectively).
- Perform surgery to correct structural abnormalities such as perivulvar dermatitis and recessed vulva (see Chapter 54) that may predispose an animal to infection if untreated.
- If necessary, use low-dose antibiotic therapy as prophylaxis.
- Modification of the diet is not necessary, although increasing water intake and encouraging frequent voiding may assist urinary defenses.

Sterile Struvite Uroliths

Prevention of sterile struvite uroliths involves modification of the diet. Although the feeding of theses diets is logical, no evidence-based medicine studies exist to show long-term benefits to decrease stone formation.

- Because struvite is more soluble in acidic urine (pH <6.8), prevention usually involves feeding one of the several commercially available diets designed to acidify the urine. Excessive acidification of the urine (<6.0) should be avoided as this may indicate excessive effects on systemic acidosis.
- Dietary magnesium restriction may also be of benefit.

Calcium Oxalate Uroliths (See Table 79-4)

The cause of calcium oxalate urolith formation is not completely known. No treatment has been shown to be completely effective in prevention of recurrence. Question owners about any dietary supplements or medications (e.g., vitamin C, calcium, and glucocorticoids) that may increase calcium absorption or calciuresis. Any underlying disease such as hyperadrenocorticism that may predispose an animal to calcium oxalate stone formation should be controlled as well as possible.

- In dogs, feeding a protein- and sodium-restricted diet may delay recurrence. Less acidifying diets may decrease calciuresis. Choosing diets that promote a neutral pH or a pH between 6.5 and 7.0 may be of benefit. Strongly alkalinizing diets are not recommended because they may promote struvite urolithiasis.
- In dogs, if a neutral to slightly alkaline urine pH is not accomplished by diet alone, supplementation with potassium citrate (50–75 mg/kg PO q12h adjusted to alkalinize urine) may be of benefit, although the evidence for this is less convincing in veterinary literature than in human literature. A similar dose has been suggested for cats, but the efficacy of this is even less clear than in dogs.
- For cats with calcium oxalate uroliths, increasing water intake by feeding canned diets or diets with water added is our primary recommendation for prevention of recurrence. Several commercial feline diets are marketed for calcium oxalate prevention.
- Feeding high-fiber, protein-restricted, and phosphorus-restricted diets have been considered but are not documented to be successful.
- Other treatments that have been proposed for both dogs and cats include vitamin B_6 and hydrochlorothiazide (2 mg/kg PO q12h for dogs, 1 mg/kg PO q12–24h for cats). At present, no evidence-based medicine exists for these treatments. In animals with hypercalcemia, administration of hydrochlorothiazide or other thiazide diuretics is contraindicated because it may worsen the hypercalcemia. In these cases, treatment should be aimed at correcting the hypercalcemia rather than controlling the calciuresis.

▼ ***Key Point*** Because calcium oxalate uroliths are highly recurrent, frequently monitor urinalyses and survey abdominal radiographs in these patients.

Ammonium Urate Uroliths

Associated with Portosystemic Shunt

- If the vascular shunt can be repaired or attenuated (see Chapter 72), the risk of ammonium urate urolith formation should decrease. No further treatment may be indicated.
- If the shunt is not repairable, then a low-protein, alkalinizing diet may be beneficial (e.g., Prescription Diet i/d; Hills) in conjunction with appropriate medical therapy (see Chapter 71). The protein source may be of more importance than the amount of protein in the diet. Diets high in vegetable or dairy protein have a lower purine load than those derived from other protein sources.
- Dry formulations of low purine diets alone are much less effective in prevention of urate crystalluria compared with the canned version of the same formulation or the same dry diet mixed with an equal volume of added water.
- Allopurinol is not effective in animals with these calculi associated with PSS.

Not Associated with Portosystemic Shunt

- In dogs, feeding a low-protein, alkalinizing diet (e.g., Prescription Diet canine u/d; Hills) has been successful in preventing recurrence in approximately 80% of cases. As mentioned above, diets high in veg-

etable or dairy protein have a lower purine load than those derived from other protein sources.
- Canned formulations or dry diets with added water are more effective in controlling crystalluria than dry diets alone.
- If urate crystalluria persists despite feeding an appropriate preventive diet, administer allopurinol (10–20 mg/kg PO divided into two doses q24h for dogs). No preventative dose of allopurinol is published for cats.
- In cats, feeding a low-protein, alkalinizing diet alone may allow successful dissolution of urate stones.
- Dogs and cats being treated with allopurinol are at increased risk of developing xanthine uroliths, as well as other drug side effects. Monitor these patients closely during treatment.

Calcium Phosphate Uroliths

- Identify and treat of any predisposing factors, for example, hyperparathyroidism (see Chapter 32) or overly alkaline urine.
- If urine alkalinizers have been used to prevent calcium oxalate or other uroliths, discontinue or reduce the dose to establish a more neutral urine pH.

Cystine Uroliths

- A low-protein, alkalinizing diet is highly successful in preventing formation of cystine uroliths. Cystine solubility increases in alkaline urine; therefore, maintaining a urine pH of >7.5 is important.
- If the urine pH is not >7.5, administer potassium citrate (initial dosage of 50–75 mg/kg PO q12h; adjust the dosage to induce a urine pH >7.5).
- Alternatively, in dogs, 2-MPG (tiopronin, Thiola) (15–20 mg/kg PO q12h) can be given with alkalinization therapy without modifying diet. Occasionally, regenerative anemia and myopathy have been noted with use of this drug. One study also described altered behavior in the form of aggression of which owners should be made aware.

Xanthine Uroliths

- Primary xanthine urolithiasis is uncommon and, when present, is likely due to an inborn error of metabolism such as xanthine oxidase deficiency.
- Xanthine uroliths are most commonly associated with allopurinol administration. Occurrence of xanthine urolithiasis warrants dose reduction or discontinuation of allopurinol.
- Use of a low purine diet may help prevent xanthine, as well as urate, uroliths (e.g., Prescription Diet u/d; Hills).

Silica Uroliths

- Silica content is much higher in plant-based proteins than in animal proteins. Avoiding diets high in plant protein may reduce the recurrence of silica urolithiasis.
- Since there is a tenuous association between animals ingesting large amounts of soil and occurrence of silica urolithiasis, attempt to prevent this behavior in animals with these calculi.

Bladder Infection

Bacterial UTI is the most common infectious disease of the urinary bladder. Fungal cystitis is occasionally observed, particularly in animals that are immunosuppressed; however, many cases are self-limiting. Parasitic cystitis occurs rarely and is usually asymptomatic.

Etiology

Bacterial Cystitis

Bacterial cystitis is most often the result of ascending infection from bacterial contamination of the vulva, perivulvar skin, vestibule, or prepuce. This often results from fecal contamination of these areas, ascent of normal flora, or exposure to organisms in the environment (e.g., nosocomial infections). The body has many defense mechanisms to prevent bacterial invasion of the urinary bladder. Natural resistance factors, inherent to the urinary tract, include complete and frequent unidirectional voiding of urine, mucosal defense barriers, and antimicrobial properties of concentrated, normal urine. Therefore, any breach in these defense mechanisms may result in bacterial colonization of the urinary bladder.

- Bacterial cystitis is a common cause of lower urinary tract disease in dogs, with females affected more frequently than males.
- The most common organisms causing bacterial cystitis include *Escherichia coli* (40–50% of cases) and *Staphylococcus, Proteus, Streptococcus,* and *Enterobacter* species.
- Diseases that cause polyuria and polydipsia or those that affect host immunity may predispose an animal to development of UTI.
- Anatomic or functional abnormalities that affect the urethral tone or the integrity of the urethral and vulvar barriers to bacteria may also be predisposing factors. These include incontinence (of any cause), recessed vulva, perivulvar dermatitis, and urethral sphincter mechanism incompetence.

▼ ***Key Point*** In cats younger than 10 years, bacterial cystitis occurs in only 1% to 2% of cases of lower urinary tract disease. In cats older than 10 years, however, bacterial cystitis may occur in as many as 50% of cases.

- As in dogs, feline diseases that impair urine-concentrating ability predispose cats to UTI. Renal failure is

the most common disease associated with bacterial cystitis in older cats.
- Causative bacteria in cats are similar to those observed in dogs. Increased risk of bacterial UTI also occurs in cats following urethral catheterization (especially indwelling catheters) and perineal urethrostomy.

Fungal Cystitis

- Fungal cystitis is rare compared with bacterial cystitis and occurs mostly in patients that are immunocompromised. Yeast and fungi observed in urine usually represent contamination of the sample. Of organisms that represent true infections, *Candida* species is the most common.
- On occasion, other fungi and algae (e.g., *Blastomyces, Cryptococcus, Aspergillus,* and *Prototheca* and *Trichosporum domesticum*) may be observed in urine, but these have not been reported as isolated infections and instead represent one component of disseminated fungal infection (see Chapter 20).

Bladder or Urinary Tract Parasites

- Rarely, parasitic ova or adult worms are identified in urine samples or within the bladder.
- *Capillaria* and *Angiostrongylus* adults have both been identified within the urinary bladder. In most cases, however, clinical signs relate to infection elsewhere rather than aberrant bladder infection, although hemorrhagic cystitis has been reported with *Capillaria* infection.
- *Dioctophyma renale* is a parasite of the kidneys, but if a gravid female worm is present in the kidney, ova may be observed in urine. This would not be expected to cause lower urinary tract signs.

Clinical Signs

- Clinical signs of lower urinary tract disease are typically acute in onset if the UTI is the primary disease process.
- Clinical signs include gross hematuria, dysuria, and pollakiuria. Animals may also display inappropriate urination. A strong odor to the urine may be detected by the owner, but this is not a sensitive index for infection.
- Some patients with factors predisposing them to UTI may have a more protracted history with waxing and waning signs.

▼ ***Key Point*** Systemic signs are not expected with isolated lower UTI. If signs of systemic illness are present, perform further diagnostic evaluation for a predisposing primary disease or upper UTI.

- Polyuria and polydipsia may be observed with underlying renal failure, hyperthyroidism, diabetes mellitus, hyperadrenocorticism, pyelonephritis, or glucocorticoid therapy. Many of these patients lack the classic lower urinary tract signs seen with primary UTI.
- Skin, oral, or respiratory infections may be observed with immunosuppressive therapy or disease.
- Clinical signs are less likely to be observed when an infection occurs in association with polyuric states or immunosuppressive disease.
- Clinical signs of fungal cystitis are usually similar to those of bacterial cystitis.
- A surprising number of dogs presenting to referral hospitals have positive urine cultures without clinical signs referable to the urinary tract.

Diagnosis

Physical Examination

Physical examination may be normal. Abdominal palpation may reveal bladder pain or thickening of the bladder wall. Examination findings that relate to the predisposing cause may be observed (e.g., prostatic mass, hepatomegaly and alopecia with hyperadrenocorticism, and weight loss, uveitis, harsh lung sounds, and draining skin lesions with systemic mycosis).

Urinalysis

- The infectious agent (bacterium, fungus, yeast, or parasitic ova) is usually observed on urine sediment examination. Signs of inflammation are often present with bacterial cystitis but are usually not present with fungal or parasitic cystitis.
- Urine sediment may appear inactive if the animal is immunocompromised (e.g., hyperadrenocorticism, glucocorticoid therapy, feline leukemia virus, or immunodeficiency virus infection). For this reason, routine urine culture should be done in animals with these diseases.

▼ ***Key Point*** Nitrate and leukocyte pads on urinalysis strips are not accurate for use in dogs and cats. Examine urine sediment to identify inflammation and an infectious agent. Evaluate for glucosuria indicative of underlying diabetes mellitus.

Urine Culture

Perform aerobic bacterial culture of urine (collected by cystocentesis) in suspected cases of bacterial cystitis. Quantification of the number of bacterial colony-forming units per milliliter of urine is the gold standard for diagnosis of UTIs (Table 79-6).

▼ ***Key Point*** Confirmation of bacterial UTI is best made using quantitative culture of urine samples collected by cystocentesis.

- If immediate transport to a microbiology lab is not available, use a quantitative loop (usually 0.01 ml) to

Table 79-6. INTERPRETATION OF QUANTITATIVE URINE CULTURE RESULTS

Method of Collection	Results Indicative of Infection (CFU/ml)	Equivocal Results (CFU/ml)
Cystocentesis	>1000 (usually >10,000)	100–1000
Catheterization	>1000 in male and female cats and male dogs (usually >10,000) Unreliable in female dogs; 20% of normal female dogs have >100,000	100–1000
Voided	Cultures should be avoided (not useful unless no growth) Large quantitative growth is common	

CFU/ml, colony-forming unit per milliliter.

inoculate and streak out a blood agar plate. Incubate the plated urine at 35°C for 18 to 24 hours for most common uropathogens. Submit both a urine sample and the inoculated plate to a microbiology lab for evaluation. Fastidious organisms may require 3 to 5 days for isolation.

- Select antimicrobial agents on the basis of culture and sensitivity results. This is particularly important in patients with recurrent UTI and in those exposed to any antibiotic therapy within the past month.
- The agar-gel disc diffusion method is most commonly used. It is based on expected serum drug concentrations, not urine concentrations (which are higher by 10–100× for many drugs), and thus underestimates the effectiveness of some drugs.

▼ ***Key Point*** If sensitivities are established by determining the minimum inhibitory concentration (MIC), select antibiotics that reach urine concentrations 4 times the MIC.

- Alternatively, in first-time UTI without predisposing anatomic, metabolic, or functional issues, choose antibiotics based on known biologic behavior of uropathogens.
- Urine may be submitted for a fungal culture as well, although a diagnosis of mycotic infection is often made on the basis of sediment examination. Given the rarity of fungal UTI, be certain that the fungal elements are not contaminants from the stain or the environment. Confirm with a second positive sample.

Complete Blood Count and Serum Biochemical Analysis

Rule out cystitis associated with a systemic disease (such as renal failure or hyperadrenocorticism).

Diagnostic Imaging

Perform radiographs or ultrasound to rule out primary bladder or other urogenital diseases that create anatomic abnormalities that predispose the patient to UTI (see Chapter 4).

Additional Laboratory Testing

- Perform endocrine testing in dogs suspected of having hyperadrenocorticism or cats with hyperthyroidism (see Chapters 33 and 31, respectively).
- Perform a feline leukemia virus antigen test and a feline immunodeficiency virus antibody test in cats with UTI (see Chapters 8 and 9, respectively).

Treatment

Bacterial Cystitis

Always select antimicrobial agents on the basis of culture and sensitivity results.

- ***Uncomplicated infection:*** Treat uncomplicated cystitis with the appropriate antimicrobial for 10 to 14 days. If clinical signs resolve and this is a first-time infection, no follow-up is generally needed. However, consider reculture of the urine 3 to 7 days after completion of antibiotic therapy to document sterile urine.
- ***Complicated infection:*** Consider bacterial cystitis complicated if it is recurrent or associated with an underlying risk factor. Give antimicrobial therapy for 3 to 4 weeks. Obtain a urinalysis and urine culture 5 to 7 days after beginning therapy to ensure that there is no growth while on medication. Perform a final urine culture several days after cessation of therapy to document continued urine sterility.
- ***Relapsing infection:*** Relapsing infections (i.e., infection with the same bacteria following appropriate treatment) can occur if antibiotic choice, dose, or duration of therapy is inappropriate. Complicating factors or diseases that create a nidus for infection (e.g., urolithiasis or bladder diverticulum) may be present. Relapse of infection requires a reassessment of antimicrobial choice based on culture and sensitivity results and a search for and treatment of any

complicating factors. A deep-seated infection could require a second, longer course of therapy (Table 79-7).

- ***Reinfection:*** Reinfection (i.e., repeat infection with a different organism within a few weeks to months following documented eradication) generally indicates a predisposing anatomic, metabolic, or functional abnormality that increases the likelihood of development of UTI. Like relapsing infections, this necessitates reevaluation and treatment for complicating risk factors (Table 79-8). Documenting the organism responsible for infection and a negative culture following treatment is essential.
  - Consider long-term, low-dose antibiotic therapy to treat animals with frequent reinfections. This involves administering one-third to one-half of the recommended therapeutic dose of the antimicrobial once a day. This is best given at night to allow excretion and collection of the antimicrobial into the urine overnight, which maximizes contact of the antimicrobial with the bladder. Do not use this strategy for relapsing infection.
- ***Catheter-induced infection:*** Bacterial cystitis may occur as a result of urinary catheterization. If a catheter is passed only once into the urinary bladder, treatment

Table 79-7. DISORDERS TO CONSIDER FOR RECURRENT URINARY TRACT INFECTIONS

Functional/Anatomic Abnormalities
Deep-seated cystitis (chronic wall changes)
Pyelonephritis
Prostatitis
Metritis/pyometra
Neoplasia (bladder/urethra)
Small urinary calculi (previously undetected)
Urachal remnant (developmental)
Periurachal microabscesses
Ectopic ureters (developmental)
Urethral sphincter mechanism incompetence (incontinence)
Polypoid cystitis
Recessed vulva
Vestibulovaginal stenosis
Ureterocele
Bladder atony (abnormal residual urine volume)
Urethral stricture
Urethral fistula

Metabolic Conditions
Diabetes mellitus
Hyperadrenocorticism
Exogenous steroid administration
Renal failure (especially cats)
Hyperthyroidism
Immunosuppression/chemotherapy

Table 79-8. MANAGEMENT OF COMPLICATED AND RECURRENT URINARY TRACT INFECTIONS

Diagnostic Considerations
Are you certain that the disease is bacterial in origin?
Are there any predisposing anatomic abnormalities?
- Urolithiasis (upper or lower urinary tract)
- Ectopic ureters
- Neoplasia of bladder, urethra, or prostate
- Urachal diverticulum
- Polypoid cystitis
- Recessed vulva
- Chronic bladder thickening with extensive tissue changes
- Pyelonephritis
- Prostatitis

Has diagnostic imaging been adequate to exclude these problems?
Are there any underlying functional abnormalities?
- Can the animal completely evacuate the bladder such that a normal residual volume is left?
- Could primary sphincter mechanism incompetence or low urethral tone with urinary incontinence and subsequent wicking of bacteria be contributing? (See Chapter 83.)

Are there any underlying metabolic conditions (with or without obvious pyuria or bacteriuria)?
- Diabetes mellitus
- Hyperadrenocorticism
- Renal failure

Therapeutic Considerations
1. Identify and eliminate or control predisposing or complicating causes of the urinary tract infection (e.g., hyperadrenocorticism, diabetes mellitus, urolithiasis, and anatomic defects).
2. Identify causative pathogens by quantitative urine culture, and select antimicrobial drugs on the basis of antimicrobial susceptibility tests. Ideally, the agent chosen should have the narrowest possible spectrum of antimicrobial activity.
3. If signs of upper urinary tract infection are present (e.g., fever, leukocytosis, or polyuria and polydipsia), treat aggressively with appropriate dosages of antimicrobials. A longer duration of treatment (4 to 6 weeks) will be necessary for upper urinary tract or complicated lower urinary tract infections than for first-time lower urinary tract infections (10 to 14 days).
4. Reculture urine 5 to 7 days following initiation of therapy to check the efficacy of the antimicrobial agent in sterilizing urine.
5. Culture urine 3 to 5 days after the completion of therapy to confirm resolution of the infection.
6. Anticipate recurrence of infection in animals with underlying disease or anatomic abnormalities that cannot be corrected. Routine culture should be performed every 3 to 6 months in these patients even if they are asymptomatic. Counsel owners that any lower urinary tract signs should be evaluated promptly.
7. If recurrent infection continues despite routine screening and appropriate treatment, prophylactic therapy with constant low doses or pulse dosing of antibiotic therapy should be considered.

with amoxicillin or a cephalosporin should prevent infection. This can be given at the time of catheterization and for 2 to 3 days afterward. If an indwelling catheter is placed, do not administer antimicrobials while the catheter is in place. Instead, evaluate a urine sample when the catheter is removed. If bacterial cystitis is present at that time, treat appropriately based on culture and susceptibility.

Fungal Cystitis

- Treat a confirmed fungal infection whether or not the animal is symptomatic. Select the antifungal agent and dose based on the organism that is identified.
- Ketoconazole (10–20 mg/kg PO q24h or as a divided dose for dogs, 10 mg/kg PO q12h for cats), itraconazole (5 mg/kg PO q12–24h for dogs and cats), and amphotericin B (variable IV dosing) have been used successfully (see Chapter 20).
- Infusion of antifungal agents such as clotrimazole into the bladder has been reported for treatment of *Candida* spp. UTI. Altering urine pH as a means of treating fungal infection is not recommended as the sole therapy. If possible, treat any immunosuppressive disease or reduce or stop immunosuppressive medication.

Parasitic Cystitis

- Because many animals with parasitic cystitis are asymptomatic, treatment may not be warranted.
- For urinary capillariasis, give levamisole (2.5 mg/kg/d PO for 5 days). Use of fenbendazole (25 mg/kg PO q12h for 3–10 days) has been reported, but it does not appear to be as effective as levamisole.

▼ ***Key Point*** Albendazole is no longer recommended in dogs or cats because it can cause bone marrow aplasia.

Prevention

Prevention of infectious cystitis is dependent upon identifying and eliminating or controlling the underlying disease.

- Treat diseases such as diabetes mellitus or hyperadrenocorticism that may predispose the animal to infection as effectively as possible to minimize the risk of UTI.
- In patients with diseases such as renal failure, in which the predisposing factor (low urine specific gravity) cannot be corrected, regularly screen for UTI.
- Surgically correct anatomic abnormalities if they are present (e.g., bladder diverticulum or recessed vulva).

Emphysematous Cystitis

Emphysematous cystitis is a rare complication of bacterial UTI, particularly in patients with glucosuria.

Etiology

Emphysematous cystitis occurs when bacterial cystitis is caused by gas-producing bacteria such as *Clostridium* spp. These bacteria create pockets of gas within the wall of the bladder that are apparent on radiographs and ultrasound.

Clinical Signs

Clinical signs are similar to other forms of cystitis.

Diagnosis

- *History:* This type of bladder infection occurs almost exclusively in patients with glucosuria and UTI secondary to diabetes mellitus. It has also been associated with other immunosuppressive diseases such as hyperadrenocorticism.
- *Physical examination:* The urinary bladder is usually small and firm on palpation.
- *Urinalysis:* Urinalysis shows inflammation; the agent may not be observed. Perform cystocentesis carefully in these patients because the integrity of the bladder wall may be affected by gas within the bladder wall.
- *Urine culture:* Aerobic cultures may be negative if an anaerobic organism is responsible.
- *CBC and serum biochemical analysis:* These tests are usually normal unless associated with a metabolic disease such as diabetes mellitus or hyperadrenocorticism. Evidence for sepsis may be present. Evidence for bone marrow suppression may be present if associated with administration of chemotherapeutic agents.
- *Radiography and ultrasonography:* Radiography and ultrasonography show air trapped in the wall of the urinary bladder.

Treatment

- Administer an appropriate antimicrobial (e.g., ampicillin, amoxicillin, or amoxicillin-clavulanic acid) for 3 to 6 weeks.
- Treat the underlying predisposing disease, if possible. If the animal is receiving immunosuppressive or chemotherapeutic agents, consider temporarily stopping the drug or decreasing the dosage.

Prevention

- Identify animals at risk for infectious cystitis.
- Monitor for UTI periodically in animals known to have a disease that compromises their local or sys-

temic defenses and in animals receiving immunosuppressive or chemotherapeutic drugs.
- Many of these animals may not demonstrate clinical signs but may have evidence of UTI on urinalysis.

IDIOPATHIC FELINE LOWER URINARY TRACT DISEASE

Idiopathic feline lower urinary tract disease (IFLUTD) has also been called feline urologic syndrome (FUS) and feline interstitial cystitis (FIC) because of many similarities with human interstitial cystitis. Approximately 1% to 2% of cats in the United States are affected with lower urinary tract disease. In 50% to 70% of these cats that are less than 10 years of age, no definable cause can be found. In cats older than 10 years of age, IFLUTD is diagnosed in approximately 5% of the cases. Therefore, a thorough diagnostic workup should identify a primary disease in the older cats. IFLUTD can be associated with urethral obstruction, particularly in male cats. For information on diagnosis and treatment of urethral obstruction, see Chapter 81. The following discussion will emphasize non-obstructive IFLUTD.

Etiology

- The cause of IFLUTD is not known, but possibilities include viral cystitis, neurogenic inflammation, abnormal glycosaminoglycans lining the urinary bladder mucosa, unidentified bacterial infection, and mast cell–related disease.
- Since the cause of IFLUTD has not been identified, expect a variable clinical course.
- Activation of the sympathetic nervous system with enhanced norepinephrine outflow from the central nervous system appears to be a major factor in enhancing or activating inflammatory lesions. Enhanced sympathetic nervous system outflow at a time of suboptimal activation of glucocorticoids seems to be important in these cats. Studies documenting smaller adrenal glands in affected cats and a reduced response to adrenocorticotropic hormone during stress are supportive of this.
- Increased norepinephrine actively up-regulates the inflammatory response in the bladder, increases pain perception, increases mast cell degranulation, and increases detrusor muscle contraction. This may also change permeability of the bladder by effects on the mucosa.

Clinical Signs

- Clinical signs associated with IFLUTD include hematuria, dysuria, pollakiuria, and inappropriate urination, which often resolve spontaneously after 5 to 7 days. However, in some cats, signs may last for weeks or may wax and wane chronically.
- Urethral obstruction may occur in male cats (see Chapter 81).

▼ ***Key Point*** The clinical signs of IFLUTD can be identical to those seen with a bacterial UTI. UTI is rare in younger cats.

Diagnosis

- *History:* Clinical signs may be observed for a period of days before the cat is examined. There may or may not be a previous history of lower urinary tract disease.
- *Physical examination:* If urethral obstruction is absent, the urinary bladder will be small on palpation and may be painful.
- *Urinalysis and urine culture:* Hematuria and proteinuria are common, although pyuria is not a common finding. These findings can be episodic. Urine culture is negative. Crystalluria, if present, has little significance in the pathophysiology of the disease if urinary obstruction is not present.
- *CBC and serum chemistries:* These tests are normal.
- *Radiography and ultrasonography:* A small urinary bladder is observed on survey radiography. Contrast radiography and ultrasonography (see Chapter 4) may be normal or may reveal a thickened bladder wall. No uroliths or diverticula are identified.
- *Cystoscopy:* The hallmarks of IFLUTD are varying combinations of mucosal edema, glomerulations, and increased vascularity. Cystoscopy is valuable for ruling out other causes of lower urinary tract signs in cats with chronic or recurrent problems.

Treatment

Specific Treatment

- No specific treatment recommendations can be made because the cause of IFLUTD is unknown. There are few proven effective treatments for IFLUTD.
- Antibiotics are not warranted without evidence of bacterial cystitis (see previous discussion). In two placebo-controlled studies, antibiotics administered to cats with non-obstructive IFLUTD were no more effective than a placebo.
- Glucocorticoids administered to cats with IFLUTD have also not been more effective than placebo and therefore are not indicated.

Symptomatic Treatment

Environment

- Environmental enrichment may decrease baseline anxiety levels in cats prone to episodes of IFLUTD (see the Indoor Cat Initiative website for more information: http://www.indoorcat.org/index.php).
- One study of affected cats has shown an 80% decrease in recurrence of IFLUTD in cats given environmen-

tal enrichment relative to a control group whose environment was not changed.
- Providing both stimulation (e.g., toys and accessible windows to look outside) and safe areas (e.g., away from other pets and children) may be important in affected cats.

Diet and Water Intake

Increasing water intake encourages more frequent voiding. The dilution of urine may reduce noxious substances within the urine.

- Transition from dry to as much canned food as the cat will accept or add liquids (e.g., water, broth, or tuna juice) to the dry kibble.

▼ ***Key Point*** Transitioning to canned food may be the single most effective treatment of IFLUTD.

- Provide access to fresh water at all times.
  - Experiment with water bowl type, number, and location. Some cats prefer drinking from glasses rather than bowls. Most cats prefer a water container that is filled to the top.
  - Adding broth to the water bowl for flavoring may encourage water consumption.
  - Many cats prefer running water to standing water. Addition of a commercial pet fountain or a dripping faucet may encourage increased water intake.

Medical Therapy

Acute Crisis

- *Sedation or antianxiety:* Stress, or inability to cope with normal stressors, is thought to play an important role in this condition. For this reason, minimizing stress is essential in management of both acute and chronic recurrence of IFLUTD. In general, we recommend administering medications to relieve anxiety or sedatives in hospitalized patients as often as is necessary to produce visible sedation (e.g., presence of raised third eyelids in patients given acepromazine). This degree of sedation should only be necessary to control an acute episode and is not desired in patients once they are home.
  - Acepromazine (0.05–0.1 mg/kg SC q4–6h) may help reduce stress.
  - Because of the risk of acute hepatic necrosis, oral diazepam is no longer recommended in cats. In hospitalized animals, consider intravenous diazepam or intramuscular midazolam to provide sedation.
- *Analgesia:* Regardless of the underlying cause of IFLUTD, the inflammation in the bladder causes pain similar to that of any lower urinary tract inflammation. We recommend combining the antianxiety medications mentioned above with analgesics until clinical signs of cystitis resolve.
  - Butorphanol (Torbugesic) (0.2–0.4 mg/kg SC or PO q4–6h) or buprenorphine (Buprenex) (0.005–0.01 mg/kg SC or PO q6–8h) can be used. Buprenorphine may be preferable because of its prolonged duration of action (see Chapter 6).
- *Antispasmodics:* Although usually unnecessary, these drugs may be of benefit in refractory cases or in male cats for which obstruction is a concern. Options for antispasmodics include propantheline bromide (0.2–0.4 mg/kg PO q12–24h) and oxybutynin (0.5–1.0 mg/cat PO q8–12h).

Chronic Therapy

- Behavior modifying drugs such as amitriptyline, clomipramine (Clomicalm), and buspirone (Buspar) may be of benefit in cats whose signs are not controlled with environmental enrichment and increased water intake.
  - Tricyclic antidepressants (TCAs) may have powerful analgesic and anti-inflammatory effects.
  - Although results may be seen quickly, a minimum of 2 to 3 months of therapy is needed to decide if these drugs are helpful or not.
  - Never suddenly discontinue therapy with TCAs. Taper the drug slowly over 3 to 4 weeks.
- Glycosaminoglycan supplementation has been investigated, and no effect over placebo has been demonstrated.
- Anecdotal evidence suggests that pheromone therapy (e.g., Feliway) may be effective in some cases. This is most likely to be helpful in combination with environmental and dietary changes.

Prevention

The recommendations for treatment of IFLUTD (environmental enrichment, increased water intake, medical therapy) are the same as those for prevention. In general, we recommend trying environmental and dietary changes prior to chronic medical therapy, but in some refractory cases, medical management is needed.

POLYPOID CYSTITIS

Etiology

Polyps may be observed in animals with chronic urinary bladder disease. By definition, polypoid cystitis is a benign condition, but it must be differentiated from malignant neoplasia. Polyps typically represent an inflammatory response to an underlying condition such as chronic bacterial UTI or urolithiasis.

Clinical Signs

- Polyps may be subclinical or they may cause hematuria, dysuria, and pollakiuria.
- As with other inflammatory diseases of the lower urinary tract, they may cause inappropriate urination.

Diagnosis

- *History:* There may be a history of UTI because polyps are one cause of relapsing infection.
- *Physical examination:* This is usually normal. Check for evidence of neoplasia by doing careful abdominal and rectal palpation.
- *Urinalysis and urine culture:* Hematuria, pyuria, and bacteriuria are often observed. Urine cultures are usually positive.
- *CBC and serum chemistries:* These tests are usually normal.
- *Radiography and ultrasonography:* Survey radiography is usually normal unless radiodense uroliths are present. Contrast radiography and ultrasonography reveal the polyps associated with the bladder wall.
- *Cystoscopy:* Cystoscopy allows direct examination of the bladder mucosa. The endoscopic appearance of the polyps is typically different from that of malignancies, but obtain tissue samples for biopsies at the time of cystoscopy to confirm this.

Treatment

Treatment of the underlying disease sometimes results in resolution of the polyps if they are inflammatory in origin.

- It may be impossible to effectively treat an underlying UTI until the polyps are removed.
- Surgical excision is indicated if the polyps persist. Partial cystectomy or submucosal excision of the urinary bladder mucosa is indicated (see Chapter 80). Depending on the extent of the mucosal excision, reepithelization of the bladder lumen is complete between 10 and 28 days.
- Prevention of inflammatory polyps is dependent upon preventing the primary disease.

CYCLOPHOSPHAMIDE-INDUCED HEMORRHAGIC CYSTITIS

Etiology

Cyclophosphamide is an alkylating agent used frequently in the treatment of neoplasia (especially lymphoma) and occasionally in the treatment of immune-mediated diseases (see Chapter 26). Acrolein, a metabolite of cyclophosphamide that is excreted in urine, causes mucosal ulceration, necrosis of smooth muscle and small arteries, hemorrhage, and edema in some cases. The resulting sterile hemorrhagic cystitis can occur after months of treatment but has also been reported after a single dose.

Clinical Signs

The pollakiuria and stranguria that are seen are similar to other inflammatory diseases, but the degree of hematuria may be much more pronounced than in a typical UTI. Frank blood in the urine is often reported.

Diagnosis

- *Physical examination:* Pain may be elicited on bladder palpation. Blood or blood-tinged urine may be seen in the perivulvar or preputial areas.
- *Urinalysis and urine culture:* Hematuria, sometimes severe, is present; mild to moderate pyuria may be present. As indicated by the name *sterile hemorrhagic cystitis,* urine culture is usually negative.
- *CBC and serum chemistries:* These values are normal unless bone marrow suppression has occurred due to chemotherapy or unless changes secondary to the neoplasia are present.
- *Radiography and ultrasonography:* Radiographic changes will be similar to those seen with other causes of cystitis. The bladder may be small because of frequent voiding and may have thickened walls. Contrast radiography and ultrasonography reveal irregular mucosa. Blood clots may be present within the bladder lumen.

Treatment

- Discontinue administration of cyclophosphamide immediately.
- Inducing diuresis appears to be the only effective means of treating cyclophosphamide-induced cystitis, although serious necrosis and fibrosis may still occur.
- Systemic anti-inflammatory therapy has not been shown to be effective, although analgesia may help relieve some symptoms of inflammation. One report in the human literature showed resolution of clinical signs with pentosan polysulfate, a synthetic glycosaminoglycan. In this case, continuation of cyclophosphamide therapy was possible with continued use of the pentosan polysulfate.
- Infusion of dimethyl sulfoxide and formalin in the bladder has reportedly been effective, but these treatments have not been critically evaluated.

Prevention

- Once sterile hemorrhagic cystitis has occurred, the affected patient should never receive cyclophosphamide again.
- Another alkylating agent (typically chlorambucil) should be substituted if needed for continued chemotherapy or immunosuppressive therapy.
- Minimizing contact time of the acrolein with the bladder is the easiest way to prevent this complication from occurring. Administer the drug in the morning, counsel owners to take the animal out to void frequently, and encourage increased water intake (giving canned food or adding water to food).
- A recent report indicates that concurrent administration of furosemide with cyclophosphamide

decreases the risk of sterile hemorrhagic cystitis. This is likely due to furosemide-induced diuresis and may be a viable alternative to encouraging increased water consumption. Diuresis through parenteral fluid therapy is generally not needed, although it would be an effective preventative measure.

- The drug Mesna was designed to react with the acrolein in the urine, thus preventing hemorrhagic cystitis. This drug is highly effective and is routinely used in humans. It has been used safely in dogs, although infrequently because it is cost prohibitive in most cases.

URINARY BLADDER NEOPLASIA

Etiology

Neoplasms of the urinary bladder are the most frequently identified urinary tract tumor in dogs, but they account for <1% of all canine neoplasms. Bladder neoplasia is rare in cats. Bladder neoplasms tend to occur in older animals and are more frequently observed in female than in male dogs.

- The most common neoplasm of the urinary bladder is transitional cell carcinoma (TCC), a malignant epithelial tumor. Neoplasms of other types including lymphomas, fibromas, rhabdomyosarcomas, papillomas, squamous cell carcinoma, and adenocarcinomas occur less frequently.
- Rhabdomyosarcomas, although rare, are unique in their tendency to occur in younger animals (<2 years of age).
- For TCC, breed predisposition is most notable in Scottish terriers, but it is also reported in Shetland sheepdogs, collies, Airedales, and beagles. German shepherds are thought to be at reduced risk for the formation of bladder neoplasia. No breed predisposition is noted in cats.
- Previous exposure to certain lawn treatments (herbicides) and cyclophosphamide are shown to increase the risk of transitional cell carcinoma.

Clinical Signs

- Regardless of tumor type, clinical signs are similar and include hematuria, pollakiuria, and stranguria.
- Animals may not show any clinical signs in the early stages of the disease. Approximately two-thirds of bladder tumors involve the trigone region. Urethral or ureteral obstruction may occur, resulting in uremia.

▼ ***Key Point*** Bladder neoplasia is difficult to distinguish from other common urinary tract diseases such as infection or urinary calculi based on clinical signs alone.

Diagnosis

▼ ***Key Point*** Suspect bladder neoplasia in middle-aged and older dogs that present for hematuria or chronic or recurrent UTI.

- *Physical examination:* If large enough, the bladder tumor may be palpated. Perform rectal examination in all dogs with signs of urinary tract disease. This is particularly important in older dogs because extension of the mass into the urethra may be palpable. A large bladder, if the urethra is obstructed, or a large kidney, if a ureter is obstructed, may be palpated. In more advanced disease, cancer cachexia may be present. If lameness is present, consider associated hypertrophic osteopathy or bone metastasis.
- *Urinalysis and urine culture:* Hematuria and pyuria are common findings on evaluating the urine sediment. Often neoplastic cells may be observed in the urine sediment when examined by experienced personnel. Secondary UTIs are common with bladder tumors because of the inflammation and disruption of the normal mucosa that occur with neoplasia.

▼ ***Key Point*** If neoplasia is suspected, use catheterization or a voided sample instead of cystocentesis to collect urine. Cystocentesis and fine-needle aspirate of bladder masses can lead to seeding of the abdomen and skin with neoplastic cells. Ultrasonography of the bladder may be used to rule out neoplasia, making it safer to perform cystocentesis if necessary.

- *CBC and serum chemistries:* Usually normal. A mild normocytic, normochromic anemia consistent with chronic disease may be present. Azotemia may be present if the urethra or both ureters are obstructed.
- *Radiography and ultrasonography:* Survey radiography may be normal, although a large urinary bladder or a large kidney may be observed if there is urethral or ureteral obstruction secondary to the tumor. Sublumbar lymphadenopathy may be observed in cases of metastasis or severe local inflammation. Contrast cystography or ultrasonography is indicated if a tumor is suspected and survey radiographs appear normal (see Chapter 4). Lesions are most often seen as a mass or thickening in the bladder trigone. The proximal urethra is often affected as well.
- *Bladder biopsy:* Perform biopsy of the bladder mass by cystoscopy or laparotomy. Laparotomy may be the best option if resection or debulking of the mass is thought to be possible (see Chapter 80).
- *Bladder tumor antigen test:* The BTA stat test and V-BTA test (Polymedco) are urine tests designed to screen for the presence of bladder tumor antigen. Although these have a very high negative predictive value (98.6%), their positive predictive value is poor

(31%). False positives can be caused by proteinuria, pyuria, hematuria, and glucosuria, making this a poor test to distinguish neoplasia from other causes of lower urinary tract inflammation. Negative test results appear to be of value to help rule out neoplasia.

- *Traumatic catheterization:* If cystoscopy is not available to obtain a biopsy sample, tissue samples may be obtained via traumatic catheterization. Under heavy sedation with analgesia or general anesthesia, pass the largest urinary catheter possible through the urethra. Once urine is obtained, controlled, rapid movement of the catheter back and forth within the proximal urethra and bladder neck with suction will often produce small pieces of tissue that can be submitted for biopsy. Even if tissue samples are not large, neoplastic cells may be present in the sediment that will allow cytologic confirmation of neoplasia.

Treatment

- The long-term prognosis for most animals with bladder neoplasia is poor.
- Surgical excision is the treatment of choice for benign tumors and for malignant tumors that are not extensive and do not involve the trigone (see Chapter 80). Unfortunately, many bladder malignancies, especially transitional cell carcinoma, are found within the trigone, ureters, and/or urethra, making complete surgical resection difficult or impossible.
- Experience with urethrocystoscopy suggests that transitional cell carcinoma tumors are often found in multiple locations in the bladder and urethra even when only one mass is identified with contrast cystography or ultrasound.
- Transitional cell carcinomas do not respond well to most chemotherapy drugs. Administer piroxicam (0.3 mg/kg PO q48h for dogs; dosage undetermined for cats) in all cases both for its analgesic and for its antitumor properties.
- Neoplasms that are responsive to chemotherapy, such as lymphoma, should be treated accordingly (see Chapter 27).
- Investigation of intravesical infusion of chemotherapeutic agents is ongoing and may prove to be a viable treatment option.
- If urethral obstruction occurs, but the animal's quality of life is otherwise good, place a cystotomy tube to allow voiding (see Chapter 80). Monitoring for and treatment of secondary UTIs is an important component of therapy.

Prevention

Given recent evidence connecting herbicide exposure and transitional cell carcinoma, minimize contact with herbicide-treated lawns, particularly in predisposed breeds (e.g., Scottish terrier). In older animals, particularly female dogs, that have persistent or recurrent hematuria or UTI, perform a thorough diagnostic workup early in the course of disease.

BLADDER TRAUMA

Etiology

- The urinary bladder may be damaged or ruptured by any form of blunt or penetrating trauma.
- Acute or chronic bladder diseases, such as urolithiasis or urethral obstruction, may predispose the bladder to rupture.
- Iatrogenic trauma to the urinary bladder may occur secondary to problems with urethral catheterization or cystocentesis.

Clinical Signs

- Clinical signs may initially be limited to those of lower urinary tract inflammation such as hematuria, dysuria, and stranguria.
- Clinical signs of systemic illness (e.g., uremia and anuria) may be present if the bladder ruptures and urine leakage into the peritoneal cavity occurs.
- Bladder trauma can also occur as a result of displacement or entrapment, as in a perineal hernia. Investigate any abnormal swelling or protrusion in the area of perineum.

▼ ***Key Point*** Ability to urinate normally does not rule out a ruptured bladder.

Diagnosis

- *Physical examination:* Abdominal or inguinal bruising may be evident. Pain may be elicited on abdominal palpation. Fractures and other organ injury may be present. Perform rectal examination to help identify pelvic injury. Abdominal distention due to uroabdomen may be found. Even a ruptured bladder may be palpable, and ureteral rupture or small tears in the urinary bladder may still lead to uroabdomen or uroretroperitoneum. Examine the perineal area carefully as part of the physical exam for evidence of a perineal hernia (see Chapter 74).
- *Urinalysis and urine culture:* If urine can be collected, it may be hemorrhagic and may contain white blood cells. White blood cells may also be present secondary to urine in the peritoneal cavity if the sample is drawn from the abdomen rather than the bladder.
- *CBC and serum chemistries:* In cases of uroabdomen, initially all values related to the urinary system may be normal. Creatine phosphokinase and liver enzymes may be increased secondary to muscle and/or liver damage from trauma. Hyperkalemia is typically a late finding seen 2 to 4 days after uroabdomen develops. Azotemia typically takes 24 to 36 hours to develop with BUN increasing prior to crea-

tinine, although pre-renal azotemia secondary to hypovolemic or distributive shock may occur earlier than this. Hyperphosphatemia and metabolic acidosis due to uroabdomen occur after BUN and creatinine increase, although these may increase initially due to tissue trauma and shock (distributional or hypovolemic), respectively.

- *Radiography and ultrasonography:* On survey radiographs, the bladder may be small, may be present in the perineal region if herniated, or may not be visible. Abdominal fluid may be identified. Positive contrast cystography is the imaging procedure of choice for diagnosis of a ruptured bladder; perform this in all patients with pelvic fractures or a high index of suspicion for bladder rupture (see Chapter 4). Intravenous pyelography may be needed to identify ureteral rupture (see Chapter 4).
- *Abdominocentesis:* If abdominal fluid is present, perform abdominocentesis (see Chapter 3) and, along with blood samples, submit the fluid for biochemical analysis. The urea nitrogen and creatinine concentration of the abdominal fluid should then be compared with plasma to diagnose uroabdomen.

▼ ***Key Point*** The creatinine concentration will be higher in abdominal fluid than in blood if the fluid is urine. The concentration of BUN may be similar in fluid compared to plasma because smaller molecular size allows it to equilibrate more quickly than creatinine.

Treatment

- If a small rupture has occurred evidenced by minimal leakage on a positive contrast cystogram, place a urethral catheter and connect to a closed collection system for 3 to 7 days. Repeat the cystogram to confirm healing of the rent.
- If a large rupture has occurred, perform surgical repair (see Chapter 80).

Prevention

Iatrogenic trauma to the bladder is the only preventable form of bladder trauma.

- Use soft polyvinyl or Silastic catheters rather than rigid polypropylene catheters. Always lubricate the catheter well and pass the catheter slowly to minimize catheter-induced trauma. If rigid catheters are used for initial catheterization (as in blocked cats), replace them with softer catheters for indwelling use.
- If catheterization is difficult, consider flushing the catheter with sterile saline and/or water-soluble lubricant as the catheter is passed to help distend the urethra. Never force a catheter if an obstruction is encountered.
- Measure catheters prior to insertion to approximate the bladder location. Minimal advancement should be necessary once urine is observed to flow through the catheter.
- Obtain survey radiographs if there is any question about appropriate catheter placement.
- Although cystocentesis is an important diagnostic tool in veterinary medicine, it can result in bladder trauma. As with any technique, use adequate chemical or physical restraint to allow the urine sampling with minimal patient movement.
- If the bladder is friable and more susceptible to trauma (e.g., emphysematous cystitis), use extreme care in performing catheterization or cystocentesis and warn owners of the risk of bladder trauma.

Chapter 80

Surgery of the Urinary Bladder

Gretchen K. Sicard / Roger B. Fingland

Cystotomy is the most common surgical procedure of the urinary bladder in small animals and is commonly performed for removal of urinary calculi. Subtotal or total cystectomy may be indicated for management of benign or malignant urinary bladder neoplasia. The incised bladder wall heals quickly and regains nearly 100% of original tissue strength after healing. The mucosal lining of the bladder is quite delicate and easily becomes edematous, necessitating meticulous tissue handling and proper suture placement.

ANATOMY

- The urinary bladder is divided into three regions: (1) the cranial portion is the apex, (2) the caudal portion that joins the urethra is the neck, and (3) the segment between the apex and neck is the body.
- The ureteral openings and the urethral orifice form a triangular area on the dorsal aspect of the bladder called the trigone.
- The three ligaments of the bladder are composed of double layers of peritoneum. The ventral ligament extends from the ventral surface of the bladder along the ventral midline of the abdominal wall to the umbilicus. The ventral peritoneal ligament contains the urachus in the fetus. The urachus is an embryologic structure that connects the urinary bladder and the allantoic sac. The urachus closes and atrophies soon after birth, leaving a small scar at the apex of the urinary bladder. The lateral ligaments connect the lateral aspects of the bladder to the pelvic canal and enclose the ureters, deferent ducts, and umbilical arteries.
- The major blood supply to the bladder comes from the caudal vesical artery, a branch of the internal pudendal artery that lies in the pelvic fascia. The cranial vesical artery, present in only 50% of adult dogs, supplies the cranial aspect of the bladder. Venous blood drains into the internal pudendal veins. Bladder lymphatics drain into the hypogastric, sublumbar, and median iliac lymph nodes.
- Sympathetic innervation to the bladder is via the hypogastric nerve, and parasympathetic innervation is via the pelvic nerves. The hypogastric and pelvic nerves reach the bladder through the lateral ligaments near the caudal vesical arteries.

ANOMALIES OF THE URACHUS

Preoperative Considerations

- Persistent urachus results when the entire urachal canal remains patent after birth. Urine is voided through the urachal opening at the umbilicus. Treatment consists of surgical excision of the entire urachal tube.
- Vesicourachal diverticulum results when the origin of the urachus at the bladder apex fails to close. The diverticulum forms a pocket of urine, predisposing the animal to recurrent bacterial urinary tract infections (UTIs).
- Vesicourachal diverticula may be diagnosed by contrast radiography or uroendoscopy. Diverticulectomy is indicated in animals with persistent UTI. Urachal scars commonly are observed at the dome of the bladder and seldom cause a problem. In contrast to a urachal scar, a diverticulum is a discrete pouch or sac that opens into the bladder lumen.
- Urachal cysts and urachal sinuses are uncommon urachal anomalies in small animals.

Surgical Procedure—Persistent Urachus

Objectives

- Remove the patent urachus.
- Obtain specimens for bacterial culture and histopathologic analysis.

Equipment

- Standard general surgery instrument pack and suture
- Balfour retractor
- Laparotomy sponges

Technique

1. Place the animal in dorsal recumbency.
2. Prepare the ventral abdominal region for aseptic surgery.

3. Perform a routine ventral midline celiotomy from approximately 3-cm cranial to 3-cm caudal to the umbilicus.
4. Make an elliptical incision around the umbilical opening. Dissect the urachus from the surrounding tissues.
5. Place a Balfour retractor and isolate the urinary bladder with moistened laparotomy sponges.
6. Place stay sutures in the bladder to facilitate retraction.
7. Create a full-thickness elliptical incision in the apex of the bladder around the origin of the patent urachus.
8. Submit the patent urachus for histologic analysis.

▼ ***Key Point*** Resect the entire urachus. Simply ligating the urachus at the bladder apex may result in a vesicourachal diverticulum, which can predispose the animal to persistent UTI.

9. Submit samples of the excised vesicourachal junction for bacterial culture and susceptibility testing.
10. Remove the stay sutures and laparotomy sponges. Close the bladder as described under "Cystotomy," "Technique."
11. Close the abdominal wall routinely.

Postoperative Care and Complications

- Postoperative complications are rare.
- Administer antibiotics based on the results of bacterial culture and susceptibility testing. Prolonged (>4 weeks) antibiotic therapy may be necessary to reduce the risk of recurrent UTI.
- See "Cystotomy," "Postoperative Care and Complications," for routine patient care.

Surgical Procedure—Vesicourachal Diverticulum Excision

Objectives

- Remove the vesicourachal diverticulum.
- Obtain samples for bacterial culture and susceptibility testing and histopathologic analysis.

Equipment

- Standard general surgery instrument pack and suture
- Balfour retractor
- Laparotomy sponges

Technique

1. Patient positioning and surgical approach are the same as those described under Persistent Urachus.
2. Do not make an elliptical incision around the umbilicus; instead, use the approach recommended for cystotomy.
3. Isolate the urinary bladder with moistened laparotomy sponges.
4. Place stay sutures to facilitate retraction.
5. Make a full-thickness elliptical incision in the bladder wall around and approximately 5 mm from the edge of the diverticulum.
6. Submit samples for histologic analysis and bacterial culture and susceptibility testing.
7. Remove stay sutures.
8. Close the bladder as described under "Cystotomy," "Technique."
9. Remove the laparotomy sponges, and close the abdominal incision routinely.

Postoperative Care and Complications

- Postoperative complications are rare. Recurrent infections after removal of the diverticulum are uncommon.
- Administer antibiotics based on the results of bacterial culture and susceptibility testing. Prolonged antibiotic therapy (>4 weeks) may be necessary. Reevaluate bacterial culture of the urine 1 week following the completion of antibiotic therapy.
- See "Cystotomy," "Postoperative Care and Complications," for routine patient care.

CYSTOTOMY

Preoperative Considerations

- Cystotomy in small animals is indicated most commonly for removal of cystic calculi.
- Neoplasia of the urinary bladder, polypoid cystitis, surgery involving the ureteral orifice(s) including neoureterostomy, and ureteral transposition require cystotomy.
- Antibiotics are not administered preoperatively unless prior urine culture indicates UTI. Otherwise, administer antibiotics intraoperatively after specimens for culture and susceptibility testing have been obtained.

Surgical Procedure

Objectives

- Open the urinary bladder to remove calculi, reimplant ureters, or explore the bladder lumen.
- Obtain samples for bacterial culture and susceptibility testing and histopathologic analysis.
- Prevent urine leakage into the peritoneal cavity.

Equipment

- Standard general surgery pack and suture
- Balfour retractor
- Laparotomy sponges
- Urinary catheter (male dogs)
- Human gallbladder scoop or sterile teaspoon to aid in stone removal
- 12-ml syringe

- 22-gauge needle
- Soft urethral catheter for patients with cystic calculi

Technique

1. Place the animal in dorsal recumbency.
2. Prepare the ventral abdominal region and vulvar or preputial area for aseptic surgery. Irrigate the prepuce with antiseptic solution and include it in the aseptic field to enable intraoperative urethral catheterization, if necessary.
3. Incise the skin and subcutaneous tissue on the ventral abdominal midline.
4. In male dogs, incise the skin and subcutaneous tissue parallel and adjacent to the prepuce. Identify and ligate the preputial branches of the caudal superficial epigastric vessels in the subcutis.
5. Incise the linea alba from the umbilicus to the pubis. (Incise from xyphoid to pubis if a full abdominal exploratory is necessary.) The paramedian approach can be used in male dogs.
6. Position the Balfour retractor. Explore the abdomen for associated abnormalities of the kidneys, ureters, prostate, urethra, and iliac lymph nodes.
7. Isolate the urinary bladder with moistened laparotomy sponges.
8. Place stay sutures at each end of the proposed cystotomy incision to facilitate retraction and atraumatic manipulation (Fig. 80-1*A*).
9. Remove urine from the bladder by cystocentesis.
10. Orient the cystotomy incision to avoid major vessels and provide optimal exposure for the procedure. A ventral incision is preferred for routine cystotomy and for exposure of the ureteral openings.

▼ ***Key Point*** A ventral cystotomy incision has no greater risk of leakage or adhesion formation than does a dorsal incision. In addition, the ureters are located well away from the ventral region, reducing inadvertent damage.

11. Plan the cystotomy incision to remove a vesicourachal diverticulum, if present.
12. Make a stab incision into the bladder with a scalpel (Fig. 80-1*B*).
13. Extend the incision proximally and distally with Metzenbaum scissors, avoiding the trigone and ureters.
14. Remove uroliths with the gallbladder scoop or sterile teaspoon.

▼ ***Key Point*** Always submit uroliths to the laboratory for stone analysis.

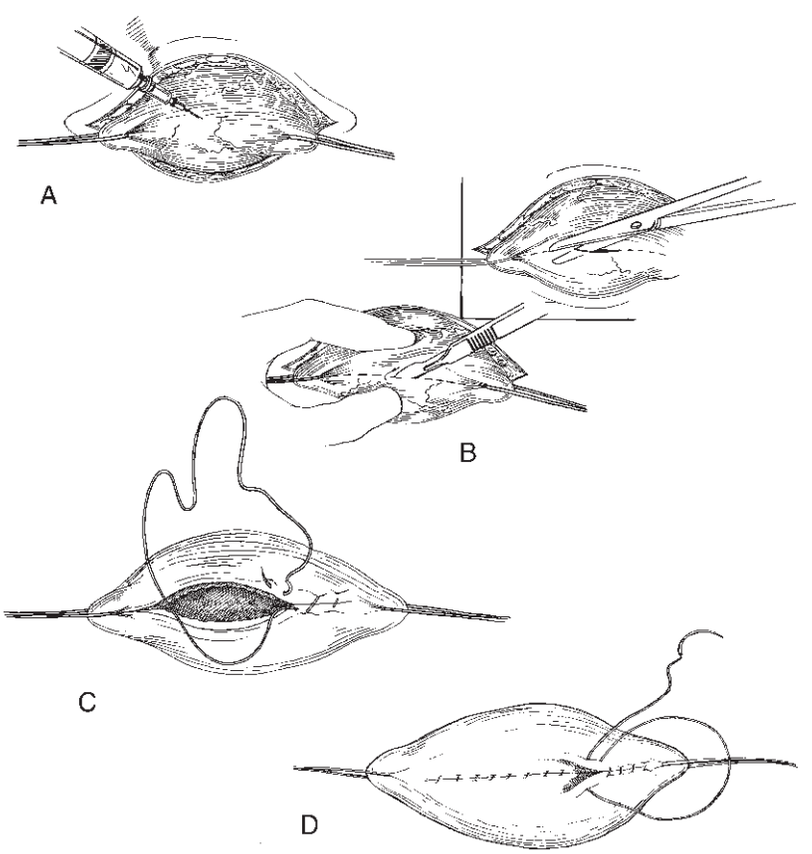

Figure 80-1. Cystotomy. *A,* With stay sutures in place, remove urine from bladder. *B,* Make stab incision with scalpel and extend with Metzenbaum scissors. *C,* After uroliths are removed and biopsy samples taken, place a Cushing pattern incorporating all tissue layers except the mucosa. *D,* Oversew the Cushing pattern with a Lembert pattern. If the bladder wall is inflamed or thickened, an appositional pattern may be used for closure.

15. Retrograde flushing may be required to remove small calculi from the proximal urethra in male dogs. Pass a sterile urinary catheter retrograde (from outside the penis) to the level of the os penis, occlude the end of the penis, and flush vigorously with sterile saline.
16. Pass a urinary catheter, both retrograde and antegrade, throughout the entire length of the urethra and feel for grit or roughness.
17. Do not close the bladder until all stones have been removed.
18. Incise a 4-mm × 1-cm full-thickness wedge of bladder wall from the edge of the cystotomy incision.
19. Submit half the wedge for histopathologic analysis and half for bacterial culture and susceptibility testing.

▼ ***Key Point*** If the animal has been on antibiotics, submit a full-thickness wedge of bladder wall for bacterial culture and susceptibility testing even if urine has been submitted for culture.

20. Remove stay sutures, and close the cystotomy (see subsequent description).

▼ ***Key Point*** Avoid incorporating the ureters in the bladder closure, especially with dorsal incisions.

21. Remove laparotomy sponges, and close the abdominal wall routinely.

Classically, cystotomy incisions are closed with a two-layer continuous inverting pattern. Synthetic absorbable suture material (3-0 to 4-0) with a swaged-on urogenital tapered needle is an ideal choice. A Cushing pattern, incorporating all tissue layers except the mucosa, is used for the first layer, followed by a Lembert pattern (Fig. 80-1 *C* and *D*).

The bladder wall may be quite thick in animals with chronic cystitis, making inversion of the wall difficult. In this situation, choose single-layer or double-layer continuous or interrupted appositional suture patterns. An appositional pattern is necessary when the cystotomy incision extends so far distally that inversion might result in occlusion of the ureters or narrowing of the urethra.

▼ ***Key Point*** The holding layer of the bladder is the submucosa.

Postoperative Care and Complications

- Hematuria for 12 to 36 hours after surgery is common.
- A transurethral catheter can be placed during surgery if necessary to maintain decompression of the bladder or to monitor urinary output. Connect to a closed collection system.
- Administer long-term (>4 weeks) antibiotic therapy based on results of bacterial culture and susceptibility testing. Based on the results of stone analysis dietary therapy may be indicated to medically manage animals with urolithiasis (see Chapter 79).
- Although rare, urine leakage from inadequate bladder closure may occur, particularly if obstruction develops distally. Monitor urine output.
- Observe for stranguria, which may occur secondary to inflammation.
- If multiple radiopaque stones were present, obtain abdominal radiographs after surgery to confirm complete stone removal.

BLADDER TRAUMA

Preoperative Considerations

- See Chapter 79, Diseases of the Urinary Bladder, for a discussion of etiology, pathophysiology, clinical signs, laboratory abnormalities, and diagnosis of ruptured bladder.
- Contusions, partial-thickness lacerations, and iatrogenic ruptures during catheterization usually heal spontaneously and are managed medically. Consider urinary diversion (transurethral catheterization or tube cystostomy) until healing is complete.
- Rupture of the urinary bladder may heal spontaneously; however, this outcome is inconsistent and unpredictable. Surgical repair is the treatment of choice.

▼ ***Key Point*** Fluid, electrolyte, and acid-base disorders (dehydration, hyperkalemia, acidosis, azotemia) must be managed prior to anesthetizing an animal for repair of a ruptured bladder.

- Animals with a ruptured bladder that cannot be anesthetized because of fluid, electrolyte, and acid-base abnormalities may be treated initially by temporary urinary diversion. Place a peritoneal dialysis catheter to drain urine from the peritoneal cavity (see Chapter 3). In addition, place a transurethral catheter to decrease the amount of urine leaking from the bladder into the abdominal cavity.
- Administer intravenous fluid therapy with isotonic saline and antibiotics. Also give sodium bicarbonate if necessary for acidosis.

Surgical Procedure

Objective

- Remove urine from the peritoneal cavity.
- Repair the ruptured bladder.
- Identify and treat other intra-abdominal injuries.

Equipment

- Standard general surgery instrument pack and suture
- Balfour retractor
- Laparotomy pads
- Suction device
- Foley catheter (if tube cystostomy is indicated).

Technique

1. Place the animal in dorsal recumbency.
2. Prepare the ventral abdominal region for aseptic surgery.
3. Perform a routine ventral midline celiotomy from the umbilicus to the pubis.
4. Perform an abdominal exploratory.
5. Isolate the urinary bladder with moistened laparotomy sponges.
6. Locate the rupture in the urinary bladder.
7. Place stay sutures to facilitate exposure of the rupture.
8. Liberally debride non-viable tissue from the edges of the rent.
9. Approximate the viable edges of the rent with 3-0 synthetic absorbable suture material using an inverting or approximating suture pattern.
10. Remove the stay sutures.
11. When the viability of the bladder wall is questionable, resect the non-viable region if possible. Alternatively, cover the area with omentum or a jejunal serosal patch.
12. Manage other intra-abdominal injuries.
13. Lavage the peritoneal cavity with copious amounts of warm, sterile, physiologic saline solution.
14. Remove residual abdominal fluid.
15. Submit samples of peritoneal fluid for bacteriologic culture and susceptibility testing.
16. Consider placing a sterile transurethral catheter to keep the bladder decompressed if the repair is tenuous or the viability of the bladder wall is questionable. Urinary diversion seldom is necessary following proper repair of ruptured bladder.
17. Close the abdominal wall routinely.

Postoperative Care and Complications

- Administer broad-spectrum antibiotics in animals with extensive tissue trauma until culture and susceptibility results can be used to direct antibiotic therapy.
- The animal may be hematuric and pollakiuric for 12 to 48 hours after surgery.
- Continue to monitor and manage fluid, electrolyte, and acid-base imbalances after surgery. Monitor urine output.
- If a transurethral catheter is in place to decompress the bladder when the repair is tenuous, remove it 2 to 3 days after surgery.
- See "Cystotomy, Postoperative Care and Complications," for routine patient care.

SUBTOTAL CYSTECTOMY

Preoperative Considerations

- Subtotal cystectomy is performed most commonly in an attempt to cure or palliate an animal with bladder neoplasia. Subtotal cystectomy may be indicated to remove benign lesions, such as traumatic or congenital diverticula (see under "Anomalies of the Urachus"), polyps, intramural granulomas, and devascularized areas of bladder wall.
- Therapeutic results are related to the size and location of the bladder neoplasm and the presence or absence of metastasis. Animals with bladder neoplasia must undergo thorough diagnostic testing, including thoracic and abdominal radiography, contrast radiographic studies, and cytologic evaluation prior to surgical intervention.
- Neoplasms located in accessible areas of the bladder (apex and body) can be removed by partial cystectomy. Subtotal cystectomy may require reimplantation of the ureter(s) when there is extensive involvement of the neck or trigone of the bladder. In this situation, the type of lesion and overall prognosis must be considered prior to performing a procedure with such a high rate of morbidity.

▼ ***Key Point*** A substantial portion of the non-trigone bladder, perhaps greater than 75%, can be excised with few untoward effects.

Surgical Procedure

Objective

- Remove abnormal section of bladder wall.
- Biopsy a bladder mass.
- Maintain reservoir function of bladder.

Equipment

- Standard general surgery instrument pack and suture
- Balfour retractor
- Sterile urinary catheter

Technique

1. Patient positioning, surgical approach, and isolation of the bladder are as described previously under "Cystotomy," "Technique."
2. If neoplasia is suspected, explore the entire abdomen for metastasis. Biopsy regional lymph nodes.
3. Locate the area to be removed by gentle palpation.
4. Isolate the bladder with moistened laparotomy sponges. Seeding of tumor cells from transition cell carcinoma into the abdominal cavity or surgical incision has been reported.
5. Excise the abnormal bladder wall, including at least 1 cm of normal-appearing tissue on all sides.

6. Ureteral transplantation may be necessary. Refer to Chapter 78.
7. If neoplasia is suspected, change gloves and obtain clean instruments prior to closure of the bladder to prevent tumor seeding.
8. Close the bladder with 3-0 or 4-0 synthetic absorbable suture material in an appositional or inverting pattern (see "Cystotomy," "Technique").
9. Remove the moistened laparotomy sponges.
10. Close the abdomen routinely.

Postoperative Care and Complications

- Adjunct radiotherapy or chemotherapy may be beneficial following subtotal cystectomy for bladder neoplasia.
- Hematuria and pollakiuria are commonly observed after subtotal cystectomy.
- Frequent voiding may persist due to loss of reservoir volume.
- The reservoir function of the bladder returns, at least partially, by 3 months.
- See "Cystotomy," "Postoperative Care and Complications," for routine patient care.

TUBE CYSTOSTOMY

Preoperative Considerations

- Tube cystostomy is indicated for temporary diversion of urine from the urethra.
- Dogs with metabolic alterations resulting from obstruction to urine outflow frequently are unable to tolerate general anesthesia.
- When transureteral catheterization is not possible or desired, diversion of urine via tube cystostomy permits delay of definitive repair of urethral trauma or removal of urethral calculi until metabolic alterations are corrected.
- Tube cystostomy is a practical means of temporary urine diversion when the bladder has lost contractile function.
- A permanent cystostomy catheter can be placed to relieve urine outflow obstruction in a dog with inoperable bladder neoplasia. Relatively long-term (months) palliation can be achieved with minimal complications.
- General anesthesia usually is not needed for tube cystostomy. Narcotic analgesics, such as oxymorphone, combined with local infiltration of lidocaine or bupivacaine, are adequate.

Surgical Procedure

Objective

- Divert the flow of urine from the urethra via a Foley or de Pezzer catheter placed into the bladder.

Equipment

- Standard general surgery instrument pack and suture
- Foley catheter with intact balloon or de Pezzer catheter (recommended for long-term use)
- Small Gelpi or Weitlaner retractor

Technique

1. Administer oxymorphone, 0.1 to 0.3 mg/kg intravenously, another appropriate analgesic, or inhalant anesthesia by mask (see Chapter 2).
2. Position the animal in dorsal recumbency.
3. Prepare the ventral abdominal region for aseptic surgery.
4. Infiltrate the abdominal wall with lidocaine or bupivacaine in the area of the planned paramedian incision—in the caudal ventral abdomen approximately 3 cm lateral to the midline.
5. Make a 4-cm incision in the caudal ventral abdomen on midline. Avoid incising the distended urinary bladder. Place the self-retaining retractor.
6. Pass the Foley or de Pezzer catheter through the abdominal wall via a paramedian stab incision made adjacent to the celiotomy incision.
7. Place a pursestring suture in the wall of the bladder on the ventral side near the apex. Use 3-0 synthetic absorbable suture material with a swaged-on taper needle.
8. Pass the Foley or de Pezzer catheter into the bladder through a stab incision in the center of the pursestring suture.
9. Tighten and tie the pursestring suture. Do not occlude the catheter.
10. Inflate the balloon of the Foley catheter with sterile saline.
11. Preplace four sutures of 2-0 or 3-0 synthetic absorbable material between the bladder and the abdominal wall, where the catheter exits.
12. Secure the bladder to the body wall by tying the preplaced sutures (Fig. 80-2).
13. Close the abdominal incision routinely.
14. Secure the Foley catheter to the skin using the Chinese finger trap knot (see Chapter 3).

Postoperative Care and Complications

- The catheter can be attached to a closed sterile urine collection system (preferred) or capped and drained intermittently.
- Place an Elizabethan collar on the animal to prevent mutilation of the system.
- Deflate the balloon and withdraw the catheter when it is no longer needed. If the catheter has been in place for approximately 7 days, the stoma will heal spontaneously. Earlier removal may require surgical closure of the bladder and abdominal wall.
- A low-profile gastrostomy tube can be placed at the time of surgery, or a Foley or de Pezzer tube can be

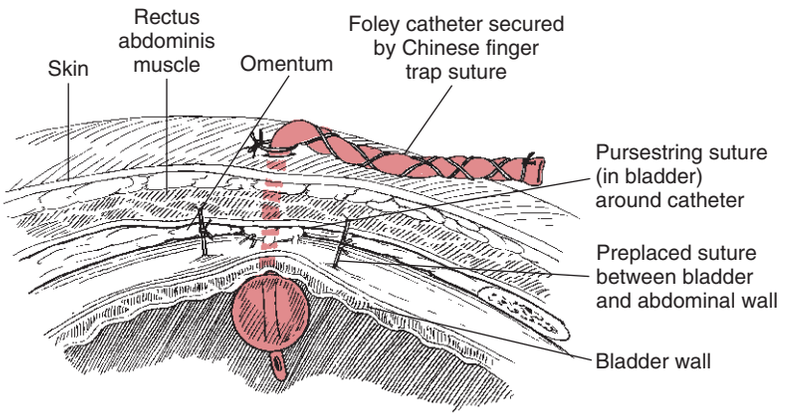

Figure 80-2. Suture and tube placement for tube cystotomy.

replaced with a low-profile tube after stoma formation. A low-profile tube can provide easier management and better cosmesis for longer-term use.

- Rarely, adhesions between the bladder and peritoneum from tube cystostomy can inhibit complete bladder emptying. Placement of the catheter in the body of the bladder rather than the apex helps prevent this problem.

Chapter

81 Diseases of the Urethra

Hilary K. Matthews

CONGENITAL URETHRAL DISORDERS

Congenital diseases of the urethra are uncommon in both dogs and cats. The infrequency and small numbers have limited descriptions of congenital urethral diseases primarily to case reports. Puppies and kittens are often euthanized because of clinical symptoms associated with complete or partial urinary outflow obstruction or urinary or fecal incontinence before a definitive diagnosis is obtained. Many of these conditions have a poorly understood etiopathogenesis. Male puppies seem to be over represented in this class of disorders.

Etiology

- *Rectal urethral fistula* is due to incomplete division of the embryonic cloaca into the cranial ureterovesicular segment and the caudal rectal segment by the urorectal fold. This condition is thought to be heritable in the bulldog, but is thus far unproven.
- *Urethral hypoplasia* is often associated with uterine hypoplasia and vaginal aplasia with the uterine horns terminating in the dorsum of the urinary bladder. This is also called *congenital urethral sphincter mechanism incompetence*. Urinary incontinence occurs in almost all cases of this anomaly.
- *Urethral hypospadias* is often associated with pseudohermaphroditism, true hermaphroditism, in utero exposure to androgen inhibitors or estrogens, and inadequate production of androgens by the fetal testes. The result is incomplete fusion of the urethral groove resulting in the urethral opening occurring on the ventral aspect of the penis and prepuce. This defect occurs in combination with penile hypospadias and a bifid scrotum.
- *Epispadias* occurs in males and females and results in a dorsally displaced urethra.
- Other congenital urethral anomalies include urethral duplication, urethral agenesis, dilation/diverticulum of the pelvic urethra, urethral stricture and stenosis, urethral ectopia, accessory meatus, anterior or posterior urethra valves, and penile anomalies that secondarily affect the urethra such as apenia, megalopenis, and micropenis.

Clinical Signs

- In animals with a rectal urethral fistula, urine exits from the rectum, which may result in loose fecal material or diarrhea.
- Some urethral anomalies such as stricture and hypoplasia/aplasia result in signs of lower urinary tract outflow obstruction and potentially uremia.
- Other possible signs include urinary incontinence, urine scalding of the perineal region with resultant pyoderma, and persistent or recurrent urinary tract infections.

Diagnosis

- Many of the congenital urethral abnormalities are visible on physical examination or vaginal examination.
- Retrograde urethrogram or a vaginourethrogram can further locate and define the nature and extent of the abnormality. Voiding cystourethrography can also be a useful diagnostic modality (see Chapter 4).
- Vaginoscopy and urethroscopy may be useful as further defining tools. However, small patient size, and availability of an endoscope with a small diameter to provide visualization of the urethra, is sometimes a limiting factor.

Treatment

▼ ***Key Point*** Treatment of congenital urethral anomalies by surgical correction should only be attempted if the anomaly is causing clinical signs or husbandry problems.

- Correct urinary obstruction to stabilize the animal prior to additional diagnostics and treatment.
- Surgical correction of rectal urethral fistulas, hypospadias, strictures, urethral duplication, urethral dilation or diverticulum, and urethral hypoplasia can be attempted. Outcome of surgical intervention for these disorders is complicated and can be unrewarding or associated with a variety of complications, especially if not performed by a surgeon with advanced training.

- Medical treatment for incontinence may be necessary, especially in cases of urethral dilation or diverticulum formation, and urethral hypoplasia (see Chapter 83).

URETHRAL OBSTRUCTION

Etiology

- Complete or partial obstruction of the urethra is commonly encountered in veterinary practice. Almost any type of disease that affects the urethra can result in some degree of urethral obstruction. There are two classes of urethral obstruction: structural and functional.
  - *Structural urethral obstruction* is caused by anything that physically blocks the urethral lumen or compresses the urethral lumen from outside the urethra. Common examples include urethral calculi, neoplasia, mucous plugs, blood clots, and compression from external trauma to the pelvis area or lymphadenopathy. Strictures are also classified as a structural urethral obstruction. Inflammatory processes such as urethritis may result in swelling of the mucosa of the urethra that results in obstruction.
  - *Functional urethral obstruction* can be secondary to neurologic suprasacral spinal lesions, termed *reflex dyssynergia,* or may be idiopathic.

Clinical Signs

- Clinical signs are attributable to partial or complete urethral obstruction.
- With partial obstruction stranguria, pollakiuria, dysuria, hematuria, inappropriate urinations, and urine dribbling may occur.
- Complete urethral obstruction results in signs of uremia within a few days of the obstruction. The owners may note that the animal makes frequent attempts to urinate, but produces no urine.
- Functional urethral obstruction typically results in normal initiation of voiding, followed by a decrease in urine flow with the typical signs of partial urinary obstruction.

Diagnosis

Physical Examination

- On physical examination the urinary bladder may be by distended, turgid, and painful on palpation.
- It may or may not be possible to manually express the urinary bladder to determine urethral patency. Perform this procedure carefully to avoid urinary bladder rupture.
- Palpation of the urethra per rectum may reveal urethral thickening, calculi, or a mass.
- Exteriorize the penis to evaluate occlusion at the tip of the penis. Masses, calculi, and urethral plugs can be present in this location, causing obstruction, and are often overlooked on the initial examination.

▼ ***Key Point*** Carefully palpate the urethra at the base of the os penis in all male dogs as this is the most common site of urethral obstruction due to urolithiasis.

Complete Blood Count and Serum Chemistry Profile

- Blood should be submitted for a complete blood count and serum biochemical profile testing. Animals with complete urinary obstruction may have life-threatening metabolic abnormalities such as hyperkalemia, metabolic acidosis, and azotemia that require immediate attention.
- If complete obstruction has existed for approximately 2 to 3 days, signs of uremia may be present and reflected on the serum biochemical profile.

Electrocardiogram

- If the patient is bradycardic, monitor the electrocardiogram (ECG) to identify cardiac arrhythmias.

Urinalysis

- Submit a urine specimen obtained by cystocentesis for urinalysis and aerobic bacteriolgic culture.

Radiography

- Obtain abdominal radiographs including the perineal and preputial region to locate radiodense calculi in the urinary bladder or urethra.
- Consider contrast urethrography and/or urethroscopy after the patient is stable to further define the location and extent of the obstruction if necessary (see Chapter 4).

Treatment

▼ ***Key Point*** Regardless of the cause of urinary obstruction, the first step in patient treatment is stabilization.

Patient Stabilization Measures for Urinary Obstruction

- Place an indwelling intravenous catheter. Patient stabilization and treatment of metabolic abnormalities take precedence over decompression of the urinary bladder.
- Begin rehydrating the patient with a potassium-free fluid such as 0.9% NaCl until the serum potassium status is known. Animals that have complete urinary obstruction frequently have severe dehydration and

may experience hypovolemic shock. Adjust the fluid therapy to meet the patient needs.

- If bradyarrthymias and sinoatrial standstill secondary to hyperkalemia are present, use the following measures to drive the potassium back into the cells thereby lowering serum potassium:
  - Administer 0.9% NaCl. This will often normalize the serum potassium following relief of the obstruction if the serum potassium is 7 mEq/L or less.
  - Sodium bicarbonate given intravenously (IV) over 5 to 10 minutes at a dose of 0.5 to 1 mEq/kg. If necessary, then infuse an additional 1 to 2 mEq/kg slow IV over 30 to 60 minutes. This will rapidly decrease serum potassium and maintain it for several hours.
  - Consider 20% dextrose at 1 to 2 ml/kg IV over 30 to 60 minutes. This can be followed with regular insulin at 0.2 to 0.4 U/kg IV and 50% dextrose at 4 ml/unit of insulin slow IV. Dilute the 50% dextrose to a 2.5% to 5% solution.
  - Consider 10% calcium gluconate at 0.2 to 0.5 ml/kg IV over 15 minutes while monitoring an ECG to provide cardioprotective effects from the hyperkalemia. This treatment alone does not lower serum potassium; one of the above-listed treatments is additionally required.
  - Recheck serum electrolytes every 2 to 4 hours as needed.
- Provide aggressive thermal support as necessary.

Relief of the Urethral Obstruction

- After appropriate medical stabilization, place a urinary catheter to decompress the bladder and relieve the obstruction. If sedation or anesthesia is necessary for this procedure, care should be taken in drug selection as these patients are commonly volume depleted and have cardiovascular compromise.
- *Urethral hydropropulsion* is generally required to push urethral calculi back into the urinary bladder (see discussion later in this chapter). Rigid polypropylene catheters are most useful in the initial decompression of the urinary bladder, but should be replaced by softer and less reactive catheter material for indwelling use. Red rubber, Silastic, and silicone materials are superior for indwelling use. Place an Elizabethan collar on the animal after the indwelling urethral catheter has been placed and secured.
- Cats with urinary blockage due to urethral plugs or calculi do not commonly have associated urinary tract infection. Therefore, empirical use of antimicrobials in cats with urethral plugs is not warranted. Administer antimicrobial treatment if the urine culture is positive for bacteria. If urine was not obtained for culture at the time the cat was unobstructed, obtain samples for culture at the time the urinary catheter is removed. Use empirical or prophylactic antimicrobials only in cases of urinary obstruction that have clinical signs of urosepsis which are supported by findings on the urinalysis.
- Maintain a closed urinary system and measure urine output every 4 to 6 hours. Handle all connections to the urinary catheter and closed collection system in a sterile manner to prevent nosocomial infection. Measuring urine output is important since post-obstruction diuresis is common. Quantifying urine output will help determine intravenous fluid therapy dosages and alert the clinician if oliguria or anuria is a problem (see Chapter 5).
- To guard against reobstruction, maintain the indwelling urinary catheter until the animal is taken to surgery for surgical removal of the retropulsed calculi. In cases of feline urinary obstruction where a urethral plug is removed, maintain the catheter for 24 to 48 hours. Administer medications to relieve urethral spasm (acepromazine 0.05–0.1 mg/kg IM, IV, or SC q6–8h) and pain (butorphenol 0.2 mg/kg IM, IV, or SC q6–8h). If the cat can produce a good urine stream post obstruction, had not been obstructed for a prolonged period, and had minimal particulate matter flushed out of the urethra and/or bladder, an indwelling urinary catheter is not necessary.
- If post-obstructive diuresis occurs, potassium supplementation to the intravenous fluids and high fluid rates may be necessary to match the urine output.
- Recheck the serum biochemical profile and electrolytes in approximately 24 hours to ensure normalization of the values.
- Carefully monitor the urine stream diameter in cats with urethral plugs with attention to ease and frequency of urination for at least 12 hours prior to discharge from the hospital.

Technique for Urethral Hydropropulsion

- Sterile 0.9% NaCl mixed in a 25% to 50% combination with sterile water-soluble lubricant (e.g., K-Y jelly) can be used as the hydropropulsion fluid. Use a volume of 12 to 20 ml depending on patient size.
- Introduce the catheter in a sterile manner as far as possible into the urethra. When resistance is felt, gently dispense the fluid mixture into the urethra to flush the calculi or urethral plug into the bladder. If the calculi or plug is flushed out of the urethral orifice, submit it for analysis to aid in future medical management of the animal.
- In male cats urethral plugs are frequently lodged at the tip of the penis. Gently massage the tip of the penis to dislodge the plug and to make it easier to flush out.
- In male dogs urethral calculi are frequency lodged at the base of the os penis. When this occurs, hydropropulsion with fluid alone may not be enough to dislodge the calculus. Dilation of the urethra coupled with hydropropulsion is necessary.
  - Advance the catheter to the site of the blockage.

- With a gloved and lubricated finger, compress the pelvic urethra. At the same time occlude the tip of the penis and flush in the fluid under pressure. This is most easily done with one person compressing the urethra while the other person occludes the urethral opening and flushes in the fluid.
- Once dilation of the urethra is appreciated, stop the compression on the urethra and advance the catheter while continuing to flush in fluid.
- Several attempts are often necessary to move the calculi back into the urinary bladder.
- If it is not possible to relieve the urinary obstruction by passing a urinary catheter, perform intermittent therapeutic cystocentesis or placement of a temporary cystostomy tube until the patient is taken to surgery to relieve the obstruction.

URETHRITIS

Proliferative (Granulomatous) Urethritis

Etiology

- This condition is most common in middle-aged to older female dogs.
- Proliferative urethritis is an infiltrative inflammatory disease that is thought to be secondary to chronic bacterial urinary tract infection and/or an immune-mediated condition.
- This has previously been called *granulomatous urethritis,* but because a true granulomatous reaction is usually not identified on histopathology, *proliferative urethritis* is the preferred term.

Clinical Signs

- Clinical signs are associated with partial or total obstruction of the urethra and include pollakiuria, dysuria, hematuria, stranguria, and urinary incontinence.
- Symptoms attributable to uremia such as depression, anorexia, vomiting, and lethargy may occur if complete urinary obstruction occurs.

Diagnosis

- Palpation of the urethra per rectum may reveal a thickened and painful urethra.
- Obtain radiographs and/or abdominal ultrasound to evaluate the bladder and identify possible cystic calculi that may be a contributing factor to this disease.
- Submit a urine sample obtained by cystocentesis for bacteriologic culture and sensitivity testing.

Endoscopy and Biopsy

- Diagnosis is best accomplished via endoscopy and biopsy of the vaginal vault and urethra. Endoscopically the lesions appear as nodular masses with finger-like projections or cylindrical masses in the urethra and the vestibule.

▼ ***Key Point*** Histopathologic diagnosis of proliferative urethritis is critical to differentiate it from neoplasia.

- Traumatic urethral catheterization or blind urethral biopsy with the endoscopy biopsy forceps can be performed to obtain a tissue sample if an appropriate size endoscope is not available.
- Histopathology of biopsy specimens reveals primarily lymphoplasmacytic and neutrophilic inflammation.

Treatment

- If the process is so severe that urinary obstruction occurs, treat for the obstructive process first (see previous section in this chapter). Consider placing a urethral catheter or temporary urinary diversion procedure such as a tube cystostomy (see Chapter 80) to provide continuous urine drainage while treating the underlying condition.
- If infection is identified based on culture and sensitivity testing of the urine, treat with the appropriate antimicrobial(s) for 3 to 4 weeks. Reculture the urine via cystocentesis once the patient has been off all antimicrobials for 3 to 5 days to ensure that the infection is resolved.
- Identify and treat any predisposing causes to recurrent or relapsing urinary tract infections that may be correctable such as hypoplastic and/or recessed vulva with an excessive perivulvar skin fold (see Chapter 92).
- Treat cystic calculi, if present (see Chapter 79).
- Treat the inflammatory aspect of the proliferative urethritis with prednisone (0.5–2 mg/kg per day as a tapering dose over several weeks) and additional immunosuppresants (azathioprine 2 mg/kg PO daily for 10–14 days, then decrease to every other day) as needed.
- Despite clinical improvement, the endoscopic appearance of the urethra may continue to be abnormal.

Bacterial Urethritis

Etiology

- Bacterial infection of the urethra is often concomitant with bacterial cystitis.

Clinical Signs

- Clinical signs of bacterial urethritis include dysuria, stranguria, pollakiuria, hematuria, urinary accidents, and potentially urethral obstruction.

Diagnosis

- Because bacterial urethritis is almost always associated with bacterial cystitis, it is safe to assume that a bacterium cultured from the urine in the bladder is the same for the urethra.

▼ ***Key Point*** The best diagnostic test for bacterial urethritis is urine obtained via cystocentesis and submitted for identification and antimicrobial susceptibility testing.

Treatment

- Administer a systemic antimicrobial agent (or agents) based on urine culture and sensitivity testing for a minimum of 3 to 4 weeks. Reculture the urine via cystocentesis after the patient has been off antimicrobials for 3 to 5 days to ensure that the infection is cleared.
- Urethral obstruction may occur if significant urethral inflammation with resultant swelling and spasm has occurred secondary to the infection. These cases are treated by placing an indwelling urinary catheter for approximately 3 to 7 days until the inflammation has subsided. A soft red rubber silicone or Silastic catheter is preferable to a polypropylene catheter as it will be less irritating for indwelling use.
- Consider an anti-inflammatory dose of prednisone for the first 3 to 5 days to help decrease urethral inflammation.
- If urethral spasm is severe it may be helpful to treat the patient with drugs that relax the smooth and skeletal muscle of the urethra. Acepromazine (0.05–0.1 mg/kg IV, IM, or SC q8h), diazepam (0.2 mg/kg IV q8h), or phenoxybenzamine (5–15 mg PO q8h in the dog and 2.5–7.5 mg PO q8h in the cat) are reasonable choices in such cases.

URETHRAL TRAUMA

Etiology

- Anything that causes external trauma to the pelvic, perineal, or prepucial region of an animal may result in urethral trauma. Common causes are being hit by car, bite wounds, or any type of blunt or penetrating trauma.
- Iatrogenic trauma can be induced by urethral catheterization or uroendoscopy.

Clinical Signs

- Depending on the degree and location of the urethral trauma, a variety of clinical signs may occur.
- Trauma resulting in swelling, inflammation, and bruising may produce signs of partial to complete lower urinary obstruction. Dysuria, stranguria, pollakiuria, hematuria, and urine dribbling may be seen.
- A complete tear in the proximal urethra may result in uroabdomen and resultant signs of uremia.
- Complete urethral tears that result in urine leaking into the surrounding tissues produce severe inflammation and bruising. The skin may become necrotic secondary to the urine leakage. The affected area may extend from the perineal region to the inguinal area and down the rear thighs.

Diagnosis

- Suspect trauma to the urethra in all cases of trauma to the pelvic region. It is often difficult to distinguish if the swelling and bruising in the perineal region following trauma to the perineal region is due to the insult alone, or if concurrent urethral rupture has occurred.
- Carefully monitor the patient, including urea nitrogen and creatinine concentrations, electrolytes, and urinations. Post-renal azotemia will become evident if a full-thickness urethral tear has occurred.
- Palpate the abdomen and attempt to ballot a fluid wave.
- If abdominal distension occurs, perform a diagnostic abdominocentesis (see Chapter 3) to determine if urine and/or blood is accumulating in the peritoneal cavity. If urine is leaking into the peritoneal cavity, analysis of the concentrations of creatinine and potassium in the abdominal fluid will be greater than those levels in the serum.
- The concentration of urea nitrogen is typically increased in both the serum and abdominal fluid in patients with urine leakage into the peritoneal cavity.

Radiology

- Obtain plain abdominal radiographs and ultrasound (see Chapter 4).
- Perform positive contrast urethrography to definitively diagnose a urethral tear. Leakage of the contrast material is seen into the adjacent tissues and/or into the abdomen. Narrowing or attenuation of the contrast material may be seen in urethral stenosis or stricture secondary to urethral trauma.

Treatment

- Treat severe urethral swelling resulting in partial to complete urethral obstruction and partial urethral

tears by aseptic placement of an indwelling urinary catheter (red rubber, Teflon-coated, silicone, or Silastic). Use a urinary catheter size that approximates the normal urethral size so that urethral stenosis does not occur. Connect the catheter to a closed urinary collection system. Maintain the indwelling catheter for 1 to 4 weeks depending on the severity of the lesion.

- If necessary, administer urethral antispasmodic (acepromazine 0.05–0.1 mg/kg PO, SC, IM, or IV q8h or diazepam 0.2 mg/kg IV q6–8h), anti-inflammatory (prednisone/prednisolone 0.5–2 mg/kg PO or SC or dexamethasone 0.25–1 mg/kg IV or SC daily), and analgesic (butorphenol 0.2 mg/kg IV, SQ, or IM q6–8h) medications.
- Do not administer prophylactic antimicrobials for the sole reason that an indwelling urinary catheter has been placed. This may result in a urinary tract infection with resistant bacteria. Use antimicrobials to treat confirmed urinary infection. Bacterial culture of urinary catheter tips can be unreliable.
- Submit a cystocentesis urine sample for culture and sensitivity testing 3 to 5 days after the catheter is removed. The normal host defense mechanisms can clear many bacteria that are present in the urine at the time the urinary catheter is removed. Waiting to culture the urine 3 to 5 days after catheter removal allows time for this to occur.
- If necessary, perform surgical repair of complete urethral tears once the patient is medically stable (see Chapter 82). If primary repair is not possible, perform urethrostomy. Studies have shown that the urethral tear will usually heal using an indwelling urinary catheter if a section of mucosa that bridges the defect is still present.

URETHRAL STRICTURE

Etiology

- Urethral stricture may be acquired or congenital.
- Acquired stricture may be secondary to trauma, chronic inflammation or infection, neoplasia, or urethral calculi.
- Orphan puppies and kittens may suck on the external genitalia of littermates resulting in stricture formation.
- Iatrogenic stricture may result from traumatic or repeated urethral catheterization.

Clinical Signs

- Signs of lower urinary tract dysfunction, such as dysuria, stranguria, hematuria, and urine dribbling, are common.
- The owner may observe that the animal takes a long time to urinate, makes repeated attempts, and cannot produce a good urine stream.
- Lack of urine production may be noted if the stricture is complete.

Diagnosis

- The urinary bladder may feel enlarged, turgid, or painful if there is partial to complete urinary obstruction.
- If the urethra is completely occluded by the stricture, signs of uremia may be present and can be confirmed on a serum biochemical profile.
- Palpation of the urethra per rectum may be helpful in distal strictures. Dilation cranial to the stricture may be palpated.
- Perform positive contrast urethrography (see Chapter 4) or urethroscopy to make a definitive diagnosis.

Treatment

- Catheterize the urethra, if possible, to provide urine drainage.
- Determine if there are any underlying causes for the stricture and treat that process.
- Surgical intervention such as perineal, prepubic, or scrotal urethrostomy is required in many cases (see Chapter 82).
- Balloon dilation of the strictured area can be attempted. This is most likely to be of benefit in idiopathic or congenital cases.

URETHRAL PROLAPSE

Etiology

- Urethral prolapse occurs when mucosa of the urethra everts through the external urethral orifice.
- The cause of this condition is often unknown, but sexual excitement may play a role.
- Cystitis or urethritis may be predisposing or concomitant conditions.
- Young male brachycephalic breeds are predisposed, including bulldogs, Boston terriers, and Shar-Peis. Bulldogs between the ages of 9 and 13 months are commonly affected, and a genetic or congenital factor is speculated in this breed.

Clinical Signs

- Clinical signs are attributable to partial obstruction of the lower urinary tract or bleeding from the end of the prepuce. Stranguria, dysuria, urinary incontinence, and hematuria are common. Some owners may find that the dog is licking incessantly at the penis and discover a mushroom-shaped mucosal lesion associated with the tip of the penis.

Diagnosis

- Exteriorization of the penis is required to make a diagnosis. The everted urethral mucosa can easily be seen and commonly appears as a round or doughnut-shaped dark red mass at the tip of the penis.
- Obtain urine by cystocentesis for culture and susceptibility testing to rule out a bacterial infection as a predisposing cause.

Treatment

▼ ***Key Point*** Surgery is the treatment of choice for urethral prolapse.

- This condition rarely spontaneously resolves.
- Conservative management with sedation and subsequent manual reduction of the prolapse can be tried. The prolapse generally recurs with this form of treatment unless the prolapse is very minimal.
- Surgical resection of the prolapse is the best method of treatment (see Chapter 82). However, recurrence can occur postoperatively.
- If sexual excitement seems to play a role, recommend castration.
- Adjunctive treatments include anti-inflammatory and antispasmodic medications, antibiotics if bacterial urethritis is present, limiting trauma to the area by use of an Elizabethan collar and sedation.

URETHRAL NEOPLASIA

Etiology

- Tumors affecting the urethra include squamous cell carcinoma, transitional cell carcinoma, leiomyoma, rhabdomyosarcoma, adenocarcinoma, hemangiosarcoma, and undifferentiated sarcoma.

▼ ***Key Point*** Transitional cell carcinoma and squamous cell carcinoma are the most common tumor types of the urethra.

- Tumors of the urethra are relatively uncommon in dogs and more rare in cats. The most common signalment is middle-aged to older female dogs. Beagles are reportedly at an increased risk.
- Prostatic adenocarcinoma and transitional cell carcinoma may extend from the gland into the urethra in male dogs.
- In the male dog the most common tumor location is the prostatic urethra.
- These tumors tend to be slow growing. They commonly spread to the local surrounding tissue and the regional lymph nodes, especially the sublumbar lymph nodes. Metastasis to the lung and bone are not uncommon. There is often concurrent urinary bladder involvement.

Clinical Signs

- Signs of urethral neoplasia are attributed to partial or complete obstruction of the urinary tract. Stranguria, hematuria, pollakiuria, dysuria, urinary incontinence, and potentially urethral obstruction are possible.
- If urethral obstruction is complete, signs of uremia may also occur.

Diagnosis

- Palpation of the urethra per rectum may reveal a thickened and painful urethra.
- The urinary bladder may be distended and/or turgid if there is partial to complete urinary obstruction.
- Obtain a urine sample for culture since there is often concurrent urinary tract infection.

Radiology

- Abdominal radiographs or ultrasound may reveal a distended urinary bladder with sublumbar lymphadenopathy.
- If the patient is experiencing lameness or back pain, radiographs of the painful region are indicated to evaluate for the presence of bony metastasis.
- Three-view thoracic radiographs are recommended to evaluate for metastatic disease to the lungs.
- Positive contrast urethrography or vaginogram may show the location and extent of the disease/mass (see Chapter 4). The urethral mucosa appears irregular and thickened. A radiolucent filling defect may be seen when a mass is present.

Biopsy

- Obtain a tissue sample by traumatic catheterization, blind biopsy, or endoscopy. If a diagnosis cannot be obtained from these modalities, consider surgical exploration and biopsy.

Treatment

▼ ***Key Point*** Palliative treatment is the most realistic option for urethral neoplasia.

- If the patient is fully obstructed by tumor mass and associated inflammation, it may not be possible to pass a urinary catheter to relieve the obstruction. In such cases perform periodic cystocentesis or place a cystostomy tube (see Chapter 80) to provide drainage of the urinary bladder.
- In patients with distal urethral disease, surgical excision with permanent urethrostomy may be possible (see Chapter 82).
- With proximal urethral disease, perform permanent tube cystostomy to provide urinary drainage if surgical intervention is not possible (see Chapter 80).

- Palliative chemotherapy may be useful based on the tumor type. Piroxicam (0.3 mg/kg) daily to every other day is frequently a helpful palliative measure for transitional cell carcinoma. Monitor renal function every 2 to 4 months while on this drug. To minimize gastroenteritis, administer piroxicam with food. Consider giving misoprostol (1–5 mcg/kg PO q8h) for patients showing signs of gastroenteritis.
- If metastasis to the bone has occurred, administer analgesics. Nonsteroidal anti-inflammatory medications are generally inadequate to control pain associated with metastatic bone pain. Consider prescribing narcotics (transdermal fentanyl) or tramadol (1–4 mg/kg PO up to q6h in the dog and ¼ of a 50-mg tablet PO q12h in the cat).
- Newer modalities such as laser ablation of the tumor to reestablish the patency of the tumor-obstructed urethra have been tried with mixed success.
- Because most tumors are diagnosed when the disease is advanced, the prognosis is very poor. About 20% to 30% have already metastasized at the time of diagnosis, and surgical cure is rarely possible.

Chapter

82 Surgery of the Urethra

Dale E. Bjorling / Támara M. Da Costa Gómez

Urethral disorders in dogs and cats frequently result in partial or complete obstruction. Emergency care may be required to restore the flow of urine and to treat metabolic imbalances. Calculi within the urethra are often accompanied by urinary tract infection (UTI) and cystic calculi. Aggressive medical and dietary management is required after surgery to prevent recurrence. Be careful during surgical manipulation of the urethra to minimize the potential for postoperative scar tissue formation and subsequent urethral obstruction.

▼ ***Key Point*** Correct metabolic imbalances in an animal with urethral obstruction prior to performing general anesthesia and prolonged operative procedures.

ANATOMY

Male Canine Urethra

- The urethra in the male canine is divided into three parts: the *prostatic, membranous,* and *cavernous* or penile portions.
- The urethral sphincter is not a discrete structure in the dog. Urethral pressure profiles demonstrate a zone of increased pressure that extends from the prostatic urethra into the membranous urethra. Of the components of the urethral sphincter closure mechanism (fibroelastic tissue, smooth muscle, striated muscle), smooth muscle is probably primarily responsible for maintaining tone in the resting state. Therefore, alpha-adrenergic agonists may be successful in the treatment of sphincter mechanism incompetence.
- The smooth muscle of the urethra is innervated by autonomic nerves arising from the pelvic plexus. The striated musculature receives innervation from branches of the pudendal nerve.
- The distal portion of the penile urethra lies within the os penis. Dilation of the urethra is limited within the os penis and in the perineal portion of the urethra, as it curves around the ischium. These are common locations for calculi to become lodged within the urethra.

▼ ***Key Point*** The most common sites of intraluminal urethral obstruction in male dogs are the base of the os penis, ischiatic arch, and prostate.

Male Feline Urethra

- The male feline urethra consists of three parts: (1) the *preprostatic,* which lies between the bladder and the prostate gland and is relatively longer than the corresponding portion of the male canine urethra; (2) the *prostatic* part, which extends from the prostate to the bulbourethral glands; and (3) the *penile* urethra. Immediately caudal to the bulbourethral glands, the urethral lumen rapidly narrows from approximately 4 mm in diameter to 1 mm. This diameter is maintained through the remainder of the penile urethra. When the penis is retracted, the prostatic and proximal penile urethra may assume the appearance of a flattened or gentle "s," which complicates urethral catheterization unless the penis is manually extended.
- An area of increased pressure thought to correspond to the sphincter mechanism is found in the urethra caudal to the prostate. Despite a decrease in intraurethral electromyographic activity after perineal urethrostomy (PU) in male cats, urinary incontinence is an uncommon occurrence. This may be due to the smooth muscle fibers as well as the remaining striated fibers of the urethral sphincter, which results in resting urethral pressure greater than intravesicular pressure during bladder distension.
- The urethra is innervated by branches of the pudendal nerve and receives autonomic fibers from the pelvic plexus.

Female Canine and Feline Urethra

- The urethra in the female dog and cat is relatively short in comparison to the male and corresponds to the portion of the male urethra found cranial to the level of the mid-prostate. The female urethra is also relatively larger in diameter and more distensible than the corresponding male urethra.
- It appears unlikely that a discrete urethral sphincter is present in either dogs or cats. The urethral pres-

sure profile does not demonstrate a discrete increase in pressure, but the major increase in urethral pressure develops in the mid-urethra of the female dog. A localized area of increase in urethral pressure has been observed in female cats associated with striated musculature near the external urethral orifice.
- The female urethra is innervated by autonomic fibers of the hypogastric and pelvic nerves and sensory and motor fibers from the pudendal nerve.
- Obstruction of the female urethra is extremely uncommon because of its short length, wide diameter, and relative distensibility.

URETHRAL ANASTOMOSIS

Preoperative Considerations

- Perform urethral anastomosis for treatment of urethral disruption, prostatectomy, stricture formation, or removal of granulomatous or neoplastic masses.
- Perform a retrograde positive contrast urethrocystography to identify the location of obstruction or disruption.
- Treat animals that are uremic or have other metabolic disorders as a result of urethral obstruction or leakage of urine into the periurethral tissues prior to inducing anesthesia and performing surgery.

▼ ***Key Point*** Treat incomplete lacerations or defects (discussed later in this chapter) by placing an indwelling urethral catheter to divert the flow of urine for 2 to 3 weeks. This form of treatment will be successful only when intact urethral mucosa bridges a portion of the injured area.

Surgical Procedure

Objectives

- Remove diseased or traumatized tissue.
- Restore urethral continuity.
- Minimize the potential for postoperative stricture formation.

Equipment

- Standard surgical instruments and suture
- Urethral catheters of appropriate diameter and length
- Gelpi or Weitlaner self-retaining retractors
- Monofilament non-absorbable suture (4-0 or 5-0) or synthetic absorbable suture (4-0 or 5-0)
- Delicate instruments for manipulation of the urethra (optional)
- Magnification (optional)
- Penrose drains, or closed suction drains if cellulitis or tissue necrosis due to extravasation of urine has occurred

Technique

1. The positioning of the animal (dorsal recumbency or ventral recumbency in a perineal stand) depends upon the portion of the urethra to be operated upon.
2. With the animal positioned appropriately, prepare the overlying skin for aseptic surgery.
3. Pass a sterile urethral catheter from the external urethral orifice in a retrograde direction to facilitate identification of the proximal end of the distal portion of the urethra.
4. If the distal end of the proximal portion of the urethra cannot be identified, perform a cystotomy and pass a urethral catheter in an antegrade direction.
5. Excise the damaged portions of the urethra. Although it is critical that a tension-free anastomosis be performed, do not be reluctant to debride and resect an adequate amount of urethra to properly treat the disease process.

▼ ***Key Point*** If the urethra cannot be reconstructed without undue tension across the anastomotic site, consider alternatives, such as prepubic urethrostomy.

6. With the urethral catheter in place, perform the anastomosis by placing full-thickness sutures in a simple interrupted pattern.
7. Place the first suture through the dorsal aspect of the urethra.
8. Cut the ends of the suture at a sufficient length so that they may be grasped by a forceps.
9. Gently rotate the urethra to facilitate placement of subsequent sutures. Placing the first two sutures 180 degrees apart facilitates appropriate apposition of the ends of the urethra and suture placement. Preplacement of sutures may help ensure accurate placement of sutures.
10. Place sutures evenly; six to eight sutures are usually sufficient to perform a satisfactory anastomosis.
11. Maintain a soft, preferably balloon-tipped catheter that approximates the diameter of the urethral lumen connected to a sterile urine collection bag for 7 to 10 days after surgery.
12. If necessary, use an Elizabethan collar to prevent catheter displacement. Alternatively, place a cystostomy catheter to divert the flow of urine from the urethra (see Chapter 80).
13. Close the incision routinely.
14. Submit calculi for analysis or culture, or submit tissue for histopathology if indicated.

Postoperative Care and Complications

- If the urethral catheter is removed prematurely, a decision must be made regarding whether or not to replace the catheter. If resistance is encountered

during attempts to pass the urethral catheter, replacement is abandoned.
  - Consider performing a retrograde positive contrast urethrocystogram to evaluate the integrity of the surgical site.
- Monitor the animal carefully for evidence of urine leakage.
- Warn the owners of the potential for postoperative stricture (most commonly observed 2–3 weeks after surgery), and advise them to carefully observe the animal during urination for evidence of urethral obstruction.
- Perform a retrograde positive contrast urethrocystogram 2 to 3 months after surgery to evaluate the urethral diameter at the anastomotic site.
- Treat infection or urinary calculi appropriately.

URETHROTOMY IN THE MALE DOG

Preoperative Considerations

- Perform this procedure to remove urethral calculi lodged proximal to the os penis or in the perineal urethra and to temporarily divert the flow of urine.
- If the animal is azotemic and depressed, this procedure can be performed without sedation by infiltrating the tissue overlying the urethra with local anesthetic.
- If calculi remain in the kidneys, ureters, bladder, or urethra after urethrotomy, perform definitive surgery to remove the calculi after the animal is stabilized.
- Perform urethrotomy only after attempts to pass a urethral catheter or to flush calculi in a retrograde direction into the bladder have failed.

Surgical Procedure

Objectives

- Relieve urethral obstruction.
- Remove urethral calculi.
- Pass urethral catheter.
- Allow patient stabilization prior to definitive repair.

Equipment

- Scalpel, hemostats, thumb forceps, Metzenbaum scissors
- Urethral catheter
- Suture to secure the urethral catheter

Technique

1. Restrain the dog in dorsal (prescrotal urethrotomy) or lateral recumbency (perineal urethrotomy). Prescrotal urethrotomy is the preferred technique.
2. If the procedure is not being performed under general anesthesia, infiltrate the skin and subcutaneous tissues overlying the urethra with local anesthetic.
3. Prepare the skin overlying the intended site of urethrotomy for aseptic surgery.
4. Make an incision 1 to 2 cm in length over the urethra at the level of obstruction.
5. Using a combination of blunt and sharp dissection, expose the appropriate area of the urethra.
6. In the prescrotal location, identify the retractor penis muscles and retract them laterally. The urethra appears as a purple structure on the midline flanked on either side by the white penile tunic.

▼ ***Key Point*** Take care to incise the urethra on the midline. The urethra is a highly vascular structure and will bleed briskly when incised.

7. Remove calculi from the urethra with forceps.
8. Pass a urethral catheter from the urethrotomy site into the bladder. Catheterize the distal urethra (retrograde and/or antegrade) to ensure patency.
9. Maintain the urethral catheter after surgery to monitor urine output and diminish the likelihood of subsequent urethral obstruction prior to surgical removal of cystic calculi.
10. Leave the urethrotomy open to heal by second intention or suture with 4-0 monofilament synthetic absorbable suture in a simple interrupted or simple continuous pattern.

Postoperative Care and Complications

- Hemorrhage may be observed intermittently, usually associated with urination, for 7 to 14 days after surgery. The flow of urine dislodges clots, and urokinase (a plasminogen activator found in urine) interferes with clot formation. This complication may be minimized by suturing the urethrotomy site.
- If the urethrotomy site is sutured, seroma or abscess formation may occur.
- On rare occasion, a stricture may form at the urethrotomy site. This is more likely when the urethral mucosa has sustained significant damage.
- Treat UTI and calculi with appropriate antibiotic and dietary therapy and other interventions to prevent reformation of calculi. Inform the owner that surgery will not cure this problem and appropriate medical therapy is critical to a satisfactory outcome.
- If calculi from the bladder pass into the urethra, urethral obstruction may recur despite the urethrotomy.
- If the skin incision is made too close to the scrotum, the testes may prolapse through the skin incision. Treat this prolapse by suturing the caudal aspect of the incision.
- Swelling and edema of the scrotum and testes may be observed because of inflammation associated with the urethrotomy or subcutaneous accumulation of urine. Subcutaneous accumulation of urine occurs infrequently if the urethrotomy incision is made near the proximal end of the os penis.

- Prolonged urethral obstruction and distension of the bladder may cause a loss of detrusor function of the bladder, resulting in loss of contractile function of the bladder (see Chapter 83 for treatment).

URETHROSTOMY IN THE MALE DOG

Preoperative Considerations

- Urethrostomy results in a permanent opening for the urethra and is performed proximal to the site of narrowing, obstruction, or destruction of the urethra. Perform urethrostomy in the male dog in the perineal, scrotal, prescrotal, or prepubic location.
- Urethrostomy is most often performed in the scrotal position, because the urethra is wide and superficial at this location. Minimal hemorrhage occurs, and a cosmetic result is achieved. Avoid urethrostomy in the perineal position because of the potential for urine scalding of the caudal surface of the thighs. Prepubic urethrostomy is discussed later in this chapter.

▼ ***Key Point*** Inform the owner that urethrostomy will not cure UTI or urinary calculi. In fact, urethrostomy may predispose the animal to UTI. However, the overall incidence of UTI after urethrostomy in male dogs is low.

- Urethrostomy decreases the potential for urethral obstruction due to passage of calculi but does not eliminate it. Calculi of sufficient diameter may still become lodged in the urethra proximal to the site of urethrostomy.

▼ ***Key Point*** Scrotal urethrostomy necessitates castration of the animal. Inform the owner prior to undertaking surgery.

- Stabilize azotemic animals prior to undertaking a prolonged anesthetic and operative procedure.

Surgical Procedure: Scrotal Urethrostomy

Objectives

- Allow discharge of urine proximal to the site of urethral obstruction or destruction.
- Diminish the possibility of urethral obstruction due to urinary calculi.

Equipment

- Standard surgical instruments and suture
- Monofilament non-absorbable suture (4-0 or 5-0) and synthetic absorbable suture (2-0 or 3-0) with swaged taper or taper-cut needle (preferred)
- Urethral catheter
- Delicate forceps for manipulation of the urethra (optional)
- Magnification (optional)

*Technique**

1. Place the dog in dorsal recumbency.
2. Prepare the caudal ventral abdomen, prepuce, scrotum, and ventral perineal region for aseptic surgery.
3. Make a circumferential incision around the scrotum at the point of reflection of the skin from the ventral body wall (Fig. 82-1*A*). Preserve enough skin to minimize tension on the suture line.
4. Isolate, ligate, and divide the spermatic cords and vessels by a combination of sharp and blunt dissection.
5. Free the scrotum and testes of their attachments to the ventral abdomen and penis and remove them (Fig. 82-1*B*).
6. Retract the paired retractor penis muscles laterally.
7. Secure the tunic of the penis to the subcutaneous tissues with four to six interrupted sutures of absorbable material (2-0 or 3-0) (Fig. 82-1*C*).
8. Place these sutures in such a manner that an adequate amount of skin is available to be sutured with minimal tension to the site of incision in the ventral urethra.
9. Make an incision in the ventral surface of the urethra for the length of the urethrostomy site (approximately 5 cm) (Fig. 82-1*D*).

▼ ***Key Point*** Make the urethral incision precisely on the ventral midline to facilitate urethrostomy closure.

10. If tension is encountered as the skin is drawn toward the edge of the urethra, adduct the stifles. This usually diminishes the amount of tension placed on the skin in this position.
11. Suture the urethral mucosa to skin with 4-0 or 5-0 monofilament non-absorbable suture in an interrupted or continuous pattern (Fig. 82-1*E* and *F*). Include a small bite of urethral tunic with the bite of mucosa, since the mucosa is friable and has poor suture-holding capacity. Place sutures from inside the urethral lumen (mucosa) to outside (skin) to improve apposition of mucosa to skin. The distal continuation of the urethra into the os penis remains open.

Postoperative Care and Complications

- Apply an Elizabethan collar to prevent postoperative self-mutilation.

*The procedure for scrotal urethrostomy is described. A similar technique is used to create urethrostomy in the perineal or prescrotal position.

Figure 82-1. Scrotal urethrostomy. *A,* Make an incision encircling the scrotum. *B,* Ligate and sever the spermatic cord and vessels and remove the scrotum and testes. *C,* The retractor penis muscles are drawn laterally; secure the subcutaneous tissues to the tunica albuginea. *D,* Make an incision on the ventral midline of the urethra. Placement of a catheter facilitates identification of the urethra. *E,* Suture the urethra to the skin. *F,* The cranial opening of the urethra at the urethrostomy site remains open. (From Smeak DD, Fingeroth JM: Scrotal urethrostomy. In Bojrab MJ (ed): Current Techniques in Small Animal Surgery, 3rd ed. Philadelphia: Lea & Febiger, 1990, p 381.)

- Hemorrhage may be observed intermittently from the urethrostomy site. This is particularly noticeable when the animal urinates. In the immediate postoperative period, treat this by applying pressure or a cold compress. Sedation of the animal, particularly with acepromazine (which may decrease the systemic blood pressure), may also decrease the incidence of hemorrhage. Warn the owner that hemorrhage may occur for up to 2 weeks after the surgery. Clinical studies have found decreased postoperative hemorrhage with the continuous suture pattern.
- Remove sutures 2 weeks after surgery. Sedate animals that are difficult to handle for suture removal.

▼ ***Key Point*** Inform the owner that the removal of the sutures may result in intermittent hemorrhage from the urethrostomy site for 2 to 3 days.

- Treat UTI and urinary calculi by appropriate antibiotic, dietary, and medical therapy (see Chapter 79). Inform the owner that urethrostomy will not treat UTI or prevent calculi formation and that urethral obstruction may recur if calculi form.
- Leakage of urine into the subcutaneous tissues is uncommon.
- Stricture formation is extremely uncommon but may occur. If this happens, reconstruct the urethrostomy

and carefully appose the mucosa to skin without tension.
- Scalding of the inner surface of the thighs by contact of the skin with urine is extremely uncommon. Apply petroleum jelly to the skin surrounding the stoma to reduce this problem until sutures are removed.
- Prolonged urethral obstruction and distention of the bladder may result in a loss of detrusor function of the bladder.
- Urinary incontinence due to surgery has not been reported.

PERINEAL URETHROSTOMY IN THE MALE CAT

Preoperative Considerations

- This procedure is performed most often in cats that suffer recurrent urethral obstruction because of idiopathic lower urinary tract disease, also referred to as feline interstitial cystitis (FIC) and feline urologic syndrome (FUS). Improved dietary management of this disorder has greatly decreased the need for urethrostomy in cats (see Chapter 79 for discussion of this disorder).

▼ ***Key Point*** Performance of PU will not cure FIC or FUS, and signs of this disorder may persist after surgery. Inform the owner that the surgery is performed to diminish the probability of urethral obstruction and not to cure FIC or FUS.

- This procedure can be used to treat any form of urethral obstruction due to lesions of the urethra distal to the bulbourethral glands.
- Castration and amputation of the distal penis are necessary for PU in cats. Inform the owner of these procedures.

Surgical Procedure

Objectives

- Create a cutaneous opening of the urethra of satisfactory diameter near the bulbourethral glands.
- Minimize tension across the suture line to decrease the potential for stricture formation.
- Preserve urethral sphincter function.

Equipment

- Standard surgical instruments and suture
- Delicate instruments for manipulation of the urethra
- 3.5 to 8 Fr. catheter
- Fine periosteal elevator (Freer)
- Monofilament suture (4-0 or 5-0), taper-cut needle
- Magnification (optional)

Technique (Fig. 82-2)

1. Place the cat in ventral recumbency with the hindquarters slightly elevated.
2. Secure the tail in a forward position.
3. Place a purse-string suture around the anus (Fig. 82-2*A*).
4. Completely evacuate urine from the bladder.
5. Prepare the perineal area surrounding the scrotum and prepuce for aseptic surgery.
6. If the cat is intact, make an incision at the reflection of the scrotum from the surrounding skin. This incision encircles the scrotum and continues ventrally along the line of reflection of the prepuce from the perineal skin.
7. If the cat has previously been castrated, make an incision encircling the prepuce and scrotal remnant. Ventrally, the incision comes to a point.
8. Isolate, ligate, and divide the spermatic cords and vessels.
9. Sharply divide the ventral attachments of the penis to the pelvic floor near their attachment to the penis.
10. Continue sharp and blunt dissection circumferentially adjacent to the penis until the ischiocavernosus muscles are identified. Take care to restrict dissection to the area immediately adjacent and ventral to the penis.
11. Divide or free the ischiocavernosus muscles and penile ligament of their attachments to the ischium to allow the penis to be drawn caudally. The muscles will bleed profusely if incised.
    a. Incise the fascia overlying the attachment of the ischiocavernosus muscles to the ischium.
    b. Sever the attachment of the ischiocavernosus muscles to the ischium with a periosteal elevator. This usually results in minimal hemorrhage.
12. Continue blunt dissection in a cranial direction until the penis is freed of its ventral attachments and the caudal aspect of the bulbourethral glands lies at the level of the skin incision.
13. Limit dorsal dissection to minimize the potential for postoperative incontinence. If exposure of the proximal, dorsal urethra is inadequate, careful dissection of dorsal urethra tissues may be necessary.
14. Retract the penis in a caudal direction, and pass a catheter into the urethra (Fig. 82-2*B*).
15. Identify the retractor penis muscle on the dorsal aspect of the penis and excise it as far proximally as possible (Fig. 82-2*C*).
16. Excise the distal penis and prepuce and discard, along with the scrotum and testes.
17. With the urethral catheter in place, make an incision in the dorsal aspect of the urethra to the level of the bulbourethral glands.

▼ ***Key Point*** Continue the incision cranially until the portion of the urethra that enlarges in diameter (typically at the level of the bulbourethral glands) is reached.

18. Secure the tunic of the penis distal to the bulbourethral glands to the subcutaneous tissues by a

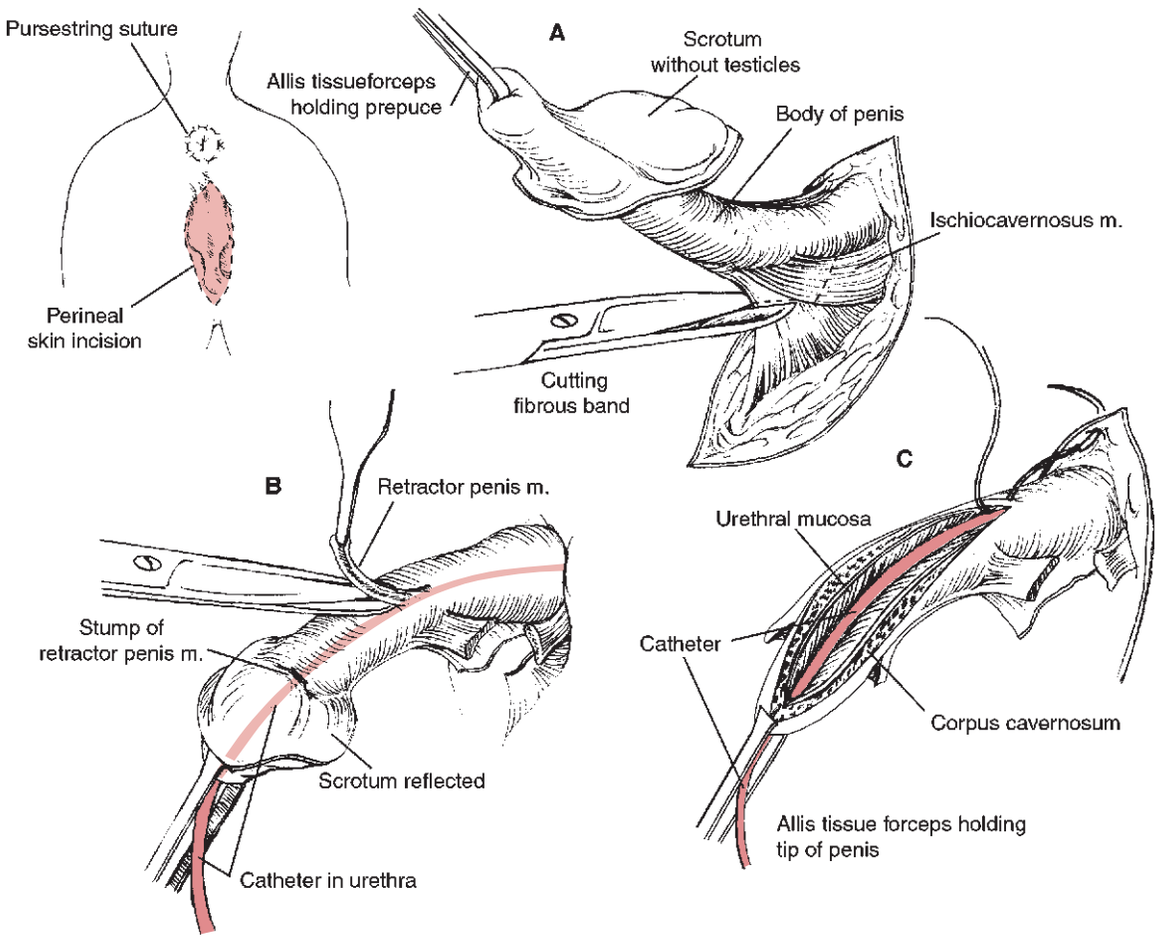

Figure 82-2. Perineal urethrostomy in the cat. *A*, Make an elliptical incision around the scrotal and prepuce (inset), and sharply incise the ventral fibrous attachments of the penis and the ischiocavernosus muscles. *B*, Carefully dissect and remove the retractor penis muscle from the dorsal aspect of the urethra. *C*, Incise the urethra exactly on the dorsal midline, and suture the urethra to skin using fine monofilament suture. Be sure to achieve accurate apposition of urethral mucosa to the skin.

few (two to four total) interrupted sutures of synthetic absorbable material (3-0 or 4-0). Place these sutures so that the skin may be brought to the edge of the urethral incision without tension across the suture line.

▼ ***Key Point*** Ensure that the urethral mucosa is well apposed to the skin to prevent stricture formation.

19. Suture the skin to the edge of the urethra. Place the first suture through the apex of the incision through the urethra and the most dorsal aspect of the skin incision.
20. Place interrupted sutures on either side from dorsal to ventral to create a satisfactory urethrostomy opening. Use monofilament non-absorbable suture (4-0 or 5-0).
21. After sutures have been placed along the urethra for a distance of approximately 1.5 cm, excise the remaining penis.

▼ ***Key Point*** Creation of a drain board distal to the urethrostomy will decrease the risk of urine scald of the perineum postoperatively.

22. Place and tighten an encircling absorbable suture submucosally around the exposed end of the penis. This will diminish hemorrhage from the body of the penis.
23. Close the remainder of the skin incision: subcutaneous tissue with absorbable suture in a continuous pattern skin with non-absorbable suture in an interrupted or continuous pattern.
24. Remove the urethral catheter upon completion of the surgery. Upon completion, a 5 to 8 Fr. catheter should pass into the bladder with ease.
25. Remove the purse-string suture around the anus.

Postoperative Care and Complications

- Place an Elizabethan collar to prevent self-inflicted damage of the urethrostomy site.

- Hemorrhage is frequently observed after surgery. In the early postoperative period, control this by applying pressure or cold compresses (ice packs). Tranquilization of the animal may be helpful in controlling prolonged hemorrhage.
- Stricture of the urethrostomy site is one of the most commonly observed complications.
- This complication most often results from failure to satisfactorily free the penis from its attachments within the pelvic canal, causing tension on the suture line; poor mucosa-to-skin apposition; or failure to continue the urethral incision far enough cranially.
- Subcutaneous leakage of urine may result in cellulites, abscessation, or dehiscence. This leakage usually results from poor mucosa-to-skin apposition, especially at the proximal aspect of the urethrostomy.
- Urinary or fecal incontinence is infrequently observed after PU in cats.
- The overall incidence of UTI in cats after PU is low; however, it is more commonly observed in these cats than in male cats that have not undergone the procedure.
- Perineal hernia has been reported after PU in male cats but is rare.
- Obstruction of the urethra may occur after PU because of the persistence of FIC/FUS or the development of urinary calculi.
- Prolonged urethral obstruction and bladder distension may result in a loss of detrusor function of the bladder (see Chapter 83).

PREPUBIC URETHROSTOMY

Preoperative Considerations

- Perform this procedure for treatment of diseases that cause a loss of urethral structure or function distal to the prostatic and pelvic portions of the urethra.
- This procedure can be performed in male or female animals.
- This can be performed as a salvage procedure following a failed PU in the cat.
- If a sufficient length of urethra and the associated innervation remain intact, the animal retains urinary continence.
- If this procedure is to be performed in a male dog with an enlarged prostate, a partial prostatectomy may also be necessary. This prevents the enlarged prostate within the subcutaneous tissues from interfering with the appropriate placement of the stoma.

Surgical Procedure

Objectives

- Create a new urethral opening on the ventral abdominal surface using the remaining length of urethra.
- Retain urinary continence.

Equipment

- Standard surgical instruments and suture
- Balfour retractors
- Monofilament non-absorbable suture (4-0 or 5-0)
- Urethral catheter
- Delicate instruments for manipulation of the urethra (optional)
- Magnification (optional)

Technique

1. Place the animal in dorsal recumbency.
2. Prepare the caudal surface of the ventral abdomen for aseptic surgery.
3. Make an incision on the ventral midline of the abdomen from the umbilicus to the pubis in female dogs and cats and male cats and in a parapreputial location in male dogs.
4. Examine the bladder, prostate (in male dogs), and urethra.
5. Identify the diseased portion of the urethra.
6. Transect the urethra, retaining the maximal amount of normal proximal urethra.
7. Resect the affected urethra if neoplasia is present.
8. Ligate vessels leading to the distal portion of the urethra and associated tissues.

▼ ***Key Point*** Take care during dissection to preserve the innervation and vascular supply of the bladder neck and proximal urethra located along the dorsolateral surface.

9. If difficulty is encountered in identifying the lumen of the proximal urethra, pass a catheter in a retrograde direction or perform a cystotomy to allow passage in an antegrade direction.
10. Bring the proximal urethra and adjacent structures to the level of the skin incision, and select an appropriate, tension-free site to create the stoma.
11. Create the stoma on the ventral midline in female dogs and cats and male cats and in a parapreputial position in male dogs. The stoma can be placed in the incision through which the abdominal cavity was entered. Position the stoma to allow the urethra to curve in a gentle arc through the ventral abdominal wall to avoid kinking or obstructing the urethra (Fig. 82-3).
12. Avoid twisting the urethra when passing it through the abdominal wall.
13. Close the abdominal wall in a standard manner, leaving 1.5 to 2.0 cm of the distal end of the proximal urethra exposed. The abdominal wall is not tightly closed in the area through which the urethra passes.
14. Secure the adventitia surrounding the urethra to the subcutaneous tissues with two absorbable sutures.

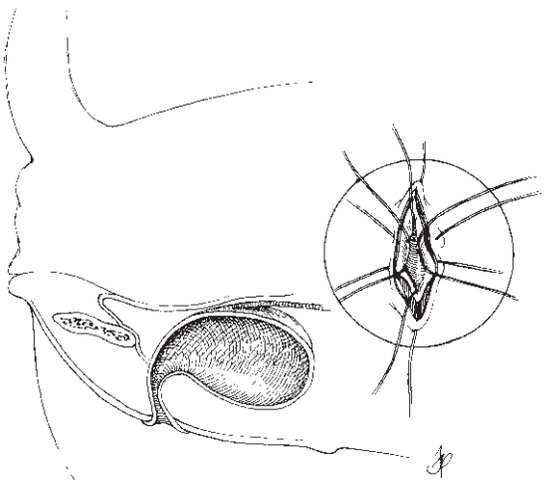

Figure 82-3. Prepubic urethrostomy. The urethra is brought across the body wall at a "gentle angle" to prevent urethral obstruction. Make an incision on the ventral surface of the urethra, and suture the urethra to the skin. (From Bjorling DE: Traumatic injuries of the urogenital system. Vet Clin North Am Small Anim Pract 14:61, 1984.)

15. Make an incision 1.5 to 2.0 cm in length on the ventral surface of the distal end of the proximal urethra. This is done to increase the diameter of the stoma.
16. Close the subcutaneous tissues in a standard manner.

▼ ***Key Point*** In obese animals or animals with redundant skin in the area of the urethral stomas, resection of skin and fat may be required to prevent obstruction of the stoma by adjacent skin folds.

17. Suture the cut edge of the urethra, including the mucosa, to the skin with monofilament non-absorbable suture (4-0 or 5-0) in an interrupted pattern to create the urethrostomy opening.
18. Close the remainder of the skin incision in a standard manner.
19. Catheterization of the urethra may facilitate accurate placement of sutures through the wall of the urethra.
20. Do not leave the catheter in place after surgery unless monitoring of urine output is necessary.

Postoperative Care and Complications

- Use an Elizabethan collar to prevent trauma after surgery.
- Leakage of urine into the subcutaneous space or abdominal cavity will result in cellulitis or peritonitis. Prevent this by accurate suture placement during the operative procedure.
- Stricture formation is an unusual complication of this procedure. When stricture occurs, revise the opening.
- If the procedure is performed appropriately and a satisfactory length of proximal urethra is available, urinary continence is retained. If urinary continence is lost, treat with alpha-agonists (see Chapter 83) to increase urethral tone. This therapy may or may not be successful if nerve or muscle function is lost.
- Prepubic urethrostomy predisposes an animal to ascending UTI. Frequent reevaluation and urine culture is recommended after the surgery.
- Loss of urinary continence predisposes to scalding of the ventral abdominal surface with urine.
- Urethral obstruction may occur if the position of the stoma results in an acute angle in the urethra relative to the bladder neck.

URETHRAL PROLAPSE IN THE MALE DOG

Preoperative Considerations

- Urethral prolapse occurs most often in young brachycephalic dogs.
- The most common complaint of the owner is that the dog develops hematuria or has bleeding from the penis when it becomes excited. Hemorrhage is usually self-limiting.
- After the exposed urethral tissue has been traumatized, hemorrhage may recur during or following urination because of dislodgement of blood clots by the flow of urine.
- Diagnose urethral prolapse by direct observation of exposed urethral tissue that appears as a fleshy ring surrounding the external urethral orifice. Extrude the penis from the prepuce to observe urethral prolapse.
- If the animal is not to be used for breeding, castration may help control urethral prolapse.

Surgical Procedure

Objectives

- Prevent hemorrhage from the tip of the penis.
- Excise exposed urethral tissue and prevent recurrence.
- Maintain an adequate urethral lumen.

Equipment

- Standard surgical instruments and suture
- Tourniquet or Penrose drain
- Urethral catheter
- Monofilament non-absorbable suture (4-0 or 5-0)

Technique

1. Place the dog in dorsal recumbency.
2. Prepare the interior of the prepuce and the penis for aseptic surgery.
3. Extrude the penis from the prepuce.

4. Pass a urethral catheter into the urethra until the tip lies approximately at the level of the scrotum.
5. Apply a tourniquet to the penis caudal to the os penis. The tourniquet will maintain the penis in an exteriorized position and minimize hemorrhage. Use a commercial tourniquet or a tourniquet created with a forceps and Penrose drain.
6. Partially excise the exposed urethral mucosa. Incise through the distal extent of the penile tunic and urethra, extending around half the circumference of the distal penis. This incision is proximal to damaged urethral mucosa and provides an exposed edge of the penile tunic, which is subsequently sutured to the urethra.
7. Suture the cut edge of the urethra to the tunic of the penis with monofilament non-absorbable suture (4-0 to 5-0) in an interrupted or continuous pattern. If a continuous pattern is used, avoid creating a "purse-string" effect.

▼ ***Key Point*** The purpose of initiating closure prior to complete excision of the urethral tissue is to prevent retraction of the urethral tissue within the penis and to facilitate accurate suture placement.

8. After the incision that has been made is partially closed, excise the remainder of the exposed urethral tissue by continuing the incision circumferentially.
9. Close the remainder of the defect with monofilament non-absorbable suture with a similar pattern.
10. Remove the tourniquet and urethral catheter.

Postoperative Care and Complications

- Intermittent hemorrhage may persist for 2 to 3 days (or longer) after surgery. This is usually associated with urination or excitement. If hemorrhage is excessive, re-examine the tip of the penis. Active bleeding from gaps in the closure may require placement of additional sutures. Tranquilization (e.g., with acepromazine) of the dog may decrease hemorrhage.
- Recurrence of urethral prolapse is uncommon. If this occurs, repeat the surgery and strongly recommend castration.
- Self-mutilation may occur and is discouraged by placing an Elizabethan collar or by using sedation.
- Sedate the dog for suture removal.
- Urethral prolapse rarely occurs in older animals. If observed in older animals, rule out a tumor at the tip of the penis. If there is concern that the tissue excised may be neoplastic, submit this tissue for histopathologic evaluation. Tumors of the distal urethra and penis are extremely uncommon.

Chapter

83 Disorders of Micturition

Mary Anna Labato

Micturition involves the passive storage and the active voiding of urine. Processes that interfere with the storage and voiding of urine are termed micturition disorders. The loss of voluntary control of micturition is defined as urinary incontinence.

Most cases of micturition disorders have been reported in middle-aged and geriatric dogs. The clinical importance of these disorders is twofold:

- Incontinence is unacceptable to most owners; if not adequately treated, this disorder may result in euthanasia of the pet.
- Micturition disorders may lead to unresponsive urinary tract infection, resulting in an ascending pyelonephritis.

▼ ***Key Point*** It is critical that the etiology of micturition disorders be diagnosed correctly in order to properly implement treatment.

NORMAL ANATOMY AND PHYSIOLOGY OF THE URINARY BLADDER

In order to recognize the many possible manifestations of micturition disorders it is imperative to understand the anatomy of the bladder, its functional composition, and the neurophysiology of micturition.

Bladder Function

Bladder function is primarily under the influence of smooth muscle. The body of the bladder contains smooth muscle, referred to as the detrusor muscle. The outlet conduit is composed of the trigone and proximal urethra. The smooth muscle fibers of the detrusor continue into the proximal urethra, forming a functional internal urethral sphincter mechanism. The distal urethra is composed of striated skeletal muscle and functions as an external sphincter.

During the storage phase of micturition, the bladder functions as a low-resistance, high-capacity reservoir. The urethra functions as a high-resistance barrier. The reverse is true during the voiding phase: The bladder acts as a muscular pump and the urethra is a low-resistance vessel.

The bladder functions like a compliant balloon as it fills, with pressure remaining lower than urethral resistance. With the initiation of normal urination, urethral resistance decreases and a phasic contraction of the detrusor muscle empties the bladder.

Nervous Control

Nervous control of the bladder and urethra is a combination of autonomic and somatic interactions. The micturition reflex is integrated by numerous interneurons and synapses between the sympathetic and the parasympathetic systems.

Parasympathetic Innervation

Parasympathetic innervation is supplied to the detrusor by the pelvic nerve, which arises from sacral spinal cord segments (S1–S3). Stimulation of the pelvic nerve results in detrusor contraction.

Sympathetic Innervation

Sympathetic innervation is supplied via the hypogastric nerve, which is composed of preganglionic fibers exiting the lumbar spinal cord (L1–L4) and synapses in the caudal mesenteric ganglion. Sympathetic innervation is supplied to both the detrusor and urethral smooth muscles and facilitates the storage phase of micturition. Alpha-adrenergic fibers synapse in smooth muscle in both the trigone and the urethra. Stimulation results in contraction of these muscles and forms a functional internal urethral sphincter mechanism. There are also alpha-adrenergic fibers that have a modulating effect on the external urethral sphincter. Beta-adrenergic fibers synapse in the detrusor muscle; stimulation results in relaxation.

Somatic Innervation

The pudendal nerve, which arises from sacral spinal cord segments (S1–S3), provides somatic stimulation to the striated urethral musculature.

Higher Centers of Innervation

For voluntary control of micturition to occur there must be integration among the cerebral cortex, the pons, and

the spinoreticular tract. A second pathway from the cerebral cortex to the sacral nuclei coordinates voluntary sphincter control. In addition, cerebellar neurons inhibit nervous transmission to the reticulospinal pathways in the pons.

ETIOLOGY OF MICTURITION DISORDERS AND INCONTINENCE

Disorders of micturition and continence can be divided broadly into two types: neurogenic and non-neurogenic (Table 83-1).

Neurogenic Disorders

There are three types of neurogenic disorders: lower motor neuron, upper motor neuron, and detrusor-urethral dyssynergia.

Lower Motor Neuron Bladder

Lower motor neuron, or atonic, bladder results from lesions involving the sacral spinal cord segments or pelvic nerve, including intervertebral disc disease, cauda equina syndrome, sacroiliac luxations, sacrococcygeal fracture or separation, and tumors (e.g., spinal lymphoma). This type of disorder causes both detrusor and sphincter areflexia. Dribbling of urine with the

Table 83-1. DISORDERS OF MICTURITION

Type of Disorder	Clinical Signs	Treatment
Neurogenic		
Lower motor neuron bladder	Distended, easily expressed Continuous incontinence No perineal or bulbospongiosus reflex No detrusor reflex	No effective therapy, Manual expression 3–4 times daily Trial with bethanechol chloride Concurrent antibiotics
Upper motor neuron bladder	Large, firm bladder Difficult manual expression initially Increased sphincter tone +/− detrusor reflex	Aseptic intermittent catheterization Concurrent antibiotics Antispasmodics or smooth muscle relaxants Long-term management usually frustrating
Detrusor-urethral dyssynergia	Large, non-expressible bladder Initiation of urine stream with abrupt disruption of urination Intact spinal reflexes Bladder easily catheterized	Prazosin Other alpha-antagonists Baclofen Diazepam Dantrolene
Non-neurogenic		
Hormone-responsive incontinence	Older, neutered animal Voluntary control of urination with intermittent incontinence Incontinence usually when relaxed or asleep	Diethylstilbestrol (females) Testosterone (males) Phenylpropanolamine
Urethral incompetence (stress incontinence)	Loss of voluntary control when placed in a stressful situation or at rest Ability to urinate voluntarily	Phenylpropanolamine Imipramine
Urge incontinence (detrusor hyperreflexia)	Frequent small urinations Hyperreflexive detrusor Urine spraying Stranguria	Flavoxate Oxybutynin Dicyclomine Propantheline bromide
Overdistension atony	Large flaccid bladder Continuous incontinence Large residual urine volume Intact perineal and bulbospongiosus reflex No detrusor reflex	Remove mechanical obstruction Indwelling bladder catheterization Bethanechol chloride
Paradoxical incontinence	Stranguria Persistent urine dribbling Large, turgid bladder that is difficult to express	Remove obstruction Indwelling catheterization Surgical exploration Cystoscopy
Ectopic ureter(s)	Continuous or intermittent dribbling of urine Ability to urinate voluntarily	Surgery Phenylpropanolamine
Pelvic bladder	Loss of voluntary control when placed in a stressful situation or at rest Ability to urinate voluntarily	Phenylpropanolamine Surgery

bladder remaining full is often referred to as overflow incontinence.

Upper Motor Neuron Bladder

Upper motor neuron, or automatic, bladder results from a lesion involving the spinal cord above the sacral spinal cord segments, such as intervertebral disc disease, tumor, or trauma. This disorder causes incomplete reflex detrusor contraction and spasticity of the urethral sphincter, with resulting incomplete emptying of the bladder.

Voluntary control is lost and manual expression is difficult if not impossible. After a period of days to weeks, the spinal reflexes resume. Non-voluntary micturition is initiated when the threshold capacity of the bladder is reached (automatic bladder).

Detrusor-Urethral Dyssynergia

In this condition, the initiation of the detrusor reflex resulting in voiding is followed by an involuntary contraction of the urethral sphincter. Detrusor-urethral dyssynergia refers to involuntary contraction of the external urethral sphincter in the postprostatic urethra (detrusor-striated muscle sphincter dyssynergia) or contraction of smooth muscle in the bladder neck and prostatic urethra (detrusor-smooth muscle sphincter dyssynergia) during detrusor contraction. It results from lesions or partial lesions (masses, degeneration) of the reticulospinal tract. Increased sympathetic activity of both the smooth and striated urethral musculatures may result from a lesion cranial to or involving the caudal mesenteric ganglion.

Non-Neurogenic Disorders

A number of disorders resulting in urinary incontinence are non-neurogenic in origin. A brief description of each disorder follows.

Hormone-Responsive Incontinence

Hormone-responsive incontinence is one of the most frequently diagnosed disorders. It is a disorder of older animals (mean age of occurrence is 8 years); however, it has been documented in animals as young as 8 to 9 months.

Hormone-responsive incontinence is seen primarily in spayed female dogs, which may be predisposed because of decreased sex hormone believed to contribute to normal urethral muscle tone and mucosal integrity.

Occasionally, hormone-responsive incontinence occurs in castrated male dogs, and it has been reported infrequently in neutered male and female cats.

Urethral Incompetence (Stress Incontinence)

This is the most common non-hormonal cause of urinary incontinence in small animals. Stress incontinence is a syndrome reported in women that consists of involuntary release of urine secondary to an increase in intra-abdominal pressure without detrusor atony or detrusor hyperreflexia. Urethral incompetence is the veterinary counterpart of stress incontinence. The cause is thought to be urethral smooth muscle incompetence or malposition of the vesicourethral junction or urethra.

Urge Incontinence (Detrusor Hyperreflexia)

Urge incontinence is due to involuntary detrusor contractions resulting in frequent voiding of small volumes of urine. The condition may result from an inflamed or irritated bladder or occasionally from partial spinal long tract or cerebellar involvement. The syndrome is commonly seen in cats that suffer from cystitis or idiopathic feline lower urinary tract disorders. An idiopathic form has been documented in cats and dogs without any evidence of cystitis.

Detrusor Atony from Overdistention

This results from a mechanical or functional outflow obstruction, causing separation of the tight junctions of the detrusor muscle. Subsequent contractions of the detrusor muscle are weak and ineffectual. A functional outflow obstruction may have a neurogenic component. It usually is the result of excessive sympathetic stimulation to the urethra, resulting in increased urethral tone. Common examples of mechanical obstruction are as follows:

- Urethral obstruction (especially in cats)
- Cystic and urethral calculi
- Neoplasia of the trigone or urethra
- Severe urethritis
- Stricture of the urethra
- Prostate disease

Obstruction causes an increase in urine volume until the intravesicular pressure can overcome the urethral resistance. Once the urethral pressure has been overcome, dribbling of urine occurs because of ineffectual detrusor contractions.

Paradoxical Incontinence

This is similar to overflow incontinence from detrusor atony. It is involuntary dribbling of urine associated with an outflow obstruction. It often results from a partial urethral obstruction caused by urethral calculi, neoplasia, or urethritis. The difference between the two conditions is a matter of duration and whether the atony is temporary or permanent. Paradoxical incontinence is of a shorter duration. When the partial obstruction is relieved, normal function returns, and the detrusor contracts effectively.

Ectopic Ureter(s)

Ectopic ureter and other congenital urethral malformations are a common cause of urinary incontinence.

The abnormal location of the ureteral orifice(s) within the bladder neck, urethra, or vagina results in continuous or intermittent leakage of urine (see Chapter 77).

Pelvic Bladder and Urethral Dysplasia

This is a condition in which the neck of the bladder is located extremely caudally in the pelvic canal and the urethra is shortened or displaced. It is most often associated with incontinence in young intact female dogs, but some dogs with pelvic bladder do not exhibit urinary incontinence.

Incontinence that accompanies a pelvic bladder is attributed to two components of the disorder:

- The extreme caudal displacement of the bladder into the pelvic canal, limiting the bladder distension.
- The abnormal position of the urethra in these animals. The dysplastic urethra may take on a variety of appearances, from short and dilated to S-shaped.

CLINICAL SIGNS

- *Incontinence:* Dribbling of urine, loss of voluntary control, and urine-scald dermatitis.
- *Abnormal micturition:* Inability to urinate, disruption of the urine stream, stranguria, dysuria, and abdominal pain or discomfort.
- *Lower motor neuron bladder:* Dribbling of urine and a large distended bladder that is easily expressed by manual compression.
- *Upper motor neuron bladder:* A full bladder that is difficult to express initially. Voluntary control of micturition is lost. After a period of days to weeks, the spinal reflexes resume and non-voluntary micturition is initiated when the threshold capacity of the bladder is reached. Incomplete and inappropriate urination is the result.
- *Detrusor-urethral dyssynergia* (differentiate from mechanical obstruction): Initiation of voiding, often after a period of hesitation, that then is abruptly disrupted; stranguria.
- *Hormone-responsive incontinence:* Normal voluntary urination with involuntary dribbling when the animal is relaxed or asleep.
- *Urethral incompetence (stress incontinence):* Signs similar to hormone-responsive incontinence; also involuntary loss of urine when placed in a stressful or new situation.
- *Detrusor hyperreflexia:* Frequent small urinations, stranguria, and urine spraying in cats; small bladder (compare with detrusor atony from overdistention).
- *Detrusor atony from overdistention:* Stranguria, dysuria, persistent urine dribbling; large distended bladder.
- *Paradoxical incontinence:* Same clinical signs as detrusor atony.
- *Ectopic ureter(s):* Continuous or intermittent dribbling of urine, usually with the ability to urinate appropriately and voluntarily. Most commonly diagnosed in young female dogs.
- *Pelvic bladder:* Same as urethral incompetence.

DIAGNOSIS

History

The history is of the utmost importance; include the following items:

- Reproductive status
- If animal was neutered, age at neutering
- Age at onset of problem
- Previous medical problems, especially those involving the urogenital system
- Previous history of trauma
- Description of the abnormality
- If the problem is incontinence, ask the following:
  - Is it continuous or intermittent?
  - What is the amount of urine passed?
  - Is the animal aware that urine is being passed?
- If the animal has difficulty urinating, ask the following:
  - How frequent is urination?
  - Is there nocturia, dysuria, or hematuria?

Physical Examination

Perform a general examination, with particular attention to the urogenital system, and perform a neurologic examination (see Chapter 125).

- Palpate the bladder carefully prior to and immediately following voiding to evaluate the extent of distention, tone, and ease with which the bladder may be manually expressed.
- Lower motor neuron lesions generally are associated with easy manual expression and reduced sphincter tone.
- Upper motor neuron lesions generally are associated with difficult manual expression and increased sphincter tone.
- In the neurologic examination, evaluate the innervation of the urogenital system.
- The perineal reflex evaluates the pudendal nerve. Pricking or pinching the skin of the perineum should result in anal sphincter contraction.
- The bulbospongiosus reflex evaluates the integrity of both the pudendal nerve and the sacral spinal segments. Squeezing the distal portion of the penis or vulva will cause anal sphincter contraction.
- Perform a rectal examination to evaluate the prostate gland, the pelvic diaphragm, and the anal tone.

▼ ***Key Point*** Observe the animal when urinating to verify the micturition abnormality.

- Measure the residual urine volume. Allow the animal to void until urine is no longer passed; catheterize the

bladder and collect and measure any residual urine. In a normal animal, the residual urine volume should not exceed 0.4 ml/kg.

Endoscopy

- Perform uroendoscopy if ectopic ureters are suspected.

▼ ***Key Point*** Uroendoscopy is considered the "gold standard" for the diagnosis of ectopic ureters but requires specialized equipment and skill.

Laboratory Evaluation

- Evaluate renal function by determining blood urea nitrogen (BUN) and serum creatinine concentration.
- To evaluate for associated urinary tract infection, perform cystocentesis and submit urine for urinalysis, culture, and sensitivity. If possible, do this before any bladder catheterization.

Radiographic Examination

Both survey and specialized studies may be useful.

- Use survey radiographs to evaluate any obvious abnormalities in the bladder, urethra, pelvis, or spine.
- Use contrast radiographic studies (intravenous urography, retrograde urethrocystography, and vaginourethrography) and contrast enhanced computed tomography (CT) (see Chapter 4) to evaluate for the following:
  - Ectopic ureters
  - Bladder wall thickening
  - Calculi
  - Urachal diverticulum
  - Prostatic enlargement
  - Urethral strictures
  - Pelvic bladder, urethral dysplasia
  - Skeletal abnormalities in the pelvis

Urodynamic Studies

Urodynamic studies to evaluate micturition disorders routinely consist of the cystometrogram and urethral pressure profile; electromyography also may be a part of the study. These specialized modalities are readily available at most veterinary institutions and are becoming increasingly common in private referral practices.

- The cystometrogram is a pressure-volume recording that measures bladder tone and volume, threshold volume and pressure, maximum contraction pressure, and the detrusor reflex.
- The urethral pressure profile measures intraurethral resistance and identifies and localizes areas of increased or decreased resistance.
- Electromyography can evaluate coordination of muscular activity between the detrusor and the urethral sphincter. Electromyography is usually performed on the anal sphincter; however, using specialized catheters that incorporate electrodes, it can be performed directly on the urethral sphincter.

Diagnosis of Individual Disorders

Lower Motor Neuron Bladder

- The bladder typically is large, distended, and easily expressed.
- The incontinence is continuous.
- There is a loss of perineal, bulbospongiosus, and detrusor reflexes.

Upper Motor Neuron Bladder

- The bladder is large, turgid, and initially extremely difficult to express.
- There is a history of an inability to urinate.
- Frequently there is concomitant hindquarter paresis or paralysis.

Detrusor-Urethral Dyssynergia

- Diagnosis is made by observation; commonly there is stranguria, initiation of voiding, and then abrupt disruption of the urine stream.
- Palpation often reveals a large, non-expressible bladder.
- The bladder is easily catheterized.
- There is no evidence of stricture or obstruction when a retrograde contrast cystourethrogram is performed. A cystometrogram reveals an intact pelvic nerve; however, the urethral pressure profile reveals increased resistance.

Hormone-Responsive Incontinence

- There is a history of neutering and subsequent intermittent incontinence.
- Palpation commonly reveals a small bladder.
- Urinalysis may or may not show evidence of cystitis.
- Typically there is response to sex hormone supplementation.

▼ ***Key Point*** Urinary tract infection results in an exaggeration of the incontinence; if infection is present, resolve it before making a diagnosis of hormone-responsive incontinence.

Urethral Incompetence (Stress Incontinence)

- There is a history of intermittent incontinence when the animal is at rest or placed in a stressful situation.
- Palpation reveals a small bladder.
- The animal is able to urinate voluntarily.
- There is no evidence of infection on urinalysis.
- There are no radiographic abnormalities.

Urge Incontinence or Detrusor Hyperreflexia

- The bladder is small on physical examination.
- Cystometrography reveals involuntary smooth muscle contractions during the filling phase of micturition.

Contractions can be spontaneous or provoked but cannot be suppressed.
- Urodynamically, detrusor instability usually appears as a rapid, involuntary increase of >15 cm of water pressure during the filling phase of the cystometrogram. However, there is voluntary control of urination.
- In cases associated with cystitis, there may be a history of urine spraying or infection, and there is evidence of inflammation on urinalysis. A urine culture may be positive or negative.
- With cystitis, the bladder may be thickened on palpation, and a contrast cystourethrogram may reveal bladder wall thickening.
- In idiopathic detrusor hyperreflexia, there is no evidence of cystitis and no abnormalities on contrast cystourethrograms.

Detrusor Atony from Overdistention

- There is a history of continuous incontinence and urine outflow obstruction.
- Abdominal palpation reveals a large, flaccid bladder.
- Neurologic examination reveals intact perineal and bulbospongiosus reflexes, yet there is an absent or weak detrusor reflex.
- There is a large residual urine volume.
- Urodynamic studies may help rule out a neurogenic component.

Paradoxical Incontinence

- Base the diagnosis on the results of a urinalysis and of plain, and often contrast, radiographs.

Ectopic Ureters

- Most common cause of urinary incontinence in young female dogs.
- Breeds of dogs most commonly affected include Labrador retriever, Golden retriever, Siberian husky, Newfoundland, standard poodle, toy poodle, soft-coated wheaten terrier, and Skye terrier.
- There usually is a history of continuous incontinence with ability to urinate voluntarily. Usually a small bladder is revealed on abdominal palpation.
- On the physical examination, urine-soaked fur often is seen along the rear legs.
- Make a definitive diagnosis by uroendoscopy or contrast radiography (intravenous urography, retrograde vaginocystography, or contrast-enhanced CT).
- Perform uroendoscopy to identify the locations of the abnormal ureteral orifice(s) and any other anatomic malformations.

Pelvic Bladder

- Incontinence is usually intermittent.
- There are voluntary urinations.
- Involuntary urine dribbles from vulva or prepuce.
- Urine "soiling" of the perineum, prepuce, tail, or caudal thigh.
- Urine spots or pools are present where dog has been lying down.
- Degree of incontinence caused by a pelvic bladder often exceeds that seen with urethral incompetence.
- Contrast cystourethrography may be required for full identification of caudally displaced bladder and may demonstrate a short, widened urethra or a urethra with a prominently convoluted appearance.

TREATMENT

Individual Disorders

Individual disorders are discussed in terms of their treatment modalities. See Table 83-2 for details of treatment, including drug dosages.

▼ ***Key Point*** Urocystitis commonly is associated with micturition disorders. Treat the underlying infection as well as the individual disorders.

Lower Motor Neuron Bladder

- Manually express the bladder 3 or 4 times daily.
- Long-term therapy for this disorder has not been successful.
- Bethanechol may be administered to increase detrusor contractions. Side effects such as vomiting, diarrhea, salivation, and anorexia may limit the drug's usefulness.
- Complications include urine scalding, decubital ulcers, and recurrent urinary tract infections.
- Agents that have been used experimentally to treat an atonic or hypocontractile bladder include metoclopramide, which has been reported to directly stimulate detrusor contractions in humans and dogs, and prostaglandins E_2 and F_2, which have been shown to stimulate both detrusor and urethral smooth muscle.

Upper Motor Neuron Bladder

- Initially, it is difficult to express the bladder manually. Because of the risk of bladder rupture, do not attempt this until manual evacuation of the bladder is tolerable.
- Instead, aseptically catheterize the patient at least 3 times daily to completely empty the bladder. Avoid using an indwelling catheter because of the risk of urinary tract infections.
- Perform frequent urinalyses with culture and sensitivity testing.
- Antibacterial agents may be indicated, especially with long-term intermittent catheterization.

Detrusor-Urethral Dyssynergia

Treat by decreasing sympathetic tone or with muscle relaxants (see Table 83-2).

Table 83-2. PHARMACOLOGIC MANAGEMENT OF MICTURITION DISORDERS

Drug	Class	Indications	Dosage	Side Effects	Contraindications
Baclofen (Lioresal, Ciba-Geigy)	Skeletal muscle relaxant	Detrusor-urethral dyssynergia	Dogs: 1–2 mg/kg q8h PO	General muscle weakness Gastrointestinal upset	
Bethanechol chloride (Urecholine, Merck Sharp and Dohme)	Parasympatho-mimetic	Detrusor atony	Dogs: 2.5–30 mg/dog q8h PO Cats: 2.5–5.0 mg/cat q8h PO	Vomiting Diarrhea Salivation Anorexia	Urethral obstruction
Dantrolene (Dantrium, Norwich Eaton)	Skeletal muscle relaxant	Functional urethral obstruction due to increased external urethral tone	Dogs: 3–15 mg divided q8–12h PO	Generalized muscle weakness Hepatotoxicity	
Diazepam (Valium, Roche Products)	Skeletal muscle relaxant	Functional urethral obstruction due to increased external urethral tone	Dogs: 2–10 mg q8h PO	Sedation	
Dicyclomine (Bentyl, Marion Merrill Dow)	Anticholinergic, direct-acting smooth muscle relaxant	Detrusor hyperreflexia Urge incontinence Obstructive uropathy	Dogs/cats: 10 mg q6–8h PO	Diarrhea Sedation	Hyperthyroidism Cardiac disease Prostatic hypertrophy
Ephedrine (various brand names and manufacturers)	Alpha-adrenergic agonist	Urethral sphincter incompetence	Dogs: 5–15 mg q8h PO Cats: 2–4 mg q8h PO	Restlessness Hypertension Excitability	Hypertension
Estrogen (Diethylstilbestrol, various veterinary compounding pharmacies)	Female sex hormone	Hormone-responsive incontinence	Dogs: 0.1–1.0 mg/day for 3 days, then 1.0 mg once weekly PO	Induces signs of estrus Bone marrow toxicity	
Flavoxate (Urispas, SmithKline & French)	Anticholinergic, smooth muscle relaxant	Detrusor hyperreflexia Urge incontinence	Dogs/cats: 100–200 mg q12–24h PO	Increased intraocular pressure Tachycardia	Glaucoma
Imipramine (Tofranil, Geigy)	Tricyclic antidepressant	Urethral incompetence	Dogs: 1 mg/kg q8h PO Cats: 2.5–5.0 mg q12h PO	Tachycardia Tremors Hyperexcitability Seizures	
Oxybutynin (Ditropan, Marion Merrell Dow)	Anticholinergic, smooth muscle relaxant	Detrusor hyperreflexia	Dogs/cats: 5 mg q8–12h PO	Diarrhea Sedation	Hyperthyroidism Cardiac disease Prostatic disease
Phenoxybenzamine (Dibenzyline, SmithKline & French)	Alpha-adrenergic blocker	Functional outflow obstruction	Dogs/cats: 0.25–0.5 mg/kg q8h PO Dogs (alternate): 2.5–20.0 mg/day PO	Nausea Hypotension Increased intraocular pressure	Glaucoma Diabetes mellitus
Phenylpropanolamine (various brand names and manufacturers)	Alpha-adrenergic agonist	Urethral sphincter incompetence Hormone-responsive incontinence	Dogs: 1–2 mg/kg q12h PO Cats: 1 mg/kg q12h PO	Restlessness Hypertension	Hypertension
Prazosin (Minipress, Pfizer)	Alpha-adrenergic blocker	Functional outflow obstruction	Dogs: 0.5–2.0 mg q12–24h PO Cats: 0.5–1.0 mg q12–24h PO	Hypotension Syncope Nausea/vomiting Diarrhea	Glaucoma Diabetes mellitus Caution with concurrent phenobarbital or sulfonamides

Table 83-2. PHARMACOLOGIC MANAGEMENT OF MICTURITION DISORDERS—cont'd

Drug	Class	Indications	Dosage	Side Effects	Contraindications
Propantheline bromide (Pro-Banthine, Schiapparelli Searle)	Anticholinergic	Detrusor hyperreflexia Urge incontinence	Dogs: 7.5–30.0 mg q8–24h PO; start low Cats: 7.5 mg q24–72h PO	Vomiting Xerostomia Sedation Constipation Increased intraocular pressure	Glaucoma
Testosterone cypionate (DEPO-testosterone, Upjohn)	Male sex hormone	Hormone-responsive incontinence	Dogs: 1–2 mg/kg q2–4wk IM	Prostatic enlargement Male sexual characteristics	
Testosterone propionate	Male sex hormone	Hormone-responsive incontinence	Dogs: 0.5–1.0 mg/kg 2–3 times per week SC or IM	Prostatic enlargement Male sexual characteristics	

From Handbook of Small Animal Practice. New York: Churchill Livingstone, 1992. Reprinted with permission from Churchill Livingstone.

- Consider using alpha-adrenergic blocking agents, such as phenoxybenzamine, prazosin, and terazosin, to decrease internal sphincter resistance.
- In addition to its alpha-1 antagonism in urethral smooth muscle, prazosin can cause a centrally mediated decrease in somatic input to the external urethral sphincter.
- Consider diazepam and dantrolene as skeletal muscle relaxants to decrease external sphincter resistance.
- Baclofen is a skeletal muscle relaxant that decreases muscle tone by a depressive effect on the central nervous system (CNS). The drug inhibits medullary interneurons and spinal reflexes. Baclofen decreases muscle spasticity by reducing the activity of gamma-efferent neurons, which decrease the sensitivity of muscle spindles that initiate striated muscle stretch reflexes.

Hormone-Responsive Incontinence

Replacement of the sex hormone is necessary for successful treatment (see Table 83-2).

- Treat female dogs with diethylstilbestrol or an alpha-adrenergic agonist.

▼ ***Key Point*** Do not use estradiol cypionate because of the potential for bone marrow suppression.

- Testosterone cypionate may be used in male dogs. Minimal side effects have been noted except for prostatic enlargement.
- In some instances, animals develop a tolerance for hormonal replacement. Additional therapy with a sympathetic alpha-agonist that increases urethral tone is then indicated (see Table 83-2).

Urethral Incompetence (Stress Incontinence)

Treat with drugs that increase urethral tone (see Table 83-2).

- The most successful drugs are the sympathomimetic alpha-adrenergic agonists, which directly increase urethral smooth muscle tone. The drug of choice is phenylpropanolamine; an alternate drug is ephedrine.
- Imipramine is a tricyclic antidepressant agent that causes inhibition of norepinephrine reuptake at the synaptic level and results in increased urethral tone.

Urge Incontinence (Detrusor Hyperreflexia)

Treat with drugs that reduce detrusor hyperspasticity and relax smooth muscle (see Table 83-2).

- Flavoxate is an anticholinergic drug that decreases detrusor hyperspasticity. Start with the lowest possible dosage and slowly increase until signs are alleviated or side effects are encountered.
- Direct-acting smooth muscle relaxants are promising in the treatment of this syndrome. These drugs also have a mild anticholinergic effect. Recommended drugs include oxybutynin, dicyclomine, and propantheline bromide (marked anticholinergic effects).

Detrusor Atony from Overdistention

This is the single disorder in which indwelling urinary catheterization for up to 7 to 14 days is indicated to keep the bladder as small as possible in order to re-establish tight junction connections in the detrusor muscle. When indwelling catheterization cannot be accomplished, tube cystostomy is an alternative (see Chapter 80).

- Remove the obstruction or primary cause. Occasionally anti-inflammatory therapy is indicated.
- Perform frequent urinalyses and administer appropriate antibiotics based upon susceptibility results.
- The cholinergic drug bethanechol has been used successfully to stimulate detrusor contractions in both neurogenic and non-neurogenic atonic bladders (see Table 83-2). It is effective for postobstructive atony; however, be careful to ensure urethral patency.
- When the overdistension is caused by increased urethral resistance, administer an alpha-adrenergic blocker prior to giving the bethanechol.

Paradoxical Incontinence

Treat by relieving the obstruction. Retropulsion of calculi or urethrostomy or surgical exploration (e.g., for neoplasia) may be required (see Chapter 82).

- In some instances, indwelling catheterization may be indicated (e.g., severe urethritis) until the inflammation resolves.

Ectopic Ureter(s)

Treat by surgically re-establishing urine drainage into the bladder lumen (ureteral transposition or neoureterostomy (see Chapter 78).

- Ectopic ureters are often associated with other urinary tract abnormalities (urethral incompetence) that may be treated with alpha-adrenergic agonists.

Endoscopic Injections

Teflon

Teflon injections have been used clinically and experimentally for the treatment of urethral sphincter incompetence in dogs. A Teflon paste is injected endoscopically into urethral and periurethral tissues. This procedure inflates the tissues and compresses the urethral lumen at the site of injection.

Collagen

Collagen-based agents have supplanted Teflon products. Submucosal implantation of glutaraldehyde cross-linked collagen has had good results. One study found 75% of collagen-treated dogs becoming continent after one or two injections, with no complications.

▼ ***Key Point*** Consider collagen implantation for dogs that are not responsive to pharmacologic treatment. Also consider collagen implantation for dogs that continue to be incontinent after surgical correction of ectopic ureters.

Surgical Techniques

Several surgical treatments for incontinence have been described in the veterinary literature and include sling urethroplasty, colposuspension, and urethral compression (cystourethropexy or urethral banding). Surgery for disorders of the urinary system and micturition are discussed elsewhere in this text (see Chapters 78, 80, and 82).

Chapter

84 Diseases of the Prostate Gland

Nancy D. Kay

Diseases of the prostate gland are common in middle-aged and older dogs. Medium- and large-breed dogs (especially Doberman pinschers) are more commonly affected. Although cats have prostate glands, for unknown reasons feline prostatic disease is extremely rare. This chapter discusses canine prostatic disease only.

ETIOLOGY

Several types of prostatic disease exist and some may occur simultaneously (e.g., prostatic cyst with abscessation or prostatic neoplasia with bacterial prostatitis).

Benign Prostatic Hyperplasia

To some degree, both hypertrophy (increased size) and hyperplasia (increased numbers) of prostatic cells account for enlargement of the gland in all middle-aged and older non-castrated dogs.

▼ ***Key Point*** Benign prostatic hyperplasia is the most common disorder of the prostate gland.

- Causes of benign prostatic hyperplasia include an imbalance in the ratio of androgens to estrogens, increased numbers of androgen receptors, and increased tissue sensitivity to androgens.
- Dihydrotestosterone is the main androgen that promotes prostatic hyperplasia.

Squamous Metaplasia

This morphologic alteration of prostatic epithelial cells is caused by estrogen stimulation arising from an exogenous or endogenous (e.g., Sertoli cell tumor) source.

Cystic Hyperplasia

This condition refers to multiple fluid-filled cavities within the prostatic parenchyma that result from the obstruction of glandular excretory ducts.

- Cystic hyperplasia commonly is associated with benign prostatic hyperplasia and squamous metaplasia.

Paraprostatic Cyst

These fluid-filled structures develop adjacent to the prostate gland and result from fluid accumulation within embryologic vestiges (uterus masculinus). The cystic lining may become calcified.

Prostatic Infection

- Bacterial prostatitis occurs when normal host resistance is altered.
- Predisposing causes include disruption of normal glandular architecture (benign hyperplasia, squamous metaplasia, neoplasia, parenchymal cysts), urethral diseases, urinary tract infections, alterations in urine flow, altered prostatic secretions, and host immune dysfunction.
- Infection usually occurs by an ascending route, although hematogenous spread of bacteria also may occur.
- The most common pathogens are *Escherichia coli, Staphylococcus, Proteus mirabilis, Streptococcus,* and *Mycoplasma.* Less common isolates include *Klebsiella, Brucella canis, Pseudomonas,* and *Ureaplasma.* Anaerobic infections are rare.
- In rare cases, disseminated (systemic) mycotic infections, such as *Blastomyces, Cryptococcus,* or *Coccidioides,* can cause prostatitis (see Chapter 20).

Idiopathic Prostatitis

Idiopathic (non-bacterial) prostatitis has been documented in dogs.

- Clinical signs are similar to those associated with chronic bacterial prostatitis.
- The etiology of the inflammation is uncertain.

Prostatic Abscess

Prostatic abscesses are either extensions of bacterial prostatitis in which obstruction of an excretory duct has occurred or secondary infection of a preexisting cyst.

Prostatic Neoplasia

Neoplasia is relatively rare compared with other forms of canine prostatic disease.

- Prostatic adenocarcinoma and transitional cell carcinoma are most common.
- Previously, castration was thought to prevent the development of prostatic cancer. In one study, 19 of 43 dogs had been castrated at least 3 years before the development of prostatic disease. More recent studies have also concluded that castration at any age has no sparing effect on the development of prostate cancer. Tumors from neutered dogs tend to be more highly undifferentiated and often metastasize to the lung. This may reflect a more aggressive neoplastic process or delayed detection of the disease.
- Development of prostatic cancer in dogs may not be hormonally mediated or may be influenced by hormones of non-testicular origin. Hormones produced by the adrenal and pituitary glands may play a significant role.
- Metastasis is common. Frequent sites of metastasis include lymph nodes (regional and distant), bones (near and distant), and visceral organs.

CLINICAL SIGNS

Clinical signs associated with canine prostatic disease are variable. Depression, anorexia, and vomiting are systemic manifestations of bacterial prostatitis or prostatic abscessation. Other clinical signs do not correlate well with etiology (Table 84-1). Hematuria and blood dripping from the prepuce are the most frequent signs seen with most types of prostatic disease. In animals with uncomplicated benign prostatic hyperplasia, however, clinical signs frequently are absent until prostatomegaly becomes severe.

- *Hematuria* is caused by reflux of blood from the prostatic urethra into the bladder. It also may be associated with a concurrent bacterial cystitis.
- *Urethral discharge* results from the exudation of blood, pus, and/or prostatic fluid into the prostatic urethra. This fluid drips passively from the penile urethra and is often blood tinged.
- *Stranguria* is present if partial or complete urethral obstruction results from prostatic enlargement.
- *Fecal tenesmus* or a *change in stool diameter* occurs when prostatic gland enlargement encroaches on the rectum. *Constipation* may be secondary to avoidance of pain associated with defecation.
- *Fever, depression, anorexia, vomiting,* and *diarrhea* are signs of systemic involvement and are most commonly associated with bacterial prostatitis or prostatic abscessation.
- *Recurrent urinary tract infection* in a male dog may be associated with non-resolving or recurrent bacterial prostatitis.
- *Abdominal distention* may be caused by a paraprostatic cyst or prostatic abscess.
- *Caudal abdominal pain, lumbar pain,* and/or *hind limb stiffness* may be associated with metastasis of prostatic neoplasia to bone or muscle or with peritonitis associated with prostatic abscess.
- *Hypertrophic osteopathy* may occur secondary to prostatic disease such as tumors.
- *Hind limb pitting edema* may occur secondary to lymphatic invasion by metastatic tumors.
- *Urinary incontinence* can be caused by impingement on the pelvic nerves by an adjacent prostatic mass (tumor or abscess) or from inflammation of the urethra from urinary tract infection.
- Other clinical conditions that may be associated with prostatic disease include *impaired libido, infertility, sepsis, ketoacidotic diabetes mellitus, perineal hernia,* and *testicular tumor.*

DIAGNOSIS

Localizing and defining the etiology of diseases of the prostate gland can be a challenging task. Until recently, few diagnostic techniques have combined reliability and

Table 84-1. INCIDENCE OF CLINICAL SIGNS ASSOCIATED WITH PROSTATIC DISEASE

Prostatic Disease (No. of Cases)*	Hematuria	Blood Dripping from Prepuce	Stranguria	Tenesmus	Depression/ Anorexia	Vomiting	Diarrhea	Abdominal Pain	Hind Limb Deficit	Chronic UTI
Bacterial prostatitis (12)	4	3	2	2	3	2	2	1	0	2
Nonbacterial prostatitis (7)	1	2	0	0	0	0	0	1	0	3
Hyperplasia (16)	7	6	1	1	0	0	1	0	0	4
Neoplasia (4)	3	3	2	3	0	0	0	0	1	0
Squamous metaplasia (2)	2	0	1	0	0	0	0	0	0	1

*Some prostate glands were affected by more than one disease process.
UTI, urinary tract infection.
Kay ND, Ling GV, Johnson DL: Clinical diagnosis of canine prostatic disease using a urethral brush technique. J Am Anim Hosp Assoc 25:517–526, 1989.

specificity of results with safety and ease of application. The ideal method for the diagnosis of prostatic disease should localize the disease to the prostate gland and eliminate other parts of the urinary and reproductive tracts as sources of the disease.

Physical Examination

Abdominal palpation in dogs with prostatic disease may reveal abdominal pain, abdominal distention, or the presence of an abdominal mass.

▼ ***Key Point*** A rectal examination is essential in the diagnosis of prostatic disease.

- In rectal examination, palpate ventrally for the prostate gland and dorsally for iliac lymph node enlargement or lumbar pain.
- Evaluate the prostate gland for location, size, symmetry, surface contour, consistency, movability, and pain. The normal prostate gland is bilobed, intrapelvic, symmetric, smooth, movable, and non-painful.
- As the prostate gland enlarges with disease, it may move cranially over the pelvic brim. Therefore, simultaneous rectal and caudal abdominal palpation may be helpful.

▼ ***Key Point*** The prostate gland of a normal Scottish terrier may be up to 4 times larger than those of other breeds.

Imaging Studies

Abdominal Radiography

Abdominal radiography rarely determines the specific etiology of prostatic disease, but it can reveal various associated abnormalities, including the following:

- Prostatomegaly
- Prostate gland asymmetry
- Abnormal fluid-filled mass in the caudal abdomen
- Prostate gland mineralization
- Iliac lymph node enlargement
- Vertebral or pelvic bone periosteal reactions
- Decreased soft tissue detail in the caudal abdomen due to tissue inflammation
- Urine or fecal retention

▼ ***Key Point*** Prostate gland mineralization and iliac lymph node enlargement are often but not always associated with prostatic neoplasia.

Urethrography

Positive-contrast retrograde urethrography may help localize the disease process. However, there is no correlation between the urethroprostatic reflux and the type of prostatic disease. Reflux may be observed in some dogs without prostatic disease.

Ultrasonography

Ultrasonography can be used to evaluate the prostate location, size, and architecture and to guide percutaneous needle aspiration or needle core biopsy. Ultrasound observations may include the following:

- Prostatomegaly
- Intraprostatic cyst or abscess (appears as focally hypoechoic or anechoic)
- Paraprostatic cyst
- Focal or multifocal areas of increased echogenicity (may represent bacterial prostatitis or neoplasia)
- Shadowing (may represent bacterial prostatitis or neoplasia)
- Prostatic calculi
- Iliac lymphadenopathy

Laboratory Studies

Complete Blood Count and Serum Biochemistry

- Hemogram abnormalities do not consistently correlate with the occurrence of infectious or noninfectious prostatic diseases. An exception is neutrophilic leukocytosis, which is consistently associated with acute, fulminant bacterial prostatitis.
- A mild to moderate nonregenerative anemia may occur in chronic inflammatory or neoplastic prostatic disease.
- An increase in serum alkaline phosphatase commonly accompanies bacterial prostatitis and prostatic neoplasia. It is not known which alkaline phosphatase isoenzyme is responsible.

Urinalysis and Urine Culture

- Bacterial cystitis and bacterial prostatitis may occur independently.
- Urinalysis and urine culture are always indicated for animals with signs of urinary tract disease. However, they may not be useful in the diagnosis of prostatic disease.
  - For example, urine sediment examination is not reliable for the diagnosis of prostatic neoplasia, and urine cultures can be negative in dogs with bacterial prostatitis or prostatic abscess.
  - For this reason, in addition to urine, evaluate prostatic fluid, prostatic tissue, or both in dogs suspected of prostatic disease.

Prostatic Fluid or Tissue Culture

This procedure is necessary for documentation of bacterial prostatitis. *Mycoplasma* organisms require specialized culture media (pleuropneumonia-like organism [PPLO] agar); therefore, specifically request this culture (see "Specimen Collection" for techniques for collection of microbiology specimens).

Prostatic Fluid Cytology

Cytologic studies may identify benign prostatic hyperplasia, squamous metaplasia, bacterial prostatitis, nonbacterial prostatitis, and prostatic neoplasia (see "Specimen Collection" for techniques for collection of cytology specimens).

Serum and Seminal Plasma Markers

- Prostate-specific antigen is not detected in canine serum or seminal plasma.
- Serum and seminal acid phosphatase activities do not differ between normal and diseased dogs.
- Serum canine prostate–specific esterase activity is higher in dogs with benign prostatic hyperplasia than in normal dogs.

Specimen Collection

Ejaculate Specimen

For ejaculate collection, handle the dog in a quiet environment. Many dogs are more responsive if exposed to a female in estrus or to vaginal swabs obtained from a female in estrus (Table 84-2).

Advantages

- It is relatively easy to perform.
- It is safe.
- It can be done without chemical restraint.
- It is inexpensive.
- It provides specimens for bacterial culture.

Disadvantages

- Success depends on the animal's compliance, which may be diminished if the animal is old, ill, weak, nervous, overexcited, or in pain.
- It is difficult to effectively separate the prostatic fluid component from the presperm and sperm components.
- A positive bacterial culture fails to localize the disease process. Potential sources of infection include the testes, epididymides, deferent ducts, prostate gland, and urethra. A distal urethral culture with quantitation of organisms collected before ejaculation is useful in interpreting ejaculate specimen culture results.
- The ejaculate specimen is not useful for cytology.

Table 84-2. TECHNIQUE FOR COLLECTION OF EJACULATE SPECIMEN

1. Retract the prepuce and gently cleanse the tip of the glans penis with a sterile gauze sponge.
2. Apply digital pressure with one hand at the base of the penis proximal to the bulbus glandis.
3. With the other hand, manipulate the penis within the sheath.
4. Collect the specimen in a sterile container.
5. The first two components of the ejaculate (presperm and sperm) are milky in appearance. Separate these from the third component, which is clear prostatic fluid, by collecting into two different sterile containers.
6. Perform a bacterial culture on the prostatic fluid.

Prostatic Wash Specimen

A prostatic wash specimen has potential microbiologic and cytologic applications (Table 84-3).

Advantages

Advantages of this technique are similar to those of ejaculate specimen collection.

Disadvantages

- Results may be inaccurate due to urine and urethral contamination, as well as volume dilution by urine. Microbiology results are non-interpretable in cases with concurrent bacterial cystitis.
- The prostate gland may not be within reach for effective rectal massage (abdominal prostatic massage may be effective).
- Overzealous massage can rupture a prostatic abscess or cause sepsis in dogs with acute bacterial prostatitis.

Urethral Brush Specimen (Figs. 84-1 and 84-2)

This technique uses a 90-cm microbiology specimen brush designed for bronchoscopic use (Microbiology Specimen Brush, Microvasive; Watertown, MA) (Table 84-4).

Advantages

Advantages of this technique are similar to those of ejaculate specimen collection and prostate wash, *plus the following:*

- The disease process is localized to the prostate gland; urethral contamination is minimized because of the plug in the tip of the catheter.

Table 84-3. TECHNIQUE FOR PERFORMING PROSTATIC WASH

1. Pass a urethral catheter into the bladder and remove all urine.
2. Flush the bladder with 5 ml of sterile physiologic saline solution and save the fluid. Label this specimen Sample 1.
3. Retract the catheter tip and align it with the caudal pole of the prostate gland (positioning is determined via rectal palpation).
4. Massage the prostate gland for 1 minute.
5. Flush 5 ml of sterile physiologic saline solution slowly through the catheter while the urethral orifice is occluded around the catheter to prevent retrograde loss of sample.
6. Advance the catheter into the bladder as the fluid is aspirated. Save the fluid and label it Sample 2.
7. Quantitate bacterial numbers in both specimens to ascertain the significance of bacterial growth in the prostatic fluid specimen (Sample 2).

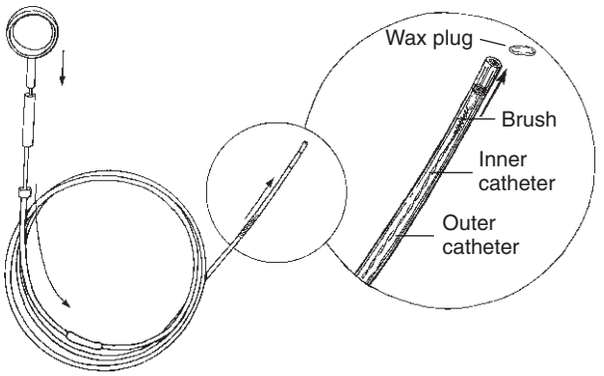

Figure 84-1. The microbiologic specimen brush used for obtaining prostatic urethral specimens.

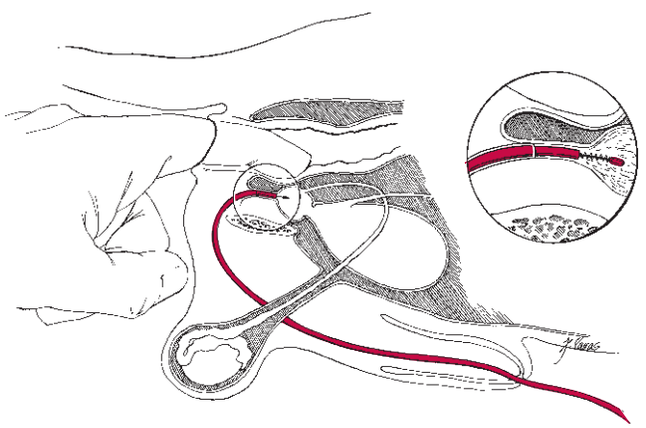

Figure 84-2. With the catheter positioned in the prostatic urethra, advance and retract the brush 5 or 6 times *(inset)*.

Table 84-4. TECHNIQUE FOR OBTAINING URETHRAL BRUSH SPECIMEN

1. Place the animal in lateral recumbency.
2. Retract the prepuce and cleanse the end of the glans penis with a sterile swab.
3. Advance a sterile, 90-cm microbiologic specimen brush (Microbiology Specimen Brush, Microvasive; Watertown, MA) into the urethra (see Fig. 84-1).
4. Direct an assistant to use rectal palpation to align the tip of the catheter with the caudal pole of the prostate gland (see Fig. 84-2). The catheter is then held in this position.
5. Have the assistant massage the prostate gland per rectum for 1 minute.
6. Advance the inner catheter approximately 1 cm within the urethra, thereby dislodging the absorbable catheter plug (see Fig. 84-1).
7. Advance and retract the microbiologic brush 5 or 6 times within the prostatic urethra for sample collection (see Fig. 84-2).
8. Following sample collection, retract the brush and inner catheter and remove the apparatus from the urethra.
9. Expel any fluid within the catheter into a test tube containing 3 ml of sterile lactated Ringer's solution.
10. Extend the brush, remove with sterile scissors, and drop into the same test tube.

- Useful cytologic and microbiologic information is obtained.

Disadvantages

- The specimen brush cannot be reused, which makes the procedure relatively expensive.
- The prostate gland may not be within reach for effective rectal massage (prostate massage through the abdominal wall is typically not effective).
- Overzealous massage can rupture a prostatic abscess or cause sepsis in dogs with acute bacterial prostatitis.

Ultrasound-Guided Prostatic Aspirate

This technique uses ultrasonography to guide the insertion of a needle into the prostate gland. Its documented use is for the diagnosis of bacterial infection and possibly neoplasia.

Advantages

- It is a safe procedure in non-infectious conditions.
- It accurately localizes the source of bacterial infection to the prostate gland.

Disadvantages

- Specialized equipment and skills are required.
- Chemical restraint usually is necessary.
- Aspiration of a prostatic abscess has the potential to result in peritonitis; seeding of the abdomen with neoplastic cells may occur with prostatic neoplasia.

Prostate Gland Biopsy

- Before performing biopsy, evaluate the animal for normal coagulation status.
- Several techniques have been described for prostate biopsy, including transperineal, transrectal, transabdominal, and ultrasound-guided biopsy and biopsy via laparotomy or laparoscopy (see Chapter 85).
- Ultrasound-guided prostate gland biopsy uses ultrasonography to assist in directing the biopsy instrument into the gland.
- The frequency of complications is less than with some other biopsy techniques, and the success of obtaining a definitive diagnosis is enhanced because focal lesions can be identified ultrasonographically.
- Chemical restraint, as well as specialized skill and equipment, are necessary.
- If ultrasonography is not available, biopsy via laparotomy is the most accurate, although the most invasive, technique.

- Several complications from prostate gland biopsy are possible (Table 84-5).

TREATMENT

Treatment of canine prostatic disease is based on the specific diagnosis. Conservative management (castration and drug therapy) of canine prostatic disease is discussed in this chapter. Surgical management of prostatic disease is discussed in Chapter 85.

Benign Prostatic Hyperplasia and Sterile Cystic Hyperplasia

Therapy may not be indicated if clinical signs are absent. However, it is advisable to caution owners that problems associated with prostatomegaly may develop.

Descriptions of various treatment modalities follow.

Castration

- Castration (see Chapter 87) is the treatment of choice in dogs not intended for breeding.
- A significant decrease in prostate gland size occurs within 1 to 4 weeks following castration.

Estrogen Therapy

- Theoretically, estrogen acts to decrease prostatic tissue mass by decreasing the concentration of gonadotropin-releasing hormone, which, in turn, decreases the concentration of testosterone. However, estrogen may act directly on the prostate gland to cause stromal hypertrophy and squamous metaplasia.
- It also may alter prostatic secretions and increase the gland's susceptibility to infection.
- Bone marrow suppression is a potential serious side effect.

▼ ***Key Point*** Because of potentially serious side effects, estrogen is contraindicated for the treatment of benign prostatic hyperplasia.

Megestrol Acetate

- Megestrol acetate interferes with the conversion of testosterone to dihydrotestosterone, the main androgen that promotes prostatic hyperplasia. This drug is also thought to increase metabolic clearance of androgens, as well as cause direct pituitary suppression.

▼ ***Key Point*** Megestrol acetate effectively decreases the size of the prostate gland without impairing fertility in cases of benign prostatic hyperplasia.

- Administer 0.55 mg/kg q24h PO for 4 weeks; then give the same dosage once a week. Do not use for longer than 32 consecutive days.
- This drug reportedly produces a decrease in the size of the prostate gland without decreasing the number of spermatozoa. Thus, a treated animal subsequently may be used for breeding purposes.

Finasteride

- Finasteride is an azasteroid that inhibits activity of the enzyme 5-alpha-reductase, which therefore prohibits the conversion of testosterone to dihydrotestosterone.
- Finasteride is reported to cause a decrease in prostatic size of 48% to 70% by 8 to 12 weeks of treatment.
- Administer 0.1 to 1 mg/kg/day (one 5-mg tablet daily for dogs weighing 5–50 kg). The optimum duration of therapy is unknown.
- Neither side effects nor decreased fertility have been reported.

▼ ***Key Point*** Finasteride has been reported to effectively decrease the size of the prostate gland without impairing fertility in cases of benign prostatic hyperplasia.

Delmadinone Acetate

- Delmadinone acetate (Tardak, Pfizer) is an androgen inhibitor licensed for use in dogs in some countries other than the United States and Canada.
- It is recommended for the treatment of benign prostatic hyperplasia, perianal tumors, and hypersexuality.
- Delmadinone acetate is administered SC or IM at doses of 1.5 to 2.0 mg/kg for dogs less than 10 kg, 1.0 to 1.5 mg/kg for dogs 10 to 20 kg, and 1.0 mg/kg for dogs greater than 20 kg; subsequent doses in 3- to 4-week intervals usually are necessary.
- Effects are observed within 2 to 4 days. A second treatment is recommended at 8 days if no improvement is noted.
- Concurrent use of other steroid drugs should be avoided, and this drug is contraindicated in dogs with a history of decreased fertility or lack of libido if they are to be used for breeding.

Other Hormone-Manipulating Drugs

New drugs, which work either by lowering serum testosterone (flutamide), blocking conversion of testosterone

Table 84-5. COMPLICATIONS ASSOCIATED WITH PROSTATE GLAND BIOPSY

Periprostatic hemorrhage	Hematuria
Perineal hematoma	Septicemia
Urethral perforation	Fever
Perineal abscessation	Peritonitis
Dissemination of neoplastic cells	Urethral fistula formation

to dihydrotestosterone (finasteride), or decreasing gonadotropin-releasing hormone (leuprolide) may show promise in the future for treating benign prostatic hypertrophy. However, minimal information is currently available regarding use of these drugs in dogs.

Squamous Metaplasia

- Discontinue any source of exogenous estrogen.
- Castration is the treatment of choice. Examine the testicles histopathologically for the presence of an estrogen-secreting Sertoli cell tumor.

Bacterial Prostatitis

Principles of Antibiotic Therapy

See Table 84-6 for specific drugs and dosages.

- Select an antibiotic based on urine or prostatic fluid culture and susceptibility results.

▼ ***Key Point*** The ideal antibiotic for bacterial prostatitis is lipid soluble and therefore capable of penetrating the blood-prostate barrier. Antibiotics of choice include erythromycin, chloramphenicol, trimethoprim-sulfa, clindamycin, oleandomycin, and enrofloxacin.

- The ideal antibiotic has a relatively low degree of protein binding, which allows greater drug availability for diffusion into the prostate gland. Chloramphenicol is highly protein bound; therefore, it should be used at the higher end of the recommended dosage range (see Table 84-6).
- In cases of bacterial prostatitis, the pH of the prostatic fluid is usually acidic. Antibiotics that work best in an acidic environment are erythromycin, enrofloxacin, clindamycin, trimethoprim-sulfa, and chloramphenicol. Ciprofloxacin and norfloxacin do not appear to penetrate into the prostate gland as readily as enrofloxacin.
- Continue antibiotic therapy for a minimum of 4 weeks. Reculture the prostatic fluid 5 to 7 days after the onset of therapy to document the in vivo effectiveness of the antibiotic and again in 2 to 3 weeks following discontinuation of therapy.
- If initial culture and susceptibility results cannot be obtained, a good initial treatment choice is trimethoprim-sulfa, chloramphenicol, or enrofloxacin.

Table 84-6. ANTIBIOTICS RECOMMENDED FOR THE TREATMENT OF BACTERIAL PROSTATITIS

Drug	Dosage
Trimethoprim-sulfa (multiple manufacturers)	15 mg/kg q12h PO or SC
Chloramphenicol (multiple manufacturers)	50 mg/kg q8h PO, IV, SC, or IM
Erythromycin (multiple manufacturers)	10 mg/kg q8h PO
Clindamycin (Antirobe, Upjohn)	5–10 mg/kg q8h PO, IV, or IM
Enrofloxacin (Baytril, Bayer)	5 mg/kg q12h PO*

*This is twice the manufacturer's current recommended dosage.

Treatment of Concurrent Septicemia or Peritonitis

- Evaluate the patient for abdominal effusion.
- Obtain abdominal fluid and/or blood for bacterial culture and susceptibility testing and select an appropriate antibiotic.
- Obtain a blood specimen for bacterial culture and susceptibility.
- Monitor the patient for hypoglycemia.
- Administer IV fluids and parenteral antibiotics.
- If a prostatic abscess is thought to be the source of septicemia, surgical drainage of the abdomen and treatment of the prostate is indicated (see Chapter 85).
- Treat peritonitis as described in Chapter 76.

Castration

Castration diminishes the potential for recurrence of bacterial prostatitis, but do not perform castration until the patient is clinically stable and has been on antibiotic therapy for at least 1 to 2 weeks. Rule out a prostatic abscess or paraprostatic cyst, because castration alone typically is not curative for these conditions.

Idiopathic Prostatitis

- Because idiopathic prostatitis in dogs has only recently been described and the etiology is unknown, effective therapy has not been reported. Castration is likely to be beneficial.
- Treatment of idiopathic prostatitis in humans has included tetracycline, corticosteroids, anticholinergic drugs, and muscle relaxants. No consistently positive results have been reported.

Paraprostatic Cysts and Prostatic Abscesses

- Medical therapy consists of antibiotics if infection is present and treatment of concurrent septicemia, peritonitis, or hypoglycemia.
- Paraprostatic cysts and prostatic abscesses are indications for surgical therapy (see Chapter 85).

Prostatic Neoplasia

Multiple therapeutic modalities exist; however, the prognosis in cases of prostatic neoplasia is poor.

Radiation Therapy

- Intraoperative radiation therapy is currently the treatment of choice. It is well tolerated by the patient and has few side effects.
- Radiation therapy is not indicated if metastasis is detected. The most common site for metastasis is the iliac lymph nodes. Other sites include lungs, omentum, mesentery, pelvis, and lumbar vertebrae.

Prostatectomy

Prostatectomy (see Chapter 85) is associated with a high rate of complications including urinary incontinence and urethral stricture and is typically not offered as a treatment.

Noninvasive Ultrasonic Subtotal Ablation

This experimental technique uses high-intensity, focused ultrasound to ablate the prostate gland without damaging surrounding tissues.

Chemotherapy

No known protocols have any documented efficacy.

Castration

Castration is of questionable benefit. The cancer growth may not be hormonally mediated, or it may be affected by non-testicular hormones (adrenal androgens or estrogens, luteinizing hormone [LH], follicle-stimulating hormone [FSH], prolactin, or growth hormone).

Estrogen Therapy

Estrogen therapy suppresses gonadotropin secretion by the pituitary gland, which, in turn, decreases the level of testicular testosterone secretion. As with castration, non-testicular hormones are unaffected.

Total Androgen Blockade

The advantage of a total androgen blockade over castration is that all sources of androgen production are affected rather than just testicular androgens.

- Luteinizing hormone-releasing hormone (LH-RH) agonists cause a transient rise followed by a paradoxical decrease in FSH, LH, and testosterone release. This decrease may be due to down-regulation of, or a decrease in, the number of pituitary LH-RH receptors. There is minimal information about use of these drugs in veterinary medicine.
- Ketoconazole (see Chapters 20 and 33 for details of ketoconazole therapy) inhibits testicular and adrenal testosterone synthesis and decreases the testosterone level to that of a castrated dog in 24 to 48 hours. The dosage range in humans is 400 to 1200 mg/day. Currently, a dosage for the treatment of canine prostatic neoplasia has not been determined, but dosages reported in limited studies vary from 20 to 30 mg/kg/day PO.
  - Ketoconazole has been shown to have a significant effect on hormonal production by the adrenal gland in the treatment of canine hyperadrenocorticism at an oral dose of 30 mg/kg once daily or divided twice daily. A similar dosage may be effective in the treatment of canine prostatic neoplasia.
  - Dosages of 10 to 30 mg/kg/day are tolerated by most dogs when used for antifungal therapy.

Chapter 85

Surgery of the Prostate Gland

Harry W. Boothe

Surgical procedures of the prostate gland include biopsy, drainage procedures (including ultrasound-guided percutaneous needle drainage, drain tube placement, omentalization, and marsupialization), and resection procedures (partial or complete resection of prostatic cysts and partial or complete prostatectomy). Perform orchidectomy of the patient with prostatic disease either before or at the time of prostatic surgery (see Chapter 87 for castration technique). Prostatic disorders that may require surgery include hyperplasia, trauma, infection (abscess), cyst formation, and neoplasia. A thorough understanding of prostatic anatomy is necessary before performing surgery. Information in this chapter refers only to the dog because prostatic disease is extremely rare in cats. See Chapter 84 for additional information on prostatic diseases.

ANATOMY

- The prostate gland completely encompasses the proximal portion of the male urethra at the neck of the bladder.
- The position of the prostate is age dependent; the prostate is confined to the pelvic cavity until about 4 years of age and is essentially totally within the abdomen by 10 years of age.
- The dorsal prostatic surface is flattened and has a mid-dorsal sulcus. The gland has a relatively thick capsule and is divided into right and left lobes by a prominent median septum.
- The two deferent ducts enter the craniodorsal surface of the prostate.
- The blood supply is closely allied to the nerve supply, with both being located in the lateral pedicles and entering the prostate dorsolaterally. The prostatic artery gives off branches to the ductus deferens, urethra, urinary bladder, ureters, and rectum. Damage to branches of the prostatic artery may result in devascularization of surrounding structures.
- The hypogastric (sympathetic) and pelvic (parasympathetic) nerves follow the vasculature.

▼ ***Key Point*** The hypogastric and pelvic nerves are required for micturition and continence. Avoid iatrogenic trauma to these structures.

- The prostatic lymph vessels empty into the median iliac lymph nodes.

BIOPSY

Preoperative Considerations

- Accurate preoperative assessment of prostatic size, consistency, and location is important. Palpation (both rectal and abdominal), radiography (including contrast radiography), and ultrasonography are helpful in gaining this information. Ultrasound can also be used to assist in obtaining fine needle aspirates of the prostate (see Chapter 84).
- Adequate immobilization of the prostate gland during biopsy is indicated, particularly when using needle biopsy techniques.

▼ ***Key Point*** Perform aspiration of the prostate before needle biopsy to exclude abscessation.

Procedure for Percutaneous Needle (Punch) Biopsy

Objectives

- Obtain a representative sample of the prostate gland for histologic and microbiologic evaluation.
- Avoid entering the prostatic urethra.
- Minimize blood loss and potential dissemination of infection.

Equipment

- Tru-Cut or similar type of biopsy needle (one-handed model) or Franklin-Silverman needle
- Scalpel blade and handle

Technique

1. Place the dog in sternal recumbency with the tail positioned over the back.
2. Prepare the perineal region from the base of the tail to ventral to the level of the ischial tuberosities.
3. Direct an assistant to exert gentle pressure on the caudal abdomen to move the prostate gland into the pelvic inlet.

4. Perform rectal examination to define the position of the prostate gland.
5. Incise the perineal skin (5 mm long) just off the midline midway between the anus and the ischial tuberosity.
6. Insert the biopsy needle in the closed position through the prostatic capsule under digital control within the rectum by the other hand.
7. Fully insert the inner cannula into the prostate gland and, while holding the inner cannula stationary in its extended position, sharply advance the outer cannula over the inner rod.
8. Remove the biopsy needle in a closed position.
9. Verify that an adequate biopsy has been obtained by seeing prostatic tissue in the specimen notch.
10. Place the biopsy sample in the appropriate containers for histologic and microbiologic testing.

Surgical Procedure: Wedge Biopsy

Equipment

- Standard general surgical pack and suture
- Laparotomy sponges
- Balfour retractors

Technique

1. Place the dog in dorsal recumbency on a level surgery table.
2. Aseptically prepare the ventral abdominal region from the xiphoid process to caudal to the pubic brim.
3. Incise the skin and ventral abdominal wall from the umbilicus to the pubis while avoiding the prepuce. Use a midline abdominal approach. Alternately, a paramedian approach to the caudal abdomen can be used.
4. Gently retract the urinary bladder cranially using a stay suture. Isolate the prostate gland with moistened laparotomy sponges.
5. Excise a representative wedge of prostatic tissue, while avoiding the urethra on the midline and the dorsolateral aspect of the prostate gland, using a scalpel blade.
6. Close the prostatic defect (simple interrupted or continuous pattern, absorbable suture).
7. Routinely close the ventral abdominal incision in three layers.

Postoperative Care and Complications

Short Term

- Closely monitor for hemorrhage, including hematuria, infection, and urine leakage.
- Monitor for postoperative orchitis and scrotal edema.

Prognosis

- The prognosis depends on the disease process(es) present.
- Prostatic biopsy is usually associated with minimal patient morbidity.

DRAINAGE PROCEDURES

Preoperative Considerations

- Perform ultrasonography to determine the degree and location of cavitation within the prostatic parenchyma.
- Distinguish between infectious and non-infectious causes of fluid retention within or near the prostate gland.
- Perform microbiologic testing of prostatic fluid to assist in selection of an antimicrobial agent.
- When prostatic abscessation is present, drainage, omentalization, or resection of diseased parenchyma is indicated.
- Perform orchidectomy before or at the time of a prostatic drainage procedure.

▼ ***Key Point*** Always biopsy and obtain culture samples from the prostate as part of the drainage procedure.

- Choice of drainage procedure (i.e., ultrasound-guided percutaneous needle drainage, placement of drain tubes, omentalization, or marsupialization) depends on the size and location of prostatic cavitation. Large cystic lesions may be more amenable to partial resection and omentalization.

Objectives

- Thoroughly evacuate cavitary lesion(s).
- Create a common cavity to provide ventral drainage (surgical drainage).
- Thoroughly lavage the cavity at the time of drainage (surgical drainage).
- Avoid entering the prostatic urethra if possible.
- Minimize blood loss and dissemination of infection.

Procedure for Ultrasound-Guided Percutaneous Drainage

Equipment

- Ultrasound unit with a 7.5- or 8.5-MHz transducer (see Chapter 4)
- 22-gauge spinal needle, extension set, and syringe

Technique

1. Place the dog in dorsal or lateral recumbency (use sedation or anesthesia).
2. Aseptically prepare the abdominal region.
3. Examine the prostate ultrasonographically in both sagittal and transverse planes using a prepubic approach.
4. Measure and record prostatic size and appearance and any cavitary lesions.

5. Insert the needle using ultrasound guidance and completely drain the cavitary lesion(s).
6. Submit fluid samples for cytologic and microbiologic testing.

Surgical Procedure: Omentalization

Equipment

- Standard general surgical pack and suture
- Penrose drain(s)
- Suction apparatus, tubing, and tip
- Laparotomy sponges
- Balfour retractors

Technique

1. Place the dog in dorsal recumbency. Catheterize the urethra.
2. Aseptically prepare the ventral abdominal region from the xiphoid process to caudal to the pubic brim.
3. Incise the skin and ventral abdominal wall from the umbilicus to the pubis while avoiding the prepuce.
4. Isolate the prostate from the rest of the peritoneal cavity, using laparotomy sponges.
5. Incise the lateral aspects of each prostatic lobe.
6. Temporarily position a Penrose drain around the prostatic urethra within the parenchyma.
7. Remove fluid, using suction and lavage after digitally creating a common cavity. Obtain biopsy and culture samples.
8. Introduce the greater omentum through one capsulotomy wound by using forceps, which is placed through the contralateral prostatic wound (Fig. 85-1).
9. Pass the omentum around the prostatic urethra and exit it through the same capsulotomy wound through which it was introduced.
10. Suture the omentum to itself (horizontal mattress pattern, absorbable suture; see Fig. 85-2).
11. Routinely close the ventral abdominal incision.

Surgical Procedure: Placement of Drain Tube(s)

Equipment

- Same as for omentalization, plus red rubber urethral catheter

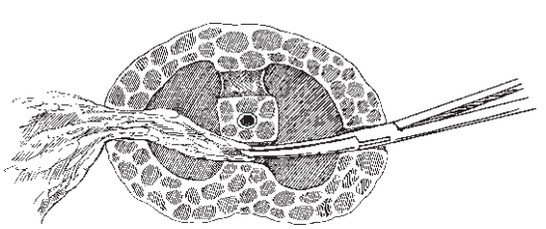

Figure 85-1. Intracapsular omentalization procedure. The greater omentum is introduced into the dorsal abscess cavities by using a forceps. (From White RAS, Williams JM: Intracapsular prostatic omentalization: A new technique for management of prostatic abscesses in dogs. Vet Surg 24:392, 1995.)

Technique

1. Refer to steps 1 to 4 under "Surgical Procedure: Omentalization."
2. Incise the ventrolateral aspect of the prostatic lobe(s) containing the fluid. Avoid vessels and nerves contained in the lateral pedicles.
3. Remove fluid, using suction and lavage after digitally creating a common cavity. Obtain biopsy and culture samples.

▼ ***Key Point*** Creation of a common prostatic cavity during any drainage procedure improves drainage and decreases the probability of recurrence.

4. Place one or more drains into the prostatic cavity while avoiding the urethra using one of the following methods:
   a. Pass Penrose drain(s) ($\frac{1}{4}$ inch) through the cavity to exit on the ventrolateral aspect of each lobe (Fig. 85-3).

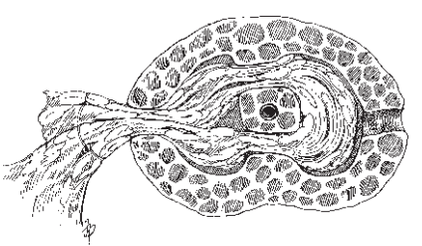

Figure 85-2. The omentum has been packed in the prostate gland encircling the urethra and has been sutured to itself. (From White RAS, Williams JM: Intracapsular prostatic omentalization: A new technique for management of prostatic abscesses in dogs. Vet Surg 24:393, 1995.)

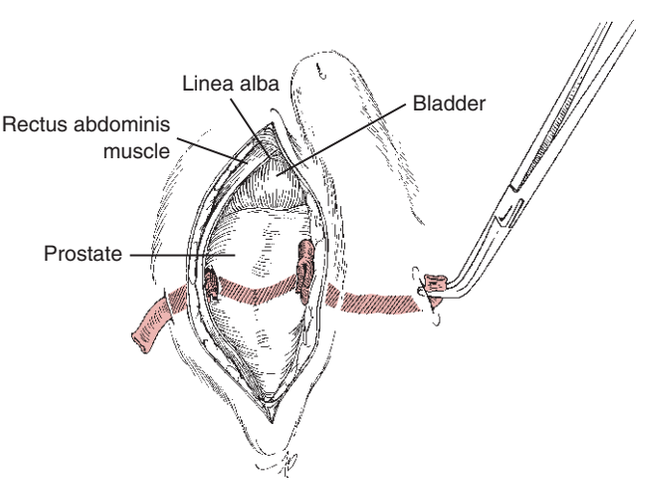

Figure 85-3. Prostatic drainage procedure. A single Penrose drain has been placed within the abscess cavity of the prostate and exits on the ventrolateral aspects of the gland. The ends of the drain are placed through the body wall and skin on each side of the prepuce.

b. Position a single red rubber catheter to permit continuous drainage of the prostatic cavity.
5. Exteriorize the end(s) of the drain tube(s) through the body wall approximately 2 cm lateral to the prepuce, and suture the drain to the skin.
6. Routinely close the ventral abdominal incision.

Surgical Procedure: Marsupialization

Equipment

- Same as for omentalization.

Technique

1. Refer to steps 1 to 4 under "Surgical Procedure: Omentalization."
2. Incise the ventrolateral aspect of the fluid-filled prostate and evacuate fluid, using suction and lavage after digitally creating a common cavity. Obtain biopsy and culture samples.
3. Incise the skin (5 cm long), subcutaneous tissue, and abdominal musculature just lateral to the prepuce on the side opposite the original skin incision.
4. Place the walls of the prostatic cavity near the skin incision and appose the wall adjacent to the prostatic incision to the external rectus fascia (simple continuous pattern, absorbable suture) and the incised prostatic edges to the skin (simple interrupted pattern, non-absorbable suture).

▼ ***Key Point*** If a paraprostatic cyst is present and can be dissected free from surrounding tissues, resection of all or most of the cyst is indicated. Pack the cyst remnant with omentum. This eliminates the complications associated with marsupialization.

5. Routinely close the ventral abdominal incision.

Postoperative Care and Complications

Short Term

- Closely monitor for hemorrhage, peritonitis, and septicemia.
- Prevent self-inflicted trauma to the drain(s) or the stoma site (marsupialization) or drain tubes by using a side brace or Elizabethan collar until the drains are removed.
- Continuous suction drainage using a single red rubber catheter and a suction reservoir may be more effective in evacuating prostatic cavities than simple gravity drainage; however, such drainage requires more conscientious postoperative patient observation and care.
- Passage of urine through the drainage tubes may occur but usually resolves in a few days.
- Prostatic abscessation requires aggressive medical therapy to eliminate infection and usually responds better to omentalization or drain tube placement than to marsupialization.
- Remove drains about 3 weeks postoperatively.
- Administer an appropriate antibiotic (see Chapter 84) to patients with prostatic abscessation for 2 to 4 weeks after the hospitalized period.

Long Term

- Long-term complications of prostatic tube drainage procedures include urinary incontinence (46% incidence), recurrent urinary tract infection (30% incidence), recurrence of prostatic abscessation (18% incidence), and urethrocutaneous fistula formation (2% incidence).
- Carefully monitor response to therapy through urine or prostatic fluid culture and susceptibility testing, as well as ultrasonography, if available, after discontinuing antibiotics.

Prognosis

▼ ***Key Point*** Paraprostatic cysts respond best to complete or partial surgical removal, because recurrence following drainage may occur and require additional drainage procedure(s), usually within 6 weeks of the initial drainage procedure.

- Prostatic abscessation has the potential for significant morbidity and mortality, and immediate postoperative mortality may approach 25%.
- The incidence of postoperative sepsis and shock approximates 33%. Rupture of a prostatic abscess results in a mortality rate of approximately 50%.
- Patients with prostatic abscessation that survive the initial 2 weeks after surgery will likely make a satisfactory recovery.

PARTIAL (SUBTOTAL) PROSTATECTOMY

Preoperative Considerations

- Be familiar with the vascular and regional anatomy of the prostate and surrounding structures.
- Perform partial prostatectomy for stable patients with recurrent abscessation and for dogs with cystic disease that have not responded to more conservative methods (i.e., orchidectomy and drainage).

▼ ***Key Point*** Complete rather than partial prostatectomy is indicated for prostatic neoplasia.

- Pass a urethral catheter to the urinary bladder to aid in identification of the urethra.

Surgical Procedure

Objectives

- Remove as much diseased prostatic tissue as possible while maintaining urinary continence.

- Avoid traumatizing the prostatic urethra.
- Maintain the blood supply to the prostatic urethra and adjacent organs.

Equipment

- Standard general surgical pack and suture
- Electrocoagulation unit with both coagulation and cutting capabilities
- Laparotomy sponges
- Balfour retractors

Technique

1. Refer to steps 1 to 4 under "Surgical Procedure: Omentalization."
2. Isolate and ligate all major vessels leading to the prostate, while staying immediately adjacent to the prostate gland.
3. Incise and remove the prostate to within approximately 5 mm of the lateral aspect of the prostatic urethra, using scissors and electrocoagulation, cutting electrocoagulation, or an ultrasonic surgical aspirator (Fig. 85-4).
4. Routinely close the ventral abdominal incision.

Postoperative Care and Complications

Short Term

- Submit excised tissue for histologic and microbiologic evaluation.
- Maintain urinary diversion (i.e., indwelling urethral catheter) for approximately 5 days.
- Prevent self-inflicted trauma to the urinary catheter by using either an Elizabethan collar or side brace until the catheter is removed.
- Shock, urine leakage, and urinary incontinence are potential short-term complications of partial prostatectomy.

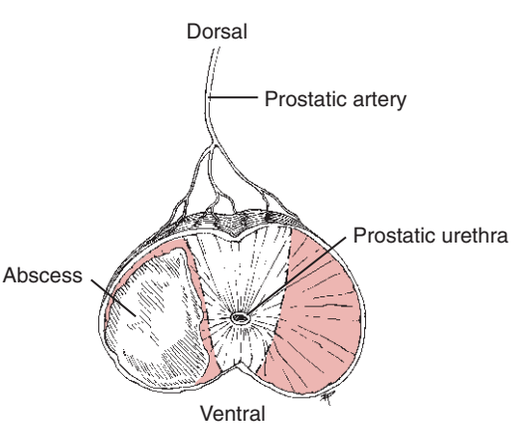

Figure 85-4. Partial (subtotal) prostatectomy technique. The shaded area denotes the prostatic parenchyma to be removed to within approximately 5 mm of the prostatic urethra using sharp dissection and/or an ultrasonic surgical aspirator.

Long Term

- Nocturnal urinary incontinence has been identified as a long-term complication of partial prostatectomy in approximately 50% of patients.

Prognosis

- The prognosis depends on the disease process(es) present.
- Resolution of prostatic and urinary tract infection is likely following partial prostatectomy and appropriate antimicrobial therapy.

TOTAL PROSTATECTOMY

Preoperative Considerations

- Indications for total prostatectomy include severe trauma, localized neoplasia with no apparent metastasis, and recurrent prostatic abscessation unresponsive to other, less invasive surgical procedures.

▼ ***Key Point*** Urinary incontinence is a common complication of total prostatectomy.

Surgical Procedure

Objectives

- Remove the entire prostate gland.
- Preserve the blood supply to the urinary bladder and urethra.
- Preserve as much urethra as possible.
- Perform an accurate urethral anastomosis.

Equipment

- Standard general surgical pack and suture
- Electrocoagulation unit
- Laparotomy sponges
- Urethral catheter
- Balfour retractors

Technique

1. See steps 1 to 4 under "Surgical Procedure: Omentalization."
2. Expose the prostate by careful dissection through the periprostatic fat as close to the prostate as possible.
3. Ligate and divide the prostatic vessels and ductus deferens close to the gland.
4. Carefully dissect the prostatic tissue from the urinary bladder and urethra, using sharp and blunt dissection.
5. Transect the urethra as close to the prostate and as far from the bladder neck as possible.
6. Transect the urethra as close to the caudal extent of the prostate as possible.

7. Remove the prostate by slipping it off the urinary catheter, and reposition the catheter into the urinary bladder. Submit the gland for histologic and microbiologic evaluation.
8. Approximate the urethral ends in an end-to-end fashion (simple interrupted pattern, synthetic absorbable suture), starting at the dorsal aspect of the urethra. Temporarily leave suture tags long and use them to help rotate the urethra to facilitate the anastomosis.
9. Thoroughly lavage the abdomen before closure.
10. Provide urinary diversion by performing a prepubic tube cystostomy (see Chapter 80) or by maintaining placement of the urethral catheter for approximately 2 weeks (longer if delayed healing is expected).
11. Routinely close the ventral abdominal incision.

Postoperative Care and Complications

Short Term

- Prevent self-inflicted trauma to the catheter by using a side brace or Elizabethan collar.
- Complications include urinary incontinence, urine leakage at the urethral anastomosis, and urethral stricture.

Long Term

- Urinary incontinence may be a long-term complication. Treat incontinence using drugs to increase proximal urethral tone (see Chapter 83).

Prognosis

- Prostatic neoplasia in the dog is most commonly malignant (adenocarcinoma or transitional cell carcinoma); metastasis is most common to the median iliac lymph nodes, periprostatic tissue, urinary bladder, pelvic structures, and lung (see Chapter 84).
- Successful treatment of prostatic neoplasia is difficult because of its aggressive biologic behavior; micrometastasis to adjacent tissues is probable, even when no gross evidence of metastasis exists.

Chapter 86

Diseases of the Testes and Scrotum

Thomas K. Graves

A number of congenital and acquired diseases affecting the testes and scrotum are commonly recognized in small animal patients. Traumatic, infectious, and inflammatory diseases of the testes or scrotum are less common but may result in discomfort to the patient warranting presentation. Most dogs with testicular diseases have no clinical signs with the exception of infertility in breeding dogs.

DISEASES OF THE TESTES

Etiology

Congenital Disorders

Cryptorchidism

- Cryptorchidism is a common hereditary disorder in which one or both testicles fail to descend to the normal scrotal position. The disorder is recognized in both dogs and cats and is a sex-linked autosomal recessive trait.
- In dogs, toy breeds, boxers, and German shepherds are predisposed; in cats, the Persian breed is predisposed.
- In dogs, testicular descent occurs by 10 days of age, but it may be delayed 8 weeks or longer.
- Cryptorchid testes may be located within the abdominal cavity, within the inguinal ring, or subcutaneously in the prescrotal region.
- Unilateral cryptorchidism is more common than bilateral (75%).
- Dogs with bilateral cryptorchidism are sterile, whereas those with unilateral cryptorchidism are fertile. Undescended testicles are abnormal and have abnormal spermatogenesis because of the exposure to high body temperature.
- Even sterile dogs with cryptorchidism have normal libido, and male characteristics because testosterone secretion from interstitial cells is preserved.

▼ ***Key Point*** Perform bilateral orchiectomy (see Chapter 87) for all cryptorchid animals to eliminate the potential risk of testicular neoplasia, male feminizing syndrome, and testicular torsion and because it is a hereditary disorder.

Male Pseudohermaphroditism

- Affected dogs have testes, and XY chromosomes, but have external or internal female genitalia.
- The testes are hypoplastic and cryptorchidism is common.
- Abnormalities in the development of the prepuce and penis may also be noted.

Testicular Feminization Syndromes

- These dogs or cats have XY chromosomes but have partial or complete failure of masculinization.
- The syndrome is due to X-linked mutations in the androgen receptor gene.
- There can be a certain degree of testicular development in some animals. Others, although male, can be phenotypically female with no noticeable testicular development.

XX Sex Reversal

This chromosomal abnormality is associated with testicular abnormalities, as well as other genital malformations in dogs. (See Chapter 88.)

Acquired Disorders of the Testes

Orchitis-Epididymitis

Infectious Orchitis-Epididymitis

- Infection of the testes and epididymis can come from penetrating wounds, can be acquired hematogenously, or can come from spread of infections of the urogenital tract, including the prostate.
- Aerobic bacteria are most common.
- *Brucella canis* is an important cause of orchitis-epididymitis.
- *Mycoplasma* organisms have been implicated.
- Viral causes of orchitis-epididymitis include canine distemper virus and feline infectious peritonitis.
- *Blastomyces* organisms can be implicated in endemic areas.

- *Rickettsial* infections such as ehrlichiosis and Rocky Mountain spotted fever can be associated with testicular or epididymal infection.

Immune-Mediated Orchitis

- Normally, the blood-testis barrier prevents immune responses to spermatozoal antigens.
- When this barrier is disrupted, orchitis can ensue, and it is associated with lymphocytic infiltration of the testes and infertility.

Testicular Neoplasia

- Testicular tumors are relatively common in dogs and uncommon in cats.
- Primary testicular tumors include Sertoli cell and interstitial cell tumors and seminoma.
- Testicular neoplasia is 9.6% to 13.6% more likely in cryptorchid patients due to prolonged exposure of the retained testicle to normal body temperatures.
  - The contralateral descended testicle demonstrates the same neoplastic cells in 40% of the cryptorchid dogs.
  - Testicular neoplasia is rarely seen in cryptorchid cats.
- Most testicular tumors in dogs are so slowly metastatic as to be considered benign.
- Most testicular tumors in non-cryptorchid dogs are incidental findings in older patients. Intra-abdominal testicular tumors are usually suspected based on age, signs of hyperestrogenism or hypertestosteronism, and history of cryptorchidism.
- Sertoli cell tumors can result in male feminizing syndrome including hair loss (see Chapter 51), gynecomastia, hematologic abnormalities, testicular atrophy, and squamous metaplasia of the prostate.

Trauma

- Trauma to the testes and scrotum can lead to chronic orchitis-epididymitis or ischemia, so prompt attention to testicular trauma is necessary.

Testicular Torsion

- Testicular torsion can occur in cryptorchid or normal testes and is associated with acute onset of pain.
- Torsion results in swelling of the testicle and spermatic cord due to complete or partial obstruction of arterial blood flow and venous drainage.

Secondary Testicular Disorders

- Testicular dysfunction and infertility can occur secondary to endocrine diseases such as hyperadrenocorticism, diabetes mellitus, and hypothyroidism.
- A full metabolic evaluation is useful for dogs presenting for infertility.

Other Testicular Diseases

- Sperm granuloma can develop when sperm cells accumulate in the spermatic ducts, and a chronic inflammatory response ensues.
- Spermatocele is a sperm-containing dilation of the duct system and is considered a benign lesion.
- Varicocele is a dilation of the spermatic vein, which can lead to thrombosis but may also be a benign lesion.

Clinical Signs

- In some animals with testicular diseases, no clinical signs are noticed by the owner.
- Infertility is a common clinical sign.

Orchitis-Epididymitis

- Infection, trauma, or immune-mediated disease can cause pain and inflammation of the testes.
  - Animals may have scrotal swelling and a stiff gait. Frequent licking of the scrotum may be observed.
- Infectious disease of the testes can involve other components of the urogenital system, so clinical signs of prostatic disease (e.g., straining to urinate or defecate) can be present, as can signs of lower urinary tract infections (hematuria, stranguria, pollakiuria).
- Testicular inflammation can be associated with systemic signs of inflammation (e.g., depression, anorexia, and fever).

Neoplasia

- Estrogen from Sertoli cell tumors can result in feminization (testicular atrophy, infertility, gynecomastia), bone marrow suppression, alopecia (see Chapter 51), and squamous metaplasia of the prostate. Testosterone from interstitial cell tumors can result in prostatic hypertrophy, perianal adenoma, and other androgen-dependent changes. Seminoma has also been associated with hyperestrogenism.

Torsion

- Dogs with testicular torsion can present with acute, severe pain and swelling of the scrotal testicle. Testicular torsion occurring in cryptorchid patients may present with clinical signs of acute abdominal pain and vomiting.

Secondary Testicular Diseases

- Testicular diseases occurring secondary to endocrine and metabolic disorders are accompanied by clinical signs of the underlying primary disease.

Diagnosis

Physical Examination

- Perform a complete physical examination for all animals presented for testicular diseases or infertility (Fig. 86-1).

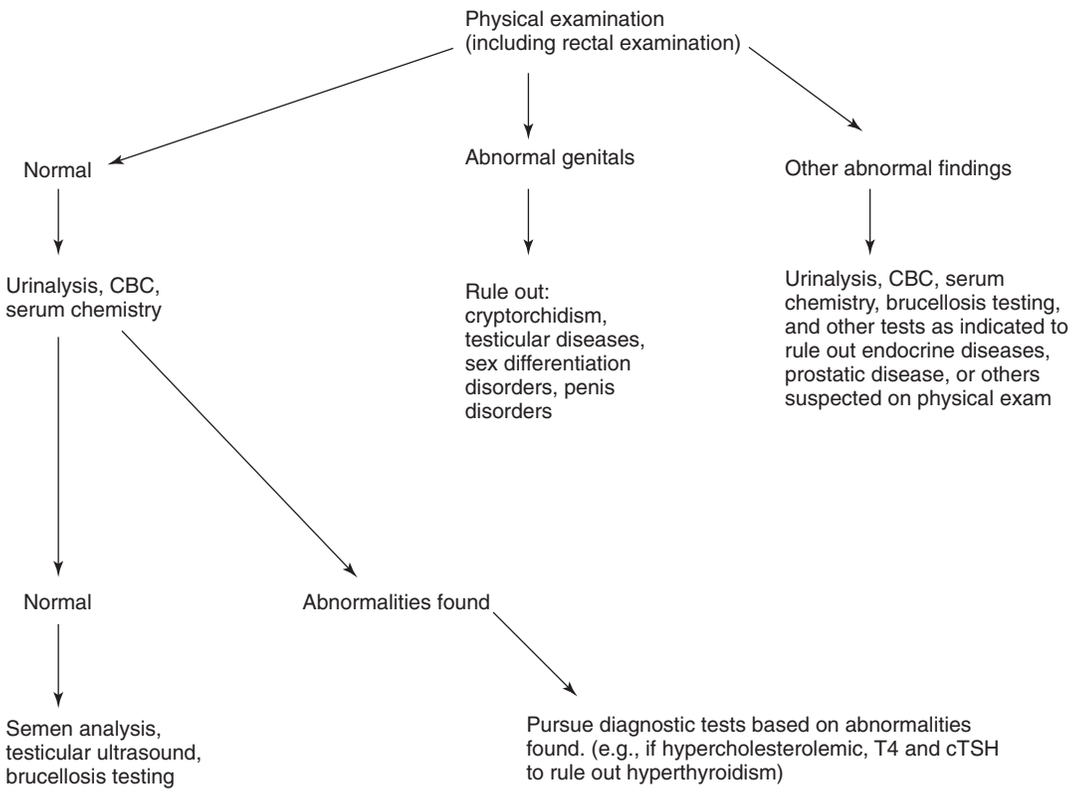

Figure 86-1. Algorithm for diagnosis of male infertility.

- Normally, the scrotum should contain two testicles of approximately equal size and shape. Testicles should be freely moveable within the scrotum.
- There is variability in testicular size among breeds of dogs and among individuals of the same breed.
- Cryptorchidism is diagnosed on physical exam, often as an incidental finding. Non-scrotal testes are found most commonly lateral to the prepuce or in the inguinal area. Abdominal testes usually cannot be palpated unless a neoplasm is present.
- The presence of one enlarged testicle indicates possible neoplasia, granuloma, spermatocele, varicocele, inflammation, or torsion. Assess for pain and the consistency of the testis, and distinguish the epididymis from the testis.

▼ ***Key Point*** An enlarged, firm testicle suggests neoplasia, whereas an enlarged, painful testicle is more consistent with orchitis.

- One abnormally small or irregular testicle in the presence of one normal testicle suggests a degenerative process due to local disease (e.g., chronic inflammation).
- Two small, soft testicles are consistent with testicular degeneration due to chronic inflammation, systemic conditions that cause testicular degeneration (e.g., some endocrine disorders), failure of normal testicular development, or normal aging.
- Perform rectal examination to assess the prostate gland and pelvic urethra in inflammatory disorders of the testes.
- Perform complete examination of the penis and prepuce because congenital developmental disorders of the testes are often associated with penis/prepuce malformations.

Routine Laboratory Tests

- Since many testicular disorders can be associated with systemic illness, perform complete blood count, serum biochemistry, and urinalysis as part of the diagnostic evaluation. These tests will aid in the diagnosis of inflammatory diseases, infectious diseases, neoplasia, and infertility.

Brucellosis Testing

- Brucellosis serology is first evaluated by the rapid slide agglutination test done in a hospital.
  - Because this test can have false-positive results, confirm a positive result with serology performed in a commercial diagnostic laboratory (see Chapter 19).

Diagnostic Imaging

- Ultrasonography can be used to detect undescended testicles.
- Ultrasonography can be used to detect testicular tumors. It can also help differentiate testicular lesions from epididymal lesions and can be used to guide fine-needle aspirates of the testes.
- Evaluate the prostate with ultrasonography in animals with testicular disorders since a variety of prostatic changes can occur.
- Although most testicular tumors are slow to metastasize, consider thoracic radiography to evaluate for metastatic tumors.

Semen Evaluation

Semen collection and evaluation is commonly performed to evaluate testicular abnormalities in breeding dogs. However, this procedure is technically difficult and not routinely performed in cats. In cases of infertility or inflammatory diseases, semen evaluation is indicated (see Chapter 94).

Technique

- Collect semen by retracting the prepuce caudally and manually stimulating the penis.
- If an artificial vagina is used, sterilize it before use to minimize contamination from penile and preputial mucosa commensal organisms. Alternatively, collect semen into a sterile cup placed at the tip of the penis. Most dogs ejaculate willingly and with minimal stimulation.
- Canine sperm is ejaculated in three fractions:
  - The first is a clear pre-sperm fraction of very small volume, composed of prostatic fluid.
  - The second is the sperm-rich fraction and is milky white in a volume ranging from 0.5 to 5 ml.
  - The third fraction is again clear, is composed of prostatic fluid, and can have very large volumes.

▼ ***Key Point*** The third fraction is not useful for semen analysis; separate it from the first two fractions. The third fraction may be useful to detect prostatic disorders.

  - Do not collect semen from an animal with obvious, overt inflammation of the testes. Collection of semen in these cases will not likely be possible, and testicular samples can be collected by fine-needle aspiration instead.

Semen Color and Consistency

- Blood-tinged semen can be the result of traumatic collection or prostatic disease.
- A non-opaque second fraction is consistent with oligospermia.
- Dogs with orchitis-epididymitis may have flecks or clumps of discolored debris in the semen consistent with purulent material.

Sperm Count

- Use a hemocytometer, using either the white or the red blood cell method, for determining the number of sperm per milliliter of ejaculate. Multiply this number by the volume of the ejaculate to determine the total sperm count.
- A normal canine ejaculate contains more than 200 million sperm cells.

Motility

- More than 70% of canine sperm should be progressively motile.
- To assess motility, place a drop of ejaculate on a warmed microscope slide covered with a warmed cover slip. Use microscope objectives of both 40× and 100×.

Morphology

- Abnormalities of morphology should not be seen in more than 20% of spermatozoa.
- Primary abnormalities are the result of abnormal spermatogenesis and include cytoplasmic droplets in the proximal midpiece, thickened midpiece, or misshaped heads.
- Distal cytoplasmic droplets can indicate epididymal disease.
- Secondary abnormalities occur in the epididymis and distally, so they are not due to abnormal spermatogenesis but can be due to post-testicle disorders or poor sample handling. These abnormalities include coiled or bent tails and detached heads.

Semen Cytology

Air-dried slides of semen samples can be stained and examined for inflammatory cells and infectious organisms.

Semen Alkaline Phosphatase

- Azoospermia can be the result of blockage of the epididymis. Because the canine epididymis produces alkaline phosphatase, the finding of a low activity of alkaline phosphatase in a semen sample indicates the absence of epididymal fluid.
- The normal range of alkaline phosphatase activity in canine semen is above 4,000 IU/L.

- Semen alkaline phosphatase activity is measured by the same methods as serum alkaline phosphatase activity.

Semen Culture

- Perform bacterial culture of the semen to diagnose infectious orchitis-epididymitis.
- Samples for culture include manually collected semen samples or testicular fine-needle aspirates.
- Culture results must be interpreted carefully in light of possible contamination from urogenital tract infections and from normal flora of the penis and prepuce.
- In general, semen culture from a dog with active bacterial infection should yield more than 10^5 colony-forming units per milliliter.
- Dogs with chronic infections can have false negative bacterial cultures.

Fine-Needle Aspiration

- Cytology of testicular/epididymal aspirates can reveal infectious organisms, inflammatory cells, or neoplastic cells.
- Normal testicular aspirates should contain sperm cells in their various stages of development.
- Chronic inflammation resulting in testicular atrophy and azoospermia can make collection of diagnostic fine-needle aspirates of the testes difficult.

Testicular Biopsy

- Surgical biopsy of the testicle is indicated to investigate azoospermia when no cause has been found by other diagnostic methods (see Chapter 87).
- Immune-mediated orchitis is an uncommon complication of testicular biopsy.

Diagnosis of Testicular Feminization Syndromes

- Diagnosis depends on demonstration of bilateral testes (although they may be intra-abdominal and minimally developed), XY chromosomal status, and positive response to a human chorionic gonadotropin (hCG) or gonadotropin challenge test to demonstrate that androgens are present.
  - Challenge testing is done by measuring testosterone in the serum 4 hours after hCG administration or 1 hour after gonadotropin-releasing hormone (GnRH) administration. The dose for hCG is 40 µg/kg IM in dogs and 250 µg total dose per cat IM in cats. GnRH is given at 2 µg/kg IM in dogs and 25 µg total dose per cat IM in cats.

Treatment

Cryptorchidism

- Because undescended testicles are at a highly increased risk for neoplasia, and to prevent promulgation of an undesirable hereditary trait, perform bilateral castration for cryptorchidism (see Chapter 87).

Orchitis-Epididymitis

- Castration, in combination with antibiotic therapy, is curative in most cases of bacterial orchitis-epididymitis (see Chapter 87). Assess the entire urogenital tract for sources of infection, and treat as necessary. Treat immune-mediated orchitis by castration.

Brucellosis

- Treatment of brucellosis is difficult. The infection is not always eradicated despite long-term antibiotic therapy. Combinations of a tetracycline antibiotic (doxycycline at 10 mg/kg PO bid, or tetracycline hydrochloride at 25 mg/kg PO tid) given for 4 weeks and dihydrostreptomycin (10 mg/kg IM tid during weeks 1 and 4 of tetracycline treatment) may be effective. (See also Chapter 19.)

▼ ***Key Point*** Do not breed dogs with brucellosis. Castrate these dogs to prevent spread of infection.

Testicular Neoplasia

- Perform castration for all testicular tumors (see Chapter 87). Adjunctive treatments are determined by results of histopathology and tumor staging.

Inherited Testicular Feminization Syndromes

- Perform castration (see Chapter 87).
- Because of the X-linked mode of inheritance, 50% of male offspring of a female carrier are affected, and 50% of female offspring are carriers. Care should be taken to identify carrier animals and remove them from breeding programs to prevent the disorder.

DISEASES OF THE SCROTUM

Primary diseases of the scrotum are uncommon, although changes in the scrotum are often seen in conjunction with other multisystemic diseases. In addition, generalized dermatopathies, such as those caused by dermatophytes, pyoderma, lupoid syndromes, keratinization defects, food hypersensitivities, and many others, can cause scrotal lesions.

Etiology

- *Contact dermatitis* through exposure of the scrotum to chemical irritants such as soaps or dips can cause local irritation and erythema.
- *Neoplasia* of the scrotum can occur such as cutaneous mast cell tumor, squamous cell carcinoma, and malignant histiocytic disease.

- *Environmental injury* can occur to the scrotum, such as frostbite or sunburn.
- *Drug eruption* can occur from drugs such as diethylcarbamazine, 5-fluorocytosine, and aurothioglucose.
- *Trauma,* such as abrasions, penetrating injuries, or blunt trauma causing hematoma.
- *Scrotal self-mutilation* associated with sperm granuloma, orchitis, or drug-induced pruritus or as a complication of castration.
- *Scrotal hernia* can cause abdominal contents to herniate through the inguinal canal and protrude into the vaginal process next to the spermatic cord in intact dogs. When this occurs, a scrotal swelling is noted. Strangulation of displaced contents within a scrotal hernia can cause acute severe pain and systemic illness and is a surgical emergency.

Diagnosis and Treatment

Diagnosis and treatment of primary scrotal disorders requires identification of the underlying cause. A thorough medical history aids in the diagnosis of environmentally induced scrotal injury or drug exposure. For diagnosis and treatment of specific skin disorders, see relevant chapters in Section 5.

- *Cytology* of scrotal skin can support a diagnosis of infectious or inflammatory disease (see Chapter 37).
- *Ultrasound* of the scrotum can help identify tumors, testicular adhesions, and scrotal hernia. Fine-needle aspiration and cytology of scrotal masses can identify tumor types.

▼ ***Key Point*** With severe lesions, perform scrotal ablation (with castration of intact animals) and histopathology to confirm a diagnosis, indicate treatment options, and provide prognostic information (see Chapter 87).

- Scrotal hernia repair involves castration and suture closure of the defect in the inguinal ring.

Chapter 87

Surgery of the Testes and Scrotum

Harry W. Boothe

Orchidectomy is the most commonly performed surgical procedure of the testis. The technique depends, in part, on species and location of the testes (i.e., ectopic or scrotal). Indications for performing orchidectomy are listed in Table 87-1. Testicular biopsy may be part of a fertility examination. Scrotal ablation may be part of a routine orchidectomy or for neoplasia resection, especially in older dogs. It is also performed at the time of scrotal urethrostomy and feline perineal urethrostomy.

▼ ***Key Point*** Obtain owner consent before performing orchidectomy as a primary procedure or concurrent with another surgical procedure.

ANATOMY

- The testes are positioned obliquely within the scrotum, with their long axis directed dorsocaudally.
- The scrotal testis is covered by peritoneum (parietal and visceral vaginal tunics) and a dense, white, fibrous capsule (tunica albuginea).
- The testis and epididymis are connected to the parietal vaginal tunic by the caudal ligament of the epididymis.
- The arterial and venous patterns are similar, with the right testicular artery originating from the abdominal aorta cranial to the left and the veins forming an extensive pampiniform plexus in the spermatic cord.
- The right testicular vein empties into the caudal vena cava, whereas the left terminates in the left renal vein; testicular lymphatics drain to the median iliac lymph nodes.
- The canine scrotum is located more ventrally than the feline.
- The scrotal wall consists of the skin and dartos, a layer of smooth muscle and elastic fibers.
- The external spermatic fascia attaches to the caudal aspect of the scrotum as the scrotal ligament.
- Blood supply to the scrotum is principally via branches of the external pudendal artery; lymphatic drainage is to the inguinal lymph nodes.

TESTICULAR BIOPSY

See Chapters 86 and 94 for indications.

Preoperative Considerations

- Usually only one testis is sampled.
- Incisional techniques usually provide the best tissue samples for analysis.
- Fixation of specimens in Bouin's, Zenker's, or Stieve's fixative is preferable to formalin fixation because of better preservation of architectural detail.

Surgical Procedure

Objectives

- Obtain a representative sample of the testis for histologic evaluation.
- Minimally disrupt the testicular architecture.

Equipment

- Standard general surgical pack and suture
- Sterile, thin razor blade
- Bouin's, Zenker's, or Stieve's fixative

Technique

1. Place the animal in dorsal recumbency and aseptically prepare the prescrotal area.
2. Incise the skin just cranial to the scrotum and place the testis with the epididymis away from the incision.
3. Incise the tunics with a scalpel blade and the tunica albuginea with a sterile, thin razor blade, while avoiding blood vessels.
4. Excise the bulging testicular tissue using the razor blade or, if testicular tissue does not bulge, excise a wedge of testicular parenchyma. The razor blade's sharp, flat blade makes it ideal for this procedure.
5. Close the tunica albuginea and the tunics separately (simple interrupted pattern, 4-0 absorbable suture).
6. Routinely close the skin (simple interrupted pattern, non-absorbable suture).

Table 87-1. INDICATIONS FOR PERFORMING ORCHIDECTOMY IN THE DOG AND CAT

Sterilization	Prostatic cyst
Modification of behavior patterns	Perineal adenoma
Testicular neoplasia	Perineal hernia
Severe testicular or scrotal trauma	Scrotal urethrostomy (canine)
Refractory orchitis-epididymitis	Perineal urethrostomy (feline)
Benign prostatic hyperplasia	
Suppurative prostatitis	

Postoperative Care and Complications

- Uncommon complications include hemorrhage, infection, scarring, adhesions, and atrophy.
- A temporary slight decrease in sperm count may occur.

Prognosis

- The prognosis depends on the disease process(es) present (see Chapters 86 and 94).
- Minimal patient morbidity is expected.

ORCHIDECTOMY IN THE DOG

Preoperative Considerations

- Determine the location of the testes before surgery.

Cryptorchidism

- If the animal is a unilateral cryptorchid, determine which testicle has descended and therefore which one is retained.
  - Push the normal testicle dorsally and cranially to determine which inguinal canal (right or left) it slides into.
  - Carefully palpate the inguinal canal(s) to determine if the retained testicle is located there or in the abdominal cavity.
- In a cryptorchid animal, approach an abdominal testis through a paraprepucial skin incision and an extra-abdominal ectopic testis by incising directly over the testis (usually in the inguinal region).
- Histologically examine all ectopic and grossly abnormal testes.

Surgical Procedures

Objectives

- Remove both testes.
- Remove scrotal testes using either the closed or the open method (choice of technique is the surgeon's preference).
- Minimize postoperative complications and patient morbidity.

Equipment

- Standard general surgical pack and suture

Technique for Scrotal Testis (Closed Technique)

1. Place the dog in dorsal recumbency and aseptically prepare the prescrotal area. Avoid clipping and scrubbing the scrotal skin to minimize dermal irritation.
2. Incise the prescrotal skin on the midline while gently pushing one testis toward the skin incision.
3. Incise the subcutaneous tissue and spermatic fascia over the testis to expose the parietal vaginal tunic.
4. Exteriorize the tunic-covered testis and, using scissors, incise the spermatic fascia and scrotal ligament close to the testis.
5. Reflect the fat and fascia surrounding the parietal vaginal tunic using a gauze sponge to enable maximal exteriorization of the spermatic cord.
6. Double-ligate the intact spermatic cord and vaginal tunics using transfixation ligatures of absorbable suture material (Fig. 87-1).
7. Transect the spermatic cord and cremaster muscle distal to the ligatures and return them to the inguinal region.
8. Routinely close the subcutaneous tissue (simple interrupted pattern, absorbable suture) and skin (simple continuous intradermal pattern, absorbable suture).

Technique for Scrotal Testis (Open Technique)

1. Exteriorize the testis as described for the closed technique.
2. Incise the parietal vaginal tunic where ligatures are to be placed on the spermatic cord.
3. Double-ligate the spermatic cord using transfixation ligatures of absorbable material.

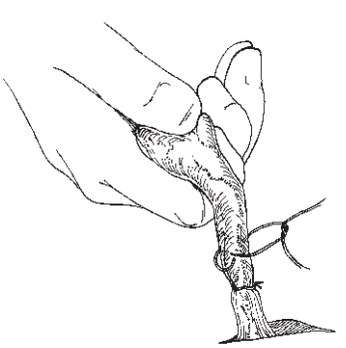

Figure 87-1. Transfixation (double) ligation of the intact spermatic cord. The suture needle is carefully passed through the ductus deferens of the spermatic cord. The entire spermatic cord, vaginal tunics, and cremaster muscle are enclosed in the ligature.

4. Alternatively, incise the parietal vaginal tunic over the testis and then double-ligate the spermatic cord using transfixation ligatures of absorbable material.
5. Ligate the parietal vaginal tunic and cremaster muscle using a transfixation ligature; transect the spermatic cord and cremaster muscle, and return them to the inguinal region.
6. Routinely close the subcutaneous tissue (simple interrupted pattern, absorbable suture) and skin (simple continuous intradermal pattern, absorbable suture or routine skin closure with monofilament non-absorbable suture).

Technique for Abdominal Ectopic Testis

1. Place the dog in dorsal recumbency and aseptically prepare the ventral abdominal region from the xiphoid process to caudal to the pubic brim.
2. Incise the skin and ventral abdominal wall from the umbilicus to the pubis while avoiding the prepuce. A midline abdominal approach is used. In a unilateral cryptorchid dog, a paramedian abdominal approach can be used on the side of the retained testicle.
3. Locate the ectopic testis by tracing one of the following:
   - Ductus deferens from its prostatic termination
   - Testicular artery from its aortic origin
   - Testicular vein from its termination in the caudal vena cava (or left renal vein)
   - Gubernaculum testis to the testis
4. Double-ligate the testicular vessels and ductus deferens.
5. Transect the vessels and ductus deferens; remove the testis and submit it for biopsy.
6. Routinely close the ventral abdominal incision in three layers.

Technique for Extra-Abdominal Ectopic Testis

1. Place the dog in dorsal recumbency and prepare the pubic region.
2. Incise the skin and subcutaneous tissue directly over the testis. Remove any loose connective tissue to expose the spermatic cord.
3. Double-ligate and transect the spermatic cord.
4. If the testis is not found subcutaneously, extend the incision into a paramedian approach to the abdomen and find the testis, as previously described.
5. Routinely close the subcutaneous tissue (simple interrupted pattern, absorbable suture) and skin (simple interrupted pattern, non-absorbable suture).

Postoperative Care and Complications

Short Term

- Use an Elizabethan collar to help prevent self-inflicted trauma. Intradermal skin closure also helps prevent self-trauma to the incision.
- Consider postoperative analgesic administration (see Chapter 6).
- Scrotal bruising and inflammation may occur, particularly following the open technique.
- Hemorrhage may occur and can be serious. Severe scrotal swelling from hemorrhage may necessitate scrotal ablation.
- Scrotal infection may require drainage or scrotal ablation.
- Inadvertent prostatectomy has been reported as a complication of removal of abdominal ectopic testes.

Prognosis

- Prognosis following orchidectomy of the cryptorchid dog is generally favorable even with testicular neoplasia, which usually is benign.

ORCHIDECTOMY IN THE CAT

Preoperative Considerations

See "Orchidectomy in the Dog."

Surgical Procedure

Objectives

See "Orchidectomy in the Dog."

Equipment

- Standard minor surgical pack

Technique

1. Position the cat in dorsal recumbency with the rear limbs pulled cranially, and aseptically prepare the perineal region.
2. Incise the scrotum over each testis and expose the testis.
3. Grasp the parietal vaginal tunic with hemostats, separate it from the testis, and excise it.
4. Separate the ductus deferens from the rest of the spermatic cord and separate it from the testis.
5. Tie two square knots in the spermatic cord, using the ductus deferens and spermatic vessels as separate strands, and transect the spermatic cord distal to the knots.
6. Alternatively, ligate the spermatic cord using an instrument-tied overhand knot with absorbable suture material or by tying the spermatic cord on itself.
7. Do not suture the scrotal incision.

▼ ***Key Point*** Do not perform the traction avulsion technique of feline orchidectomy because of the potential for significant postoperative complications, including hemorrhage and urethral avulsion.

Postoperative Care and Complications

See "Orchidectomy in the Dog."

Prognosis

See "Orchidectomy in the Dog."

SCROTAL ABLATION

Preoperative Considerations

- Indications include severe trauma, neoplasia, ischemia, scrotal abscess, orchidectomy in old dogs with pendulous scrotums, scrotal urethrostomy, and feline perineal urethrostomy.

▼ ***Key Point*** Plan the skin incisions to leave sufficient skin for tension-free closure.

Surgical Procedure

Objectives

- Reduce postoperative problems following orchidectomy in the dog.
- Allow incision into the urethra and subsequent urethrostomy.
- Remove redundant scrotal tissue.

Equipment

- Standard general surgical pack and suture

Technique

1. Place the animal in dorsal recumbency and prepare the periscrotal region.
2. Incise the skin in an elliptical, curvilinear fashion near the base of the scrotum, with the incisions curved toward the scrotum (Fig. 87-2).
3. Transect the scrotal septum after orchidectomy and routinely close the subcutaneous tissue (simple interrupted pattern, absorbable suture) and skin (simple interrupted pattern, non-absorbable suture).

Postoperative Care and Complications

Short Term

- Consider postoperative analgesic administration (see Chapter 6).
- Prevent self-inflicted trauma to the incision. This may require an Elizabethan collar.

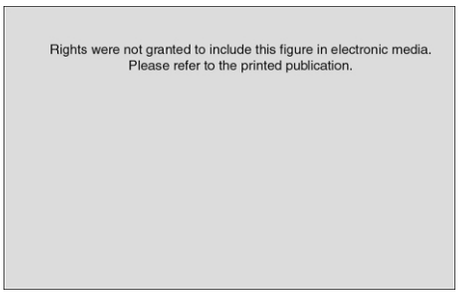

Figure 87-2. Ablation of the scrotum in the dog. The curved scrotal skin incision curves toward the scrotum to ensure tension-free closure of the incision. (From Harvey CE: Scrotal ablation and castration in the dog. J Am Anim Hosp Assoc 9:170, 1973.)

- Common complications include hemorrhage, particularly associated with urethrostomy procedures (see Chapter 82), infection, and dehiscence.

Prognosis

- Minimal patient morbidity is expected.

Chapter 88

Diseases of the Penis and Prepuce

Thomas K. Graves

Animals with diseases of the penis and prepuce can be presented for a variety of clinical signs. Commonly, discharge or hemorrhage from the prepuce is the presenting complaint. Other clinical problems associated with penis and prepuce disorders are abnormal urination, neoplasia, inability to mate, or persistent penile erection. Urethral diseases are discussed in Chapter 81.

ETIOLOGY

Congenital Disorders of the Penis and Prepuce

Congenital disorders of the penis and prepuce are uncommon in dogs and cats. Congenital malformations of the penis are often associated with preputial malformations. Clinical signs may result from either the inability to retract the penis into the prepuce or the inability to extend the penis from the preputial orifice.

Persistent Penile Frenulum

- During the perinatal period, the surface of the glans penis and the preputial mucosa separate. When this separation fails, abnormal connective tissue, most commonly joining the ventral midline of the distal penis and prepuce, persists, resulting in the inability of the penis to extrude fully from the prepuce.

Hypospadia

- Hypospadia results from abnormal closure of the urethral tube during development and can cause one or more abnormal urethral orifices located anywhere along the length of the urethra.
- Most commonly, the abnormal orifice is located along the ventral aspect of the penis and prepuce, but it may extend through the scrotal region to the perineal region. The condition is due to incomplete masculinization during development, and it can be associated with an underdeveloped penis and/or with preputial malformations.
- An androgen receptor defect is responsible for lack of normal penile development under the influence of dihydrotestosterone.
- Familial hypospadia has been recognized in Boston terriers.
- Teratogens have been implicated in hypospadia in other species but not in dogs and cats.

Penile Hypoplasia

- Hypoplasia can occur with failure of masculinization, as seen in androgen receptor defects, and has been observed in both dogs and cats.
- Ambiguous genitalia can be found in XX sex reversal syndromes. Affected dogs can exhibit multiple penile and preputial abnormalities and are sterile.
  - Breeds reported with XX sex reversal include English cocker spaniel, American cocker spaniel, Weimaraner, beagle, Doberman pinscher, pug, Kerry blue terrier, soft-coated wheaten terrier, German shorthaired pointer, and Pomeranian.
- Female pseudohermaphroditism, in which the chromosomal sex is XX and ovaries are present, results from the presence of androgens during fetal development. Affected animals can exhibit clitoral enlargement or any degree of penile development, which can mimic penile hypoplasia.
- Penile hypoplasia can result in urine pooling, causing irritation and inflammation of the preputial lining.

Phimosis

- Phimosis occurs when the preputial opening is too small (preputial stenosis) to allow extrusion of the penis. Pooling of urine within the prepuce can result in inflammation and infection (balanoposthitis).

Os Penis Deformity

- Deformity of the os penis can result in deviation of the penis.
- Copulation may be impaired due to excessive flaccidity of the penile tip.

Acquired Penile Disorders

Priapism

- Priapism is defined as persistent, abnormal penile erection and is due to failure of venous outflow of blood from the erect penis.
- The causes are often not well understood. A persistent erection that is associated with hyperactive behavior or sexual arousal is not considered priapism. Also, priapism must be differentiated from other disorders that cause persistent swelling of the penis, such as hematomas that can be observed in association with trauma or coagulopathies.

▼ ***Key Point*** Priapism is considered a medical emergency. Stasis of blood in the engorged penis can lead to thrombosis and ischemia.

- In men, priapism can be drug-associated, caused by use of alpha-adrenergic antagonists, antidepressants, and phosphodiesterase inhibitors used to treat erectile dysfunction (e.g., sildenafil). With more widespread use of these drugs in people, animal toxicities causing priapism are likely.

Trauma

- There are numerous causes of blunt or penetrating trauma that can affect the preputial region and possibly the penis in small animal patients.
- Penile damage may be clearly evident in some animals presented as trauma emergencies. In other animals, trauma to the penis, due to such causes as animal bites, mating mishaps, human malice, or iatrogenic trauma from repeated catheterizations, can present with preputial discharge and swelling, pain, fever, or other signs of inflammation.
- Penile hematoma resulting from trauma may mimic priapism.

Foreign Body

- Foreign bodies can become lodged within the prepuce surrounding the penis and can create significant damage and inflammation.
- Grass awns, mulch, other plant materials, or small particulate materials can lodge with the prepuce, creating significant inflammation and resultant balanoposthitis.
- Circular constricting lesions from preputial hair rings or other foreign objects within the prepuce can result in constriction of the penis, venous stasis, swelling, and paraphimosis.

Neoplasia

- Benign and malignant neoplasms involving the prepuce and penis are relatively uncommon in dogs and cats.

Transmissible Venereal Tumor

- This tumor is usually seen in young dogs and presents as a reddened, irregular mass on the mucosa of the penis.
- It is transmitted sexually and can affect either sex.

Preputial Tumors

- The most commonly seen preputial tumors are cutaneous mast cell tumors, affecting the skin of the prepuce, and transmissible venereal tumors.

Other Tumors

- Urethral tumors can involve the penis. Examples of such tumors include transitional cell carcinoma and squamous cell carcinoma.
- Osteosarcoma of the os penis has been reported in the dog.

Balanoposthitis

- Balanoposthitis is inflammation of the prepuce and penis. The most common cause is bacterial infection, which can occur secondary to preputial or penile malformation, trauma, a lodged foreign body, or spontaneously.
- Non-bacterial causes of balanoposthitis, such as herpesvirus and *Blastomyces dermatitidis*, have been seen but are uncommon.
- Balanoposthitis is common in dogs but extremely uncommon in cats.
- Because of the abundance of normal flora in the prepuce, balanoposthitis can be associated with many different bacteria.

Paraphimosis

- Paraphimosis is a disorder in which the penis, following extrusion during an erection, is unable to retract back into the prepuce.
- The condition occurs when the penile mucosa adheres to the skin, mucosa, or hair of the prepuce.
- When retraction of the penis is attempted, the prepuce rolls in on itself, creating an inadequate opening to allow retraction of the penis.
- Paraphimosis can lead to edema of the penis, and chronic paraphimosis can result in ischemic damage and necrosis.

CLINICAL SIGNS

- *Purulent preputial discharge* can be seen with balanoposthitis, a foreign body, trauma, or any penile malformation that results in abnormal urine flow and infection.

- *Hemorrhagic discharge* is seen in some cases of balanoposthitis, trauma, or a lodged foreign body.
- With *abnormal urination,* the urine stream may be misdirected, urine dribbling may occur after urine pooling in the prepuce, and urine scalding can be seen on the perineal and abdominal skin.
- A *persistent erection* is a clinical sign of priapism and, in some cases, paraphimosis.
- *Pain, swelling, and inflammation* may occur in animals with penile and/or preputial trauma, inflammation, or foreign bodies. Fever and other systemic signs may also occur with these disorders.
  - If the urethra is damaged or obstructed by penile or preputial swelling, the animal may be unable to urinate.
- *Inability to copulate* may be the only sign of a penile or preputial disease.

▼ ***Key Point*** Unwillingness to breed a bitch can be a sign of penile or preputial pain due to inflammation or trauma, or it can be due to pain associated with a persistent penile frenulum.

DIAGNOSIS

History

- Obtain a thorough history of breeding attempts, urinary patterns, presence of preputial discharge, and traumatic events to help with diagnosis of penis and prepuce disorders.

▼ ***Key Point*** Dogs with penile and preputial disorders will often have a history of excessive licking of the affected area.

Physical Examination

- Perform a complete physical examination, including rectal examination to evaluate the prostate, pelvic urethra, and sublumbar lymph nodes. Thoroughly examine the penis and prepuce.
- A small amount of greenish discharge is a normal finding in dogs, especially in sexually intact dogs, but is abnormal in cats.

Prepuce

- The prepuce should be pain free and should move easily over the surface of the penis as the penis is extruded from the prepuce.
- Examine the preputial orifice to detect phimosis. The orifice should be a longitudinal slit located slightly ventrally at the tip of the prepuce. The opening should be large enough to allow the penis to be extruded fully.

Penis

- The penis should be light pink in color and moist, with a palpable os penis (in dogs) and the urethral orifice located at the tip.
- The feline penis is difficult to examine without sedation. In a sedated cat, the penis has an elongated conical tip with small barbs (in intact males), and the urethral orifice located at the tip.
- Fractures of the os penis can be palpable, and there is typically local swelling.
- In cases of penile trauma, gently pass a urethral catheter, with sterile lubrication, to assess the patency of the urethra.
- Thoroughly investigate any swelling. Swelling may be associated with trauma, neoplasia, hematoma, or foreign bodies.
- If an erect penis is evident, examine it carefully to differentiate priapism from paraphimosis. With paraphimosis, there is often an inverted roll of preputial skin strangulating the penis and preventing retraction back into the prepuce. Paraphimosis can also be from a hair ring encircling the shaft of the penis. Erection can be mimicked by a severe penile hematoma.
  - A persistent erection can be due to prolonged sexual arousal in a dog. Remove the dog from premises in which semen was collected or in which an estrual bitch has been. An erection caused by sexual stimulus may also subside if a cold compress is applied gently.

Laboratory Tests

Complete Blood Count

- Complete blood count is indicated in severe trauma, inflammation, or if hematomas of the penis or prepuce are found. Hematomas can be due to thrombocytopenia or other bleeding disorders.

Serum Chemistry

- Serum chemistry is indicated in the staging of any possible neoplastic disorder or if an animal has signs of systemic illness, inflammation, or severe trauma.

Urinalysis

- Urinalysis is important in the workup of any patient with abnormal urination. Urethral neoplasia can extend to the penis, and urine sediment examination may reveal neoplastic cells. Preputial and penile abnormalities can be associated with urinary tract infection.

Cytology

- Cytology of preputial discharge can be helpful in the diagnosis of balanoposthitis. In balanoposthitis, large numbers of bacteria and toxic neutrophils are seen.

In balanoposthitis due to blastomycosis, fungal organisms can be seen on cytology. Preputial cytology can also reveal neoplastic cells.
- Because of the many bacteria that make up the normal flora of the prepuce, bacterial culture is usually not helpful.

Diagnostic Imaging

- *Radiography* of the penis can reveal fractures of the os penis.
- *Contrast retrograde urethrography* is indicated in penile trauma to evaluate the patency of the urethra and to rule out rupture of the urethra (see Chapter 4).
- *Ultrasound* of the prepuce and penis may be indicated if adhesions prevent extrusion of the penis in chronic inflammatory or neoplastic conditions.
- *Computed tomography or magnetic resonance imaging* of the spinal cord, lumbosacral region, and lower urinary tract may be indicated as part of a complete evaluation in neutered male dogs presented with priapism.

Karyotype Analysis

- Sex differentiation disorders can be investigated by determining which sex chromosomes are present on cytogenetic evaluation.
  - This test is not done commonly, and it requires a fresh, cooled (not frozen) blood sample submitted in a lithium heparin tube (green top) to allow culture of leukocytes needed for karyotyping.

TREATMENT

▼ ***Key Point*** Keep the penis moist and protected from environmental damage or preputial adhesions during therapy for many penile/preputial diseases.

Surgical Treatment of Congenital Disorders

- Phimosis and persistent penile frenulum can be treated surgically (see Chapter 89).

Priapism

- Protect the penis against environmental exposure and damage. Frequently apply sterile lubricant jelly.
- If possible, replace the penis within the prepuce. If necessary, place a temporary purse-string suture at the preputial orifice to maintain the penis within the prepuce.
- If there has been significant trauma or drying of the penile mucosa, apply topical antibiotic ointments.
- Non-ischemic priapism can respond to medical therapy with antihistamines or anticholinergic drugs if used within the first few hours of priapism. Administer diphenhydramine (25–50 mg/dog IV) and atropine (0.02–0.04 mg/kg IV). Benztropine, a compound drug containing diphenhydramine and atropine, can be used (0.015 mg/kg IV).
- Alpha-adrenergic agonists have been used successfully to treat priapism in men; consider using in dogs with priapism. Examples of these drugs include phenylephrine, pseudoephedrine, and metaraminol.
- Advanced ischemia will result in necrosis and may require amputation of the penis and scrotal urethrostomy (see Chapter 89).

Trauma

- Clean, debride, and suture penile wounds as necessary.
- Use systemic antibiotics (e.g., amoxicillin-clavulanic acid) for open wounds.
- If open wounds are present, extrude the penis from the prepuce and clean 2 to 3 times daily with a dilute chlorhexidine solution to prevent penis-to-prepuce adhesions.
- Treatment of urethral damage depends on severity, but maintenance of urethral patency by placement of an indwelling urinary catheter is usually necessary (see Chapters 81 and 82).
- Fractures of the os penis may be treated conservatively or surgically, depending on the degree of displacement.

Neoplasms of the Penis

- Treatment of penile neoplasia is surgical excision. The surgical decision to perform a complete or partial penile amputation is based on location and extent of the lesion, determination of malignancy, and presence of urethral obstruction.
- Complete penile amputation requires diversion of the urinary outflow (see Chapter 89).

Transmissible Venereal Tumor

- Spontaneous remission is possible but not predictable.
- Medical treatment with vincristine once weekly (0.5–0.7 mg/m^2 IV) given for 2 weeks beyond apparent remission is usually curative (see Chapter 26 for more information on chemotherapy).
- Radiation therapy can be curative.

Balanoposthitis

- Clean the preputial cavity with antiseptic solutions (e.g., dilute chlorhexidine solution).
- Topical antibiotic creams (e.g., a neomycin, polymyxin, and bacitracin combination) can be helpful.
- Apply an Elizabethan collar to prevent licking of the prepuce.
- Treat underlying disorders.
- See Chapter 20 for treatment of blastomycosis.

- Castration usually results in diminished preputial discharge (see Chapter 87).

Paraphimosis

- Restore the normal anatomic position of the penis in the prepuce. This usually relieves edema and inflammation.
  - Sedate or anesthetize the animal if necessary.
  - Cleanse and lubricate the penis to facilitate replacement into the prepuce. Apply cool saline soaks or hypertonic dextrose solution if necessary to reduce edema.
  - Remove constricting preputial hair or foreign material.
- If mucosal damage to the penis is evident, cleanse and apply topical antibiotic cream.
- Consider surgery to cranially advance the prepuce in dogs with incomplete preputial coverage of the penis (see Chapter 89).
- In severe, long-standing cases, damage to the penis is extensive enough to necessitate amputation (see Chapter 89).

Chapter 89

Surgery of the Penis and Prepuce

Harry W. Boothe

Surgical procedures of the penis and prepuce include the following:

- Penile amputation to treat traumatic or neoplastic lesions
- Enlargement of the preputial orifice to treat phimosis or paraphimosis
- Cranial advancement of the prepuce to treat minor deficiency in preputial length
- Severance of persistent penile frenulum

Diagnosis and medical treatment of penile problems are discussed in Chapter 88.

ANATOMY

Penis

- The feline penis is shorter, directed caudally, and covered with small papillae compared with its canine counterpart, but both species have three principal penile divisions: root, body, and distal portion (glans).
- The penile corpora contain enlarged venous spaces and have two principal divisions: the corpora cavernosa and the corpus spongiosum.
- Each corpus cavernosum (right and left) arises from the ischial tuberosity, continues distally in the dorsolateral part of the penile body as far as the os penis, and is covered by the tunica albuginea.
- The corpus spongiosum originates within the pelvic cavity, surrounds the penile urethra throughout its course, and supplies both the bulbus glandis and the pars longa glandis in the distal penis.
- The os penis is located in the penile body and is attached to the bulbus glandis, pars longa glandis, and tunica albuginea.
- The four paired extrinsic penile muscles in the dog are the retractor penis, ischiocavernosus, bulbospongiosus, and ischiourethralis.
- The principal blood supply to the penis is from three branches of the artery of the penis, which are continuations of the internal pudendal artery: artery of the bulb, deep artery of the penis, and dorsal artery of the penis.
- Venous drainage occurs via the internal and external pudendal veins. Lymphatic drainage is to the inguinal lymph nodes.
- See Chapter 82 for penile anatomy associated with perineal urethrostomy in cats.

Prepuce

- The canine and feline prepuce covers the non-erect penis.
- Paired preputial muscles extend from the xiphoid cartilage to the dorsal preputial wall.
- Blood supply is via the caudal superficial epigastric artery and the dorsal artery of the penis; lymphatic drainage is to the inguinal lymph nodes.

PENILE AMPUTATION

Preoperative Considerations

- The location and extensiveness of traumatic or neoplastic penile lesions determine the site of penile amputation. Animals with urethral prolapse that recurs after attempts to resect urethral mucosa may require partial penile amputation. Non-surgical management of certain neoplasms of the penis (e.g., transmissible venereal tumor) may be preferable (see Chapter 88).
- Preputial shortening may be indicated after partial penile amputation.
- Bilateral orchidectomy, scrotal ablation, and scrotal (preferred) or perineal urethrostomy are indicated following extensive penile amputation.

Surgical Procedure

Objectives

- Provide hemostasis by ligation of blood vessels and closure of the tunica albuginea.
- Create a permanent urethrostomy by suturing urethral mucosa to either penile mucosa or skin.
- Avoid an osteotomy by positioning the amputation site either cranial or caudal to the os penis.

Equipment

- Standard general surgical pack and suture
- Penrose drain tubing for temporary tourniquet application

Technique for Partial Amputation

1. Place the dog in dorsal recumbency, prepare the preputial cavity by multiple flushes with chlorhexidine solution (Nolvasan, Fort Dodge), and catheterize the urethra.
2. Maintain penile exteriorization from the prepuce by placing Penrose drain tubing in tourniquet fashion around the penis as far caudally as possible.
3. Create bilateral flaps of the tunic and cavernous tissue, using sharp dissection, proximal to the os penis while leaving the urethra intact (Fig. 89-1*A*).
4. Dissect the urethra and transect it just distal to the proposed amputation site.
5. Transect the os penis, if necessary, with bone-cutting forceps at the base of the flap.
6. Identify and ligate blood vessels after loosening the tourniquet, and appose the tunica albuginea and flaps of erectile tissue (simple interrupted pattern, absorbable suture).
7. Suture urethral mucosa to penile mucosa over the ventral portion of the end of the penile stump (simple interrupted, absorbable suture) after incising the urethra along its ventral midline (Fig. 89-1*B,C*).

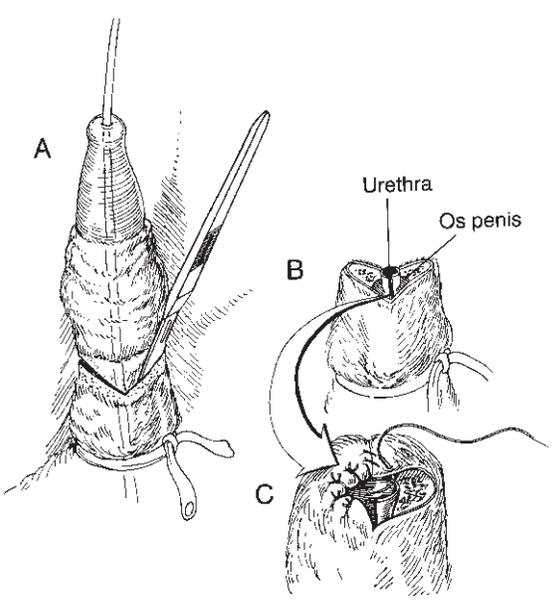

Figure 89-1. Closure of the end of the penis following partial penile amputation. The urethral mucosa is sutured to penile mucosa near the ventrum of the incision, while the remainder of the end of the penis is closed.

Technique for Subtotal Penile Amputation

1. Place the dog in dorsal recumbency and prepare the ventral abdominal and perineal regions.
2. Incise the skin in a curvilinear fashion from just cranial to the prepuce, along each side of the prepuce, to an appropriate level on the perineal midline.
3. Isolate and temporarily encircle the penis cranial to the scrotum, using a heavy ligature proximal to the initial transection site.
4. Transect and remove the penis, prepuce, testes, and scrotum.
5. Exteriorize the proximal portion of the penis through a separate midline perineal skin incision or through the caudal aspect of the original skin incision. Remove the temporary ligature, provide definitive hemostasis, and close the tunica albuginea over the end of the penis (simple interrupted pattern, absorbable suture).
6. Perform a scrotal or perineal urethrostomy (depending on how much of the penis is amputated) proximal to the penile amputation site (simple interrupted or continuous pattern, non-absorbable sutures) (see Chapter 82).
7. An alternative sequence of steps is to perform the urethrostomy first, followed by penile amputation. This allows having a urethral catheter in place while performing the urethrostomy.
8. Routinely close the ventral abdominal incision.

Postoperative Care and Complications

- Administer postoperative analgesics (see Chapter 6).
- Prevent self-inflicted trauma with an Elizabethan collar or a side brace.
- See Chapter 82 for postoperative care and complications of urethrostomy.
- Hemorrhage and/or hematoma formation may occur at the penile amputation or urethrostomy site.

Prognosis

- The prognosis depends on the disease process(es) present.
- Urethral stricture may occur if healing is complicated (e.g., urethral mucosal dehiscence occurs).
- Minimal long-term patient morbidity is expected.

ENLARGEMENT OF THE PREPUTIAL ORIFICE

Preoperative Considerations

- Use this procedure to correct phimosis (multiple attempts may be necessary in the young dog) or paraphimosis. Position the incision on the dorsal aspect of the prepuce to avoid persistent exposure of the glans penis.

- Perform castration of the patient (see Chapter 87), as well as preputial orifice reconstruction, to reduce the possibility of paraphimosis recurrence following erection.

Surgical Procedure

Objectives

- Enlarge the preputial orifice to allow unrestricted movement of the penis in and out of the prepuce.
- Minimize fibrous tissue formation by accurately apposing tissues.
- Completely excise neoplasms, if present.

Equipment

- Standard general surgical pack and suture.

Technique

1. Position the dog in dorsal recumbency and aseptically prepare the paraprepuital area.
2. Depending on the degree of phimosis, either excise a wedge-shaped segment of skin or make an incision through the subcutaneous tissue and preputial mucosa on the dorsal surface of the prepuce to enable exteriorization of the end of the penis.
3. Appose the preputial mucosa to the skin (simple interrupted pattern, non-absorbable sutures).

Postoperative Care and Complications

- Administer postoperative analgesics (see Chapter 6).
- Prevent self-inflicted trauma to the surgical site (an Elizabethan collar may be necessary).
- Postoperative fibrosis may create an insufficient preputial orifice.
- Patient growth may necessitate another surgical procedure.

Prognosis

- If a tumor was present, the prognosis generally is good, provided there was a complete excision.

CRANIAL ADVANCEMENT OF THE PREPUCE

Preoperative Consideration

- This procedure is indicated in dogs with incomplete preputial coverage of the penis to prevent penile desiccation and irritation. Only minor deficiencies (<1–2 cm) in preputial length can be corrected by advancing the prepuce cranially along the abdominal wall.

Surgical Procedure

Objective

- Achieve complete coverage of the distal penis.

Equipment

- Standard general surgical pack and suture.

Technique

1. Place the dog in dorsal recumbency and aseptically prepare the ventral abdomen.
2. Make a U-shaped incision in the skin immediately cranial to the prepuce.
3. Dissect this part of the prepuce from the abdominal skin, advance the prepuce cranially until the penis is covered, and mark this point on the skin.
4. Make a similar U-shaped incision in the skin at the mark and excise the skin between the two incisions.
5. Suture the prepuce to its cranial position (two-layer closure: subcutaneous tissue with simple interrupted, absorbable suture and skin with simple interrupted, non-absorbable suture).

Postoperative Care and Complications

- Administer postoperative analgesics (see Chapter 6).
- Although adequate penile coverage may be achieved at surgery, exposure of the distal penis may recur postoperatively.
- Prevent self-inflicted trauma with an Elizabethan collar.

Prognosis

- Repair of congenital preputial defects has a guarded prognosis.
- An extensive preputial deficiency may require partial or subtotal penile amputation (preferred) or preputial reconstruction.

CORRECTION OF PERSISTENT PENILE FRENULUM

Preoperative Considerations

- The penile frenulum normally ruptures by puberty.
- The persistent penile frenulum usually is composed of minimally vascular connective tissue.

▼ ***Key Point*** Diagnose persistent frenulum by extruding the penis manually or by observing penile deviation during erection.

Surgical Procedure

Objective

- Sever the persistent penile frenulum to enable painless extrusion of the penis from the prepuce.

Equipment

- Standard minor surgical pack.

Technique

1. Place the dog in lateral recumbency and aseptically prepare the preputial cavity.
2. Exteriorize the penis and excise the penile frenulum with scissors. Control hemorrhage with local pressure.

Postoperative Care and Complications

- Prevent self-inflicted trauma.

Prognosis

- The prognosis is good.

Chapter 90

Diseases of the Ovaries and Uterus

Thomas K. Graves

DISEASES OF THE OVARIES

Disorders of the Ovarian Cycle

Etiology

Disorders of the ovarian cycle are seen when ovarian secretion of estrogen and/or progesterone are abnormal. Hormonal abnormalities can be associated with cystic ovarian disease, ovarian dysgenesis, ovarian neoplasia, ovarian remnants, and secondary conditions that affect ovarian function. Ovarian cycle abnormalities usually manifest as abnormalities in reproductive events. The hormonal, physiologic, cytologic, and behavioral events of the normal estrus cycle are presented in Table 90-1.

Clinical Signs

Failure to Cycle or Persistent Anestrus

- Primary anestrus in bitches is defined as failure to enter an estrous cycle by 24 months of age.
- Prolonged anestrus is defined as interestrous intervals of greater than 1 year in the bitch and 1 month in the cycling queen.
- Failure to cycle should be differentiated from "silent heat," in which outward manifestations of estrus are not observed. This happens especially in young bitches in their first cycle.
- If clinical signs of endocrine disorders (hypothyroidism or hyperadrenocorticism) are present, these conditions should be pursued as an underlying cause (see Chapters 31 and 33).
- Basenji, Tibetan mastiff, and dingo breeds can have long interestrous intervals as a normal breed variation.
- Failure to cycle can be associated with intersex conditions (see Chapter 94).
- Luteal cysts that persistently secrete progesterone can delay estrus.

Short Interestrous Intervals

- Four months or less between ovarian cycles is considered abnormal as the uterus requires an adequate amount of time to repair and regenerate, permitting normal implantation on subsequent breedings.
- The most common clinical manifestation is failure to conceive.
- The German shepherd sometimes has short interestrous intervals (4–5 months) that are not associated with infertility.

Prolonged Estrus

- Estrus is considered prolonged if the signs persist greater than 35 days in the bitch and greater than 16 days in the queen.
- The most common cause is follicular ovarian cyst.
- "Split heat" can be confused with prolonged estrus. In a split heat, proestrus ends and estrus does not begin until 2 to 4 weeks later, giving the false impression of prolonged estrus.
- Functional ovarian tumors can secrete estrogen and cause clinical signs of prolonged estrus, but these are uncommon.

Diagnosis

Physical Examination

Careful physical examination can yield findings consistent with secondary causes of ovarian disease (e.g., dermatologic findings in endocrine diseases).

Examine the vulva to determine degrees of swelling and types of discharge that suggest various stages of the estrous cycle (see Table 90-1).

Vaginal Cytology Technique

- Insert a saline moistened cotton-tipped swab into the cranial vagina. Direct the swab dorsally through the vestibule, then redirect to advance the swab cranially. Avoid contact with the floor of the vestibule and vagina so that the clitoral fossa or urethra is not entered.
- Once removed from the vagina, roll the swab several times across the surface of a glass slide and allow to air dry.
- Stain slides with various stains such as Diff-Quick.
- The stage of the estrous cycle is determined by the cells present (see Table 90-1).

Table 90-1. EVENTS OF THE CANINE ESTRUS CYCLE

	Proestrus	Estrus	Diestrus	Anestrus
Duration	0–17 days	3–21 days	2 months	4 months or more
Behavior	Receptivity to male increases Male interest increases	Receptive to male "flagging" Male very interested	Refuses to mate Male may still be attracted	Will not mate Males not attracted
Vulva	Swelling begins and increases	Vulva is large and turgid	Swelling subsides	Normal
Vaginal Discharge	Sanguineous	Sanguineous progressing to clear	Mostly clear, sometimes a little blood during early diestrus	No discharge
Vaginal Cytology	Mostly parabasal and intermediate cells Some superficial cells	Mostly superficial and anuclear squamous cells	Dramatic shift to parabasal and intermediate cells with superficial cells disappearing	No superficial cells No anuclear squamous cells Rare intermediate cell Mostly parabasal cells
Hormonal Events	Estradiol steadily rises Progesterone remains low	Estradiol declines LH surge at onset of estrus Progesterone begins to rise, followed by ovulation	Estradiol remains low Progesterone stays above 15 ng/ml and drops as diestrus ends	Progesterone low Estradiol variable FSH elevated

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Hormonal Analysis

Estradiol

- Typical serum concentrations are 5 to 10 pg/ml during anestrus, 10 to 100 pg/ml during proestrus. During estrus and diestrus, serum estrogen concentrations are often undetectable.
- Elevated serum estrogen concentrations are sometimes found in cystic ovarian disease, but this is not consistent.

▼ ***Key Point*** Estrogen concentrations fluctuate widely and are unreliable indicators of estrous stages.

Progesterone

- Serum concentrations of progesterone greater than 8 ng/ml are consistent with ovulation.
- Parturition occurs at the end of diestrus when the serum concentration of progesterone falls below 1 to 2 ng/ml.
- The finding of increased progesterone concentrations in an animal suspected of prolonged anestrus indicates that a luteal cyst may be present, or that a normal estrus cycle occurred and was not clinically observed.
- A low concentration of serum progesterone during diestrus indicates inadequate luteal function, and may be an underlying reason for infertility.

Ultrasound

Abdominal ultrasonography can be useful for identifying cystic structures on the ovary, but it is difficult to differentiate normal from abnormal follicular structures.

Laparoscopy and Exploratory Surgery

Ovarian disease is definitively diagnosed by visual examination of the ovaries using laparoscopic or an open celiotomy approach.

Treatment

Failure to Cycle or Persistent Anestrus

- Induction of estrus can be attempted, but success in inducing a fertile estrous cycle is unpredictable at best.
- The GnRH analogue, d-Trp^{6}-GnRH (Decapeptyl), has been used to induce estrus in bitches and queens by giving 1 µg/kg subcutaneously every 8 hours until estrus begins, and then half the dose q8h for an additional 3 days.
- Diethylstilbestrol has been used to induce estrus at 5 mg PO daily until 2 days after the onset of estrus.
- Estrus can be induced in the queen by exposure to 12 continuous hours of bright light per day. This results in estrus within 1 to 2 months.
- Porcine follicle-stimulating hormone given at 2 mg/cat IM daily has been used to stimulate estrus in cats.

▼ ***Key Point*** Clinicians using hormonal induction of estrus should be aware that gonadotropins can predispose to the development of cystic ovaries.

Prolonged Estrus

- The most reliable means of treating follicular ovarian cysts is to rupture them manually during exploratory laparotomy, or to remove the ovaries completely.

- Medical induction of ovulation has been reported using GnRH (Cystorelin) at 2.2µg/kg IM once daily for 3 days.
- In the queen, ovulation can be induced mechanically. Insert a lubricated small rectal thermometer (or another similar probe) into the vagina and manipulate in a pulsatile fashion for about 5 seconds at 15-minute intervals 4 to 5 times. This mimics copulation and causes a surge in luteinizing hormone (LH) that results in ovulation in most queens.

Ovarian Remnant Syndrome

Etiology

- Ovariohysterectomized dogs and cats exhibiting clinical signs of estrous are likely to have ovarian remnant syndrome, which is due to incomplete removal of all ovarian tissue at the time of ovariohysterectomy.
- Cats are more likely to have ovarian remnants than are dogs.

Clinical Signs

Clinical signs of estrus typically reoccur between 1 and 3 years following ovariohysterectomy.

Diagnosis

- Diagnosis can be confirmed by vaginal cytology and hormonal assay.
- The finding of increased serum progesterone concentrations that are consistent with diestrus in a female with clinical signs of estrus indicates the presence of ovarian tissue.
- Evaluation of LH levels will also confirm the presence of ovarian tissue in a spayed female. High serum concentrations of LH are normal in a spayed female due to lack of negative feedback from the ovaries. A low LH level is an excellent indicator that a spayed female has ovarian tissue present.
- Definitive diagnosis is made by exploratory laparotomy and biopsy of the remnant tissue.

Treatment

- Treatment is by abdominal exploratory and removal of the ovarian remnants (see Chapter 91 for a description of ovariohysterectomy).

▼ ***Key Point*** Perform the exploratory when the animal is in estrus since the ovarian tissue will be more vascular and easier to identify.

- Ovarian remnant tissue is found in its normal anatomic location near the caudal pole of each kidney.
- Nearly half of cases have bilateral remnants.

Ovarian Neoplasia

Etiology

- Ovarian neoplasia is uncommon in small animals, but several types have been reported.
- The more commonly reported tumors in dogs include granulosa cell tumors (which can cause hyperestrogenism), adenoma, adenocarcinoma, and germ cell tumors such as teratoma and dysgerminoma.
- In cats, granulosa cell tumors, which are more often malignant than in the dog, are most common. Teratoma has also been reported.
- Granulosa cell tumors can occur in ovarian remnants.

Clinical Signs

- Ovarian tumors often cause no clinical signs.
- Functional granulosa cell tumors can cause signs of hyperestrogenism (persistent estrus, gynecomastia, anemia, bone marrow suppression, dermatologic signs) or can underlie infertility in the bitch or queen.
- Granulosa cell tumors can be large enough to cause abdominal distention.
- Malignant ovarian tumors can cause abdominal effusions, systemic illness, and signs of metastatic disease involving any number of organ systems.

Diagnosis

- Clinical signs of hyperestrogenism, palpable abdominal mass, or abdominal effusion aid in the diagnosis.
- Perform a complete blood count, serum chemistry profile, and urinalysis to investigate effects of hormonal imbalances.
- Measurement of serum concentrations of estradiol are not always reliable due to fluctuations in hormone secretion and cannot effectively differentiate between a functional ovarian neoplasm and ovarian remnant syndrome.
- Abdominal radiography can reveal a mass effect in the region of the kidneys. Also perform thoracic radiography to evaluate for metastasis.
- Perform abdominal ultrasound to identify ovarian tumors.
- Ovariectomy and histopathologic examination provide a definitive diagnosis (see Chapter 91). Examine regional lymph nodes and obtain tissue samples for histopathology at the time of exploratory laparotomy.

Treatment

Ovariohysterectomy is the recommended treatment for ovarian neoplasia (see Chapter 91). Surgery may not be curative in animals with malignant disease. Consider adjunctive therapy (e.g., chemotherapy) in these animals.

DISEASES OF THE NON-PREGNANT UTERUS

Pyometra

Etiology

- Progesterone normally causes endometrial gland growth and fluid secretion, as well as decreased myometrial contractility and retention of uterine contents. These hormonal effects are necessary to sustain pregnancy, and serum progesterone concentrations are normally elevated throughout diestrus, finally decreasing to below 1 to 2 ng/ml just prior to parturition.
- The non-pregnant uterus typically goes through the same hormonal cycle as a gravid one, and cystic endometrial hyperplasia (CEH) can occur.
- Bacteria from the lower genital tract can colonize the uterus leading to infection. The most commonly isolated bacteria from pyometra are *Escherichia coli*.

Risk Factors for Pyometra

- Previous treatment with progestins such as megestrol acetate predisposes the patient to the development of pyometra. Progestins are sometimes used in bitches to suppress estrus and are used for dermatologic and behavioral conditions, although their use should be minimized.
- Pyometra may also be more common in bitches treated with estrogens, as is sometimes done to prevent pregnancy in mismating incidents. Estrogens potentiate the uterine effects of progesterone.
- A genetic component to pyometra has not been identified.
- Nulliparous bitches (which have had no puppies) have a highly increased risk of pyometra compared with multiparous bitches.

Clinical Signs

- Because the disorder is progesterone dependent, clinical signs should begin sometime after the onset of diestrus. Therefore, a history of estrus within the preceding weeks is common. Although progesterone is needed to initiate CEH and pyometra, the condition can persist after diestrus has ended, and some cases are diagnosed several weeks after progesterone would be expected to be elevated.
- Vaginal discharge is a common clinical sign. When vaginal discharge is observed, the pyometra is said to be "open," referring to patency of the cervix.
- Pyometra in the absence of vaginal discharge is referred to as "closed," meaning that uterine contents are unable to drain through a closed cervix. Whether the cervix is actually patent or not in a given case of pyometra is usually not investigated, and a true difference between these two classifications may not exist.
- The vaginal discharge of pyometra is usually purulent but can be a combination of pus and blood.
- Dehydration and depression are common in pyometra.
- Polyuria is a common finding in dogs with pyometra and is thought to be a bacterial endotoxin effect on the renal urine concentrating mechanism. Polyuria is not noted in cats with pyometra.
- Vomiting, inappetence, and general signs of systemic illness are often present.
- Fever may be noted but, surprisingly, is not common.
- The clinical signs of pyometra can be nonspecific, especially in cats.

Diagnosis

Diagnostic tests in suspected cases of pyometra are essential to differentiate between pyometra and pregnancy.

History and Physical Examination

- Obtain a thorough breeding history and timing of clinical signs in relation to the estrous cycle.
- Physical examination may or may not reveal vaginal discharge. Cats and some dogs may keep themselves clean enough that discharge goes unnoticed, but gentle opening of the vulva may reveal residual discharge in the vestibule.
- Abdominal palpation may reveal an enlarged fluid-filled uterus or tubular mass.
- In severe cases, animals can be in septic shock and can present in circulatory collapse.

Laboratory Tests

- Complete blood count commonly shows neutrophilia with toxic changes and/or a left shift. Neutrophil counts can be extremely high, sometimes over 100,000 cells/μl. A mild nonregenerative anemia is usually present, which can be masked by severe dehydration. In septic patients, there may be a leukopenia with a high percentage of band neutrophils (degenerative left shift).
- Serum biochemistry abnormalities can include azotemia and hyperproteinemia (from dehydration), as well as liver enzyme elevations.
- Perform urinalysis to investigate causes of polyuria and polydipsia. Do not obtain the urine by blind cystocentesis because of the risk of penetrating the uterus. Common urinalysis findings included isosthenuria, bacteriuria, and proteinuria.

Vaginal Cytology and Culture

- Cytology of a vaginal swab reveals a septic exudate with endometrial cells present.
- Bacterial culture of the exudates can be performed to identify a bacterial pathogen.

- Obtain samples for culture through a sterile vaginal speculum or use a guarded swab to prevent contamination from normal vaginal flora.
- Culture and antimicrobial drug sensitivity results can aid in the selection of antibiotics.

Diagnostic Imaging

- Radiographs of the abdomen may reveal an enlarged, fluid-dense tubular structure that is consistent with pyometra, but this is not always seen. Fetal calcification is not seen until roughly 45 days of gestation, so care must be taken to differentiate a fluid-filled uterus from a gravid one.
- Abdominal ultrasound is extremely useful in diagnosis of pyometra and can also detect the presence of a fetus (see Chapter 4).

Treatment

Fluid Therapy

- Aggressive fluid therapy is especially important in septic or dehydrated animals. Lactated Ringer's solution is a good choice for correction of dehydration and management of septic shock (see Chapter 5).
- Administer fluid therapy to even relatively stable animals prior to treatment of the pyometra itself.

Antibiotic Therapy

- Due to the wide range of possible bacterial pathogens in pyometra, administer broad-spectrum antibiotics. Because *E. coli* is a common pathogen, choose an antibiotic that is effective against this organism.
- Dehydrated, inappetent, vomiting, or severely depressed animals or those for whom surgery is planned should be given parenteral antibiotics. Oral antibiotics can be given if appropriate for the individual patient.

Recommended Antibiotics

- Combination of ampicillin (20 mg/kg q8h) and enrofloxacin (2.5 mg/kg q12h)
- Combination of cephalothin (20 mg/kg q8h) and amikacin (5 mg/kg q12h)
  - Because of potential nephrotoxicity, avoid amikacin in animals with questionable or documented impaired renal function.
- Amoxicillin/clavulanate (12.5–25 mg/kg q12h)

Medical Management

Prostaglandins

- When pyometra is encountered in valuable breeding bitches, in which ovariohysterectomy is not preferred, medical therapy with prostaglandin F2-alpha ($PGF_{2\alpha}$) can be used.
- It is commonly recommended that $PGF_{2\alpha}$ therapy only be used in young bitches without signs of systemic illness and that treatment be reserved for open-cervix pyometra. There is little evidence, however, to support these recommendations, and, in my experience, $PGF_{2\alpha}$ therapy can be successful regardless of the clinical presentation.
- $PGF_{2\alpha}$ causes uterine contraction, relaxation of the cervix, and expulsion of uterine contents.
- Closed-cervix pyometra patients are thought to be at risk for uterine rupture or pressure-driven expulsion of uterine contents through the oviduct, both resulting in peritonitis, but this is not well established.
- Several synthetic analogues of $PGF_{2\alpha}$ have been investigated in the dog, but most clinicians have used the natural product (Lutalyse), and it is the preferred drug.
- $PGF_{2\alpha}$ can cause adverse reactions including nausea, abdominal pain, panting, mydriasis, defecation, salivation, fever, and nesting behavior. These side effects are less pronounced with lower doses of the drug.
  - Adverse reactions develop quickly after drug administration and are anecdotally less severe if the patient is exercised (e.g., walked briskly) for 20 minutes following $PGF_{2\alpha}$ administration. Adverse reactions also become milder as the course of therapy progresses.
- Bitches undergoing successful $PGF_{2\alpha}$ therapy have subsequent conception rates and litter sizes similar to those of bitches not having pyometra.
- Once having undergone $PGF_{2\alpha}$ therapy, redevelopment of pyometra on subsequent estrous cycles is a risk. For this reason, bitches should be bred on each subsequent estrous cycle if possible.

▼ ***Key Point*** Carefully calculate the dose of $PGF_{2\alpha}$ because the drug can be very toxic.

Protocol for Prostaglandin F2-alpha Therapy

- Begin fluid and antibiotic therapy, and continue antibiotics for 2 weeks past the end of $PGF_{2\alpha}$ therapy.
- Administer $PGF_{2\alpha}$ at a dosage of 0.1 to 0.2 mg/kg subcutaneously bid for 3 to 5 days or more.
- Little effect on vaginal discharge is seen on the first day of treatment.
- On subsequent days, $PGF_{2\alpha}$ therapy often results in an increase in vaginal discharge as the uterus is evacuated.
- Monitor uterine contents by ultrasound, and continue treatment until evidence of uterine fluid is no longer seen and vaginal discharge has stopped.
- Treatment for more than 5 to 6 days is said to be associated with a poor prognosis, but this is not well established and bitches treated for considerably longer periods can be fertile.

Surgical Management

- Ovariohysterectomy is the most definitive treatment of pyometra, especially for dogs not intended for future breeding (see Chapter 91).
- Administer fluid therapy and antibiotics as discussed under "Medical Management" in this section.

- Consider placement of closed suction drains or open peritoneal drainage if uterine rupture and gross peritonitis is present (see Chapter 76).

DISEASES OF THE PREGNANT UTERUS

Etiology

Uterine diseases that occur during pregnancy can result in abortion. Abortion is not always due to uterine disease per se but can also be caused by fetal genetic or developmental abnormalities, by toxic drugs or teratogens, by hormonal influences that result in a shortened diestrus (e.g., luteal failure or glucocorticoid excess), or by non-uterine disorders of the bitch or queen that result in the inability to carry a pregnancy to term.

Infectious Diseases

- In dogs, *Brucella canis* and herpesvirus are probably the most important pathogens causing abortion.
- Other pathogens associated with abortion included canine distemper virus, canine parvovirus, *Toxoplasma gondii, Neospora caninum,* and various bacteria.

▼ ***Key Point*** The association between *Mycoplasma canis* and reproductive disorders has not been proven. *Mycoplasma* and *Ureaplasma* organisms are found in normal canine reproductive tract, as well as in bitches with reproductive disorders, so a cause-and-effect relationship is not established. Experimental infection with *Mycoplasma* can cause metritis in the bitch.

- In cats, feline panleukopenia virus and feline herpesvirus are most commonly associated with abortion.
- Feline retroviral infections can also result in pregnancy loss.
- *Mycoplasma* infections, as in dogs, have not been established as a cause of abortion in cats.

Brucellosis

B. canis is a small, gram-negative, intracellular parasite that grows in placental tissue (and others) and infects the uterus and fetus (see also Chapter 19).

Herpesvirus

Herpesvirus infections can cause abortion in both dogs and cats (see also Chapter 16). Prevalence of infection is very high in both dogs and cats. In kennels, infection rates may be as high as 85%.

Clinical Signs

- Most affected bitches have no clinical signs other than abortion. Abortion can occur at any time during pregnancy.
- Lymphadenopathy may be found.
- Non-reproductive tissues can be affected in brucellosis, causing clinical signs of uveitis, discospondylitis, lymphadenitis, and dermatitis.
- The most common clinical signs of herpesvirus infections are upper respiratory signs.

Diagnosis of Brucellosis

- The rapid slide agglutination test (RSAT) detects cell wall antigens of *B. canis* that are also components of some other bacteria, so this test is not specific and false-positive results can occur. The RSAT is, however, highly sensitive and is easily performed as a cage-side test. A positive RSAT must be confirmed with further serologic testing.
- Agar-gel immunodiffusion (AGID) tests to detect *Brucella* species cytoplasmic antigens are very specific and are used to confirm a diagnosis of brucellosis.
- Stillbirth and neonatal death are more common sequelae to infection than abortion.

Treatment

Brucellosis

- Treatment of brucellosis is difficult. The infection is not always eradicated despite long-term antibiotic therapy. Combinations of a tetracycline antibiotic (doxycycline at 10 mg/kg PO q12h or tetracycline hydrochloride at 25 mg/kg PO q8h) given for 4 weeks and dihydrostreptomycin (10 mg/kg IM q8h during weeks 1 and 4 of tetracycline treatment) may be most effective (see Chapter 19).
- Results of serologic tests and blood cultures for *B. canis* will become negative after treatment, even if a chronic infection persists. Eradication of *B. canis* may not be possible.

▼ ***Key Point*** Bitches with brucellosis should never be used for breeding and must be spayed to prevent spread of infection.

- *B. canis* infections are uncommon in human brucellosis, but zoonotic infections have been reported. For this reason, and because of the difficulty in treating an infection, dogs with brucellosis are sometimes euthanized.
- There is no vaccine available to prevent brucellosis in dogs.

Herpesvirus

Most herpesvirus infections in dogs are subclinical, and abortion, stillbirth, and neonatal death usually occur only if the initial infection occurs during gestation. A bitch aborting a litter due to herpesvirus infection is unlikely to abort the next litter due to the same infectious cause. Treatment is not effective or needed.

DISORDERS OF PARTURITION AND DYSTOCIA

- Dystocia is common in dogs. It can occur because conformation of the birth canal is inadequate to allow parturition, because of a relatively oversized fetus, or because of factors that affect the normal contractile function of the uterus.
- Toy-breed dogs with large heads and relatively small pelvic canals are predisposed to dystocia.
- In breeds such as bulldogs and Pekingese, dystocia is so common that breeders typically request cesarean sections without allowing bitches to progress past the initial stage of labor.
- Brachycephalic cat breeds and the Devon Rex are also predisposed.
- Uterine inertia is common in many breeds and the cause is not known.

Normal Labor

Traditionally, the labor process is divided into three stages. In stage 1, dilation of the cervix and uterine contractions occur. In stage 2, the offspring is delivered, and in stage 3, the placenta is delivered. The terminology used in dogs and cats is borrowed from the human terminology but is less appropriate for animals with multiple births. The lines between these stages are not obvious, and dogs and cats can alternate between delivery of pups and kittens and delivery of placentas. For these reasons, the traditional stages of labor are not presented here, but a description of the process is given in a stepwise fashion.

Events of Normal Parturition

- Prior to the onset of labor, a transient temperature drop (usually below 100°F) occurs in the dog. For this reason, owners of pregnant bitches are instructed to monitor the temperature twice daily during the last week of gestation. In cats, monitoring of rectal temperature during late gestation is not typically done.
- During or following the temperature drop the cervix dilates and uterine contractions begin. This step can go unnoticed by pet owners.
- During cervical dilation and initial contractions, bitches typically refuse food and may vomit, shiver, and become restless. Queens are consistently anorectic before and during parturition.
- Nesting behavior can be evident at this point.
- Typically, after 6 to 12 hours, active contractions and straining to deliver a fetus begin. At this point, the cervix is fully dilated and a fetus enters the birth canal.
- The chorioallantoic membranes are sometimes first seen as a bubble protruding from the vulva, and amniotic fluid may be passed.
- Although the time is highly variable, delivery of the first pup or kitten typically occurs in less than 4 hours. Toy breeds or breeds predisposed to dystocia should not be allowed to strain for more than 2 hours before delivery of a first fetus.
- Once a fetus is within the birth canal and is evident externally, it should pass easily from the dam within seconds. A pup or kitten easily palpated in the vagina or protruding from the vulva without being fully delivered is a cause for concern; use gentle traction to help the delivery. It is common for the attendant to manually assist the delivery of each pup or kitten.
- Variability on fetal position during delivery is common in dogs and cats. Both cranial and caudal presentations are normal. Fetal posture can be with the neck flexed or extended. The fetal position in the vagina is almost always dorsal.
- Immediately following delivery, fetal membranes are removed manually from the head to allow breathing. The umbilical cord should be clamped about 2 cm from the body wall, severed, and ligated.
- Inspect the oral cavity of the newborn and remove excess fluid by gentle suction. Check for cleft palates.
- Place the newborn in a clean towel. Stimulate and dry by rubbing. Do not swing newborn puppies between the attendant's legs, as is commonly practiced, because this can result in injury and can remove surfactant from the airways. Also, it has no benefit over safer methods to remove fluids and stimulate respiration.
- Subsequent deliveries can happen rapidly or can be delayed for considerable periods of time. Bitches will often rest, sometimes for up to 2 hours between deliveries.
- Intense straining should produce a pup or kitten within less than 20 minutes.
- Passage of placentas is variable. Sometimes delivery of each fetus is followed by delivery of a placenta. Sometimes they are delivered simultaneously. Sometimes entire litters can be delivered before placentas are passed.
- A dark green or brown discharge is common during and following labor. It occurs because a placenta has been detached from the uterine wall. The appearance of this discharge without delivery of a pup is cause for concern because placental detachment results in fetal oxygen deprivation.

Etiology

Maternal Causes

Uterine Inertia

Possible causes of uterine inertia (lack of uterine contractions) include fatigue, hypoglycemia, and hypocalcemia, but in most cases the cause is unknown. Uterine inertia can be classified as primary (inherent problem with the uterus or underlying systemic disorder) or secondary (persistent straining against an obstruction).

Anatomic Abnormality

- The pelvic canal may be abnormally small due to previous pelvic fractures or as a developmental abnormality in brachycephalic breeds and others.
- Uterine malposition from uterine torsion or prolapse can occur.
- Vaginal or vulvar hypoplasia, persistent bands of tissue in the vagina, or strictures can be present (see Chapter 92).

Fetal Causes

Oversized Fetus

- Single-fetus pregnancies can produce an abnormally large fetus.
- Hydrops fetalis is a condition of fetal edema, referred to by dog breeders as "water puppies." The cause is usually undiagnosed but can be from conditions such as immune-mediated vasculitis and congestive heart failure in other species.
- Hydrocephalus can result in a relatively oversized fetus.

Fetal Death

Fetal death can cause metritis, resulting in dystocia.

Diagnosis

- Obtain a thorough history to determine length of gestation and events of parturition.
- Normal gestation in the dog averages 66 days (range of 64–71 days) and in the cat averages 64 days (range of 59–70 days).

Physical Examination

- Examine the perineum first for evidence of a partially delivered fetus. If no partially delivered fetus is present, perform a full physical examination to investigate signs of systemic illness that may cause dystocia and to assess the uterus by abdominal palpation.
- Digitally examine the vagina using sterile technique. When the cranial vaginal wall is stroked with a fingertip, vaginal and abdominal contractions can be felt.
  - The absence of contraction is consistent with, but not diagnostic for, uterine inertia.

Diagnostic Imaging

- Obtain abdominal radiographs to assess fetal size and health, as well as to determine the number of fetuses.
- Radiographic signs of fetal death include intrafetal gas, overlap or misalignment of bones (especially skull bone overlap), or fetal demineralization.
- Perform abdominal ultrasound to assess fetal heart rate. Normal canine fetuses have heart rates greater than 200 bpm. If the fetal heart rate is less than 180 bpm, severe fetal stress is present and immediate cesarean section is indicated.

Laboratory Tests

- Obtain blood for a complete blood count and serum biochemistry.
  - Hypoglycemia and/or hypocalcemia may be present.
- Mild anemia is normal in full-term bitches and queens.

▼ ***Key Point*** If possible, measure the serum progesterone concentration. If it is greater than 2 ng/ml, the pregnancy is not at full term.

Criteria for Diagnosing Dystocia

- If it has been more than 24 hours since the rectal temperature dropped in a bitch, and labor has not begun
- A full-term queen that has been anorectic for more than 24 hours
- Prolonged gestation (>70 days from breeding)
- Active straining for >30 to 60 minutes without expulsion of a fetus
- Resting phase between delivery of a fetus >4 hours with known retained fetuses
- Intermittent weak contractions for >2 hours without delivery of a fetus
- Systemic signs of illness (e.g., fever, severe weakness, and vomiting)
- Signs of severe pain during parturition
- Purulent or hemorrhagic vaginal discharge
- Evidence of fetal death

Treatment

Medical Management

- If both mother and offspring appear healthy, and there is no obstruction, consider oxytocin therapy. Oxytocin (0.25 U/dog IM or SC) increases the frequency of uterine contractions.
- A pup should be delivered within 30 minutes of oxytocin administration.
- Animals not responding to oxytocin within 30 minutes are candidates for cesarean section.

▼ ***Key Point*** Repeated doses of oxytocin are usually not helpful and are not recommended because the hormone can cause placental separation and fetal death. Sustained uterine contractions induced by oxytocin can also cause decreased fetal blood supply.

- *Calcium gluconate* is sometimes given prior to oxytocin because calcium is necessary for muscle contraction, and calcium administration can increase uterine contraction even if the measured serum calcium concentration is normal.

- 10% Calcium gluconate is given as a very slow intravenous bonus (through an indwelling catheter to avoid the risk of extravasation) at a dosage of 0.2 ml/kg.

▼ ***Key Point*** Do not administer calcium salts subcutaneously because they are irritating and can cause tissue necrosis and subcutaneous calcium deposition.

Indications for Caesarian Section (see Chapter 91)

- No response to medical management
- Uterine inertia
- Maternal pelvic or vaginal abnormality or systemic illness
- Oversized fetus
- Evidence of fetal death
- Owners concerned about loss of newborns during a difficult parturition (e.g., brachycephalic dog)
- Hypocalcemia or hypoglycemia in the bitch or queen; parturition rarely resumes following correction of these biochemical abnormalities, so perform cesarean section along with treatment for hypoglycemia or hypocalcemia

POSTPARTUM UTERINE DISORDERS

Bacterial Metritis

Etiology

Bacteria can ascend into the uterus and cause severe, life-threatening infection following normal parturition, prolonged dystocia, parturition with retained fetus or placenta, or abortion.

Clinical Signs

- History of recent parturition (usually within a week).
- Hemorrhagic, fetid, mucopurulent vaginal discharge is common.
- Depression, lethargy, anorexia, vomiting, and any sign of systemic illness can be present.
- The abdomen can be painful on palpation, and a turgid uterus can be palpated. Uterine involution in a normal postpartum period is not complete by this time, so palpation findings are subjective.
- Patients can present in septic shock.

Diagnosis

- Urinalysis, complete blood count, and serum chemistry can show results consistent with sepsis, dehydration, and, if advanced, multiple organ failure.
- Vaginal cytology yields degenerate neutrophils and bacteria.
- Bacterial culture of the vaginal discharge is useful in selecting an antibiotic.
- Perform abdominal ultrasound to detect a dead fetus, retained placenta, uterine enlargement, and abdominal effusions associated with peritonitis.
- Obtain abdominal radiographs to detect retained dead fetuses.

Treatment

- Fluid therapy is essential, and shock doses of intravenous fluids are often needed.
- Add potassium and glucose to the fluids as needed (indicated by serum chemistry profile results).
- Administer broad-spectrum antibiotics (see under "Pyometra"). Choose antibiotics based on antimicrobial sensitivity testing if possible.
- Oxytocin therapy has been recommended to evacuate uterine contents, but this hormone is not effective more than 48 hours after parturition. Endogenous oxytocin should have already maximally stimulated its receptors, so there is little rationale for its use.
- Because of the risk of sepsis and death, exploratory laparotomy and ovariohysterectomy are necessary (see Chapter 91).

Uterine Prolapse

- Rarely, the uterus can prolapse immediately following parturition.
- The condition is diagnosed by the finding of tissue protruding from the vulva following parturition.
- Treatment involves manual reduction of the prolapsed tissue, or, if tissue is devitalized, amputation. For a discussion of surgical treatment of uterine prolapse, see Chapter 91.

Subinvolution of Placental Sites

Etiology

- The process of uterine involution occurs for up to 3 months postpartum but is usually essentially complete by 6 weeks. During that period, a hemorrhagic, sometimes brownish, and mucoid discharge from the vagina is normal. Early in the process of uterine involution, the discharge can seem quite copious.
- In some bitches, placental attachment sites are invaded by trophoblastic cells, these sites fail to regress normally, and hemorrhage persists.
- Subinvolution of placental sites (SIPS) is most common in younger bitches.
- SIPS is not known to occur in the cat.

Clinical Signs

Persistent vaginal bleeding for more than 6 weeks postpartum in an otherwise normal bitch is the typical clinical sign of SIPS.

Diagnosis

- Examination of a vaginal smear from a bitch with SIPS reveals hemorrhage, parabasal cells, and, sometimes, the presence of trophoblastic cells.
- Blood loss due to SIPS is rarely clinically significant. Monitor red blood cell count or packed cell volume if indicated.
- If clinical anemia develops, other causes of blood loss should be investigated.

Treatment

- SIPS eventually resolves without treatment.
- Bitches are commonly fertile following an episode SIPS, and the condition does not necessarily develop following subsequent pregnancies.

UTERINE NEOPLASIA

Etiology

- Tumors of the uterus are rare in dogs and cats, probably because of the high prevalence of ovariohysterectomy.
- Endometrial adenocarcinoma is the most common uterine tumor of the queen, and leiomyoma and leiomyosarcoma are the most common uterine tumors of the bitch.
- A variety of other tumors have been reported in dogs and cats, but they are very uncommon.

Clinical Signs

- Uterine tumors are most often found incidentally at ovariohysterectomy.
- Vaginal discharge may be present in some animals with invasive uterine tumors. Tumors of the cervix may cause bleeding.
- In cats, endometrial adenocarcinoma is typically associated with local and distant metastases to many different organs, and clinical signs referable to any organ system can be seen.

Diagnosis

- Uterine masses may be detected by abdominal palpation.
- In rare cases, cytology of vaginal discharge may yield tumor cells.
- A suspected uterine mass can be confirmed by abdominal ultrasound, whereas it is difficult to localize a mass to the uterus on plain abdominal radiographs.
- Ultrasound-guided fine-needle aspiration of a uterine mass may yield a cytopathologic diagnosis.
- Perform preoperative evaluation consisting of urinalysis, complete blood count, serum chemistry, three-view thoracic radiographs, and abdominal ultrasound to evaluate for metastatic disease.
- Definitive diagnosis is made by histopathology of surgically obtained tissues.

Treatment

- Ovariohysterectomy is the recommended treatment (see Chapter 91).
- Most bitches can be cured by complete excision of a uterine mass.

Chapter

91 Surgery of the Ovaries and Uterus

Gretchen K. Sicard / Roger B. Fingland

Surgical procedures performed on the uterus and ovaries include ovariohysterectomy, cesarean section, uterine biopsy, and rarely, ovariectomy. Uterine surgery usually is straightforward but requires sound basic surgery skills and a thorough understanding of the anatomy and physiology of the reproductive tract.

ANATOMY (Fig. 91-1)

Ovaries

- The ovaries are located 1 to 3 cm caudal to the kidneys.
- The ovaries are attached to the abdominal wall by the mesovarium, a part of the broad ligament.
- The suspensory ligament is the cranial continuation of the broad ligament and extends between the ventral third of the last two ribs and the ventral surface of the ovary.
- The proper ligament is a continuation of the suspensory ligament and extends from the caudal end of the ovary to the cranial end of the uterine horn.
- The ovarian arteriovenous complex (OAVC) lies on the medial side of the broad ligament and supplies the ovaries and the cranial portion of the uterine tube. The distal two-thirds of the OAVC is convoluted in the dog, similar to the pampiniform plexus in males.
- The left ovarian vein drains into the left renal vein; the right ovarian vein drains into the caudal vena cava.

Uterus

- The uterus consists of the cervix, body, and two uterine horns. Oviducts (uterine tubes) connect the uterine horns and ovaries.
- The uterus is attached to the dorsolateral wall of the abdominal cavity and the lateral wall of the pelvic cavity by paired double folds of peritoneum called broad ligaments.
- The round ligament is the caudal continuation of the proper ligament. The round ligament extends caudally and ventrally in the broad ligament and passes through the inguinal canal, terminating subcutaneously near the vulva.
- The uterine branch of the internal iliac artery is the main artery to the uterus. The uterine branch of the urogenital artery supplies the caudal portion of the uterus, the cervix, and part of the vagina. The uterine branch of the ovarian artery supplies the cranial part of the uterine horns.

OVARIOHYSTERECTOMY

Preoperative Considerations

- Elective sterilization is the most common indication for ovariohysterectomy. Ovariohysterectomy is the treatment of choice for most uterine diseases including pyometra, uterine torsion, cystic endometrial hyperplasia, uterine rupture, and uterine neoplasia (see Chapter 90 for a description of these diseases).

▼ ***Key Point*** Ovariohysterectomy before the first or second estrus provides a definitive protective factor against development of mammary neoplasia. After the third estrus (or approximately 2.5 years), there is no significant effect of ovariohysterectomy for the prevention of mammary neoplasia.

- An alternative method of sterilization of a female dog or cat is ovariectomy without hysterectomy. Studies have shown no difference in long-term results, or complications, between ovariectomy and ovariohysterectomy. Ovariectomy may also be considered for the surgical treatment of small animal patients with a mass lesion involving the ovary, particularly if the owner wishes to maintain the reproductive status of the animal. However, if ovarian neoplasia is suspected, ovariohysterectomy coupled with a complete abdominal exploratory is indicated to ensure complete resection of the neoplasm and examination of all abdominal viscera for evidence of metastasis.
- Whether the procedure is elective or not, perform an appropriate preoperative evaluation, including a complete history, physical examination, and appropriate blood work.

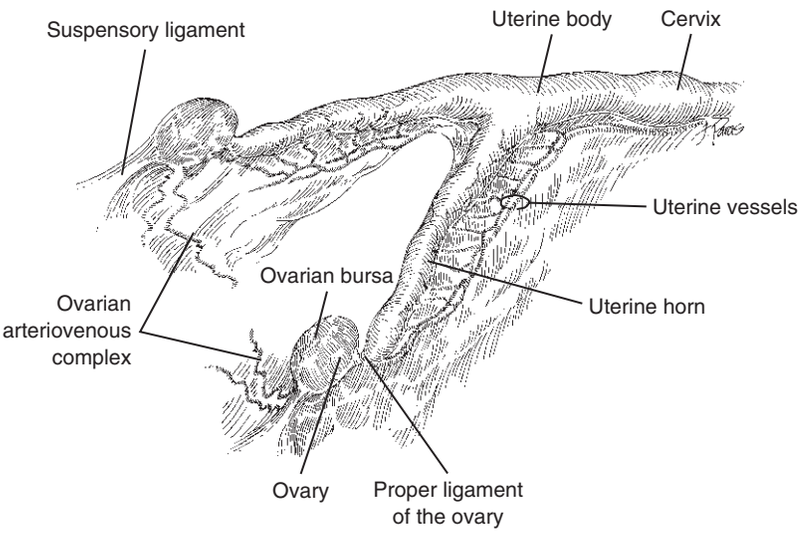

Figure 91-1. Anatomy of the uterus and ovaries.

Surgical Procedure

Objective

- To remove the uterus and ovaries

Equipment

- Standard general surgery instrument pack and suture
- Ovariohysterectomy (Snook) hook (optional)

Technique

1. After anesthetizing the animal, manually express the urinary bladder.
2. Position the animal in dorsal recumbency.
3. Prepare the entire ventral abdominal region for aseptic surgery.
4. Skin incision:
   a. *Dog:* Make a ventral midline incision extending from the umbilicus to a point halfway between the umbilicus and the brim of the pubis.
   b. *Cat:* Begin the ventral midline incision approximately 1 to 2 cm caudal to the umbilicus and extend the incision caudally 3 to 5 cm.
   c. A longer abdominal incision is required to remove an enlarged uterus (e.g., pyometra).
   d. Attempt to incise exactly on midline in lactating bitches to avoid trauma to the mammary glands.
5. Enter the abdominal cavity through the linea alba.
6. Locate the left uterine horn using the ovariohysterectomy hook or index finger. Displace the omentum and bowel cranially if necessary to find the uterus.
7. Place a small hemostat across the proper ligament to aid in caudal retraction of the ovary.
8. Grasp the ovary between the thumb and the middle fingers. Place the index finger as far proximal as possible on the suspensory ligament (Fig. 91-2*A*).
9. Place tension on the suspensory ligament by rotating the index finger caudally. Gradually increase tension on the suspensory ligament until the ligament stretches or ruptures.

▼ ***Key Point*** Avoid placing tension on the OAVC during manipulation of the suspensory ligament or when placing ligatures.

10. Identify the OAVC. Using a Rochester-Carmalt hemostatic forceps (clamp), make an opening in the mesovarium immediately caudal to the OAVC in an area clear of vessels and fat (Fig. 91-2*B*).
11. Triple-clamp and transect the OAVC (Fig. 91-2*C*).
    a. Double-clamp the OAVC with Rochester-Carmalt hemostatic forceps. Place the first clamp immediately proximal (toward the aorta) to the ovary and the second clamp approximately 5 mm proximal to the first. Place a third clamp across the proper ligament between the ovary and the uterine horn. Transect the OAVC between the middle clamp and the ovary (Fig. 91-2*D*).
    b. Alternatively, place all three clamps across the OAVC proximal to the ovary. Transect the OAVC between the middle clamp and the clamp adjacent to the ovary (Fig. 91-2*E*).

▼ ***Key Point*** Place the hemostatic forceps on the OAVC as close as possible to the ovary to prevent accidental inclusion of the ureter, but be sure to remove all of the ovarian tissue.

12. Loosely place a circumferential ligature around the proximal clamp (Fig. 91-2*F*). Tighten the ligature as the clamp is removed. In this manner, the circumferential ligature is tightened in the groove of crushed tissue created by the clamp (Fig. 91-2*G*).

▼ ***Key Point*** The clamp adjacent to the ligature may need to be loosened before knotting to ensure proper tightness of the knot.

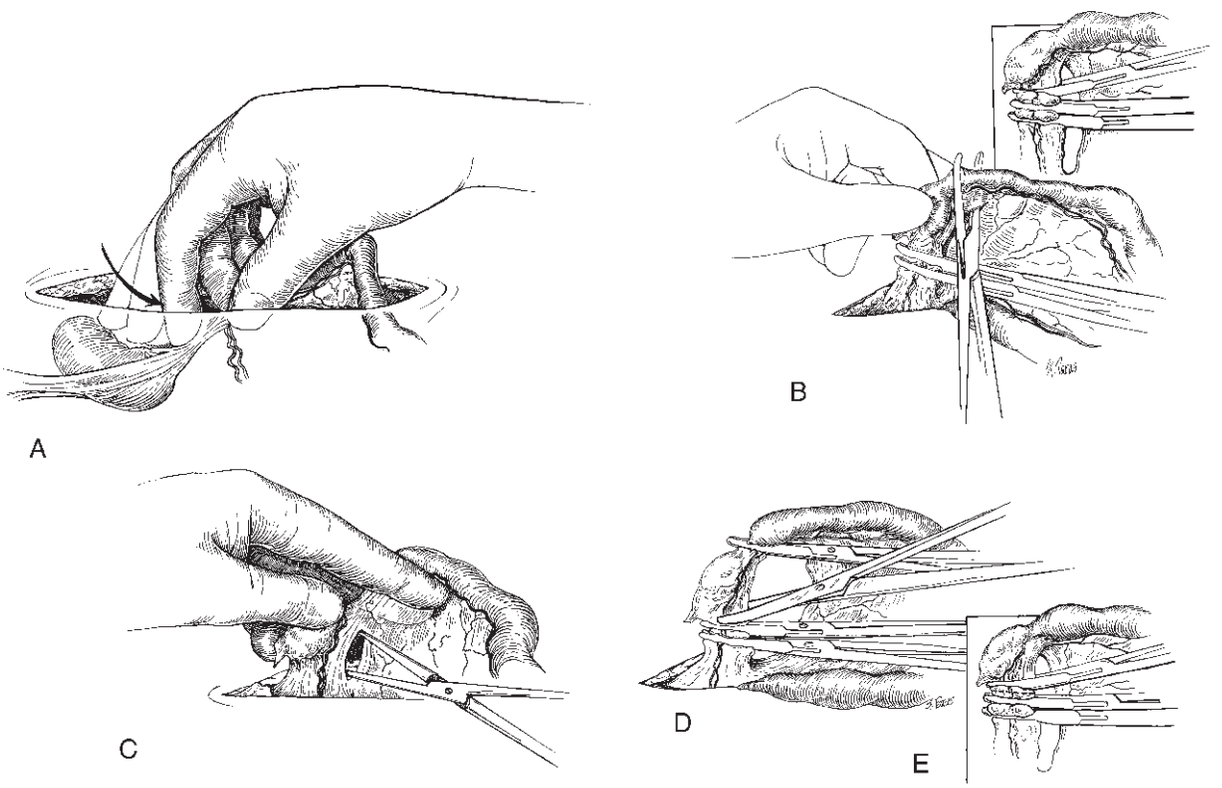

Figure 91-2. Ovariohysterectomy. *A,* Separate the suspensory ligament. *B,* Open the mesovarium immediately caudal to the ovarian arteriovenous complex (OAVC). *C,* Triple-clamp the OAVC. *D,* Transect the OAVC between the ovary and the clamp. *E,* Alternative clamp and transection method.

13. Place a transfixing ligature between the circumferential ligature and the transected end of the OAVC (Fig. 91-2*H* and *I*). A full ligature (circumferential) may be used instead of a transfixing ligature in young cats or small dogs.

▼ ***Key Point*** Never include ovarian tissue in the ligatures.

14. Grasp the OAVC distal to the ligature (without grasping the ligature) with thumb forceps, remove the middle clamp, and inspect the OAVC for bleeding. If bleeding occurs, place a second circumferential ligature on the OAVC proximal to the first.
15. Follow the left uterine horn distally to the bifurcation, locate the right uterine horn, and follow the right uterine horn proximally to the right OAVC.
16. Ligate and transect the right OAVC, as described previously.
17. Transect the broad ligament.
    a. In most preparturient animals, the broad ligament can be manually separated. Make an opening in the broad ligament adjacent to the uterine artery and vein close to the cervix (Fig. 91-2*J*). Place four fingers through the opening in the broad ligament and grasp the entire broad ligament, including the round ligament (Fig. 91-2*K*). Pull the broad ligament cranially (not ventrally) until the broad ligament and the round ligament are free (Fig. 91-2*L*).
    b. If the broad ligament is highly vascular, large vessels may be ligated individually or mass ligation of the broad ligament or portions of the ligament may be ligated.
18. Exteriorize the uterine body and locate the cervix.
19. Divide the uterine body after two ligatures are placed (Fig. 91-2*M* through *O*). Remove the entire uterus proximal to the cervix.
20. Evaluate the OAVC pedicles and the uterine body for bleeding prior to abdominal closure. The left and right OAVC are located immediately caudal to the caudal pole of each respective kidney.
    a. Locate the left OAVC pedicle by retracting the descending colon medially, exposing the left paralumbar gutter.
    b. Locate the right OAVC pedicle by retracting the duodenum medially, exposing the right paralumbar gutter.
    c. Retroflex the bladder. The ligated uterine body lies ventral to the descending colon and dorsal to the bladder.
21. Close the abdominal incision routinely.

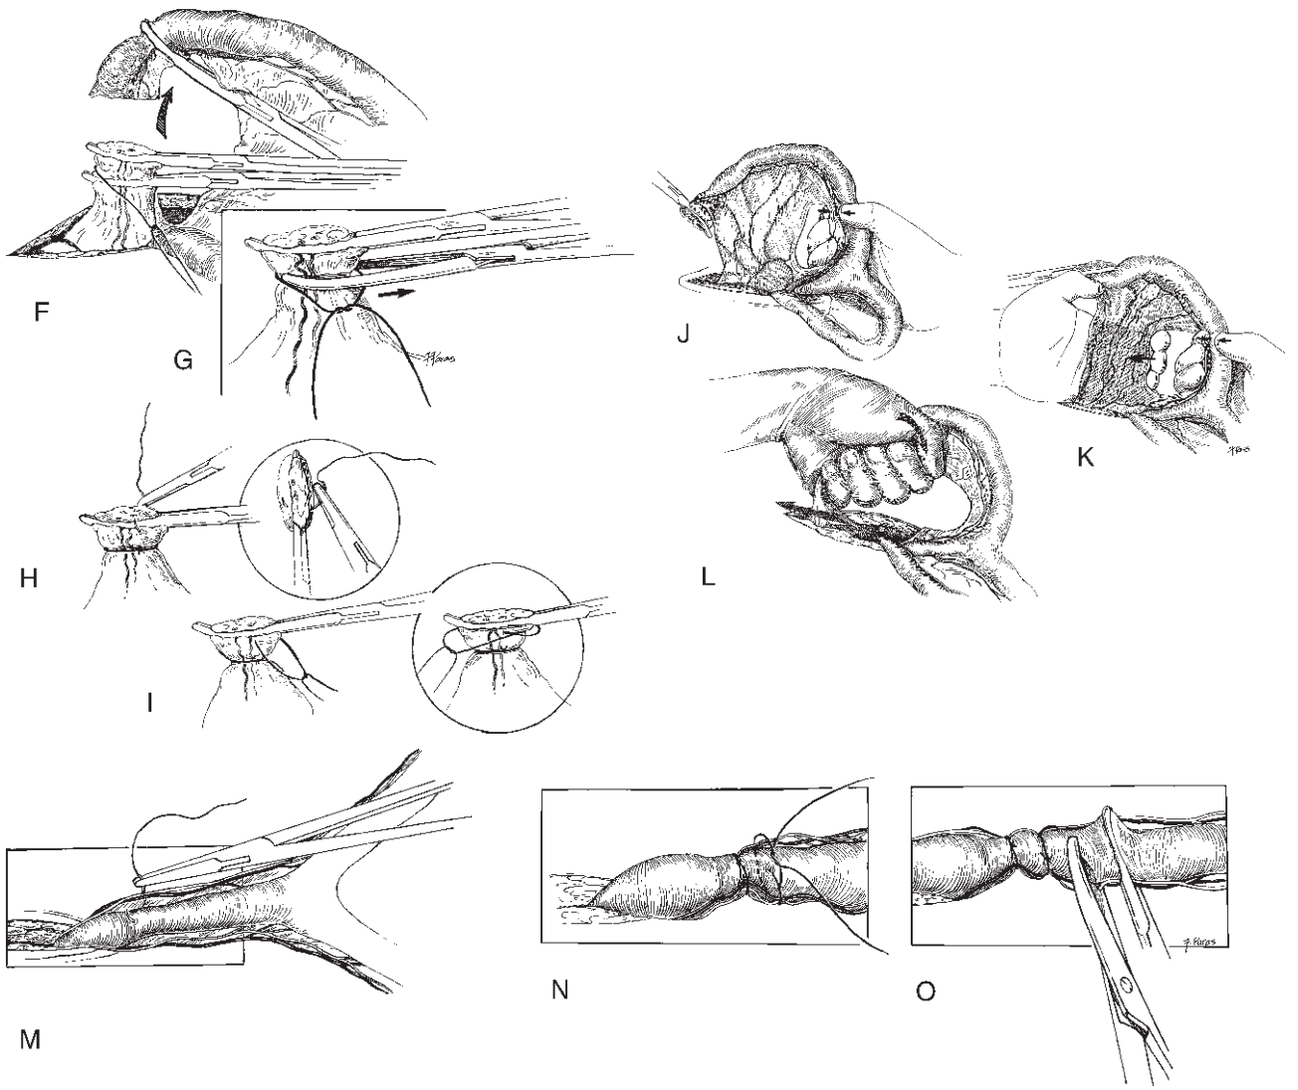

Figure 91-2. ***Continued*** *F,* Place circumferential suture around the proximal clamp. *G,* Tighten the suture in the groove of crushed tissue. *H* and *I,* Ligature pattern for transfixing ligature. *J,* Open the broad ligament adjacent to the uterine artery and vein close to the cervix. *K,* Grasp the broad ligament. *L,* Pull the broad ligament cranially until it and the round ligament are free. *M,* Place the first transfixing suture. *N,* Place the second transfixing suture. *O,* Transect the uterine body.

Postoperative Care

- Administer postoperative analgesics as needed (see Chapter 6).
- Restrict exercise and monitor for wound complications or hemorrhage after ovariohysterectomy.
- Postoperative care following ovariohysterectomy for pyometra:
  - Dogs with pyometra frequently have renal dysfunction without associated morphologic abnormalities, and they may be azotemic, oliguric, or anuric. Monitor renal function and maintain hydration after surgery. Diuresis with crystalloid fluids administered intravenously for at least 24 to 36 hours after surgery is advisable. Placement of a urinary catheter will assist with monitoring urine output (see Chapter 90 for more information on pyometra).
  - Dogs with pyometra may be toxemic or septicemic (see Chapter 90). Administer broad-spectrum antibiotics during surgery, and continue antibiotics after surgery if the animal is toxemic or septicemic or if peritonitis was present at surgery.

Postoperative Complications

Complications following elective ovariohysterectomy are rare and may include the following.

Hemorrhage

- Hemorrhage is the most common complication following ovariohysterectomy in dogs weighing more than 25 kg.
- Common causes of hemorrhage include failure to adequately tighten circumferential or transfixion

ligatures, tearing of the OAVC while breaking the suspensory ligament, failure to ligate large vessels in the broad ligament, tearing of the uterine artery due to excessive traction on the uterine body and premature removal of a clamp during ligation. In addition, persistent hemorrhage after surgery can occur in patients with undiagnosed or untreated coagulation disorders such as von Willebrand disease or specific coagulation factor deficiency (see Chapter 23).

- The incidence of hemorrhage can be reduced by maintaining meticulous surgical technique. Avoid becoming complacent during routine ovariohysterectomy.

Uterine Stump Pyometra

Uterine stump pyometra can occur if a portion of the uterine body or uterine horn is not removed and the animal has increased serum progesterone. The source of the increased serum progesterone can be endogenous from residual ovarian tissue or exogenous from progestational compounds administered for treatment of dermatitis.

▼ ***Key Point*** Complete excision of the uterine body and ovaries reduces the incidence of uterine stump pyometra.

Ovarian Remnant Syndrome (Recurrent Estrus)

- This condition results from retained functional residual ovarian tissue.
- Treatment is removal of residual ovarian tissue.

▼ ***Key Point*** To increase the likelihood of identifying residual ovarian tissue, perform exploratory celiotomy to find ovarian remnants when the dog is showing signs of recurrent estrus.

- If ovarian tissue is not located, identify both ureters and resect remnants of the OAVC pedicles bilaterally. Submit the tissue for histopathologic analysis.

Ligation of Ureter

- This complication is more likely to occur when ovariohysterectomy is associated with hemorrhage, pyometra, or cesarean section. It may also occur when the urinary bladder is distended and the trigone and ureterovesical junction are displaced cranially.
- Hydronephrosis and occasionally pyelonephritis can result.
- Ureteronephrectomy may be required.
