FIGURE 9-36 Detailed examples of open circulations. (a) A bivalve mollusk has a heart (ventricle) that pumps hemolymph into an aorta, which empties into sinuses in the foot; from there the fluid enters vessels that lead to the gills (ctenidium). The heart also pumps into a mantle vessel, which empties into the hemocoel to bathe most organs. (b) A crayfish has a dorsal heart that pumps hemolymph into arteries leading into the abdomen, where the fluid empties into sinuses. The fluid then enters vessels that travel to the anterior of the animal before returning to the heart. (c) A crab (*Callinectes sapidus*) has a heart that pumps hemolymph into a complex set of arteries that repeatedly branch into fine, capillary-like endings. This remarkable photograph shows those vessels in a resin cast that preserves their structure (shown in dorsal view). The heart (H) and pericardial sinus are situated slightly posterior to the midline of the animal. The anterior aorta (AA), anterolateral arteries (ALA), and hepatic arteries (HA) branch off of the anterior end of the heart, while the posterior aorta (PA) exits posteriorly. The ventral thoracic arteries (VTA) supply the mouthparts, and the pereopod arteries (P1–P5) supply the limbs. The branchial veins (ABV) run between the gill lamellae (GL).

9.10 Circulatory Pathways and Vessels: Closed Circulation

We now examine closed circulation in detail, starting with an overview.

Parallel and series flow are both important for reconditioning the blood

Let's return to the concepts of parallel and series flow. Circulatory fluid is constantly “reconditioned” so that its composition remains relatively constant despite an ongoing drain of supplies to support metabolic activities and the continual addition of wastes from the tissues. The organs that recondition the fluid may receive substantially more blood than necessary to meet their basic metabolic needs so they can perform homeostatic adjustments. To maximize gas exchange with the environment, gills of most fishes and lungs of birds and mammals receive all of the blood flow, that is, in series. Similarly, all blood flows from the heart of a cephalopod to its two gills, then to its two auxiliary (branchial) hearts. For gas delivery, flow in all these animals then branches in parallel fashion, in part so that large percentages of the cardiac output may be distributed to a digestive tract (to pick up nutrient supplies), to kidneys (to eliminate metabolic wastes and adjust water and electrolyte composition), and to skin (to eliminate or pick up heat) (Figure 9-37). Flow to the other organs—heart, skeletal muscles, and so on—is solely supplying these tissues' metabolic needs and can be adjusted according to their level of activity. For example, during locomotory activity in a vertebrate additional blood is delivered to the active muscles to meet their increased metabolic needs.

Because reconditioning organs receive blood flow in excess of their own needs, they can withstand temporary reductions in blood flow much better than can organs that do not have this extra margin of blood supply. In particular, the brain and heart in many vertebrates can suffer irreparable damage when transiently deprived of blood supply. (A notable exception is the zebra fish heart, which is capable of regenerating itself after a major injury.) Unless an animal is preconditioned to *ischemia* (p. 544) or has evolved a mechanism to withstand *hypoxia* (low O_2 ; p. 543), permanent brain damage can occur after only a few minutes without O_2 . (Brains in birds and mammals are particularly vulnerable because they are not enzymatically equipped to support their metabolic needs anaerobically.) In contrast, digestive organs, kidneys, and skin frequently undergo significant reductions in circulatory flow for a considerable length of time. For example, during locomotory activity in a vertebrate, some of the blood that normally flows through the digestive organs and kidneys is diverted instead to the skeletal muscles. Likewise, blood flow through mammalian skin is markedly restricted during exposure to cold to conserve body heat.

Later in this chapter, after we examine the evolution of circulation in vertebrates, you will see how the distribution of cardiac output is adjusted according to an animal body's changing needs as we examine the various vessels that make up the vascular system.

FIGURE 9-37 Distribution of cardiac output at rest. Values are for a typical human. The lungs receive all the blood pumped out by the right side of the heart, whereas the systemic organs each receive a portion of the blood pumped out by the left side of the heart. The percentage of pumped blood received by the various organs under resting conditions is indicated. This distribution of cardiac output can be adjusted as needed.

The vertebrate vascular system evolved from one circuit to two separate circuits

In the vertebrates, the closed system presumably began as a simple loop:

Heart → artery → gills → aorta and branching parallel arteries → arterioles → capillaries in body organs → veins → heart

As we noted earlier, the flow to the gills is in series with the rest of the circulation, with the rest of the flow in a parallel system. (Recall that in series flow in crustaceans, gills receive

FIGURE 9-38 Circulatory flow in fish and amphibians. (a) A typical bony fish. (b) A bullfrog (*Rana catesbeiana*), showing distribution of total flow (20.5 mL/min) through the pulmonary, cutaneous and systemic systems, and the partial separation of oxygenated and deoxygenated blood in the heart.

hemolymph *before* the heart.) While useful for maximal gas exchange, series flow creates a problem because the tiny diameters of the capillaries in the gills create an enormous resistance to flow. Consequently, blood flow from the gills to the rest of the body tends to be somewhat sluggish. This means that whereas there is sufficient oxygen in the blood, it is not rapidly delivered to body muscles. As you will see, this situation does not work on land. In the transition to land, a separate loop began to evolve for the new respiratory organ, the lung. Let us now trace this evolutionary change.

Fishes Water-breathing jawed fishes have essentially the same one-circuit flow pattern just discussed (Figure 9-38a). Hagfish (jawless fishes) are similar but have partially open systems with large sinuses in the head and under the skin. They also have *auxiliary hearts* (as you saw earlier; p. 401) in veins of the head, abdomen, and tail to assist return flow. Hagfish flow can be summarized as follows (note we are omitting the vessels from now on, because they are the same):

Systemic heart → gills → body organs and sinuses → (auxiliary hearts) → systemic heart

Air-breathing fishes such as lungfish evolved a new respiratory organ, the lung, in addition to gills. This required a separate circuit, because the lung is not always used by these fishes. This in itself would not be very efficient if the oxygenated blood returning from the lungs were to mix with the deoxygenated blood returning from the systemic veins, or if the oxygenated blood were to travel on to the gills. For this reason the lungfish heart evolved partial barriers or *septa* in the atrium and ventricle that subdivide those cham-

bers into somewhat separate pumping functions on the right and left sides. The septa reduce mixing of oxygenated with deoxygenated blood.

In lungfish, the flow to the lungs occurs after the gills, where the blood can either go to the body (during water breathing), or be diverted to the lungs (during air breathing), and is summarized as follows:

Right side of heart → gills → body organs → right side of heart (water breathing)

Right side of heart → gills → lungs → left side of heart → body organs → right side of heart (air breathing)

Amphibians As the first amphibians evolved to live part time on land, gills were lost in adults of some species. Today such amphibians primarily use their skins to absorb O_2 when they are in water, and lungs when they are in air. Thus, the pulmonary circulation evolved into a completely separate circuit, going to the lungs and skin, with the systemic circulation going to the main body without passing through a respiratory organ. The atrium is split completely into two chambers, such that amphibians have essentially a three-chambered heart (although most retain a sinus venosus and conus arteriosus). The single ventricle is not subdivided well except for some modest folds, so that oxygenated and deoxygenated blood does mix somewhat in that chamber. Flow is summarized as follows (Figure 9-38b):

Right atrium → right side of ventricle (56%) → lung (or skin) → left or right atrium → left side of ventricle (44%) → body organs → right atrium

Some Reptiles Reptiles evolved into purely air-breathing animals, relying on lungs only. The heart lost the auxiliary chambers of fishes and amphibians but retained the two atria that amphibians have. However, the ventricle is different. In most reptiles, it is one large chamber but has two large subchambers partially divided by thick muscle rather than a true septum: the *cavum arteriosum* and *cavum pulmonale*. At the top of both (and connected to both) is a small third subchamber, the *cavum venosum*. (In turtles, a true but partial septum separates the two larger subchambers.) Flow through these subchambers can follow two different pathways if the reptile is a diver (such as a turtle or seasnake). Blood flow while breathing air is as follows (Figure 9-39):

Right atrium → c. venosum → c. pulmonale → lungs → left atrium → c. arteriosum → c. venosum → body organs → right atrium

During a dive, the lungs can be bypassed via the c. venosum, a useful adaptation when the animal is holding its breath for long periods:

Right atrium → c. venosum → body organs → right atrium

Crocodiles Crocodiles and their relatives have a complete four-chambered heart with two atria and two ventricles, with this basic flow (Figure 9-40a):

Right atrium → right ventricle → lungs → left atrium → left ventricle → body organs → right atrium

The right ventricle has an apparent oddity: In addition to a vessel leading to the lungs, it also has one leading to the main body. In addition, this vessel is connected to some of the flow from the left ventricle by a short vessel, the **foramen of Panizza**. Normally, flow through this from the left ventricle is at a higher pressure, such that it blocks any flow from the right ventricle. This oddity is actually a useful adaptation, again for prolonged breath holding during a dive. The flow to the pulmonary arteries is restricted during a dive, so that pressure of the right atrium is directed into the systemic circulation:

Right atrium → right ventricle → body organs → right atrium

In the estuarine crocodile *Crocodylus porosus* and perhaps other species, there are unique, coglike valves between the right ventricle and pulmonary arteries that control this diversion of blood flow (Figure 9-40b). Unlike the loose flaps that form heart valves in other vertebrates, these are stiffer with teethlike projections, which can close during a dive, diverting flow to the main body.

Birds and Mammals The hearts of birds and mammals have a complete four-chambered structure similar to crocodiles, but without the foramen or other shunt to divert flow in different ways. Recall that these four-chambered hearts are two separate pumps fused together. Thus, mammalian and avian blood travels with this pattern (Figure 9-41):

Right atrium → right ventricle → lungs → left atrium → left ventricle → body organs → right atrium

With the complete separation of pulmonary and systemic flow, all blood pumped by the right side of the heart passes through the lungs for O₂ pickup and CO₂ removal. Then the oxygenated blood pumped by the left side of the

FIGURE 9-39 Hearts of most reptiles. (a) Flow through the heart of a varanid lizard during atrial contraction (left) and ventricular contraction (right). Arrows in red areas indicate the direction of oxygenated blood flow, and arrows in blue areas indicate the direction of deoxygenated blood flow. (b) Normal pattern of blood flow (solid arrows) through the reptile heart and pattern of blood flow (dashed arrows) for a left-to-right intracardiac shunt (e.g., during apnea, such as diving) and a right-to-left shunt (e.g., during pulmonary ventilation).

heart is parceled out in various proportions to the systemic organs through the parallel vessels that branch from the aorta. Researchers think this complete separation evolved independently in birds and mammals and was necessary for the high endothermic metabolisms of these vertebrates. A gene associated with this evolutionary step has been found; see the box, *Molecular Biology and Genomics: From Three to Four*.

Molecular Biology and Genomics

From Three to Four

The evolution of a complete four-chambered heart, in which the ventricle became completely divided by a septum, was vital for the high-powered endothermic metabolisms of birds and mammals. How did this happen? Recent research led by Benoit Bruneau has found that a single regulatory gene may have played a major role. The gene, called *Tbx-5*, codes for a “master” transcription factor (p. 31) that regulates a variety of pattern-forming genes in vertebrate embryos. In avian and mammalian hearts, the gene is expressed in a distinct pattern: It is “on” in the left but not the right ventricle, and a septum forms precisely where *Tbx-5* activity sharply changes. Mutations in this gene in humans lead to defects in the septum. When the researchers examined *Tbx-5* expression in reptiles, they discovered a striking correlation. In lizards (whose hearts lack septa), the gene is expressed evenly throughout the large single ventricle. However, in turtles (whose hearts have a partial septum), *Tbx-5* expression changes during development in the ventricle from an even pattern to a gradient, high

on the left and low on the right. Correlating with this gradient formation (which lacks the sharp drop-off in endotherms), a partial septum grows down the middle of the ventricle. Thus, a relatively simple change in regulation of this “master” gene may have led to the four-chambered heart.

You might be wondering why the ectothermic crocodilians have a four-chambered heart. Fossil evidence suggests that their ancestors were fast land-based predators, per-

haps even endothermic. Genomic evidence supports this idea. Mitochondrial DNA (mtDNA) in endotherms evolves at about twice the rate in ectotherms, a phenomenon attributed to the higher metabolic rates of endotherms. Researchers were surprised to find that alligator mtDNA has also been evolving at about the same rate as in mammals. This too hints at an endothermic ancestry. Imagine being chased by a fleet-footed crocodile with the metabolism of a lion!

FIGURE 9-41 Mammalian and avian circulation. Arteries progressively branch as they carry blood from the heart to the tissues. A separate small arterial branch delivers blood to each of the various organs. As a small artery enters the organ it is supplying, it branches into arterioles, which further branch into an extensive network of capillaries. The capillaries rejoin to form venules, which further unite to form small veins that leave the organ. The small veins progressively merge as they carry blood back to the heart.

© Cengage Learning, 2013

The fetus of a placental mammal is an exception. The fetus is not breathing, so the lungs are not functional. There are two bypasses in the fetal circulation: (1) the **foramen ovale**, an opening in the septum between the right and left atrium; and (2) the **ductus arteriosus**, a vessel connecting the pulmonary artery and aorta as they both leave the heart. These bypasses are similar to those we discussed for the crocodile heart, and have a similar function.

Now let's examine the individual vessels, focusing on mammals, with other vertebrates noted on occasion. Vessel types differ considerably in their structures and functions. We begin with an overview. *Arteries*, which carry blood from the heart to the tissues, branch into a "tree" of progressively smaller vessels, with the various parallel branches to different regions of the body. When a small artery reaches the organ it is supplying, it branches into numerous parallel *arterioles*, which provide flow control. Arterioles branch further within the organs into *capillaries*, the smallest of ves-

sels, across which all exchanges are made with surrounding cells and which is the primary goal of the entire circulation. Capillaries rejoin to form small *venules*, which further merge to form small *veins* that leave the organs. The small veins progressively unite to form larger veins that eventually empty into the heart. The arterioles, capillaries, and venules are collectively referred to as the **microcirculation** because they are only visible microscopically.

check your understanding 9.10

Discuss the major differences in circulation and heart structures among the major vertebrate groups.

9.11 Circulatory Vessels: Arteries

The consecutive segments of the vascular tree are specialized to perform specific tasks (Table 9-2). Arteries, the initial vessels, are specialized for two major functions:

1. A *rapid-transit passageways* for blood from the heart to the tissues; and
2. A *pressure reservoir* to provide the driving force for blood when the heart is relaxing (recall that the conus or bulbus arteriosus does this in fishes and amphibians; p. 402).

Arteries are wide with low total cross-sectional area and store and release pressure for high-velocity delivery

Because of their large radii, arteries offer little resistance to blood flow. However they also have another important geometrical feature: their *total cross-sectional area is lower* than those of the downstream arterioles and capillaries (Table 9-2). As we will explore in detail in the capillary discussion, this ensures that blood flows at a high velocity from heart to organs.

Now let's examine how arteries serve as a pressure reservoir. The heart alternately contracts to pump blood into the arteries and then relaxes to refill from the veins. No blood is pumped out when the heart is relaxing and refilling. However, capillary flow is continuous; that is, it does not fluctuate between systole and diastole. The driving force for the continued flow of blood to the tissues during cardiac relaxation is provided by the elastic properties of the arterial walls, whose pressures do fluctuate between systole and diastole. All vessels are lined with a layer of smooth, flattened endothelial cells (continuous with the heart's endocardial lining). Surrounding the arterial endothelial lining is a thick wall containing smooth muscle and two types of connective tissue fibers; *collagen fibers*, which provide tensile strength against the high driving pressure of blood ejected from the heart, and *elastin fibers*, which give the arterial walls elasticity so that they behave much like a balloon (Figure 9-42). Arteries of the giraffe, for example, are more richly endowed with these components in order to withstand the higher blood pressures generated by the heart.

FIGURE 9-42 Elastin fibers in an artery. Light micrograph of a portion of the aorta wall in cross section, showing numerous wavy elastin fibers, common to all arteries.

As the heart pumps blood into the arteries during ventricular systole, a greater volume of blood enters the arteries from the heart than leaves them to flow into smaller vessels downstream because the smaller vessels have a greater resistance to flow. The arteries' elasticity enables them to expand to temporarily hold this excess volume of ejected blood, storing some of the pressure energy imparted by cardiac contraction in their stretched walls—just as a balloon expands to accommodate the extra volume of air that you blow into it (Figure 9-43a). When the heart relaxes and ceases pumping blood into the arteries, the stretched arterial walls passively recoil, like an inflated balloon that is released. This recoil pushes the excess blood contained in the arteries into the vessels downstream, ensuring continued blood flow to the tissues when the heart is relaxing and not pumping blood into the system (Figure 9-43b). This property of arteries is widespread in vertebrates and other animals that have them, occurring in (for example) amphibians, reptiles, fish, cephalopods, and the open systems of crustaceans.

The maximum pressure exerted in the arteries when blood is ejected into them during systole, the **systolic pressure**, averages 120 mm Hg in humans. The minimum pressure within the arteries when blood is draining off into the remainder of the vessels during diastole, the **diastolic pressure**, averages 80 mm Hg in humans. The arterial pressure does not fall to 0 mm Hg, because the next cardiac contraction occurs and refills the arteries before all the blood drains off (Figure 9-44). A useful way to think of these pressures

FIGURE 9-43 Arteries as a pressure reservoir. Because of their elasticity, arteries act as a pressure reservoir. (a) The elastic arteries distend during cardiac systole as more blood is ejected into them than drains off into the narrow, high-resistance arterioles downstream. (b) The elastic recoil of arteries during cardiac diastole continues driving the blood forward when the heart is not pumping.

TABLE 9-2 Features of Blood Vessels (with Human Values)

Feature	VESSEL TYPE			
	Arteries	Arterioles	Capillaries	Veins
Number	Several hundred*	Half a million	Ten billion	Several hundred*
Special Features	Thick, highly elastic, walls; large radii*	Highly muscular, well-innervated walls; small radii	Very thin walled; large total cross-sectional area	Thin walled compared to arteries; highly distensible; large radii*
Functions	Passageway from heart to organs; serve as pressure reservoir	Primary resistance vessels; determine distribution of cardiac output	Site of exchange; determine distribution of extracellular fluid between plasma and interstitial fluid	Passageway to heart from organs; serve as blood reservoir

Structure**Relative Thickness of Layers in Wall**

*These numbers and special features refer to the large arteries and veins, not to the smaller arterial branches or venules.

© Cengage Learning, 2013

and the elastic recoil is to assume that the human left ventricle exerts about 200 mm Hg of systolic pressure. Of this, 120 mm Hg are used to push the blood immediately, and 80 mm Hg of pressure energy are stored in the elastic arteries. During diastole, when the ventricle pressure falls to about 0, the rebounding arteries release the 80 mm Hg as pressure to keep the blood moving.

The systolic–diastolic pressures are typically written as pairs, for example, 120/80 for humans. Values for other

mammals are not very different, for example, 130/95 for horses, 110/80 for rabbits. Birds usually have higher values, such as 180/130 for starlings. Ectotherms have lower pressures in general, such as 31/21 for frogs, 43/33 for trout, and 35/21 for lobster (open circulation). There are significant exceptions to this. Systolic pressures in an octopus can reach 75 mm Hg, whereas in a jumping spider they can reach 400 mm Hg! Recall that spiders use pressure to extend their legs, such as for jumping (pp. 422–423).

FIGURE 9-44 Arterial blood pressure. Values are for an average human. The systolic pressure is the peak pressure exerted in the arteries when blood is pumped into them during ventricular systole. The diastolic pressure is the lowest pressure exerted in the arteries when blood is draining off into the vessels downstream during ventricular diastole. The pulse pressure is the difference between systolic and diastolic pressure. The mean pressure is the average pressure throughout the cardiac cycle.

© Cengage Learning, 2013

Mean arterial pressure is the main driving force for blood flow

More important than the fluctuating systolic and diastolic pressures is the **mean arterial pressure**, which is the *average pressure* responsible for driving blood forward into the tissues throughout the cardiac cycle. Contrary to what you might expect, mean arterial pressure is not the halfway value between systolic and diastolic pressure (for example, with a human blood pressure of 120/80, mean pressure is *not* 100 mm Hg), because, at resting heart rate, about two thirds of the cardiac cycle is spent in diastole and only one third in systole. As an analogy, if a race car traveled 80 miles per hour (mph) for 40 minutes and 120 mph for 20 minutes, its average speed would be 93 mph, not the halfway value of 100 mph. Similarly, a good approximation of the mean arterial pressure can be determined using the following formula:

$$\text{Mean arterial pressure} = \text{diastolic pressure} + \frac{1}{3}(\text{systolic pressure} - \text{diastolic pressure})$$

Here is a human example at 120/80 systolic/diastolic pressures:

$$\text{Mean arterial pressure} = 80 + (120 - 80)/3 = 93 \text{ mm Hg}$$

For practice, you may want to apply this formula to another animal, using values just given for a horse, starling, and so on. It is this mean arterial pressure, not the systolic or diastolic pressures, that is generally regulated by blood pressure reflexes to be described in the final section of this chapter.

check your understanding 9.11

Explain how pressure fluctuations are dampened by arteries.

9.12 Circulatory Vessels: Arterioles

When an artery reaches the organ it is supplying, it branches into numerous *arterioles*. Despite their name (“little arteries”), they are very different from arteries. In brief, the radii (and, accordingly, the resistances) of arterioles supplying individual organs can be adjusted independently to accomplish two major functions:

1. To *variably distribute the cardiac output among the systemic organs*, depending on the body’s momentary needs, and
2. To *help regulate bodywide arterial blood pressure*.

First we discuss how arterioles affect resistance, then we look at the mechanisms involved in adjusting their resistance. Finally we will consider how such adjustments are important in accomplishing these two functions.

Arterioles are the major resistance vessels and can be dilated or constricted

The radii of arterioles can be small enough to offer considerable resistance to flow, particularly when they are constricted by their muscular layers (see following section). In fact, the *arterioles are the major resistance vessels* in the vascular tree. (Even though the capillaries have smaller radii than the arterioles, you will see later how collectively the capillaries do not offer as much resistance to flow as the collective arterioles do.) In contrast to the low resistance of the arteries, the high degree of arteriolar resistance causes a marked drop in local pressure as the blood flows through these vessels and the pressure energy dissipates. On average, human pressure falls from 93 mm Hg, the mean arterial pressure (the pressure of the blood entering the arterioles), to 37 mm Hg, the pressure of the blood leaving the arterioles and entering the capillaries (Figure 9-45). Arteriolar resistance is also responsible for converting the pulsatile systolic-to-diastolic pressure swings in the arteries into the nonfluctuating pressure present in the capillaries.

Vasoconstriction and Vasodilation Unlike arteries, arteriolar walls contain very little elastic connective tissue. However, they do have a thick layer of smooth muscle that is richly innervated by sympathetic nerve fibers. The smooth muscle layer runs circularly around the arteriole (Figure 9-46a), so when it contracts the vessel’s radius becomes smaller, increasing resistance and decreasing flow through that vessel. **Vasoconstriction** is the term applied to such narrowing (Figure 9-46c), while **vasodilation** refers to enlargement in the radius of a vessel as a result of relaxation of its smooth muscle layer (Figure 9-46d). Vasodilation leads to decreased resistance and increased flow through that vessel.

Vascular Tone Arteriolar smooth muscle normally displays a state of partial constriction known as **vascular tone**, which establishes a baseline of arteriolar resistance (Figure 9-46b). Two factors are responsible for vascular tone. First, arteriolar smooth muscle has considerable myogenic activity; that

FIGURE 9-45 Pressures throughout the mammalian systemic circulation. Values shown are for an average human. Left ventricular pressure swings between a low pressure of 0 mm Hg during diastole to a high pressure of 120 mm Hg during systole. Arterial blood pressure, which fluctuates between a peak systolic pressure of 120 mm Hg and a low diastolic pressure of 80 mm Hg each cardiac cycle, is of the same magnitude throughout the large arteries. Because of the arterioles' high resistance, the pressure drops precipitously and the systolic-to-diastolic swings in pressure are converted to a nonpulsatile pressure when blood flows through the arterioles. The pressure continues to decline but at a slower rate as blood flows through the capillaries and venous system.

is, its membrane potential fluctuates without any neural or hormonal influences, leading to self-induced contractile activity (see p. 378). Second, the sympathetic fibers supplying most arterioles continually release norepinephrine (NE, to be discussed later), which further enhances the vascular tone. This ongoing tonic activity makes it possible to either increase or decrease the level of contractile activity to accomplish vasoconstriction or vasodilation, respectively. Were it not for tone, it would be impossible to reduce the tension in an arteriolar wall to accomplish vasodilation.

Distribution of Blood Flow The amount of cardiac output received by each organ is determined by the number and caliber (diameter) of the arterioles supplying that area. Recall that flow rate (Q) = $\Delta P/R$ (p. 419). Because blood is delivered to all tissues at the same mean arterial pressure, the driving force ΔP for flow is identical for each organ. Therefore, differences in flow Q to various organs are completely determined by differences in the extent of

FIGURE 9-47 Flow rate as a function of resistance.

© Cengage Learning, 2013

vascularization (density of blood vessels) and by differences in resistance R offered by the arterioles supplying each organ. On a moment-to-moment basis, the distribution of cardiac output can be varied by differentially adjusting arteriolar R in the various vascular beds.

As an analogy, consider a pipe carrying water with a number of adjustable valves located throughout its length (Figure 9-47). Assuming that water pressure in the pipe is constant, differences in the amount of water flowing into a beaker under each valve depend entirely on which valves are open and to what extent. No water enters beakers under closed valves (high resistance), and more water flows into beakers under valves that are opened completely (low resistance) than into beakers under valves that are only partially opened (moderate resistance). Similarly, more blood flow Q goes to areas whose arterioles offer the least resistance R to its passage. You will see later how this works during elevated muscular activity, when skeletal muscles need more blood but many other organs do not.

A variety of factors can influence the level of contractile activity in arteriolar smooth muscle, thereby substantially changing resistance to flow in these vessels. These factors fall into the two hierarchy categories we saw for cardiac output: *local (intrinsic) controls*, which are important in matching blood flow to the metabolic needs of the specific tissues in which they occur; and *extrinsic controls*, which are important for diverting blood among organs to where it is needed and also for bodywide blood pressure regulation.

Local (intrinsic) influences on arteriolar radius help match blood flow with the tissues' "selfish" needs

Let's see how these controls work at the two levels. Local (intrinsic) controls are changes within a tissue that alter the radii of the vessels and hence adjust blood flow through the

tissue by directly affecting the smooth muscle of the tissue's arterioles. The goal is rapid regulation without major feedback delays: Local metabolic changes quickly alter arteriolar radius in order to match the blood flow through a tissue with the tissue's metabolic needs. Such "selfish" controls are especially important in skeletal muscle and the heart, the tissues whose metabolic activity and need for blood supplies normally vary most extensively, and in the brain, whose overall metabolic activity is relatively constant.

Local influences may be either chemical or physical in nature, including (1) local metabolic changes, (2) histamine release, (3) exposure to heat or cold, and (4) stretch. The chemical influences often work through local mediators. Let's examine the role and mechanism of each of these.

Local Metabolic Changes A variety of local chemical changes act together in a cooperative, redundant manner to bring about these "selfish" local adjustments in arteriolar caliber. Specifically, the following factors produce relaxation of arteriolar smooth muscles:

1. **Decreased O_2 .** During increased activity, such as exercise when a skeletal muscle is contracting at an elevated rate, the local O_2 concentration drops.
2. **Increased CO_2 .** More CO_2 is generated as a by-product during the stepped-up pace of aerobic metabolism that accompanies increased activity.
3. **Increased acid.** More carbonic acid is generated from the increased CO_2 produced as the metabolic activity of a cell increases. Also, lactate accumulates if the glycolytic pathway alone is used for ATP production (see p. 55).
4. **Increased K^+ .** Repeated action potentials that outpace the ability of the Na^+/K^+ pump to restore the resting concentration gradients (see p. 120) result in an increase in K^+ in the tissue fluid of an actively contracting muscle or a more active region of the brain.

5. **Increased osmolarity.** Osmolarity (the concentration of osmotically active solutes) may increase during elevated cell metabolism because of increased formation of osmotically active particles.
6. **Adenosine release.** Especially in cardiac muscle, adenosine is released in response to increased metabolic activity or O_2 deprivation (see p. 418).

By triggering relaxation of the nearby arteriolar smooth muscle, all these factors increase blood flow to that particular area, a response called **active hyperemia**, to bring in more O_2 and nutrients and remove metabolic wastes at a higher rate. Conversely, when a tissue, such as a resting skeletal muscle, is less active metabolically and thus has reduced needs for blood delivery, many of the factors above change in the opposite direction, which triggers local arteriolar vasoconstriction and a subsequent reduction in blood flow to the area. Again, local metabolic changes can adjust blood flow as needed with little delay, as could occur with neural or hormonal regulation.

Histamine Histamine is not released in response to local metabolic changes, nor is derived from vessel cells. Rather, it is released by local immune cells in tissues that are injured or during allergic reactions. It triggers an increase in blood flow into the area that is a major feature in defensive inflammatory responses (see Chapter 10).

Local Heat or Cold Exposure to heat causes localized arteriolar vasodilation. Conversely, cold exposure usually causes vasoconstriction. These processes help maintain body temperature in endotherms and some ectotherms (see Chapter 15). Therapeutic application of heat or cold to an injury takes advantage of these responses; heating promotes blood flow, bringing in oxygen and nutrients to an injured site, whereas cold reduces inflammation triggered by histamine.

Stretch Many arteriole smooth muscles myogenically respond to stretch by vasoconstricting, and conversely respond to a reduction in stretch by vasodilating. This results in a phenomenon called **autoregulation** in some organs, in which local flow Q is kept homeostatic. This occurs when external factors lead to a sudden change in blood pressure in an arteriole. For example, if pressure rises and thus flow increases, the resulting stretch of the arteriole causes it to contract to increase R , and so flow Q is restored (and vice versa for a drop in pressure). You will see why this is important in kidneys in Chapter 12.

Local Vasoactive Mediators Most of the local chemical changes do not act directly on vascular smooth muscle to change its contractile state. Instead, they arise from **endothelial cells**, the single layer of specialized epithelial cells that line the lumen of all blood vessels and heart chambers. In addition to serving as a physical barrier between the blood and the remainder of the vessel wall, endothelial cells have these functions (some of which will be described in more detail elsewhere):

- Secrete substances that stimulate new vessel growth and proliferation of smooth muscle cells in vessel walls.
- Participate in the exchange of materials between the blood and surrounding tissue cells across capillaries through vesicular transport (see p. 440).

- Influence formation of platelet plugs, clotting, and clot dissolution (see pp. 398–399).
- Participate in the determination of capillary permeability by contracting to vary the size of the pores between adjacent endothelial cells.
- Secrete *vasoactive* (“acting on vessels”) mediators in response to local chemical and physical changes (such as a reduction in O_2); these substances cause vasodilation or vasoconstriction of the underlying smooth muscle.

Let’s look at the last function more closely. Local mediators include *endothelin*, *prostaglandins* (p. 779), *epoxyeicosatrienoic acids (EETs)*, and *nitric oxide (NO)* (a widespread paracrine that is produced in numerous other tissues besides endothelial cells; p. 93). NO is the best studied and has these (and probably other) roles in promoting blood flow:

- NO causes local arteriolar vasodilation by inducing relaxation of arteriolar smooth muscle cells in the vicinity. It does so by increasing the concentration of the intracellular second messenger cyclic GMP, which leads to activation of an enzyme that reduces phosphorylation of myosin. Remember that smooth-muscle myosin can bind with actin and initiate contraction only when myosin is phosphorylated (see p. 375). In this way, NO plays an important role in controlling blood flow through the tissues and in maintaining mean arterial blood pressure. Extrinsic regulation can activate NO production, for example, in dilating the arterioles of the penis and clitoris (p. 782).
- NO interferes with platelet function and blood clotting at sites of vessel damage (p. 395; see also its role in the blood-sucking kissing bug, p. 568).

In 1998 Robert Furchgott, Louis Ignarro, and Ferid Murad received the Nobel Prize for their discovery that nitric oxide signals blood vessels to dilate. Scientists were initially skeptical when in 1986 Furchgott and Ignarro first reported that nitric oxide, a gas and common air pollutant, could be linked to so many physiological processes in the mammalian body. It was Murad in 1977 who discovered that nitroglycerin—a common treatment for heart attacks that increases blood flow to the heart—acted by generating nitric oxide. Strangely enough, Alfred Nobel, the inventor of dynamite and who endowed the foundation for Nobel Prizes in his will, was prescribed nitroglycerin—one of the components in dynamite—for heart trouble.

Extrinsic sympathetic control of arteriolar radius is important in the regulation of both blood flow during activity and arterial blood pressure

Extrinsic control allows an animal’s “higher” regulatory systems to control blood flow for the good of the entire body, for both functions of flow distribution and arterial blood-pressure regulation. Control of arteriolar radius includes both neural and hormonal influences, with the effects of the sympathetic nervous system (via NE) being dominant (as we noted earlier for vascular tone).

Sympathetic Nerve Influence The NE released from sympathetic nerve endings combines with α_1 -adrenergic receptors (see p. 163) on arteriolar smooth muscle to bring about va-

soconstriction. Cerebral (brain) and pulmonary alveolar (air sac) arterioles are the only ones that do not have α_1 receptors, so no vasoconstriction occurs in these areas. It is important that these arterioles not be reflexly constricted by neural influences, because lung and brain blood flow must remain consistent no matter what is going on elsewhere in the body. In fact, reflex vasoconstrictor activity in the rest of the cardiovascular system functions to maintain an adequate pressure head for blood flow to the vital brain and often the heart (see the box on diving mammals in Chapter 11, pp. 544–545).

Adrenal Hormone Influence The sympathetic system also works indirectly on arterioles via the “fight-or-flight” reflex through the adrenal gland medulla, which, under sympathetic stimulation, releases epinephrine and NE (p. 159). Adrenal medullary NE combines with the same α receptors as sympathetically released NE to produce generalized vasoconstriction. However, epinephrine, the more abundant of the adrenal medullary hormones, combines with both β_2 and α_1 receptors but has a much greater affinity for the β_2 receptors. Activation of β_2 receptors produces vasodilation, but not all tissues have β_2 receptors; they are most abundant in the arterioles of the heart and skeletal muscles. During sympathetic discharge, the released epinephrine combines with the β_2 receptors in the heart and skeletal muscle to reinforce local vasodilatory mechanisms in these tissues, increasing delivery of oxygen and nutrients to meet the increased energy demands. Arterioles in digestive organs and kidneys, in contrast, are equipped only with α receptors. Therefore, the arterioles of these organs undergo profound vasoconstriction (Table 9-3). Later you will see how this works during locomotory activity.

Parasympathetic Influence There is no significant level of parasympathetic innervation to arterioles in most vertebrates. Vasodilation is usually produced by decreasing sympathetic vasoconstrictor activity below its tonic level. There are exceptions. Some species have acetylcholine-releasing fibers in skeletal muscles that trigger vasodilation in anticipation of locomotor activity. And there is abundant parasympathetic vasodilator supply to the arterioles of the mammalian penis and clitoris. The rapid, profuse vasodilation induced by parasympathetic stimulation in these organs (by promoting release of NO) is largely responsible for accomplishing erection.

Extrinsic Controls and Redistribution of Blood during Muscular Activity As you have seen, intrinsic regulation can regulate blood flow to some extent during muscular activity, when skeletal muscles produce local changes that dilate their own arterioles (and *precapillary sphincters*, as you will see later). However, the extrinsic sympathetic system (both direct neural and indirect adrenal pathways) is necessary to coordinate bodywide needs. During locomotory activity, for example, not only does it boost cardiac output, but it can also vasodilate arterioles in skeletal muscle and heart in *anticipation* of activity, and, simultaneously, it can vasoconstrict arterioles in the digestive tract to divert more blood to skeletal muscles. This action can even override the gut’s “selfish” needs such as its local demand for more blood during food processing. Again you will see this function in detail later.

TABLE 9-3 Arteriolar Smooth Muscle Adrenergic Receptors

Characteristic	RECEPTOR TYPE	
	α_1	β_2
Location of the Receptor	All arteriolar smooth muscle except in the brain	Arteriolar smooth muscle in the heart and skeletal muscles
Chemical Mediator	Norepinephrine from sympathetic fibers and the adrenal medulla Epinephrine from the adrenal medulla (less affinity for this receptor)	Epinephrine from the adrenal medulla (greater affinity for this receptor)
Arteriolar Smooth Muscle Response	Vasoconstriction	Vasodilation

Extrinsic Control of Arterial Blood Pressure For the maintenance of proper arterial blood pressure, changes in arteriolar resistance are the main adjustments that extrinsic regulation can perform quickly. The formula $Q = \Delta P/R$ applies to the entire circulation as well as to a single vessel:

- **Q:** Looking at the circulatory system as a whole, *flow (Q) through all the vessels in either the systemic or pulmonary circulation is equal to the cardiac output, C.O.*
- **ΔP :** *The pressure gradient (ΔP) for the entire systemic circulation is the mean arterial pressure. ΔP equals the difference in pressure between the beginning and the end of the systemic circulatory system. Because the beginning pressure is the mean arterial pressure as the blood leaves the left ventricle at an average of 93 mm Hg (in humans) and the end pressure in the right atrium is about 0 mm Hg, $\Delta P = 93$ mm Hg (that is, 93 minus 0). (For the pulmonary circulation, $\Delta P =$ mean pulmonary arterial pressure [15 mm Hg] minus the pressure in the left atrium [0 mm Hg] = 15 mm Hg.)*
- **R:** By far the greatest percentage of the total resistance (R) offered by all the systemic peripheral vessels (**total peripheral resistance**) is due to arteriolar resistance.

Therefore, for the entire systemic circulation, rearranging $Q = \Delta P/R$ and using C.O. for flow Q gives us the following equation:

$$\Delta P = C.O. \times R$$

Mean arterial pressure = cardiac output \times
total peripheral resistance

Thus, *the extent of total peripheral resistance offered collectively by all the systemic arterioles influences the mean arterial blood pressure immensely*. A dam provides an analogy to this relationship. At the same time it restricts the flow of water downstream, a dam increases the pressure upstream by elevating the water level in the reservoir behind the dam. Similarly, generalized, sympathetically induced vasoconstriction reflexly reduces blood flow downstream to the tissue cells while elevat-

ing the upstream mean arterial pressure, thereby increasing the main driving force for blood flow to all the organs.

These effects seem counterproductive. Why increase the driving force for flow to the organs by increasing arterial blood pressure while reducing flow to the organs by narrowing the vessels supplying them? In effect, the sympathetically induced arteriolar tone helps maintain the appropriate driving pressure head. If all arterioles were dilated, blood pressure would fall substantially, so there would not be an adequate force for (1) overcoming gravity to the brain (in animals with heads above their main bodies), (2) proper flow to the heart, and (3) filtering pressure in the kidneys (see p. 579). Thus, tonic sympathetic activity constricts most vessels (with the exception of those in the brain), assuring an *adequate driving force for blood flow to the brain, heart, and kidneys* at the expense of organs and tissues that can better withstand reduced blood flow.

The medullary cardiovascular control center, other brain regions, and hormones regulate blood flow and pressure

The main region of the brain responsible for adjusting sympathetic output to the arterioles is the same as that for heart rate—the *cardiovascular control center* in the medulla of the brain stem. This is the integrating center for blood pressure and flow regulation. It in turn is under the influence of “higher” brain centers that can, among other actions, *anticipate* circulatory changes needed for activity. You’ll see later how all these systems work together when we look at cardiovascular integration at the chapter’s end.

Several other brain regions and hormones also extrinsically influence arteriolar tone. Two major ones are *vasopressin* (also regulated by the hypothalamus and important in regulating body water balance) and *angiotensin II*, part of a hormonal pathway, the *renin-angiotensin-aldosterone pathway* (important in the regulation of the body’s salt balance). Both also help maintain adequate pressure for filtration. The functions and control of these hormones are discussed in Chapters 12 and 13.

This completes our discussion of the various factors that affect total peripheral resistance, the most important of which are controlled adjustments in arteriolar radius. These factors are summarized in Figure 9-48.

check your understanding 9.12

What are the key factors that regulate dilation and constriction of arterioles, and how is such regulation useful?

9.13 Circulatory Vessels: Capillaries

Capillaries, which branch extensively to bring blood within the reach of every cell, are the ultimate functional units of circulation. As the sites for exchange of materials between the blood and tissues, they have one primary function: *to enhance diffusion*. With few exceptions, carrier-mediated transport systems do not occur across capillaries (see p. 439). Rather,

exchange of most materials across capillary walls is accomplished by the process of diffusion. Thus, evolutionary enhancements of diffusion are crucial, since diffusion is slow.

Capillary anatomy increases diffusion rates by minimizing distance ΔX while maximizing surface area A and the diffusion coefficient D of Fick’s law

Recall that diffusion follows Fick’s law (Table 3-1 and p. 76):

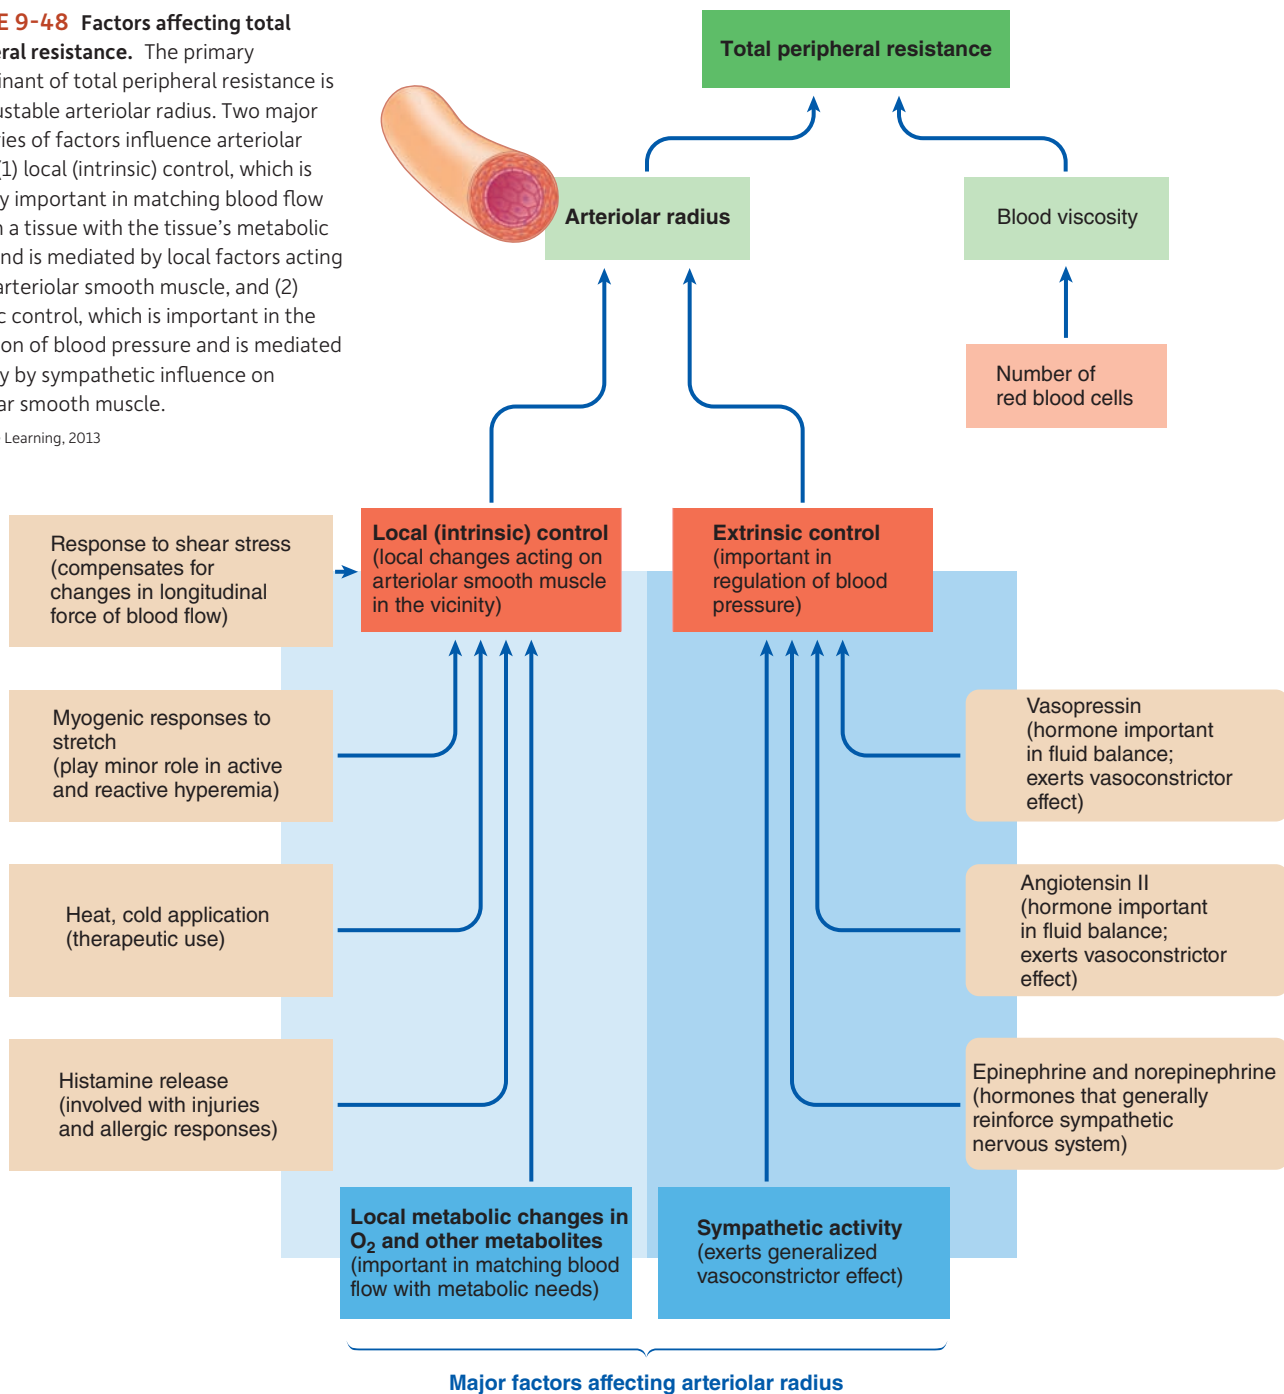

$$\text{Rate of diffusion } (Q) = \frac{\Delta C \times A \times D}{\Delta X}$$

Capillaries and regulation of their blood flow have evolved to maximize diffusion by enhancing every component of the law. Let’s start with capillary anatomy, which directly minimizes diffusion distances ΔX while maximizing surface area A and the diffusion coefficient D as follows:

1. ΔX : Diffusing molecules have only a short distance (ΔX) to travel between the blood and surrounding cells because of the following factors:
 - a. Capillary walls are very *thin* (1 μm in thickness; in comparison, the diameter of a human hair is 100 μm). Capillaries are composed of only a single layer of flattened endothelial cells—essentially the lining of the other vessel types. No smooth muscle or connective tissue is present (Figure 9-49a).
 - b. Each capillary is so *narrow* that red blood cells have to squeeze through single file (p. 391 and Figure 9-49b). Consequently, oxygen does not have to travel far from hemoglobin inside those cells to leave the capillary (or vice versa).
 - c. Because of extensive capillary *branching*, it is estimated that no cell is farther than 0.1 mm (4/1,000 inch) from a capillary.
2. A : Because capillaries are distributed in such incredible numbers (estimates range from 10 to 40 billion capillaries), a tremendous total surface area (A) is available for exchange (an estimated 600 m^2). Generally, tissues that are more metabolically active have a greater density of capillaries (*vascularization*). Muscles, for example, have relatively more capillaries than their attached tendons. Despite this large number of capillaries, at any point in time they contain only 5% of the total blood volume. As a result, a small volume of blood is exposed to an extensive surface area. If all the capillary surfaces of a human were stretched out in a flat sheet and the volume of blood contained within the capillaries were spread over the top, this would be roughly equivalent to spreading a cup of paint over the floor of a high-school gymnasium. Imagine how thin the paint layer would be!
3. D : Diffusion across capillary walls also depends on the walls’ permeability to the materials being exchanged (included in the D of Fick’s law). The endothelial cells forming the capillary walls fit together in jigsaw-puzzle fashion. In most capillaries, narrow, water-filled pores are present at the junctions between the cells (Figure 9-50). These pores permit passage of water-soluble substances. (Lipid-soluble substances, such as O_2 and CO_2 , can readily pass through the endothelial cells’ lipid bilayer.)

FIGURE 9-48 Factors affecting total peripheral resistance. The primary determinant of total peripheral resistance is the adjustable arteriolar radius. Two major categories of factors influence arteriolar radius: (1) local (intrinsic) control, which is primarily important in matching blood flow through a tissue with the tissue's metabolic needs and is mediated by local factors acting on the arteriolar smooth muscle, and (2) extrinsic control, which is important in the regulation of blood pressure and is mediated primarily by sympathetic influence on arteriolar smooth muscle.

© Cengage Learning, 2013

The size of the capillary pores varies from organ to organ. At one extreme, the endothelial cells in brain capillaries are joined by tight junctions so that pores are nonexistent. These junctions prevent transcapillary passage of materials between the cells and thus constitute part of the protective *blood–brain barrier* (p. 169). In most tissues, small, water-soluble substances such as ions, glucose, and amino acids can readily pass through the water-filled clefts, but large, non-lipid-soluble materials such as plasma proteins are excluded from passage. At the other extreme, liver capillaries have such large pores that even proteins pass through readily. This is adaptive because the liver's functions include

synthesis of plasma proteins and the metabolism of protein-bound substances such as cholesterol (see HDLs, for example, p. 389). These proteins must all pass through the liver's capillary walls. The leakiness of capillary beds is therefore a function of how tightly the endothelial cells are joined, which varies according to the different organs' needs.

Vesicular transport also plays a limited role in the passage of materials across the capillary wall. Large non-lipid-soluble molecules such as proteinaceous hormones that must be exchanged between the blood and surrounding tissues are transported from one side of the capillary wall to the other in endocytotic–exocytotic vesicles (see p. 42).

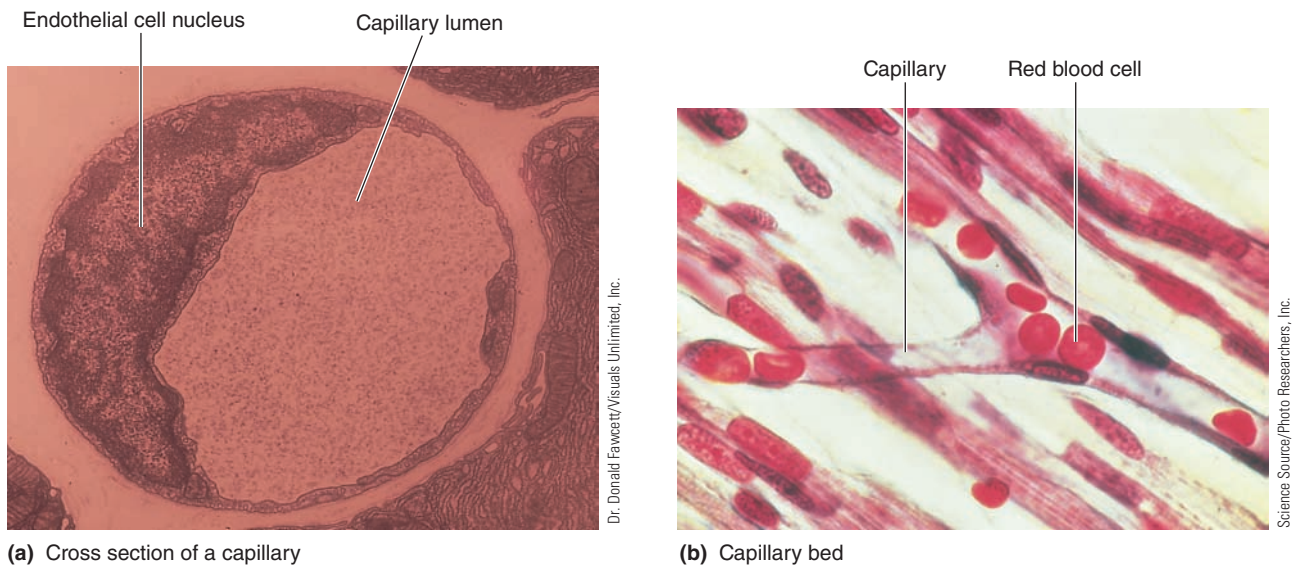

FIGURE 9-49 Capillary anatomy. (a) Electron micrograph of a cross section of a capillary. The capillary wall consists of a single layer of endothelial cells. The nucleus of one of these cells is shown. (b) Photograph of a capillary bed. The capillaries are so narrow that the red blood cells must pass through single file.

Blood composition and perfusion regulation enhance capillary-tissue concentration gradients ΔC

The component of Fick's law we have not addressed is the concentration gradient ΔC between capillary blood and tissues. It too has can be enhanced by regulation of blood

composition and **perfusion**—the volume per minute of blood entering a capillary bed. First, the chemical composition of arterial blood is carefully regulated to carry in oxygen, glucose, and other “desirable” solutes at concentrations usually higher than inside cells. Meanwhile, cells are constantly using up supplies and generating metabolic wastes. Diffusion of each solute continues independently as a result

(a) Continuous capillary **(b) Transport across a continuous capillary wall**

FIGURE 9-50 Exchanges across a continuous capillary wall, the most common type of capillary. (a) Slitlike gaps between adjacent endothelial cells form pores within the capillary wall. (b) As depicted in this cross section of a capillary wall, small water-soluble substances are exchanged between the plasma and the interstitial fluid by passing through the water-filled pores, whereas lipid-soluble substances are exchanged across the capillary wall by passing through the endothelial cells. Proteins to be moved across are exchanged by vesicular transport. Plasma proteins generally cannot escape from the plasma across the capillary wall.

FIGURE 9-51 Independent exchange of individual solutes down their own concentration gradients across the capillary wall.

© Cengage Learning, 2013

of the concentration difference ΔC for that solute between the blood and surrounding cells (Figure 9-51). This process repeats itself continuously. As cells use up O_2 and glucose,

the blood constantly brings in fresh supplies, maintaining concentration gradients that favor the net diffusion into cells. Simultaneously, ongoing net diffusion of CO_2 and other metabolic wastes from cells to blood is maintained by the continual production of these wastes at the cellular level and their constant removal from the tissue level by the circulating blood. Also, as cells increase their level of activity, they use up more O_2 and produce more CO_2 , among other things. This creates larger concentration gradients (ΔC) for O_2 and CO_2 between cells and blood, so more O_2 diffuses out of the blood into the cells and more CO_2 proceeds in the opposite direction.

Second, regulation of perfusion through capillaries also enhances concentration gradients. We have already discussed how this occurs with arterioles, which constrict or dilate to control capillary perfusion. This alters concentration gradients, for example, by bringing in more fresh, oxygenated blood. Capillaries beds can also influence perfusion, as follows. Capillaries typically branch either directly from an arteriole or from a thoroughfare channel known as a **metarteriole**, which runs between an arteriole and a venule (Figure 9-52). Unlike the true capillaries within a capillary bed, metarterioles are sparsely surrounded by wisps of spiraling smooth muscle cells to form **precapillary sphincters**, each consisting of a ring of smooth muscle around the entrance to a capillary as it arises from a metarteriole. Precapillary sphincters are not innervated, but they have a high degree of myogenic tone, such that most are closed in a resting tissue (e.g., 90% closed in resting muscle). Importantly, they are sensitive to local

FIGURE 9-52 **Capillary bed.** Capillaries branch either directly from an arteriole or from a metarteriole, a thoroughfare channel between an arteriole and venule. Capillaries rejoin at either a venule or a metarteriole. Smooth muscle cells form precapillary sphincters that encircle capillaries as they arise from a metarteriole. (a) When the precapillary sphincters are relaxed, blood flows through the entire capillary bed. (b) When the precapillary sphincters are contracted, blood flows only through the metarteriole, bypassing the capillary bed.

© Cengage Learning, 2013

FIGURE 9-53 Complementary action of precapillary sphincters and arterioles in adjusting blood flow through a tissue in response to changing metabolic needs.

© Cengage Learning, 2013

metabolic changes, acting as stopcocks to control perfusion through the particular capillary that each one guards.

Thus, arterioles and precapillary sphincters both regulate perfusion, for example during activity. As chemical concentrations start to change during activity in a region of a muscle tissue supplied by closed-down capillaries, both precapillary sphincters and arterioles in the region relax. As a result of higher perfusion due to more open capillaries, concentration gradients increase. Other parts of Fick's law are also enhanced: As capillaries open, total volume and surface area available for exchange increase, and the diffusion distance between the cells and blood decreases (Figure 9-53). Restoration of the chemical concentrations to normal causes precapillary sphincters to close once again and the arterioles to return to normal tone.

Capillary anatomy increases time for diffusion by slowing blood flow due to a high total cross-sectional area

Despite this enhancement to Fick's law, diffusion is still slow. Capillaries thus have another important feature: *Blood flows much more slowly* in them than elsewhere in the circulatory system, allowing more time for diffusion to occur.

FIGURE 9-54 Comparison of blood flow rate and velocity of flow in relation to total cross-sectional area. The blood flow rate (red curve) is identical through all levels of the circulatory system and is equal to the cardiac output (5 liters/min at rest in humans). The velocity of flow (purple curve) varies throughout the vascular tree and is inversely proportional to the total cross-sectional area (green curve) of all the vessels at a given level. Note that the velocity of flow is slowest in the capillaries, which have the largest total cross-sectional area.

© Cengage Learning, 2013

The extensive capillary branching is responsible for this slow velocity of blood flow through the capillaries. Let's see how blood slows in the capillaries.

First let us clarify a potentially confusing point. The term *flow* can be used in two different contexts—the *flow rate*, which refers to the *volume* of blood flowing through a given segment of the circulatory system per unit of time (this is the flow we have been talking about in relation to the pressure gradient and resistance), and *velocity of flow*, which refers to the linear *speed* with which blood flows forward from one point to another. Because the circulatory

system is a closed system, the volume of blood flowing through the whole system must equal the cardiac output. For example, if the heart pumps out 5 liters of blood per minute, and 5 liters of blood per minute return to the heart, then 5 liters of blood per minute must flow through the arteries, arterioles, capillaries, and veins. Therefore, the flow rate (Q) is the same at all levels of the circulatory system.

However, the *velocity* with which blood flows through the different segments of the vascular tree varies because velocity of flow is inversely proportional to the total cross-sectional area of all the vessels at any given level of the circulatory system as follows:

$$\text{Velocity of flow (cm/sec)} = \text{flow rate (cm}^3\text{/sec)} / \pi r^2 \text{ (cm}^2\text{)}$$

Even though the cross-sectional area of each capillary is extremely small compared to that of the large aorta, the *total* cross-sectional area of all the capillaries added together is about hundreds of times greater than the cross-sectional area of the aorta because there are so many capillaries (Table 9-1). Accordingly, blood slows considerably as it passes through the capillaries (Figure 9-54). This slow velocity allows adequate time for exchange of nutrients and metabolic end products between blood and tissues, which is the sole purpose of the entire circulatory system. As the capillaries rejoin to form veins, the total cross-sectional area is once again reduced, and the velocity of blood flow increases as blood returns to the heart.

As an analogy, consider a river (the arterial system) that widens into a swamp with many small, parallel channels (the capillaries), then narrows into a river again (the venous system) (Figure 9-55). The flow rate is the same throughout the length of this body of water, that is, identical volumes of water are flowing past all the points along the bank of the river and through the whole swamp. However, the velocity of flow is slower in the wide swamp than in the narrow river because the identical volume of water, now spread out over a larger cross-sectional area, moves forward a much shorter distance in the wide swamp (even though it is in many channels) than in the narrow river during a given period of time. You could readily observe the forward movement of water in the swift-flowing river, but the forward motion of water in the swamp would be harder to detect. Notice that velocity increases in the outgoing river even though driving force may be less at this point, simply because of geometry.

Interstitial fluid is a passive intermediary between the blood and cells

Exchanges between blood and the tissue cells are not made directly. Interstitial fluid, the true internal environment in immediate contact with the cells, acts as the go-between (Figure 9-56). This fluid is in a sense the evolutionary descendant of an open circulatory system. In fact, only about 20% of mammalian ECF circulates as plasma, with the remaining 80% in the interstitial fluid. Cells exchange materials directly with this fluid, the type and extent of exchange being governed by the properties of the cellular plasma membranes. Exchange is usually so thorough that the interstitial fluid takes on essentially the same composition as the incoming arterial blood, with the exception of the large plasma proteins that usually do not escape from the blood. Therefore, when we speak of exchanges between blood and tissue cells, we tacitly include interstitial fluid as a passive intermediary.

FIGURE 9-55 Relationship between total cross-sectional area and velocity of flow. The three dark blue areas represent equal volumes of water. During one minute, this volume of water moves forward from points A to points C. Therefore, an identical volume of water flows past points B1, B2, and B3 during this minute; that is, the flow rate is the same at all points along the length of this body of water. However, during that minute the identical volume of water moves forward a much shorter distance in the wide swamp (A2 to C2) than in the much narrower river (A1 to C1 and A3 to C3). Thus, velocity of flow is much slower in the swamp than in the river. Similarly, velocity of flow is much slower in the capillaries than in the arterial and venous systems.

Bulk flow across the capillary wall is important in extracellular fluid distribution

Although, as we noted earlier, passive diffusion down concentration gradients is the primary mechanism for exchange of individual solutes, *bulk flow* also occurs (recall that bulk flow or transport refers to constituents of the fluid moving

© Cengage Learning, 2013

together in bulk with the fluid itself). This process accomplishes the totally different function of determining the distribution of the ECF volume between the vascular and interstitial fluid compartments. Let's see how.

A volume of protein-free plasma actually filters out of the capillary, mixes with the surrounding interstitial fluid, and is subsequently reabsorbed. When pressure inside the capillary exceeds pressure on the outside, fluid is pushed out through the pores. The majority of the plasma proteins and blood cells are retained on the inside during this process, although a few do escape. This process is known as **ultrafiltration** (which we explore further in kidneys, Chapter 12). Because all other constituents in the plasma are carried along with the fluid leaving the capillary, the filtrate is essentially a protein-free plasma. When inward-driving pressures exceed outward pressures across the capillary wall, net inward movement of fluid from the interstitial fluid compartment into the capillaries takes place through the pores, a process known as **reabsorption**.

Factors Influencing Bulk Flow Bulk flow in this form essentially makes the so-called closed circulatory system into an open system, creating a cell-bathing fluid analogous to hemolymph. However, as you will see, its primary purpose is not molecular exchange.

Bulk flow occurs because of differences in the *hydrostatic* and *colloid osmotic pressures* between the plasma and interstitial fluid (Figure 9-57):

1. **Capillary blood pressure (P_C)** is the hydrostatic pressure exerted on the inside of the capillary walls by the blood. This pressure tends to force fluid *out of* the capillaries into the interstitial fluid. Mean blood pressure has dropped substantially by the level of the capillaries because of frictional losses in pressure in the high-resistance arterioles upstream. On the average, the hydrostatic pressure is 37 mm Hg at the arteriolar end of a tissue capillary and has declined even further to 17 mm Hg at the venular end.

2. **Plasma-colloid osmotic pressure (Π_p)** is a force caused by the colloidal dispersion of plasma proteins (p. 388); it arises because the plasma proteins remain in the plasma rather than entering the interstitial fluid. Accordingly, there is also an osmotic difference between these two regions, causing water movement from the interstitial fluid *into* the capillaries by *osmosis* (pp. 77–80). (The other plasma constituents are equal in the plasma and interstitial fluid.) The plasma-colloid osmotic pressure averages 25 mm Hg in humans and cats, 20 in dogs, 11 in chicks, 6 in turtles, and 5 in frogs.
3. **Interstitial-fluid hydrostatic pressure (P_{IF})** is the fluid pressure exerted on the outside of the capillary wall by the interstitial fluid. This pressure tends to force fluid *into* the capillaries. Because of the difficulties encountered in measuring interstitial-fluid hydrostatic pressure, the actual value of the pressure is a controversial issue. It is either at, slightly above, or slightly below atmospheric pressure. For purposes of illustration, we will say it is 1 mm Hg above atmospheric pressure.
4. **Interstitial fluid–colloid osmotic pressure (Π_{IF})** results from the small fraction of plasma proteins that leak across the capillary walls into the interstitial spaces (these are normally returned to the blood by means of the lymphatic system). This protein concentration is extremely low, so the interstitial fluid–colloid osmotic pressure is very close to zero. If plasma proteins pathologically leak into the interstitial fluid, however, as they do when *histamine* widens the intercellular clefts during tissue injury (p. 467), the leaked proteins exert an osmotic effect that tends to promote movement of fluid *out of* the capillaries into the interstitial fluid.

In summary, P_C and Π_{IF} cause movement out of the capillaries, while Π_p and P_{IF} do the opposite. Now let's analyze the fluid movement that occurs from these forces (Figure 9-57).

Net Exchange of Fluid across a Capillary Wall Net exchange at a given point across the capillary wall can be calculated as follows:

$$\text{Net exchange pressure} = (P_C + \Pi_{IF}) - (\Pi_P + P_{IF})$$

(outward pressure) (inward pressure)

A positive net pressure (outward pressure > inward pressure) represents an ultrafiltration pressure, which takes place at the beginning of the capillary as this outward pressure gradient forces a protein-free filtrate through the capillary pores, largely due to P_C . By the time the venular end of the capillary is reached, P_C has dropped, but the other pressures have remained essentially constant, so the outward pressure has fallen below that of the inward pressure. Reabsorption of fluid therefore takes place as the pressure gradient now forces fluid back into the capillary. Ultrafiltration and reabsorption, which collectively create bulk flow, are thus due to a shift in the balance between the physical forces acting across the capillary wall. No local energy expenditures are involved in this flow.

It is important to realize that we have been discussing “snapshots” at two points—at the beginning and at the end—in a hypothetical idealized capillary. The pressures used in Figure 9-57 are mammalian values, and controversial at that. In fact, a recent theory proposes that net ultrafiltration occurs throughout the length of all *open* capillaries (which would have high outward pressures), whereas net reabsorption occurs throughout the length of all *closed* capillaries (which would have low outward pressures).

Role of Bulk Flow in Fluid Balance Bulk flow plays only a minor role in the exchange of individual solutes between blood and tissues because the quantity of solutes moved across the capillary wall by bulk flow is small compared to the much larger transfer of solutes by direct diffusion. So, although this process is somewhat akin to hemolymph flow, its primary function is different. Essentially, it is extremely important in regulating the distribution of ECF between the plasma and interstitial fluid. Maintenance of proper arterial blood pressure depends in part on an appropriate volume of circulating blood. If plasma volume is reduced (for example, by hemorrhage), blood pressure falls. The resultant lowering of capillary blood pressure alters the balance of forces across the capillary walls. Because the net outward pressure is decreased while the net inward pressure remains unchanged, extra fluid is shifted from the interstitial compartment into the plasma as a result of reduced filtration and increased reabsorption. The extra fluid soaked up from the interstitial fluid provides additional fluid for the plasma, temporarily compensating for the loss of blood. Meanwhile, reflex mechanisms acting on the heart and blood vessels (to be described later) also come into play to help maintain blood pressure until long-term mechanisms, such as thirst and reduction of urinary output, can restore the fluid volume to compensate for the loss.

Conversely, if the plasma volume becomes overexpanded, as with excessive fluid intake, the resultant elevation in capillary blood pressure forces extra fluid from the capillaries into the interstitial fluid, temporarily relieving the expanded plasma volume until the excess fluid can be elimi-

nated from the body by long-term measures, such as increased urinary output.

Explain how bulk flow occurs in and out of capillaries, and its importance.

9.14 Circulatory Vessels: Lymphatic System

Even under normal circumstances, slightly more fluid is filtered out of the capillaries into the interstitial fluid than is reabsorbed from the interstitial fluid back into the plasma. On average, the net ultrafiltration pressure at the beginning of the capillary is slightly higher than the net reabsorption pressure at the vessel's end. Because of this pressure differential, on average more fluid is filtered out of the first half of the capillary than is reabsorbed in its last half. The extra fluid filtered out as a result of this deficient reabsorption is picked up by the *lymphatic system*. This accessory “open” circulation has at least two additional functions, in immune defense and in fat transport.

The lymphatic system is an accessory route by which interstitial fluid can be returned to the blood

The **lymphatic system** consists of an extensive network of one-way vessels for returning the remaining interstitial fluid to the blood. It functions much like a storm sewer that picks up and carries away excess rainwater so that it does not accumulate and flood an area. Even though only a small fraction of the filtered fluid is not reabsorbed by the blood capillaries, the cumulative effect of this process being repeated with every heartbeat results in the equivalent of more than the entire plasma volume being left behind in the interstitial fluid each day. Obviously, this fluid must be returned to the circulating plasma, and lymph vessels accomplish this task. The system is thought to occur in all vertebrates, though lymphatic vessels have been documented in only one bony fish species, the zebra fish.

Pickup and Flow of Lymph Small, blind-ended terminal lymph vessels known as **initial lymphatics** permeate almost every tissue of the body (Figure 9-58a). The endothelial cells forming the walls of initial lymphatics slightly overlap like shingles on a roof, with their overlapping edges being free instead of attached to the surrounding cells. This arrangement creates one-way, valvelike openings in the vessel wall. Fluid pressure on the outside of the vessel pushes the innermost edge of a pair of overlapping edges inward, creating a

gap between the edges (that is, opening the valve), thus permitting interstitial fluid to enter (Figure 9-58b). Once interstitial fluid enters a lymphatic vessel, it is called **lymph**. Fluid pressure on the inside forces the overlapping edges together, closing the valves so that lymph does not escape. These valvelike lymphatic openings are much larger than the pores in blood capillaries. Consequently, large particulates in the interstitial fluid, such as escaped plasma proteins and bacteria, can gain access to initial lymphatics but are excluded from blood capillaries.

Initial lymphatics converge to form larger and larger **lymph vessels**, which eventually empty into the venous system near the point where the blood enters the right atrium (Figure 9-59). In all amphibians and reptiles, as well as bird embryos, there are **lymph hearts** (usually in pairs on each side of the body) that create flow back to the blood. The flow of lymph through these hearts are assisted by movements of skeletal muscles and lungs.

Mammals and most adult birds (ostriches are an exception) do not have these distinct auxiliary hearts; flow is accomplished by two mechanisms. First, lymph vessels beyond the initial lymphatics are surrounded by smooth muscle, which contracts rhythmically as a result of myogenic initiation of action potentials. When this muscle is stretched because the vessel is distended with lymph, the muscle inherently contracts more forcefully, thereby pushing the lymph through the vessel. This intrinsic “lymph pump” is the major force for propelling lymph. Second, because lymph vessels lie between skeletal muscles, contraction of these extrinsic muscles squeezes the lymph out of the vessels. One-way valves spaced at intervals within the lymph vessels ensure the flow of lymph toward its venous outlet in the chest.

The lymphatic system is important for immune functions and fat transport

The lymph percolates through **lymph nodes** located en route within the lymphatic system. Passage of this fluid through the lymph nodes is an important aspect of immune defenses against disease. This is covered in Chapter 10. The system is also important in the absorption of fat from the digestive tract. As described in detail in Chapter 14, the end products of the digestion of dietary fats are packaged by cells lining the digestive tract into large particles (*chylomicrons*, pp. 389 and 700) that are too large to gain access to the blood capillaries but can easily enter the initial lymphatics.

check your understanding 9.14

How does lymph form? What are the functions of lymph and the lymphatic system?

9.15 Circulatory Vessels: Venules and Veins

The venous system completes the circulatory circuit. Recall that blood leaving the capillary beds enters into venules and then veins for transport back to the heart (Figure 9-41).

(a) Relationship between initial lymphatics and blood capillaries

Fluid pressure on the outside of the vessel pushes the endothelial cell's free edge inward, permitting entrance of interstitial fluid (now lymph).

(b) Arrangement of endothelial cells in an initial lymphatic

© Cengage Learning, 2013

Veins serve as a blood reservoir as well as passageways back to the heart

Veins have large radii, so they offer little resistance to flow. Furthermore, because the total cross-sectional area of the venous system gradually decreases as smaller veins converge into progressively fewer but larger vessels, the velocity of blood flow *increases* as the blood approaches the heart despite the lower pressure (to review why, see Figure 9-55).

In addition to serving as low-resistance passageways to return blood from the tissues to the heart, systemic veins

FIGURE 9-59 Mammalian lymphatic system and its relationship to the circulatory system. Lymph empties into the venous system near its entrance to the right atrium.

© Cengage Learning, 2013

also serve as a *blood reservoir*. Because of their storage capacity, veins are often referred to as **capacitance vessels**. Veins have much thinner walls with less smooth muscle than do arteries. Because collagen fibers are considerably more abundant than elastin fibers in venous connective tissue, veins have very little elasticity, in contrast to arteries. Also, unlike arteriolar smooth muscle, venous smooth muscle has little inherent myogenic tone. Because of these features, veins are highly distensible, or stretchable, and have little elastic recoil. They easily distend to accommodate additional volumes of blood with only a small increase in venous pressure. Arteries stretched by an excess volume of blood recoil (p. 430), but veins containing an extra volume of blood simply stretch to accommodate the additional blood without tending to recoil. In this way veins serve as a blood reservoir; that is, when demands for blood are low, the veins can store extra blood in reserve because of their distensibility. (Note that blood in the veins is not normally stagnant, but is moving constantly.) Under resting conditions, mammalian veins contain more than 60% of the total blood volume. When the stored blood is needed, such as during exercise, extrinsic factors (soon to be described) drive the extra blood from the veins to the heart, inducing an increased cardiac stroke volume in accordance with the Frank-Starling law of the heart (see p. 417). If too much blood pools in the veins instead of being returned to the heart, cardiac output is abnormally diminished. Thus, a delicate balance exists between the capacity of the veins, the extent of venous return, and the cardiac output. Let's now examine the factors that affect venous capacity and contribute to venous return.

Venous return is enhanced by a number of extrinsic factors

Venous capacity (the volume of blood that the veins can accommodate) depends on the distensibility of the vein walls (how much they can stretch to hold blood) and the influence of any externally applied pressure squeezing inwardly on the veins. At a constant blood volume, as venous capacity increases, more blood remains in the veins instead of being returned to the heart. Such venous storage decreases the effective circulating volume. Conversely, when venous capacity decreases more blood is returned to the heart and continues circulating. Thus, changes in venous capacity directly influence the magnitude of venous return, which in turn is an important (although not the only) determinant of effective circulating blood volume. The magnitude of the total blood volume is also influenced on a short-term basis by passive shifts in bulk flow between the vascular and interstitial fluid compartments and on a long-term basis by factors that control total ECF volume, such as salt and water balance.

Recall that *venous return* refers to the volume of blood entering each atrium per minute from the veins (pp. 416–417), and that the magnitude of flow through a vessel is directly proportional to the pressure gradient ΔP . Much of the driving pressure imparted to the blood by cardiac contraction has been lost by the time the blood reaches the venous system because of frictional losses along the way, especially in the high-resistance arterioles. By the time the blood enters the venous system, mean pressure in humans averages only 17 mm Hg (Figure 9-45, p. 433). However, because atrial

FIGURE 9-60 Factors that facilitate venous return.

© Cengage Learning, 2013

pressure is near 0 mm Hg, a small but adequate driving pressure still exists to promote the flow of blood through the large-radius, low-resistance veins.

In addition to the driving pressure imparted by cardiac contraction, five other factors enhance venous return: sympathetically induced venous vasoconstriction, skeletal muscle activity, the effect of venous valves, respiratory activity, and the effect of cardiac suction (Figure 9-60). Most of these secondary factors affect venous return by influencing the ΔP between the veins and the heart. We examine each in turn.

Effect of Sympathetic Activity on Venous Return Veins are not very muscular and have little inherent tone, but venous smooth muscle is abundantly supplied with sympathetic nerve fibers. Sympathetic stimulation produces vasoconstriction, which modestly elevates venous pressure; this, in turn, increases the pressure gradient to drive more of the stored blood from the veins into the right atrium. Even when constricted, the veins still have a relatively large diameter, thus minimizing any effect of resistance on flow.

It is important to recognize the different outcomes of vasoconstriction in arterioles and veins. Arteriolar vasoconstriction immediately *reduces* flow through these vessels because of their increased resistance (less blood can enter and flow through a narrowed arteriole), whereas venous vasoconstriction immediately *increases* flow through these vessels because of their decreased capacity (narrowing of veins

squeezes out more of the blood that is already present in the veins, thus increasing blood flow through these vessels).

Effect of Skeletal Muscle Activity on Venous Return Many of the large veins in the extremities lie between skeletal muscles, so when the muscles contract, the veins are compressed. This external venous compression decreases venous capacity and increases venous pressure, in effect squeezing fluid contained in the veins forward toward the heart. This pumping action, known as the **skeletal muscle pump** (p. 400), is one way extra blood stored in the veins is returned to the heart during locomotory activity. Increased sympathetic vasoconstriction also accompanies locomotory activity, further enhancing venous return. This also helps overcome the effects of gravity, which tends to cause blood to pool in the lower extremities of tall terrestrial animals.

Effect of Venous Valves on Venous Return Venous vasoconstriction and skeletal pumping both drive blood in the direction of the heart. Yet if you squeeze a fluid-filled tube in the middle, fluid is pushed in both directions from the point of constriction (Figure 9-61a). Why, then, is blood not driven backward as well as forward? The answer is that the large veins are equipped with *one-way valves* (spaced at 2- to 4-cm intervals in humans), which permit blood to move forward toward the heart but prevent it from moving back (Figure 9-61b). These valves also play a role in

FIGURE 9-61 Function of venous valves. (a) When a tube is squeezed in the middle, fluid is pushed in both directions. (b) Venous valves permit the flow of blood only toward the heart.

© Cengage Learning, 2013

counteracting the gravitational effects just noted. (Damage to these valves in humans leads to so-called *varicose veins*.)

Effect of Respiratory Activity on Venous Return As a result of respiratory activity, the pressure within the mammalian chest cavity averages 5 mm Hg less than atmospheric pressure (see Chapter 11). As the venous system returns blood to the heart from the lower regions of the body, it travels through the chest cavity, where it is exposed to this sub-atmospheric pressure. Thus, a pressure gradient exists between the lower veins (which are at atmospheric pressure) and the chest veins (at 5 mm Hg less than atmospheric pressure). This difference enhances flow from the lower veins to the chest veins, promoting increased venous return. This facilitation of venous return is known as the **respiratory pump**. Increased respiratory activity as well as skeletal muscle pumping and venous vasoconstriction all enhance venous return during locomotory activity.

Effect of Cardiac Suction on Venous Return The extent of cardiac filling may not depend entirely on factors affecting the veins. The heart may play a role in its own filling, as we noted earlier, by a suction effect. This would also enhance venous return. Biologists have traditionally considered that suction is the dominant force in heart filling in fishes, whereas venous pressure is the primary force in mammals. However, recent studies show that venous return pressure is probably dominant in fishes and perhaps in all vertebrates, so that suction may be a minor effect.

Explain the ways that veins return blood to the heart, including external pumping and valves.

9.16 Integrated Cardiovascular Function

We have now examined the three major components—fluid, pumps, and vessels—of a circulatory system. We end this chapter by examining how the components are integrated into a smoothly functioning delivery system—the *cardiovascular system*.

Proper gas and heat transport is the first priority and regulation of mean arterial pressure is the second priority of the cardiovascular system

Recall the crucial hemodynamic flow law (p. 419):

$$Q = C.O. = \Delta P/R \text{ or } \Delta P = C.O. \times R$$

Recall that a vertebrate can rapidly alter (1) *cardiac output* (C.O.) by varying heart rate and stroke volume, and (2) *resistance* (R) primarily by changing arteriole diameter. (Long-term regulation of blood volume will be discussed later.) Control features are aimed at regulating these two key features of circulation, for two major goals:

1. **Proper gas and heat transport.** Because oxygen and heat balance are so crucial to short-term survival, *proper blood flow for gas and heat transport is the first priority* of the cardiovascular system, in two situations:
 - a. When a mammal is at rest, C.O. must be *homeostatically* regulated to maintain consistent delivery of O₂ to key organs, especially brain, heart, and kidneys (and, CO₂ and acid must be removed properly).
 - b. During activity, C.O. cannot be homeostatic but must be *reset* higher to boost flow to skeletal muscles, and often to the skin for heat removal.
2. **Arterial blood pressure.** This is somewhat homeostatically regulated, for three reasons, the first of which directly assists gas transport, the other two as secondary priorities:
 - a. Pressure must be high enough to overcome gravity, friction, and other resistance factors; without proper pressure, the brain and other tissues would not receive adequate flow, no matter what local adjustments are made in the resistance of the arterioles supplying them. For example, if diastolic pressure drops to 50 mm Hg or less, blood cannot overcome gravity to reach the top of the human brain. Here, pressure is regulated to protect C.O. to the brain, the first priority of the system.
 - b. Pressure must be high enough for ultrafiltration in the kidneys; in mammals, a minimum average pressure of about 80 mm Hg is needed for this. Here pressure itself, not flow, is the goal of regulation.
 - c. Pressure must not be so high that it creates extra work for the heart and increases the risk of vascular damage and possible rupture of small blood vessels. Again, pressure rather than flow is the direct goal of regulation. Thus, during activity when C.O. must be reset higher, *total R in the body must be lowered* to keep the pressure from rising excessively. However, we stated that this is only somewhat homeostatic because pressures can vary without harm over a moderate range.

Overall *homeostasis of arterial pressure is the second regulatory priority*, with transport needs “trumping” pressure needs if there is a conflict. This can be seen in two situations:

- **Hypertension** (chronic high blood pressure), a common disorder of some mammals such as humans and cats. Excessive resistance R in these animals impedes flow and so ΔP is increased by the cardiovascular integrator in the medulla oblongata to restore proper C.O. In theory, the integrator could let C.O. drop to keep ΔP normal. But it does not. It allows ΔP to rise so that C.O. remains normal. (Examine the flow law to make sure you understand these physical interactions.) Presumably this response evolved because low C.O. (and thus low O_2 delivery) can be lethal within minutes, whereas high blood pressure may take years to kill.

Factors causing hypertension are often uncertain. Experiments with high-salt diets result in elevated arterial pressures in trout and in some (but not all) humans, but the mechanism is unclear. In other cases, hypertension is a symptom of certain diseases. For example, kidney failure with resulting fluid retention is a major cause in cats. In addition, factors that harden and obstruct the arteries (p. 389) eventually impede blood flow with the consequence that blood pressure increases as a means to deliver sufficient O_2 to the brain.

- **Temperature regulation.** The hypothalamus will dilate cutaneous (skin) arterioles to eliminate excess heat from a mammal's body. As a result, blood pressure can fall even though the reflex responses (which we will examine shortly) are calling for cutaneous vasoconstriction to help maintain adequate total arteriolar resistance (see Chapter 15).

Gas transport and blood pressure are monitored by arterial sensors and regulated in part by the cardiovascular control center

As we noted earlier (pp. 416 and 437), the **cardiovascular control center** in the medulla can regulate cardiac output and arteriolar resistance. As an integrator, it receives input from sensors on the afferent side. Its efferent pathway is the autonomic nervous system. Let's see how the system works in negative feedback for the two priorities:

1. **Proper blood flow for gas transport.** Delivery of O_2 and removal of CO_2 are monitored by arterial **chemosensors** in the carotid and aortic arteries. They are sensitive to low O_2 or high acid levels in the blood. These chemoreceptors' main function is to reflexly increase respiratory activity to bring in more O_2 or to blow off more acid-forming CO_2 , but they also reflexly increase blood flow by sending excitatory impulses to the cardiovascular center. Regulation using these chemosensors is also discussed in Chapter 11. Also, as you will see soon, during muscular activity the cardiovascular center can be activated in *anticipation* fashion by higher brain centers.
2. **Arterial pressure** is constantly monitored by **baroreceptors** (pressure sensors, a type of mechanoreceptor type; p. 209). The most important vertebrate baroreceptors involved in regulation of blood pressure are located in

the *aortic arch* (in amphibians, reptiles, birds, and mammals) and the *carotid sinus* (in mammals only). These are strategically located (Figure 9-62) to provide critical information about arterial blood pressure in (1) the vessels leading to the brain (the carotid sinus baroreceptor), for protecting blood flow to the brain, and in (2) the major arterial trunk before it gives off branches that supply the rest of the body (the aortic arch baroreceptor), particularly important for protecting blood flow to the heart. When deviations from normal are detected, reflex responses are initiated. Baroreceptors are sensitive to changes in both mean arterial pressure and pulse pressure. Their responsiveness to fluctuations in pulse pressure enhances their sensitivity as pressure sensors because small changes in systolic or diastolic pressure may alter the pulse pressure without changing the mean pressure.

Next let's look at those reflexes in more detail in a resting animal, then see how the system regulates gas transport and pressure during increasing muscular activity.

The baroreflex is the most important mechanism for short-term regulation of blood pressure during rest or low activity

Any change in mean blood pressure triggers an autonomically mediated **baroreflex** that influences the heart and blood vessels to adjust cardiac output and total peripheral resistance in an attempt to restore blood pressure to normal. Like any reflex, the baroreflex includes a receptor, an afferent pathway, an integrating center, an efferent pathway, and effector organs:

- The baroreceptors constantly provide information to the cardiovascular center about blood pressure by continuously generating action potentials in response to the ongoing pressure within the arteries. When arterial pressure (either mean or pulse pressure) increases, the receptor potential of these receptors increases, thus increasing the rate of firing in the corresponding afferent neurons. The converse happens when blood pressure decreases (Figure 9-63).
- The integrator, the cardiovascular control center, alters the ratio between sympathetic and parasympathetic activity to the effector organs (the heart and blood vessels). To show how autonomic changes alter arterial blood pressure, Figure 9-64 provides a review of the major effects of parasympathetic and sympathetic stimulation on the heart and blood vessels.

Let's fit all the pieces of the baroreflex together now by tracing the reflex activity that occurs to compensate for an elevation or fall in blood pressure by negative feedback. Imagine that for some reason arterial pressure rises above normal (Figure 9-65a); this could happen when a giraffe lowers its head to drink, as gravity now adds to the blood pressure going to the brain rather than reducing it. The carotid sinus baroreceptors increase the rate of firing in their respective afferent neurons. On being informed by increased afferent firing that arterial pressure has become too high, the cardiovascular control center responds by decreasing sympathetic and increasing parasympathetic activity to the car-

FIGURE 9-62 Location of the arterial baroreceptors. The arterial baroreceptors are strategically located to monitor the mean arterial blood pressure in the arteries that supply blood to the brain (carotid sinus baroreceptor) and to the rest of the body (aortic arch baroreceptor).

© Cengage Learning, 2013

FIGURE 9-63 Firing rate in the afferent neuron from the carotid sinus baroreceptor in relation to the magnitude of mean arterial pressure.

© Cengage Learning, 2013

diovascular system. These efferent signals decrease heart rate and stroke volume, and produce arteriolar and venous vasodilation, which in turn lead to a decrease in cardiac output and a decrease in total peripheral resistance, with a subsequent decrease in blood pressure back toward normal.

Conversely, when blood pressure falls below normal (Figure 9-65b), for example by gravity when an animal stands up, baroreceptor activity decreases, inducing the cardiovascular center to increase sympathetic cardiac and vasoconstrictor nerve activity while decreasing its parasympathetic output. In a giraffe raising its head from a lowered position, constriction of vessels in the lower body raises the pressure and diverts blood to the brain. This efferent pattern of activity leads to an increase in heart rate and stroke volume coupled with arteriolar and venous vasoconstriction. These changes result in an increase in both cardiac output and total peripheral resistance, producing an elevation in blood pressure back toward normal.

Regulation of gas transport and blood pressure are coordinated during locomotory activity by higher brain centers

Now let's see how these two regulatory priorities, gas transport and ΔP , interact in a common event, that of increased locomotory activity (such as an animal running away from a predator). Increased gas transport for muscles is the first priority, but also dangerous pressures must not arise. How are both goals achieved? Two major cardiovascular changes must be activated simultaneously:

1. A substantial *increase in cardiac output* (C.O.) is triggered to increase oxygen delivery by increases in both heart rate and stroke volume (recall that $C.O. = HR \times SV$); and
2. A large *increase in skeletal muscle, heart and skin blood flow* accompanied by a *decrease in overall resistance* R are achieved by dilation of arterioles in those organs. At the same time, constriction of gut arterioles diverts more blood to skeletal muscle, heart and skin. Figure 9-66 charts these changes. In summary, intense activity results in increased blood flow to those organs that most need it, while ΔP is prevented from rising too drastically as total R decreases (the increasing R in the gut is far outweighed decreasing R in the perfused organs). Indeed, there is only a modest increase in mean arterial pressure (Table 9-4).

Role of Intrinsic and Extrinsic Regulation Including Anticipation Increase in blood flow to skeletal and heart muscles occurs in part from the intrinsic mechanisms we discussed in detail earlier (pp. 416 and 434). Increasing CO_2 and acid levels, for example, dilate both local arterioles and precapillary sphincters. However, this will not replace the bodywide depletion of O_2 nor reduce bodywide acid buildup. Extrinsic regulators are needed for these adjustments. The simple

FIGURE 9-66 Magnitude and distribution of the cardiac output at rest and during moderate exercise. Values are for an average human. Not only does cardiac output C.O. increase during exercise, but also the distribution of cardiac output is adjusted to support the heightened physical activity. The percentage of cardiac output going to the skeletal muscles and heart rises, thereby delivering extra O₂ and nutrients needed to support these muscles' stepped-up rate of ATP consumption. The percentage going to the skin increases as a means of eliminating from the body surface the extra heat generated by the exercising muscles. The percentage going to most other organs is reduced. Only the magnitude of blood flow to the brain remains unchanged as the distribution of cardiac output is readjusted during activity. Note also that, as C.O. increases 2.5-fold, total peripheral resistance *R* decreases 47% so that systemic pressure ΔP does not rise drastically.

© Cengage Learning, 2013

mechanism is negative feedback: Arterial chemosensors inform the cardiovascular center that blood CO₂ and acid levels are increasing and O₂ is decreasing, so the center increases cardiac output to compensate (at the same time that the respiratory centers are stimulating breathing). But notice that extrinsic mechanisms have a *delay* problem (p. 16). Only after the blood returns through the heart and lungs and back to the aortic sensors would the cardiovascular

center “know” to change C.O. and *R*, by which time the muscles would have gone many seconds with low O₂. However, it has long been known that blood gases do not exhibit significant changes at the onset of exercise—that is, there are no feedback delays. How can this be?

The answer is *anticipation*, which occurs in at least two ways (changes that occur even if the activity does not actually take place):

TABLE 9-4 Cardiovascular Changes during Strenuous Activity

Cardiovascular Variable	Change	Comment
Heart Rate	Increases	Occurs as a result of increased sympathetic and decreased parasympathetic activity to the SA node
Venous Return	Increases	Occurs as a result of sympathetically induced venous vasoconstriction and increased activity of the skeletal muscle pump and respiratory pump
Stroke Volume	Increases	Occurs both as a result of increased venous return by means of the Frank-Starling mechanism (unless diastolic filling time is significantly reduced by a high heart rate) and as a result of a sympathetically induced increase in myocardial contractility
Cardiac Output	Increases	Occurs as a result of increases in both heart rate and stroke volume
Blood Flow to Active Skeletal Muscles and Heart Muscle	Increases	Occurs as a result of locally controlled arteriolar vasodilation, which is reinforced by the vasodilatory effects of epinephrine and overpowers the weaker sympathetic vasoconstrictor effect
Blood Flow to the Brain	Unchanged	Occurs because sympathetic stimulation has no effect on brain arterioles; local control mechanisms maintain constant cerebral blood flow whatever the circumstances
Blood Flow to the Skin	Increases	Occurs because the hypothalamic temperature control center induces vasodilation of skin arterioles; increased skin blood flow brings heat produced by exercising muscles to the body surface where the heat can be lost to the external environment
Blood Flow to the Digestive System, Kidneys, and Other Organs	Decreases	Occurs as a result of generalized sympathetically induced arteriolar vasoconstriction
Total Peripheral Resistance	Decreases	Occurs because resistance in the skeletal muscles, heart, and skin decreases to a greater extent than resistance in the other organs increases
Mean Arterial Blood Pressure	Increases (modest)	Occurs because cardiac output increases more than total peripheral resistance decreases

© Cengage Learning, 2013

1. Evidence suggests that discrete locomotory centers—thought to be in the motor cortex and/or the midbrain—induce cardiac and vascular changes for locomotory activity in *anticipatory* fashion, boosting C.O. and reducing *R* before activity leads to disturbances.
2. Perception of stress can trigger (via the hypothalamus) the widespread changes in cardiovascular activity accompanying the *fight-or-flight* response even in the absence of actual activity. This too is an anticipatory mechanism that prepares the body for action (p. 308).

Blood pressure regulation must integrate both short-term and long-term influences

As we have seen, although gas (and heat) transport is the higher priority, pressure must be regulated within a safe range once transport demands are met. Elaborate mechanisms involving the integrated action of the various components of the circulatory system and other body systems are dedicated to regulating mean arterial pressure. So far we have focused primarily on short-term regulation. But there are other, long-term influences on pressure, the most important of these being *blood volume regulation*. As we men-

tioned earlier (e.g., Figure 9-48), water and salt balance regulators affect the plasma volume, which in turn alters blood pressure. This involves the hypothalamus, kidneys, and so on (see Chapters 12 and 13).

Let's review all the factors that affect mean arterial blood pressure by working our way through Figure 9-67. Even though we've covered all these factors before, it is useful to pull them all together. The circled numbers in the text correspond to the numbers in the figure and indicate the portion of the figure being discussed.

- Mean arterial pressure depends on cardiac output and total peripheral resistance ([1] on Figure 9-67); that is, $\Delta P = C.O. \times R$.
- Cardiac output depends on heart rate and stroke volume [2], both of which increase during locomotory activity.
- Heart rate depends on the relative balance of parasympathetic activity [3], which decreases heart rate, and sympathetic activity (tacitly including epinephrine throughout this discussion) [4], which increases heart rate.
- Stroke volume increases in response to sympathetic activity during locomotory activity [5] (extrinsic control of stroke volume).

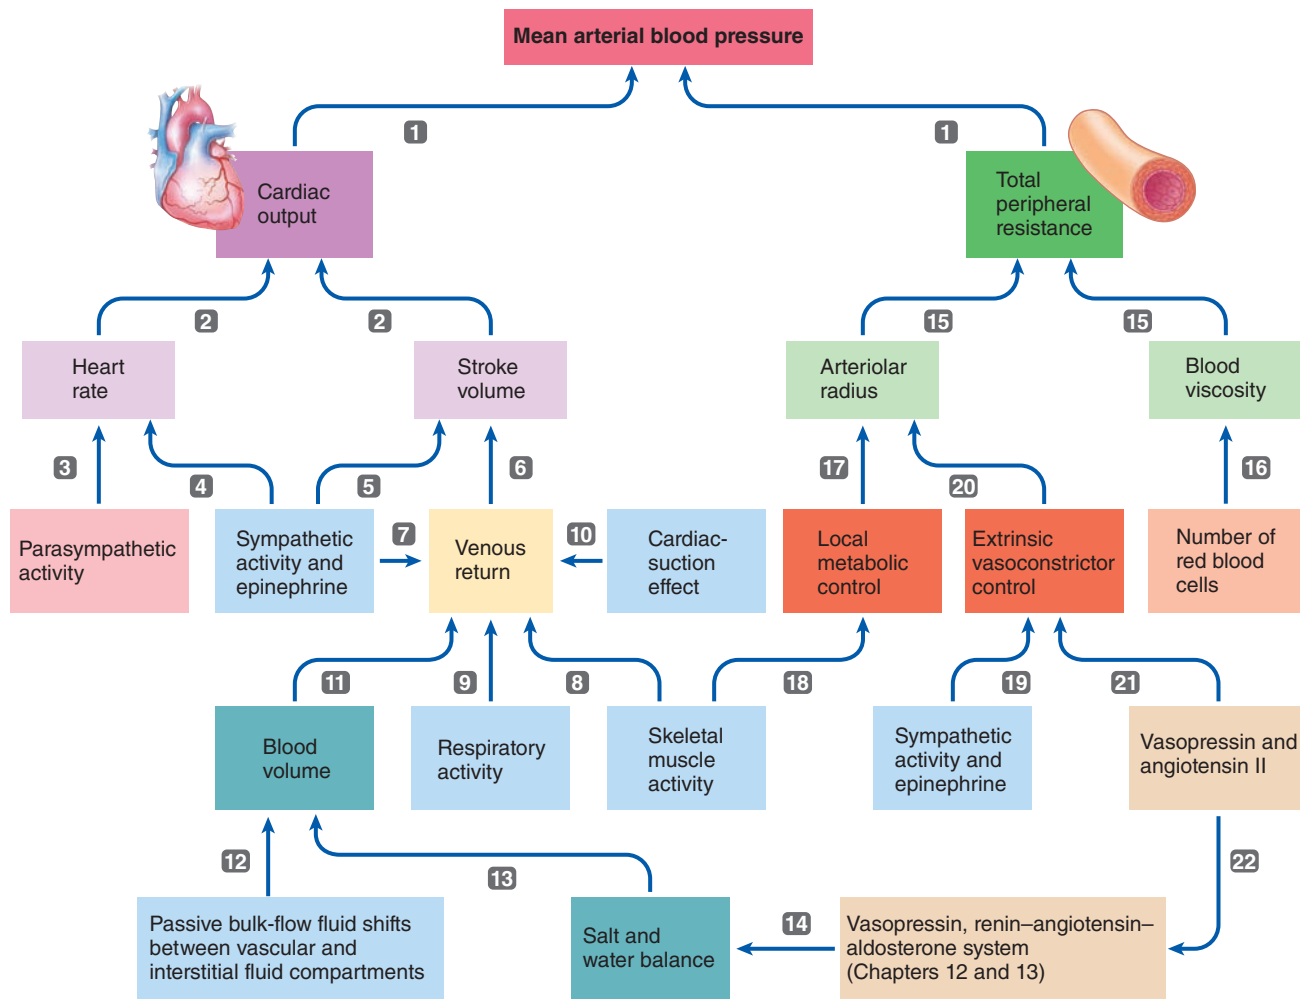

FIGURE 9-67 Determinants of mean arterial blood pressure. Note that this figure is basically a composite of Figure 9-29, p. 417, “Control of cardiac output”; Figure 9-48, p. 438, “Factors affecting total peripheral resistance”; and Figure 9-60, p. 447, “Factors that facilitate venous return.” See the text for a discussion of the circled numbers.

© Cengage Learning, 2013

- Stroke volume also increases as venous return increases during locomotory activity [6] (intrinsic control of stroke volume by means of the Frank-Starling law of the heart).
- Venous return is enhanced during locomotory activity by sympathetically induced venous vasoconstriction [7], the skeletal-muscle pump [8], the respiratory pump [9], and cardiac suction [10].
- The effective circulating blood volume also influences how much blood is returned to the heart [11]. The blood volume depends in the short term on the magnitude of passive bulk-flow fluid shifts between the plasma and interstitial fluid across the capillary walls [12]. In the long term, the blood volume depends on salt and water balance [13], which are hormonally controlled by the renin-angiotensin-aldosterone system and vasopressin, respectively [14].
- The other major determinant of mean arterial blood pressure, total peripheral resistance, depends on the radius of all arterioles as well as blood viscosity [15]. The

major factor determining blood viscosity is the number of red blood cells [16]. However, arteriole radius is the more important factor determining total peripheral resistance.

- Arteriole radius is influenced by local (intrinsic) metabolic controls that match blood flow with metabolic needs [17]. For example, local changes that take place in active skeletal muscles cause local arteriole vasodilation and increased blood flow to these muscles [18].
- Arteriole radius is also influenced by sympathetic activity [19], an extrinsic control mechanism that causes arteriole vasoconstriction [20] to increase total peripheral resistance and mean arterial blood pressure, but which also (via adrenal epinephrine) dilates skeletal muscle and heart arterioles during activity [20].
- Arteriole radius is also extrinsically controlled by the hormones vasopressin and angiotensin II, which are potent vasoconstrictors [21] as well as being important in salt and water balance [22].

Altering any of the pertinent factors produces a change in blood pressure, unless a compensatory change in another variable keeps the blood pressure within the safe range. Blood flow to any given tissue depends on the driving force of the mean arterial pressure and on the degree of vasoconstriction of the tissue's arterioles. Because mean arterial pressure depends on the cardiac output and the degree of arteriolar vasoconstriction, if the arterioles in one tissue dilate, the arterioles in other tissues will have to constrict to maintain an adequate arterial blood pressure to provide a driving force to push blood not only to the vasodilated tissue but also to the brain, heart, and kidneys. Thus, the cardiovascular variables must be continuously juggled to maintain a consistent blood pressure despite tissues' varying needs for blood.

This concludes our examination of circulatory systems. However, circulation plays a vital role in all the following chapters because it links all body systems and carries cells and molecules involved in other major processes such as respiration. Also, as we have just discussed, other systems and processes affect circulation.

Explain why regulation of gas transport and blood pressure are important, and why the former is the top priority.

Discuss the changes that occur during locomotory activity and how they are regulated.

making connections

How Circulation Contributes to the Body as a Whole

Homeostasis depends on continual delivery of needed supplies to all the cells throughout the body and on ongoing removal of wastes generated by the cells. Regulated changes such as those needed during muscular activity are also dependent on circulatory delivery and removal. Thus, circulatory systems contribute to the whole animal by serving as a body's transport system, linking all organ systems together. Circulatory systems provide a means of rapidly moving heat and materials—oxygen, nutrients, hormones, wastes, and cells—from one part of the body to another, overcoming the limits of diffusion.

Blood or hemolymph has special transport capabilities that enable it to move its cargo efficiently throughout the body. For example, O_2 is poorly soluble in water, but circulatory fluids may be equipped with O_2 -carrying proteins such as hemoglobin, often in erythrocytes (red blood cells). Likewise, homeostatically important water-insoluble hormonal messengers are shuttled in the blood by plasma protein carriers.

Specific components of blood or hemolymph perform the following additional homeostatic activities that are unrelated to transport function:

- Circulatory fluid helps maintain the proper pH in the internal environment by buffering changes in the acid-base load of the body.
- It helps maintain body temperature in endotherms by absorbing heat produced by heat-generating tissues and distributing it throughout the body, or carrying it to the body surface for elimination to the external environment.
- The electrolytes in the plasma are important in membrane excitability, which in turn forms the basis of nerve and muscle function.
- The electrolytes in the plasma are also important in the osmotic distribution of fluid between the extracellular and intracellular fluid, and the plasma proteins play a critical role in the distribution of extracellular fluid between the plasma and interstitial fluid.
- Through their hemostatic functions, clotting factors and cells minimize the loss of life-sustaining blood following vessel injury.
- Circulating immune cells, their secretory products, and certain types of plasma proteins, such as antibodies, constitute immune defense systems.

Circulation usually requires a pump such as a heart. Hearts often exhibit their own intrinsic homeostasis, such as the ability to beat continuously without external signals. Local mechanisms within the vertebrate heart ensure that blood flow to the cardiac muscle normally meets the heart's need for O_2 . In addition, the heart has built-in capabilities to vary its strength of contraction, depending on the amount of blood returned to it. The vertebrate heart does not act entirely autonomously, however. It is innervated by the autonomic nervous system and is influenced by the hormone epinephrine, both of which can vary the rate and contractility of the heart, depending on the body's needs for blood delivery.

Chapter Summary

- Circulatory systems evolved to overcome diffusion, which is extremely slow over all but very small distances, by creating bulk transport. Circulatory systems have up to three distinct components: fluid, pump, and vessels.
- Circulatory fluids contain plasma and often cells. Plasma is a water medium for inorganic ions, gases, and numerous organic solutes. Many of the functions of plasma are carried out by plasma proteins, such as antibodies. Lipoprotein such as LDL and HDL complexes carry energy lipids and structural lipids for biosynthesis.
- Respiratory pigments such as hemoglobins and hemocyanins carry oxygen. Erythrocytes in some animals contain these pigments and so serve primarily to transport oxygen. Hemopoietic tissues such as bone marrow continuously replace worn-out erythrocytes. Erythropoiesis in mammals and probably other vertebrates is controlled by erythropoietin from the kidneys.

- Thrombocytes and platelets function in clotting. Hemostasis prevents blood loss from damaged small vessels. Hemocytes and hemolymph proteins provide hemostasis in arthropods. In mammals, first vascular spasm reduces blood flow through an injured vessel. Then, platelets aggregate to form a plug at a vessel defect by positive feedback. Finally, a triggered chain reaction and positive feedback involving clotting factors in the plasma results in blood coagulation. Plasmin dissolves clots and prevents inappropriate clot formation.
- Pumping mechanisms include flagella, extrinsic skeletal muscles, peristaltic muscular pumps, and hearts (chamber muscle pumps). Many animals have primary hearts aided by auxiliary pumps, such as two extra hearts in cephalopods to aid gill flow. Arthropod hearts are dorsally located and have many valved openings.
- Vertebrate hearts evolved from a two-chambered (in fish) into a four-chambered structure, that is, crocodilian, avian and mammalian hearts are dual pumps with two atria, two ventricles. Heart valves ensure that the blood flows in the proper direction.
- Vertebrate heart walls are composed of spirally arranged cardiac muscle fibers to create squeezing action, and are interconnected by intercalated discs with gap junctions for electrical connectivity. Pacemaker cells have channels that cyclically push them to “firing” threshold to keep myogenic hearts beating independently. The sinoatrial (SA) node in the right atrium is the normal pacemaker of the mammalian heart. The spread of cardiac excitation is coordinated to ensure efficient pumping, starting at the SA node, spreading through the atria, then to the atrioventricular node and tracts running through the ventricles. The electrocardiogram (ECG) records these electrical events.
- The action potential of contractile cardiac muscle cells shows a characteristic plateau to aid pumping. Ca^{2+} entry from the ECF induces a much larger Ca^{2+} release from the sarcoplasmic reticulum also to aid pumping. Tetanus of cardiac muscle is prevented by a long refractory period, so the muscle can contract cyclically.
- Hearts alternately contract in systole to empty and relax in diastole to fill.
- Cardiac output (C.O.) depends on the heart rate times the stroke volume. Heart rate is determined primarily by antagonistic regulation of autonomic influences on the SA node. Stroke volume is determined by the extent of venous return and by sympathetic activity. Increased end-diastolic volume, which occurs during exercise as skeletal muscles squeeze more blood into the heart, results in increased stroke volume.
- The heart receives most of its own blood supply through the coronary circulation.
- Blood flow Q through vessels depends on the pressure gradient ΔP and inversely on vascular resistance R : $Q = \Delta P/R$. Pressure is dependent on many factors such as gravity; resistance depends on many factors but blood vessel radius is the most important.
- Circulatory fluids transport materials in a parallel manner, especially in closed systems, so that each organ gets a fair share of fluid. However, flow to respiratory organs may be in series for maximal gas exchange. Circulatory fluids are driven by pressure and can transmit useful force, such as extending spider legs for jumping.
- The vascular system evolved from one circuit to two separate circuits—pulmonary to the lungs and systemic to the rest of the body—in vertebrates, along with a change from a two-chambered heart to a four-chambered one.
- Arteries store and release pressure to keep blood flowing by being elastic. Arterioles control blood distribution and bodywide blood pressure by having sphincter muscles, and are the major resistance vessels. Local (intrinsic) metabolic influences on arteriolar radius help match blood flow with the tissues’ needs. Extrinsic sympathetic control of arteriolar radius (by nerves and by epinephrine) is important in the regulation of arterial blood pressure and in redistributing blood flow among organs during activity, in which blood flow is increased to skeletal muscles and reduced to the digestive tract.
- Capillary anatomy increases diffusion rates by minimizing distance ΔX while maximizing surface area A and the diffusion coefficient D of Fick’s law. Blood composition and perfusion regulation enhance capillary-tissue concentration gradients ΔC . Capillary anatomy increases time for diffusion by slowing blood flow due to a high total cross-sectional area. Interstitial fluid is a passive intermediary between the blood and cells. Bulk flow across the capillary wall is important in extracellular fluid distribution.
- The lymphatic system is an accessory route by which interstitial fluid can be returned to the blood, and is important in immune responses and fat transport.
- Veins serve as a blood reservoir as well as passageways back to the heart. Venous return is enhanced by a number of extrinsic factors, such as skeletal muscle pumping and one-way valves.
- Regulation of gas transport and mean arterial blood pressure is accomplished by controlling cardiac output, total peripheral resistance, and blood volume. C.O. must increase in exercise but ΔP must not get too high; thus, overall R is reduced (mainly by dilation in skeletal muscles). The medullary cardiovascular center and several hormones regulate these factors. Gas transport and blood pressure are monitored by arterial baroreceptors and chemoreceptors signaling the cardiovascular center.
- The baroreflex is the most important mechanism for short-term regulation of blood pressure: dropping pressure to the brain signals the cardiovascular center to alter C.O. and R to compensate. Regulation of gas transport and blood pressure are coordinated during locomotory activity by feedback and by anticipatory regulation, increasing C.O. and reducing overall R before activity. Several other systems can influence regulation, for example, those involved in salt and water balance and temperature regulation.

Review, Synthesize, and Analyze

1. Compare lipid transport in insects and mammals.
2. What are the roles of clotting factor XIII in mammals and in arthropods?
3. Compare the electrical events in heart contraction, skeletal muscle contraction, and neuron signal transmission, including similarities and differences in ion channels, Ca^{2+} release, and length of each event.

4. Define the difference between *parallel* and *series* flow in circulation, then discuss where each occurs and why. Use examples from fish and mammals.
5. Arteries and veins are both large vessels that allow for fast blood flow. But in other regards, they are quite different. Discuss the differences and why they evolved.
6. Compare delivery of nutrients and gases, and removal of wastes, in a noncephalopod mollusk and a mammal, focusing on the presence or absence of capillaries.
7. In Chapter 1, we noted the lethal positive-feedback events of congestive heart failure: A weak mammalian heart results in a drop in blood pressure. Using Figure 9-63, discuss how the fluid-retention mechanisms lead to eventual heart failure.
8. EPO injection by human athletes or injected into racehorses can increase blood viscosity. Discuss why, and also why this is potentially dangerous.
9. Using the flow law, discuss what would happen in locomotory activity if C.O. increased fivefold, as it often does during fight or flight, with no change in R .
10. Use the following diagram, where the big arrows show *flow* Q , identical in both systems.
 - a. CIRCLE the following statement(s) that is/are correct:
 - i. Velocity is SLOWER in Pipes D1–5 than in Chamber X
 - ii. Velocity is FASTER in Pipes D1–5 than in Chamber X
 - iii. Velocity is SLOWER in Pipes D1–5 than in pipe B
 - iv. Velocity is FASTER in Pipes D1–5 than in pipe B
 - b. In the diagram, if $Q = 10$, what is the individual *flow* in each of Pipes D1–5? _____; what is the *velocity* in Pipe C? _____; and the *velocity* in Pipes D1–5? _____
 - c. Which of these diagrams is like an insect system, and which like a vertebrate system? Explain.

Hagfish (jawless vertebrates) have *innate* “ready-to-go” immunity similar to that found in all animals. For example, their skin produces copious amounts of mucus that, in addition to suffocating predators, contains *antimicrobial peptides* that quickly kill most bacteria. However, unlike most other vertebrates, hagfish lack an *acquired* immune system, which first “learns” about internal invaders such as pathogenic bacteria, then responds with highly specific defenses.

Defense Systems

10.1 Evolution of Defense Systems

Animals could not survive beyond early infancy were it not for defense mechanisms. Homeostasis can be optimally maintained, and thus life sustained, only if body cells are not physically injured or functionally disrupted by pathogenic microorganisms or are not replaced by abnormally functioning cells, such as traumatized cells or cancer cells. Attack by other organisms has undoubtedly been a major feature of life for billions of years (long before multicellular animals evolved). Various defense mechanisms have been evolving all that time in a process called **coevolution**: Adaptive changes in one organism favor selection for adaptations in a second organism, which in turn favor selection for a different adaptation in the first organism, and so on. In the context of defense, this is sometimes called an evolutionary “arms race.” For example, an animal may evolve a defense mechanism against a predator or pathogen (an invader such as a disease-causing bacterium), but this provides only a temporary respite in evolutionary terms. The antagonistic species after many generations may evolve a way to overcome this defense. In turn, the first species may evolve yet another improvement to its defenses. Thus,

Paul Yantey

This poison dart frog has innate defenses such as skin mucus with antimicrobial peptides. The mucus has alkaloids toxic to other animals. Internally, the frog also has an acquired immune system.

over time, both species can evolve very sophisticated offenses and defenses.

Effective immune systems are so important that they can influence mate choice behavior in some animals. In many birds, for example, red and yellow pigment molecules called *carotenoids* (from plants) have two functions: They provide colors for male beaks

and feathers, which are used to attract females, and they benefit immunity of the birds because they function as antioxidants and suppress overactive inflammatory reactions. These are not unrelated functions, because research has revealed a linkage between mate attraction and immune function in male zebra finches. Males given extra dietary carotenoids had more brightly colored beaks and faster-responding immune systems compared to control males; moreover, females were more likely to mate with them than with control males with drabber beaks. Thus, a male’s plumage signals to the female how healthy he is, clearly a major factor in producing healthy offspring. It is unlikely that the female consciously perceives the male’s health; rather, females in the past who were predisposed to pick the most brightly colored males produced healthier offspring, spreading the genes for color preference.

Effective immunity is undoubtedly one of the most important physiological systems for survival, but it can be expensive. For example, one study in 2005 found that male crickets with stronger immune systems had weaker sperm compared to males with less robust immunity. This finding illustrates the concept of *trade-offs* in the evolution of adaptations (see p. 2).

Animal defenses target external as well as internal threats including pathogenic bacteria, viruses, parasites, and cancer

Animal defense systems fall into two broad categories. The first deals with external antagonists, primarily predators and competitors. These defenses may be *anatomic* features such as the spines of a porcupine, *chemical* agents such as the nerve inhibitor tetrodotoxin (p. 143) in the skin of a pufferfish, behavioral programs such as *escape responses* (for example, the rapid tail-flip of a lobster), and *reproductive* strategies such as the ability of coral to breed rapidly following decimation by attacking seastars. We will not consider this category of defenses any further.

The second type, and the focus of this chapter, is internal defense, called **immunity**, which is the ability to resist or eliminate potentially harmful foreign materials or abnormal cells inside or attached parasitically to the surface of an animal. The following activities are attributable to *immune systems*, which function to block, recognize, and either destroy or neutralize materials that are foreign to the “normal self.”

1. Defense against invading *pathogens*.
2. Removal of “worn-out” cells (such as aged red blood cells) and tissue debris (for example, tissue damaged by trauma or disease), which is necessary before repair can occur.
3. Identification and destruction of abnormal or mutant cells that have originated in the body. This *immune surveillance* is the primary internal defense mechanism against cancer.

The primary foreign enemies against which the immune system defends are disease-causing biological invaders called **pathogens**. The disease-producing power of a pathogen is known as its virulence. Pathogenic bacteria that invade animal bodies induce tissue damage and produce disease largely by releasing enzymes or toxins that physically injure or functionally disrupt affected cells and organs. The disruption may release nutrients for bacterial growth. Internal **parasites** include larger eukaryotes such as protozoa, yeast, fungi and animals, which take up residence inside a larger animal (called the **host**) and use the latter’s nutrients for growth and reproduction. External parasites such as leeches (annelids) and ticks (arachnids) attach to skin but exert their effects internally on the host by ingesting blood; and they may transmit microbial diseases to the host. For example, the most common tickborne disease in the Northern Hemisphere is Lyme disease. Deer ticks (*Ixodes scapularis*) infect mammals (including domestic ones) with bacteria belonging to the genus *Borrelia*. Tick saliva, which accompanies the bacteria into the wound site, contains substances that provide a protective environment for the bacteria to establish the infection where, if left untreated, can persist for years. For disease transmission to occur, the nymphal-stage tick must remain attached to the host for a period of at least 24 hours. The tick may also infect the host with *Babesia*, a protozoan that reproduces in and (and ruptures) erythrocytes in the disease *babesiosis*. Some internal parasites such as tapeworms may cause harm mostly through nutrient depletion or physical damage to host cells, but others also release damaging chemical agents. The distinction between bacterial and parasitic pathogens is thus somewhat arbitrary.

In contrast to these living cells, **viruses** are not self-sustaining cellular entities. They consist only of DNA or RNA enclosed by a protein coat. Because they lack cellular machinery for energy production and protein synthesis, viruses cannot carry out metabolism and reproduce unless they invade a **host cell** (a body cell of the infected individual) and take over the cellular biochemical facilities for their own purposes. The viral nucleic acids direct the host cell to synthesize proteins needed for viral replication, sapping the host cell’s energy resources, synthesizing toxins that can lyse (burst) the cell, and/or transforming it into a cancer cell. However, if a virus becomes incorporated into a host cell, the host defense system may destroy the cell (as you will see), because it is no longer recognized as a “normal self” cell.

Immune responses can be either innate or acquired

Internal immunity is traditionally divided into two separate but interdependent components: the ancient *innate immune systems* (which has many separate aspects) and the more recently evolved *adaptive* or *acquired immune systems*. The responses of these two systems differ in their timing and in the degree of selectivity of the defense mechanisms employed:

- **Innate immune systems** encompass an animal’s immune responses that come into play rapidly (even immediately) on exposure to any threatening agent and that *do not depend on prior exposure to that agent*. These responses are “ready-to-go” mechanisms that defend against foreign or abnormal material of almost type, including pathogens, chemical irritants, and tissue injury accompanying mechanical trauma and burns. All animal types including sponges have innate immunity mechanisms, such as *phagocytotic* cells that engulf and destroy foreign materials. Innate systems are often called *non-specific*; however, this is misleading since, as you will see, they involve binding to specific features of pathogens, such as the carbohydrates typically attached to the bacterial cell walls.
- **Acquired or adaptive immune systems**, in contrast, rely on *learned* immune responses selectively targeted against a particular foreign material following the first exposure. In essence, this component of the immune system retains *memories* of attacking pathogens in the environment. Since it requires learning, acquired immunity takes considerably more time to be mounted and takes on one specific foe at a time. Probably the most familiar components of this system are *antibodies*, which may take days or weeks to build up after your first exposure to a disease (or vaccine). Until recently, this learning mechanism was thought to have evolved only in vertebrates with jaws, but at the end of the chapter we look at recent evidence for similar systems in lampreys (jawless fish) and perhaps some arthropods and mollusks. Although this defense is often called *adaptive* immunity, many biologists feel the term should be reserved for evolutionary changes over many generations. Indeed, learned defenses are similar to *acclimatization* (see p. 17)—useful prolonged changes in a body triggered in response to a new situation. Therefore, we will use the term *acquired*.

Immune responses use pattern-recognition receptors to distinguish “self” from “nonself”

Both innate and acquired immunity require that an organism recognizes its own tissues and can distinguish them from foreign materials. This *self-recognition* ability has ancient roots: Even cells of the most primitive metazoans, the sponges (Porifera), can distinguish “self” from foreign cells. Another ancient example, illustrated in Figure 10-1a, has been called the “anemone clone wars.” Some species of these Cnidarians grow in distinct patterns: groups of densely packed sea anemones with barren areas between them. A researcher curious about this pattern discovered that each cluster is a clonal lineage; that is, all the anemones are genetically identical and arose from asexual budding starting with one individual. Furthermore, other clusters are also clones, each with their own unique genomes. The barren zones arise when one cluster grows close to another. By detecting unique molecules on the animals’ surfaces, individuals on the edge of each clone recognize the others as “non-self,” and they react violently. Using special stinging war tentacles called *acrorhagia*, the animals sting and try to drive off (or kill) the foreign anemones, leaving the rock barren in between. The recognition process is essentially the same used by internal immune systems to detect invaders (as you will see) and is also similar to the process that causes rejection of organ transplants in humans.

Recognition of self and nonself is accomplished by special **pattern-recognition receptors**, or **PRRs**, in plasma membranes, which one immunologist has called “the eyes of the innate immune system.” A prime example are **Toll receptors** in the fruit fly *Drosophila*, which participate in pattern recognition in both immunity and development. The first Toll gene was discovered in flies as a mutated nonfunctional immune gene that resulted in flies highly prone to fungal infection. Later, many immune cells in mammals were found to have similar receptors and were named **Toll-like receptors (TLRs)**. TLR and other PRRs act as sensors in the host, recognizing and binding with common foreign macromolecules, such as *lipopolysaccharides (LPS)* of the bacterial cell wall (Figure 10-1b). We will investigate PRR roles in detail later in the chapter.

Immune cells communicate with cytokines and by direct contact

A final universal aspect of immunity is the methods by which immune cells communicate during defensive reactions. The primary mechanism involves the secretion and reception of **cytokines** (*cyto*, cell, and *kinos*, movement), which are defined as *signal molecules produced by nongland cells*. These “immunohormones” are analogous to hormones, neurohormones, and neurotransmitters in the other major regulatory systems; some act locally in paracrine fashion, while others travel long distances through circulatory fluids like true hormones. In vertebrates, most cytokines are called **interleukins (IL)** (*inter*, between, and *leukin*, a protein of leukocytes or white blood cells). Vertebrate immune cells also communicate by direct contact with other cells via a so-called **immunosome**, in which two cells’ membranes join either by receptor–receptor binding or by *nanotubes* (p. 91) to initiate signaling responses. Immunosomes probably occur in nonvertebrates but have not been well studied.

FIGURE 10-1 Recognizing self vs. nonself. (a) Anemone clone wars. Conflicts occur between two colonies of sea anemones formed by asexual budding (cloning). When one colony member contacts a member of the other colony, each recognizes the other as foreign and begins an attack. The result is an open patch of habitat between the two groups. (b) Toll-like receptors (TLRs). These proteins on some mammalian immune cells have binding sites that “recognize” common components of bacterial cell walls (such as lipopolysaccharides, flagella, etc.).

Some animals behaviorally acquire defense components from other organisms

Before we examine innate and acquired immunity in depth, note that there is another form of immunity in some species. This is the “borrowing” of immune defenses from other organisms (an example of a behavioral effector, p. 16). Humans are of course renowned for this—virtually every human culture makes use of medicinal compounds from plants, fungi, and the like. In most cases, the compounds,

which aid human health, are also defense compounds in the originating species. Aspirin, for example, was originally obtained from the willow tree and is widely used to treat fever, inflammation, and pain in humans. It occurs in a wide variety of plants, where it appears to be involved in activating a plant's defense mechanisms when an infection occurs.

Other primates can also take advantage of the remedies provided by nature. For example, chimpanzees in eastern Africa swallow whole leaves of the *Aspilia* plant (a relative of sunflowers). In contrast to leaves eaten for food, which are chewed first, these leaves are probably medicinal. They contain large amounts of *thiarubrine-A*, which readily kills parasitic fungi and worms. Similarly, capuchin monkeys in Venezuela find noxious millipedes with defensive compounds called *benzoquinones*. The monkeys smear mashed millipedes on their fur, where the noxious compounds repel biting mosquitoes.

Many birds also seem to make use of defense compounds from other organisms. Most birds that reuse their nests (which may easily become breeding grounds for parasites and bacteria) are seen to line the nests with branches and leaves from certain plants. Starlings, for example, carefully select specific (often rare) plants to line their nests during breeding season. Some of these plants have been tested and are found to contain volatile defense compounds that repel external parasites such as ticks.

We now turn to a detailed look at innate defenses, starting with nonvertebrates.

check your understanding 10.1

What are the major disturbances that internal immunity defends against?

What is the basic difference between innate and acquired immunity?

How do immune systems distinguish “self” from “nonself”?

How do immune cells communicate?

10.2 Innate Immune Systems in Nonvertebrates

Because all animals have innate immunity systems, these have been evolving for a very long time. Due to this, plus the fact that the kinds of invaders and toxins encountered by animals vary so widely among species and habitats, evolution has produced a wide diversity of innate defenses. Nevertheless, there are many similarities and common themes. In particular, most animals have (1) *barrier tissues*, (2) *phagocytotic* cells that “eat” or consume invaders often in an *inflammatory* process, (3) *antimicrobial peptides* that destroy the invaders directly, and (4) *opsonin* proteins that “tag” invaders to aid recognition by phagocytotic cells. Arthropods also have an encapsulation defense. Let's examine how each of these work.

Barrier tissues are the first line of defense, using passive and active mechanisms

Barrier tissues are linings that form impermeable walls to keep invaders out. As such, they are said to be the first lines of defense. The wall aspect is a passive one, but these tissues may also have glands and other active components which can aid in impeding an invasion. The most obvious barrier is the **integument** (*integere*, “to cover”), which covers the outside of an animal's body. Examples include skin *epidermis* in mammals and exoskeletal *epicuticle* in insects. The insect *epicuticle* (the outermost layer of the exoskeleton) has layers of dense lipoproteins, waxes and protein-polyphenol complexes that form not only a tight “fence” but also provide waterproofing to limit moisture loss. Integuments often have glands that secrete defensive proteins. For example, epithelial cells in damaged moth cuticles secrete *cecropin*, an antimicrobial peptide. You will see this and other examples in detail later.

Other organs systems exposed directly to the environment also form protective barriers. These include the *digestive*, *respiratory*, and *genitourinary* systems, all of which have ducts connected to the outside world and so are potentially vulnerable to invasion. As we'll see for mammals later, their epithelial linings have glands for defensive secretions, such as microbe-killing acid in some digestive systems.

Phagocytotic cells and inflammatory responses are the major form of cell-mediated second lines of defense

If a barrier tissue is breached by an invader, so-called second lines of innate defense take over. Two of these—*phagocytotic cells* and *inflammation*—often go together. Although most nonvertebrates do not have enclosed circulatory systems, all have some form of internal fluid cavity. In these fluids are typically found wandering immune cells called **amoebocytes**, which provide what is often called *cell-mediated* defense. These patrol the fluid spaces looking out for foreign invaders. They can often distinguish “self” and “nonself” using PRRs that evolved to bind common bacterial and fungal cell wall components (Figure 10-1b), and possibly viral components. To kill the invaders, they engulf them through **phagocytosis** (“cell eating”; Figure 10-2a), the same process used by amoebas to engulf food. This involves the capture of the foreign object in an internal membrane vesicle made by *endocytosis*, fusion of that vesicle with a *lysosome* (p. 44), and digestion of the object by the lysosome's hydrolytic enzymes. In some arthropods, immune cells have also been found to make *reactive oxides* that kill microbes, just as some mammalian phagocytes do (as you will see later).

Amoebocytes may be called by different names in different animals. For example, in sponges they are called **archaeocytes**. In echinoderms, which have a fluid-filled body cavity called the coelom, these cells are called **coelomocytes**. In arthropods, mollusks, and other animals having an open circulatory system filled with hemolymph (Chapter 9), they are called **hemocytes** (Figure 10-2b). As you will see later, vertebrates have multiple types.

Inflammation-Like Responses Amoebocytes in many nonvertebrates participate in an inflammation-like response to wounds and invaders. **Inflammation** refers to immune-cell (and often fluid) buildup due to chemotaxis to the site of injury, where the cells are activated to engage in phagocytotic destruction of invaders. **Chemotaxis** is directed movement due to attraction to *chemotaxins* released at the site of damage by damaged cells and/or other immune cells. Binding of chemotaxins with protein receptors on the plasma membrane of a phagocytotic cell increases Ca^{2+} entry into it. Ca^{2+} , in turn, switches on the microfilament contractile apparatus that leads to amoeba-like crawling (p. 63). Because the concentration of chemotaxins progressively increases toward the site of injury, phagocytotic cells move toward this site along a chemotaxin concentration gradient.

In addition to creating a concentrated attack, inflammation helps keep the infection from spreading. Some of the cells also produce antimicrobial peptides (as you will see shortly). Here we find possible evolutionary precursors to the verte-

brate system. Once stimulated, phagocytotic cells (coelomocytes, etc.) in echinoderms, tunicates, worms, and insects secrete a cytokine very similar in structure to a major mammalian one called *interleukin-1* or *IL-1* (which you will encounter several times later). These IL-1 cytokines seem to coordinate the cell defenses by acting as chemotaxins to draw in phagocytotic cells and also trigger them to reproduce.

Encapsulation in Arthropods Another second line of defense found in arthropods is **encapsulation**. In this process a foreign invader that is too large for the phagocytes to engulf is walled off by a new barrier. It is commonly used by many insects against parasitic worms, fungi, and eggs laid by parasitic wasps within them (Figure 10-2c). Surface proteins on an invader trigger in certain hemocytes a cascade of enzymatic reactions, which ultimately converts **pro-phenoloxidase (proPO)**, an inactive enzyme that is always present in the cellular membrane, into the active form **phenoloxidase**. This in turn converts phenols into a variety of products, one of

which forms a black polymer called **melanin** (the same molecule that gives human skin its pigment color). Factors that attract other hemocytes to the infection site are also produced, a *positive-feedback* process to accelerate the process. The invader is surrounded with a nodule or capsule several cell layers thick, and the cells closest to the pathogen secrete the melanin to form an impermeable wall. Research studies have demonstrated that if the melanization reaction is inhibited, a higher susceptibility to microbial infection occurs.

The vertebrate clotting system (Chapter 9, p. 395) also can wall off a site of invasion. We will look at this more closely when we examine mammalian inflammation later.

Antimicrobial and other defensive peptides of barrier tissues and immune cells are common noncellular second lines of defense

Another universal second-line defense involves various **antimicrobial peptides** produced by integument, gut and other barrier tissues, phagocytotic cells, and sometimes other tissues (for example, in insects, the fat body appears to be a major source of such peptides). These are small proteins, released by injured or activated cells or free-floating in body fluids, that can bind to and often kill microbes on their own. Many of these, such as **cecropins** in the hemolymph of many insects (first discovered in the silk moth *Hyalophora cecropia*), kill bacteria by a “hole-punch” process: The proteins insert into the bacterial membrane to form pores (Figure 10-3). This hole makes the membrane extremely leaky, resulting in an influx of ECF sodium. This disrupts ions gradients, and may also be followed by an osmotic flux of water into the victim cell, causing it to swell and lyse. Cecropins and similar pore-forming peptides subsequently found in a wide variety of animals and plants are often called **defensins**. Most defensins have numerous positive charges, which are attracted to bacterial membranes to form pores because that membrane is dominated by negatively charged phospholipids. Eukaryotic membranes do not have such strong charges and so are generally safe from attack by these peptides.

Since the discovery of moth cecropin in 1981, hundreds of defensins and other defensive peptides have been found in numerous taxonomic groups including some plants, fruit flies, horseshoe crabs, frogs, fishes, and mammals. Numerous names have been given to these amazing molecules, such as *magainins* in the skin of *Xenopus* toads, *piscidins* in mast cells (p. 465) of bony fishes, *squalamine* in shark livers. Some of these peptides do not form pores, and in most cases their mechanisms are not yet understood. Moreover, some defensive peptides have been found to have antifungal, antiparasitic, and even anticancer activities. The antifungal *drosomycin* in *Drosophila* is one example. Considerable research is now being devoted to these molecules in the hopes that some might be used to fight a variety of diseases in humans and other animals. For example, *brevinin* peptides found in skin of *Rana* frogs come in different forms, some of which kill bacteria via pores, while others show ability to kill human cancer cells by activating apoptosis (p. 101).

FIGURE 10-3
Formation of pore in bacterial membrane by antimicrobial peptides.

Opsonin proteins “tag” invaders for destruction by phagocytotic cells

While phagocytotic cells can often recognize invaders with their PRRs (e.g., the Toll receptors in *Drosophila*), sometimes they need help from extracellular proteins called **opsonins**. An **opsonin** (“to prepare for eating”) enhances phagocytosis by “tagging” an invader for easy recognition by phagocytotic cells (Figure 10-4). Typically, one portion of an opsonin binds to a surface molecule of an invading bacterium while another portion binds to receptor sites specific for it on the phagocytotic cell’s plasma membrane. This link ensures that the bacterial victim does not have a chance to “get away” before the phagocyte can perform its lethal attack. Perhaps all animals have a spectrum of opsonins as innate defenses (and *antibodies*, which we’ll see later, are “acquired” opsonins in vertebrates).

One common opsonin class, best studied in arthropods and vertebrates, are the **lectins**, proteins that bind to glycoproteins on foreign cell walls. For example, *carcinolectins* in horseshoe crabs come in several forms capable of binding glycoproteins of many viruses, bacteria, and fungi. The lectins also bind to each other, causing the foreign cells to clump, much as occurs with antibodies (as you will see), and makes them easy targets for phagocytes. Also, a number of defensive proteins in many nonvertebrates have been found to contain a so-called Ig-fold. This is a region in a protein with a structure similar to the fold found in vertebrate antibodies (also called *immunoglobins* or *Ig*) that bind to foreign proteins. Although Ig-fold proteins are not antibodies, they appear to bind proteins commonly found on microbes and to act as opsonins. Indeed, these may be the evolutionary precursors of antibodies. An example of an Ig-fold protein is **hemolin**, found in the hemolymph of moths and the tobacco hornworm (*Manduca sexta*). Suppression of

Structures are not drawn to scale.

FIGURE 10-4 Mechanism of opsonin action. An opsonin protein links a foreign cell, such as a bacterium, and a phagocytic cell by nonspecifically binding with the foreign cell and specifically binding with a receptor on the phagocyte. This link ensures that the intruder does not escape before it can be engulfed by the phagocyte.

© Cengage Learning, 2013

immune responses mediated by hemolymph by means of RNA interference (p. 33) causes increased susceptibility to the insect pathogen *Photorhabdus* in the tobacco hornworm.

At least in the fruit fly *Drosophila*, opsonin tagging can also trigger release of antimicrobial peptides. Soluble PRRs circulating in the hemolymph first bind to invading bacteria. Subsequently, a PRR (activated by bacteria) binds to the Toll receptor on the fly's hemocyte immune cells, activating genes for production of antimicrobial peptides. Recent studies have found that this activation of genes uses transcription factors that are homologous between flies and mammals, suggesting an ancient history for this aspect of innate immunity.

What are the first line and three major second lines of immune defense, and how do they work?

What features of bacterial surfaces attract the attention of antimicrobial peptides?

10.3 Immune Systems in Vertebrates: Overview

Most vertebrates have not two but three lines of defenses—the two innate levels plus acquired immunity, which work in concert to contain, and then eliminate, harmful agents. As previously discussed the components of the innate system are always on guard as a rapid but limited, sometimes crude, repertoire of defense mechanisms that contain and limit the spread of infection. These ready-to-go responses work well enough for species survival most of the time (indeed, innate immunity of nonvertebrates may be superior to those in vertebrates with acquired immunity). However, in most vertebrates, the innate defenses are important for keeping highly invasive foes at bay until the acquired immune system, with its highly selective weapons, can be prepared to take over and set in motion strategies to completely eliminate the invader.

Active immune responses are regulated by feedback systems with sensors, integrators, and effectors that are primarily leukocytes and proteins

Although a few innate mechanisms are largely passive, such as the physical barrier formed by the skin, most innate and acquired mechanisms are active responses that we would expect to be regulated by feedback systems (as are almost all biological processes). Many of these feedback processes were believed to be localized to the specific tissues involved. But in recent years, immunologists have come to realize that some responses in vertebrates constitute sophisticated feedback loops coordinating many parts of the body. Indeed, some have proposed that the vertebrate immune system be considered a third “whole-body” regulatory system on a par with the neural and endocrine systems. Certainly the immune system has sensors, integrators, and effectors that communicate both locally and across the whole body. However, a single immune cell can act as more than one regulatory component (for example, as both an effector and sensor), and thus, the regulatory features are not as distinct as they are in neural and endocrine systems. Let's briefly examine these regulatory mechanisms before turning to details.

With a few exceptions, the active immune components are individual cells and extracellular proteins, rather than tissues and organs as in the neural and endocrine systems. As in all animals, vertebrate immune proteins include antimicrobial peptides and opsonins (including *antibodies*) as effectors. The cells responsible for the various immune defense strategies are the circulating **leukocytes** (white blood cells) and their noncirculating derivatives. They communicate through interleukin cytokines and through immunosynapses.

Leukocytes of innate and acquired immunity are found in circulation and localized in tissues

The key mammalian immune cells, which are found either in circulatory fluids (blood, lymph) or localized in barrier tissues, and which may participate in innate or acquired immunity or both, are briefly reviewed as follows (Figure 10-5).

Circulating Leukocytes: Sensors, Integrators, and Effectors

1. *Neutrophils* are highly mobile phagocytotic specialists that engulf and destroy unwanted materials. They are innate effectors in the sense that they correct the problem by eating disturbing agents, that is, “nonself” antigens. But because they can often recognize invaders (with PRRs) and destroy them without needing other regulatory commands, they are in some sense both sensors and effectors.
2. *Eosinophils* secrete chemicals that destroy parasitic worms and are involved in allergies.
3. *Basophils* release *histamine*, a trigger of inflammation, and *heparin*, a clotting inhibitor. They also are involved in allergic manifestations. Basophils can be considered sensor-integrators, in the same way that a home thermostat both senses temperature and regulates heating and cooling effectors (Chapter 1, p. 14), or a pancreatic islet cell senses blood glucose and releases insulin as a regulatory hormone (Chapter 7, p. 316).

FIGURE 10-5 Normal blood cellular elements and typical human blood cell count. In the far right photograph, the larger cells are erythrocytes, while the smaller objects are platelets.

4. *Monocytes* are transformed into **macrophages**, which are large, tissue-bound phagocytotic specialists, acting as effectors or as sensor-integrator-effectors such as neutrophils. Macrophages can also act as sensors in acquired immunity by becoming *antigen-presenting cells*, or *APCs*, as you will see later. Recall that microglia, “cousins” of monocytes, are the immune defense cells of the central nervous system (p. 169).
5. *Natural killer (NK) cells*, are a special class of immune cells that destroy virus-infected host cells and cancer cells. These seem to act independently as innate sensor-integrator-effectors.
6. *Lymphocytes* are the primary cells of acquired immunity in jawed vertebrates, and are classified into two types, which we’ll explore in detail later. Briefly, *B-lymphocytes* (also called simply *B cells*) secrete antibodies (effector proteins) that lead to the destruction of very specific foreign material. *T-lymphocytes (T cells)* come in three main types. One is an effector that directs destruction of virus-invaded and cancer cells, while the others are integrators that stimulate or suppress acquired immune effector responses.

Localized Leukocyte Derivatives: Sensors and Integrators

1. *Mast cells* reside in barrier tissues (integumentary, digestive, respiratory) and are analogous to sensing-integrating endocrine glands or a thermostat. They sense an invasion and secrete cytokines such as *histamine* to activate effectors in the local area under attack.
2. *Dendritic cells* also reside in barrier and many other tissues and are now thought to be the key sensors in the acquired defenses. They sense invaders via innate mechanisms but can also become antigen presenting cells (*APCs*) like macrophages to activate acquired immunity.

Although most leukocytes are circulating cells, that does not mean they are primarily in the blood or lymph itself. Most are out in the tissues on defense missions, widely dispersed throughout the body to defend in any location. Al-

most all leukocytes originate from common precursor stem cells in the *bone marrow* (see Figure 9-7, p. 394). We first examine in more detail mammalian innate immunity before turning our attention to acquired immunity.

check your understanding 10.3

What are the major functions of neutrophils, monocytes, NK cells, lymphocytes, mast cells, and dendritic cells?

10.4 Innate Immunity in Mammals

Innate defenses in mammals are similar to those you saw for other animals, but much more detail is known about them. They include:

1. *Barrier tissues and glands*.
2. *Inflammation*, sensed and integrated by *mast cells*, with phagocytotic specialists—*neutrophils* and *macrophages*—as primary effectors. *Basophils* also trigger the inflammatory process responsible for allergies.
3. *The complement system*, a group of inactive plasma proteins that, when activated, act as antimicrobial peptides and opsonins.
4. *Interferon*, a family of effector proteins that nonspecifically defend against viral infection.
5. *Natural killer (NK) cells*, which destroy virus-infected host cells and cancer cells.
6. *Symbiotic bacteria*. In the digestive system, on the skin, and in the female reproductive tract reside countless numbers of resident bacteria. For the most part these do no detectable harm (although it has been shown that some bacteria may convert antioxidants into reactive oxidants) and are often beneficial (for example, some mammalian colon bacteria synthesize vitamin K; other

FIGURE 10-6 Anatomy of the mammalian skin. The skin consists of two layers, a keratinized outer epidermis and a richly vascularized inner connective tissue dermis. Special infoldings of the epidermis form the sweat glands, sebaceous glands, and hair follicles. The epidermis contains four types of cells: keratinocytes, melanocytes, Langerhans cells, and Granstein cells. The skin is anchored to underlying muscle or bone by the hypodermis, a loose, fat-containing layer of connective tissue.

© Cengage Learning, 2013

gut bacteria are crucial to digestion in ruminants; p. 708). An additional benefit is that they can inhibit the growth of invaders, either by outcompeting them or by secreting defense chemicals. For example, “friendly” bacteria that live on the back of the human tongue convert food-derived nitrate into nitrite, which is swallowed. Acidification of nitrite on reaching the highly acidic stomach generates nitric oxide, which is toxic to a variety of microorganisms.

We will now examine the first five of these defenses in detail.

Barrier tissues form passive walls and can have active mechanisms to kill or remove invaders

Recall that barrier tissues—the first lines of defense—are those exposed to the environment.

Integument The skin (Figure 10-6), typically the largest organ of an animal, not only serves as a mechanical barrier between the external environment and the underlying tissues but is dynamically involved in defense mechanisms (and other important functions). The vertebrate **epidermis** consists of numerous layers of epithelial cells without a direct blood supply. Its cells are nourished only by diffusion of nutrients from a rich vascular network in the underlying **dermis** (the connective tissue of the skin). Newly forming cells in the inner layers constantly push the older cells closer to the surface, farther and farther away from their nutrient supply. Epidermal cells are tightly bound together by spot

desmosomes which interconnect with intracellular *keratin* filaments (see p. 65) to form a strong, cohesive, keratinized layer. As the scales of the outermost keratinized layer slough or flake off through abrasion, they are continuously replaced by cell division in the deeper layers. The keratinized layer is airtight, fairly waterproof, and impervious to most substances. It impedes passage into the body of most materials that come into contact with the body surface, including bacteria and toxic chemicals.

Special infoldings of the epidermis into the dermis form the skin’s *exocrine* glands—the sweat glands in some mammals, and sebaceous glands—as well as hair follicles. **Sweat glands** are crucial to temperature regulation (Chapter 15), but they can also produce antimicrobial peptides such as *dermcidin*, which not only help keep pathogens out of the glands but also skin wounds. **Sebaceous glands** produce the oily secretion **sebum** that is released into hair follicles. From there the sebum flows to the surface of the skin, oiling both the hairs and the outer keratinized layers of the skin to help waterproof them and prevent them from drying and cracking. Sebum may also help inhibit the growth of microorganisms.

The epidermis contains two distinct innate defensive cell types. **Melanocytes** produce the pigment **melanin**, which they disperse to surrounding skin cells. Melanin protects by absorbing harmful ultraviolet light rays. **Keratinocytes**, the most abundant epidermal cells, are specialists in keratin production. As they die, they form the outer protective keratinized layer. They are also responsible for generating hair, claws, talons, and nails. A surprising, recently discovered function is that keratinocytes are also important immuno-

logically. For example, they make antimicrobial peptides called *cathelicidins*, which can protect skin wounds from streptococcal bacteria. (The latter function was shown with knockout mice lacking a gene for one cathelicidin; they could not fight off infection by certain streptococcal bacteria.) Cathelicidins in humans, pigs, and cows have other functions, such as attracting other immune cells into the site of invasion during inflammation, stimulating wound healing, and triggering *apoptosis* (p. 101) of damaged body cells in the wound site.

The epidermis also synthesizes a precursor of vitamin D, which is derived from a precursor molecule closely related to cholesterol, in the presence of sunlight. The biologically active vitamin D promotes the absorption of Ca^{2+} from the digestive tract into the blood (p. 329). Recently considerable evidence has accumulated showing that vitamin D boosts the actions of many immune cells. This precursor is made by an undetermined cell type in most mammals. In birds and mammals with thick fur, the precursor is produced in sebum.

Two other epidermal cell types play important roles in acquired immunity (Figure 10-6). A type of *dendritic* cells called **Langerhans cells** serve as sensors (APCs) to activate acquired immune responses (as you will see later). In contrast, **Granstein cells** appear to serve as a “brake” on skin-activated immune responses. Significantly, Langerhans cells are more susceptible to damage by UV radiation (as from the sun) than are Granstein cells. Loss of Langerhans cells due to UV radiation can lead to the braking signals dominating, leaving the skin more vulnerable to microbial invasion and cancer cells.

The various epidermal components of the immune system are collectively termed **skin-associated lymphoid tissue**, or **SALT**. SALT probably plays an even more elaborate role in active immune defense than described here. This is appropriate, because the skin serves as a major interface with the external environment.

Other Barrier Tissues Other barrier tissues also have active innate defenses in addition to being physical barriers and having symbiotic bacteria.

- The *digestive tract* has many defenses because it is frequently exposed to ingested pathogens. Saliva contains the enzyme *lysozyme* and various *defensins* such as *histatins*, which kill bacteria and fungi and promote wound healing (all benefits of licking wounds with the tongue). Furthermore, many surviving bacteria that are swallowed are killed by the strongly acidic fluids in the stomach. Farther down the tract, the intestinal lining has **GALT** (**gut-associated lymphoid tissue**). GALT makes antimicrobial peptides such as the *defensin* HD-5 in the small intestine. HD-5 kills an intestinal bacterium called *Salmonella typhimurium*, which is spread by contaminated food and causes severe diarrhea. The gene for HD-5 was genetically engineered into mice, which are normally unable to resist *S. typhimurium*. The engineered mice all survived an orally induced infection that killed all the control mice.
- Within the *genitourinary* (reproductive and urinary) system, would-be invaders encounter hostile conditions in acidic, often salty urine and acidic vaginal secretions with “territorial” symbiotic bacteria. The genitourinary

organs also produce a sticky mucus, which, like flypaper, entraps small invading particles. Later the particles are either engulfed by phagocytes or are swept out (for example, with urination or menstrual flow).

- The respiratory system in air breathers has several defense mechanisms against inhaled invaders and particulate matter. Larger airborne particles are filtered out of the inspired air by hairs at the nasal passage entrance. Later you will learn about *lymphoid tonsils* and *adenoids*, which protect the entrance to the respiratory system. Farther down in the airways, millions of tiny cilia (see Figure 2-28, p. 61) constantly beat in an outward direction. The airways are coated with a layer of thick, sticky mucus with *cathelicidins* secreted by epithelial cells. This mucus sheet, laden with any inspired particulate debris (such as dust) that adheres to it, is constantly moved upward to the throat by ciliary action. This moving mucus is known as the **mucus escalator**. The dirty mucus is either expectorated (spit out) or in most cases swallowed. In addition, an abundance of phagocytotic specialists called the alveolar macrophages scavenge debris within the air sacs (alveoli, p. 504) of the lungs. Further respiratory defenses include common reflex mechanisms that involve forceful outward expulsion of material in an attempt to remove irritants from the trachea by *coughing* or the nose by *sneezing*.

Inflammation in part is triggered by histamine released by mast cells

Recall that *inflammation* is an innate response to invasion and tissue injury that impedes the spread of damage and brings fluids, phagocytes, and defensive proteins to the invaded or injured area. The following sequence of events typically occurs during the mammalian inflammatory response in the case of bacterial entry into a break in the skin (Figure 10-7).

Defense by Resident Tissue Macrophages On bacterial invasion through a break in the external barrier of skin, the macrophages already present in the area immediately begin phagocytizing the foreign microbes (provided they can recognize them as nonself). Although the resident macrophages are usually not present in sufficient numbers to meet a severe challenge alone, they defend against infection during the first hour or so, before other mechanisms can be mobilized.

These phagocytotic cells are studded with *Toll-like receptors* (TLRs, Figure 10-1b). TLR binding to a pathogen triggers the phagocyte to engulf and destroy the invader. There are a number of TLRs, which recognize (bind) different antigen molecules. For example, TLR2 recognizes peptidoglycans (polymer of amino acids and sugars) from bacterial cell walls, TLR5 binds to flagellin in bacterial flagella, and TLR9 recognizes bacterial DNA. Another type of pattern-recognition receptor (PRR), **retinoic acid inducible gene I (RIG-I)**, has recently been found inside immune cells and recognizes viral RNA. Phagocytes are also activated by the release of intracellular chemicals from damaged body cells.

Integration by Mast Cells: Localized Capillary Vasodilation and Increased Permeability Almost immediately on microbial invasion, mast cells detect the injury and release the

1 A break in the skin introduces bacteria, which reproduce at the wound site. Activated resident macrophages engulf the pathogens and secrete cytokines and chemotaxins.

2 Activated mast cells release histamine.

3 Histamine and cytokines dilate local blood vessels and widen the capillary pores. The cytokines also make the blood vessel wall sticky, causing neutrophils and monocytes to attach.

4 Chemotaxins attract neutrophils and monocytes, which squeeze out between cells of the blood vessel wall, a process called diapedesis, and migrate to the infection site.

5 Monocytes enlarge into macrophages. Newly arriving macrophages and neutrophils engulf the pathogens and destroy them.

FIGURE 10-7 Steps producing inflammation. Chemotaxins released at the site of damage attract phagocytes to the scene. Note the leukocytes emigrating from the blood into the tissues by assuming amoeba-like behavior and squeezing through the capillary pores, a process known as *diapedesis*. Mast cells secrete vessel-dilating, pore-widening histamine. Macrophages secrete cytokines that exert multiple local and systemic effects.

© Cengage Learning, 2013

paracrine cytokine called *histamine*. (One signal that activates mast cells in skin is a type of cathelicidin released from resident macrophages.) This causes arterioles and capillaries within the area to dilate, increasing blood flow to the site of injury and thus aiding the delivery of more phagocytotic cells and plasma proteins such as *complement* (which we will describe shortly). Mast cells also release *chemotaxins* to attract phagocytes. Histamine also increases the capillaries' permeability by enlarging the capillary pores (the spaces between the endothelial cells; see p. 440) so that plasma proteins and cells that normally are prevented from leaving the blood can escape into the inflamed tissue. The familiar

swelling that accompanies inflammation is due to these histamine-induced vascular changes. Pain is caused both by local distension within the swollen tissue and by the direct effect of locally produced substances such as *prostaglandins* on the receptor dendrites of pain neurons.

Clotting On exposure to injured tissue and to specific chemicals secreted by phagocytes on the scene, *fibrinogen*, the final factor in the clotting system, is converted into *fibrin*. Fibrin forms interstitial fluid clots in the spaces around the bacterial invaders and damaged cells. This walling off of the injured region from the surrounding tissues delays the

spread of bacterial invaders and their toxic products. (For details of clotting, see p. 395.)

Emigration of Leukocytes Due to chemotaxis, within an hour after the injury, the involved area is teeming with leukocytes that have exited from the vessels. Neutrophils arrive first, followed by monocytes, which swell and mature into macrophages. Leukocyte emigration from the blood into the tissues uses an amoeba-like mechanism known as *diapedesis*. A leukocyte pushes a long, narrow projection through a capillary pore; then the remainder of the cell flows forward into the projection. In this way, the leukocyte can wriggle its way in about a minute through the capillary pore—even though it is much larger than the pore. Outside the vessel, the leukocyte moves in an amoeboid fashion toward the site of tissue damage and bacterial invasion.

Phagocytotic Destruction of Tagged and Untagged Bacteria

Distinguishing “self” from “nonself” is aided both by phagocytic TLRs as well as the foreign particles being coated with plasma opsonins (Figure 10-4). The most important opsonins are the innate proteins of the *complement* system (see below) and *antibodies* of the acquired system (p. 474). These increase phagocytosis by neutrophils and macrophages, which clear the inflamed area of infectious and toxic agents as well as tissue debris. Phagocytosis can engulf a bacterium in less than 0.01 second. Phagocytes eventually die because of the accumulation of toxic by-products from foreign particle degradation or inadvertent release of destructive lysosomal chemicals into the cytosol. The pus that forms in an infected wound is a collection of these phagocytotic cells, both living and dead; necrotic (dead) tissue liquefied by lysosomal enzymes released from the phagocytes; and bacteria.

Nonphagocytotic Destruction of Tagged and Untagged Bacteria

Nonphagocytotic mechanisms also exist to kill invaders. For example, neutrophils also secrete cathelicidins (p. 467), and macrophages produce and release *nitric oxide* (NO), a reactive chemical that is toxic to nearby microbes (see p. 93). They can also create other toxic microbe-destroying *reactive oxygen species* (ROS, p. 53), released in bursts in the vicinity of invaders. Perhaps most important, the complement system also kills by nonphagocytotic means. As a subtler means of destruction, neutrophils secrete *lactoferrin*, a protein that tightly binds with iron, making it unavailable for use by invading bacteria that depend on high concentrations of available iron for growth. Macrophages also secrete the cytokines *interleukin-1* (IL-1) and *interleukin-6* (IL-6), which decrease the plasma concentration of iron by altering iron metabolism within the liver, spleen, and other tissues, inhibiting bacterial multiplication. Thus, for humans at least, taking iron supplements can sometimes defeat this strategy and the lactoferrin defense and make a disease (such as bubonic plague) actually worse.

Tissue Repair The inflammatory process serves not just to isolate and destroy injurious agents, but also to clear the area for tissue repair. In some tissues (for example, skin, bone, and liver), the healthy organ-specific cells surrounding the injured area undergo cell division to replace the lost cells, often accomplishing complete regeneration of the damaged region. In nonregenerative tissues such as nerve and

muscle in mammals, however, lost cells are replaced by scar tissue. Local fibroblasts, a type of connective tissue cell, start to divide rapidly in the vicinity and secrete large quantities of the protein collagen (see p. 65), which fills in the region vacated by the lost cells and forms scar tissue. Even in a tissue as readily replaceable as the skin, scar tissue sometimes forms when deep wounds permanently destroy complex underlying structures.

Mediation of Inflammation by Phagocyte-Secreted Chemicals

Microbe-stimulated phagocytes release many chemicals that function as mediators of the inflammatory response. These cytokines and effector proteins take part in a broad range of interrelated immune activities, varying from local responses to whole-body manifestations. In addition to killing invaders, these proteins stimulate mast cells (and thus boost inflammation), while others assist the clotting processes. One chemical secreted by neutrophils, *kallikrein*, converts specific plasma protein precursors produced by the liver into activated *kinins*. Activated kinins augment a variety of inflammatory events. For example, the end product of the kinin cascade, *bradykinin*, activates nearby pain receptors and thus partially produces the soreness associated with inflammation. In *positive-feedback* fashion, kinins also act as powerful chemotaxins to entice more neutrophils to join the battle.

Fever IL-1, IL-6, and TNF also all function as *endogenous pyrogen* (EP), which induces the development of fever (*pyro* means “fire”; *gen* means “production”). This response occurs when the invading organisms spread into the blood. EPs, in turn, cause the release within the hypothalamus of *prostaglandins*, locally acting chemical messengers that “turn up” the hypothalamic “thermostat” that regulates body temperature. The function of the resulting elevation in body temperature in fighting infection remains unclear. The fact that fever is such a common systemic manifestation of disease suggests it plays an important beneficial role in defense, as supported by recent evidence. For example, infected lizards will behaviorally choose a higher environmental temperature than normal (see also Chapter 15 on thermoregulation). In mammals, higher body temperatures augment phagocytosis and increase the rate of the many enzyme-dependent inflammatory activities. Furthermore, an elevated body temperature may interfere with bacterial multiplication by increasing the bacterial requirements for iron. Nevertheless, although a mild fever may possibly be beneficial, an extremely high fever can harm the central nervous system.

This list of events augmented by chemicals secreted by phagocytes is by no means complete, but it serves to illustrate the diversity and complexity of responses elicited by these mediators.

The complement system punches holes in microorganisms directly, acts as opsonins, works with antibodies, and augments inflammation

Several times now we have mentioned the *complement system*, another “second-line” defense mechanism based on free-floating proteins. These can be called into play by the presence of almost any foreign invader. The complement system is activated in two ways (Figure 10-8):

Alternate complement pathway: Binding directly to a foreign invader nonspecifically activates the complement cascade (an innate immune response).

Classical complement pathway: Binding to antibodies (Y-shaped molecules) produced against and attached to a particular foreign invader specifically activates the complement cascade (an adaptive immune response).

FIGURE 10-8 Activation of complement system via the alternate pathway and the classical pathway.

© Cengage Learning, 2013

1. By exposure to particular carbohydrate chains expressed on the surface of microorganisms but not on body cells, an innate immune response called the **alternate pathway**.
2. By exposure to antibodies produced against a specific foreign invader, an acquired immune response called the **classical pathway**. This is the source of the system's name—the fact that it “complements” the action of antibodies. In fact it is the major mechanism activated by antibodies to kill foreign cells.

The fact that the complement system is involved in both innate and acquired defense mechanisms illustrates an important point. The various components of the immune system are highly interactive and interdependent, making the system highly sophisticated and effective but also complex and difficult to sort out. As we have done a few times already, we will continue to point out significant cooperative relationships known to exist among immune features as we examine various components separately.

The Membrane Attack Complex The complement system consists of plasma proteins designated C1 to C9 that are produced by the liver and circulate in the blood in an inactive form. Once the first component, C1, is activated, it activates the next component, C2, and so on, in a sequential cascade of activation reactions. The five final components,

C5 through C9, assemble into a large, doughnut-shaped, protein complex, the **membrane attack complex (MAC)**, which attacks the surface membrane of nearby microorganisms by imbedding itself so to create a pore, just as the ancient antimicrobial peptide system (Figure 10-3). In fact, many of the complement proteins are evolutionarily related to defensins of nonvertebrates. The pore's osmotically induced lysis of the intruder is the major means of directly killing microbes without phagocytizing them.

Augmentation of Inflammation Besides the direct destruction of foreign cells accomplished by the MAC, various other activated complement components augment the inflammatory process by:

- *Serving as chemotaxins* to attract phagocytes to the site of microbial invasion.
- *Acting as opsonins* by binding with microbes and thereby enhancing their phagocytosis.
- *Stimulating the release of histamine* from mast cells in the vicinity, which in turn enhances the local vascular characteristic of inflammation.
- *Activating kinins*, which further reinforce inflammatory reactions.

NSAIDs and glucocorticoid drugs suppress the inflammatory response

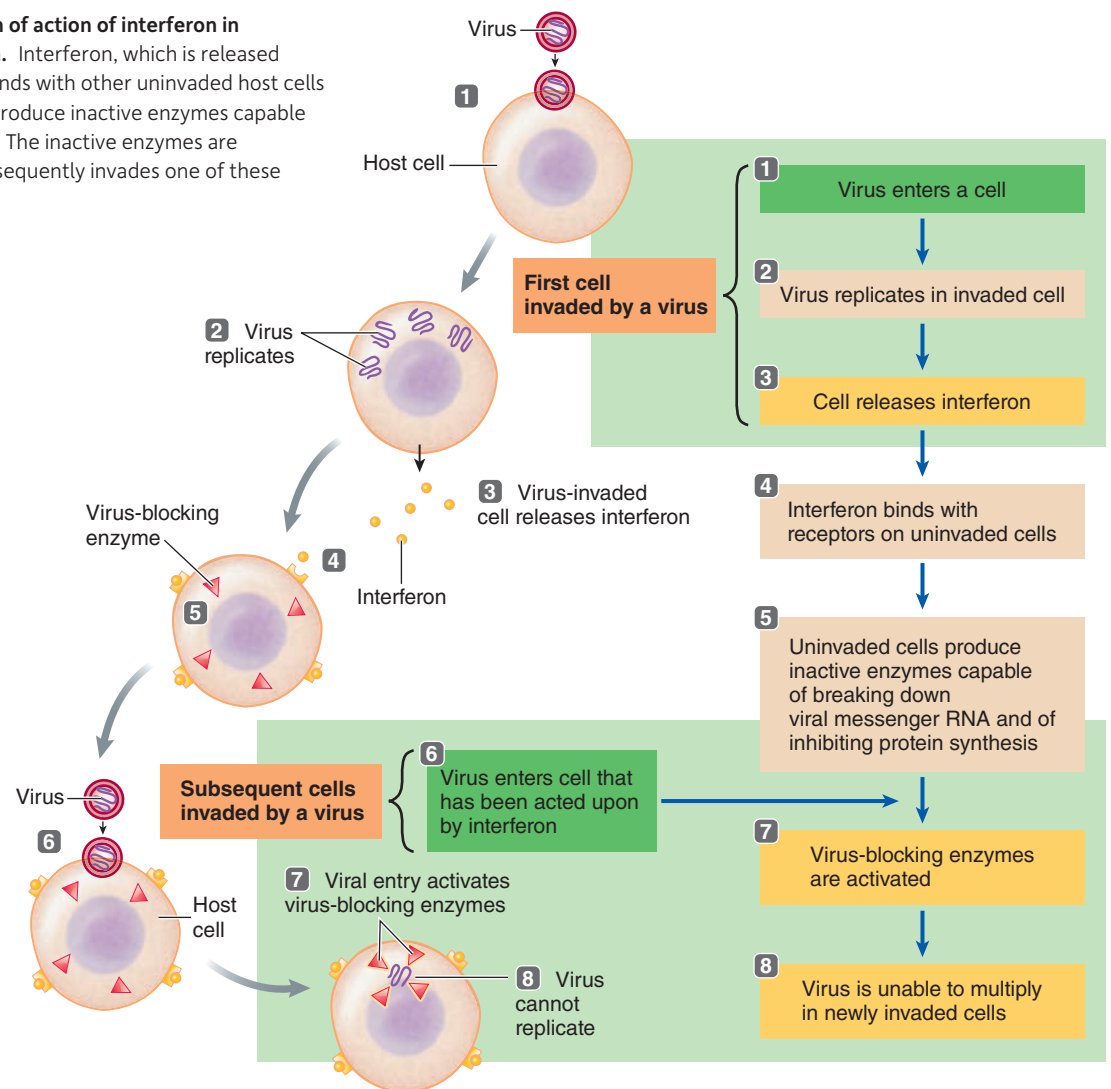

Many drugs can suppress the inflammatory process; the most effective are the *nonsteroidal anti-inflammatory drugs*, or *NSAIDs* (aspirin, ibuprofen, and related compounds) and *glucocorticoids* (drugs similar to the steroid hormone *cortisol*, which is secreted by the adrenal cortex; p. 305). For example, aspirin interferes with the inflammatory response by decreasing histamine release, thus reducing pain, swelling, and redness. Furthermore, aspirin inhibits clotting and reduces fever by inhibiting production of prostaglandins, the mediators of EP-induced fever. NSAIDs are of course widely used by humans, but they are also sometimes prescribed by veterinarians for domestic mammals to reduce inflammation.

Glucocorticoids suppress almost every aspect of the inflammatory response. In addition, they destroy lymphocytes in lymphoid tissue and reduce antibody production. These therapeutic agents, also used by humans and given to domestic mammals, are useful for treating undesirable immune responses, such as allergic reactions (for example, asthma or severe reaction to a bee sting). However, suppression of immune responses also reduces the body's ability to resist infection. Aspirin can also lead to dangerous bleeding. For these reasons, glucocorticoids and NSAIDs should be used discriminatingly.

Recent evidence suggests that cortisol, whose secretion is increased in response to any stressful situation, exerts anti-inflammatory activity even at normal physiological levels (see p. 306). According to this proposal, the anti-inflammatory effect of cortisol modulates stress-activated immune responses, preventing them from overshooting and thus protecting against damage by potentially overreactive defense mechanisms. This is probably important because there are positive-feedback loops in the inflammation response, as we saw earlier. Positive feedback can spiral out of control without some way to interrupt it.

FIGURE 10-9 Mechanism of action of interferon in preventing viral replication. Interferon, which is released from virus-infected cells, binds with other uninvaded host cells and induces these cells to produce inactive enzymes capable of blocking viral replication. The inactive enzymes are activated only if a virus subsequently invades one of these prepared cells.

© Cengage Learning, 2013

Natural killer cells destroy virus-infected cells and cancer cells on first exposure to them

Natural killer (NK) cells are naturally occurring, lymphocyte-like cells that nonspecifically destroy virus-infected cells and cancer cells by releasing chemicals that directly lyse (rupture) the membranes of such cells on first exposure to them. NK cells recognize general features of virus-infected cells and cancer cells by means largely unknown (they do not have TLRs like macrophages or specific receptors like effector T cells have). NK cells provide a rapid, nonspecific defense against virus-invaded cells and cancer cells before the more specific and abundant effector T cells become operational, which requires previous exposure and a prolonged maturation period. NK cells form an immunosynapse with their target cells in order to inject toxins into them, and they can also attach to escaping cancer cells with *nanotubes* (p. 91) that pull the target cell back like a bungee cord!

Interferon transiently inhibits multiplication of viruses in most cells

Besides the inflammatory response, another innate defense mechanism is the release of **interferon** from virus-infected cells. Interferon, a group of three related cytokines, briefly provides nonspecific resistance to viral infections by transiently interfering with replication of the same or unrelated viruses in other host cells. In fact, interferon was named for its ability to “interfere” with viral replication.

Antiviral Effect of Interferon When a virus invades a cell, the cell synthesizes and secretes interferon in response to being exposed to viral nucleic acid. Once released into the ECF, interferon binds with receptors on the plasma membranes of healthy neighboring cells or even distant cells via the blood, signaling these cells to prepare for possible viral attack. Interferon thus acts as a “whistle-blower,” forewarning healthy cells of potential viral attack. Interferon triggers potential host cells to produce enzymes that can break down viral messenger RNA and inhibit protein synthesis. Both these processes are essential for viral replication (Figure 10-9). Because

interferon activation takes place only during a limited time span, this is a short-term defense mechanism.

Anticancer Effects of Interferon Interferon exerts anticancer as well as antiviral effects. It markedly enhances the actions of cell-killing cells—the NK cells and effector T-lymphocytes—which attack and destroy both virus-infected cells and cancer cells. Furthermore, interferon itself slows cell division and suppresses tumor growth.

10.5 Acquired Immunity in Mammals: Overview

The sophisticated third line of defense of jawed vertebrates is the acquired (adaptive) immune system, which directs highly selective attacks at foreign agents but only after previous exposure to the offending invader. Modern immunology began with the discovery of this system by Edward Jenner in England in 1796 when he showed that exposing a young boy to the mild disease cowpox (from the pus of blisters on a milkmaid who had contracted cowpox from a dairy cow) gave him protection against smallpox. The system illustrates the concept of *cost-benefit trade-offs* (see p. 2) in adaptation. The acquired system (as you will see) can produce millions of different PRRs (and soluble versions called antibodies) from a relatively few number of genes to bind to very specific foreign molecules. This ability allows an individual animal to “keep up” with rapidly evolving pathogens, such as new strains of influenza virus. This may be particularly important in long-lived animals with relatively few offspring, such as sharks (in which the vertebrate system may have first evolved, as you will see later). In contrast, short-lived animals with huge numbers of offspring, such as insects, may rely more on evolutionary selection for favorable immune gene mutations over many generations.

However, were all of these variants to be produced in large quantities at once, it would be far too costly, even dangerous, in terms of energy for biosynthesis and for the heart to pump blood made viscous by a high cell density. Instead, very few of each variant is produced at first (not enough for defense), but once one variant is activated by a particular invader, it is amplified to high concentrations to take on that specific invader.

Acquired immunity includes antibody-mediated and cell-mediated responses

There are two classes of acquired immune responses:

- **Antibody-mediated, or humoral immunity**, based on B-lymphocytes (also called simply B cells). B cells trans-

form into *plasma cells*, which secrete *antibodies* (effector proteins) that directly or indirectly lead to the destruction of foreign material. B cells can be thought of as part of the effector response that specifically kills invaders. Because antibodies are bloodborne, antibody-mediated immunity is sometimes known as *humoral immunity*, in reference to the ancient Greek use of the term *humors* for the various body fluids.

- **Cell-mediated immunity with T-lymphocytes** (also called simply T cells): as noted earlier, some T cells are effectors—called *cytotoxic T cells*—that are responsible for cell-mediated immunity involving both direct destruction of virus-invaded cells and cancer cells.

Both responses depend on integrating signals from two other types of T cells: (1) **helper T cells** are the primary integrators of the acquired immune response, receiving input from sensory APC cells and then activating the effector cells; and (2) **T-regulatory cells** suppress immune responses; they are integrators that keep immune reactions in check.

Lymphocytes can specifically recognize and selectively respond to an almost limitless variety of foreign agents as well as cancer cells. The recognition and response processes are different in B cells and in T cells. In general, B cells recognize free-existing foreign invaders; effector T cells specialize in recognizing and destroying body cells gone awry. We will examine each of these processes in detail in the upcoming sections. First, we explore the different life histories of B and T cells and the role of *lymphoid tissues*.

Lymphoid tissues store, produce, and/or process lymphocytes

The term lymphoid tissues (Figure 10-10) refers collectively to the tissues that store, produce, and/or process lymphocytes. These include the *lymph nodes*, *spleen*, *thymus*, *tonsils*, *adenoids*, *bone marrow*, aggregates of lymphoid tissue in the lining of the digestive tract (**GALT**, p. 467), and the lymphoid system of the skin (**SALT**, p. 467). Lymphoid tissues of barrier tissues are strategically located to intercept invading microorganisms before they have a chance to spread very far. For example, the lymphocytes populating the *tonsils* and *adenoids* are situated to respond to inhaled microbes, whereas microorganisms invading through the digestive system immediately encounter lymphocytes in the *appendix* (in some primates including humans) and other **GALT** such as *Peyer's patches* (Figure 10-10). Potential pathogens that gain access to the lymph are filtered through *lymph nodes*, which have sticky chambers as well as many lymphocytes and macrophages. The *spleen*, the largest of the lymphoid tissues, performs immune functions on the blood similar to those the lymph nodes perform on the lymph. The spleen's macrophages and lymphocytes clear the blood that passes through it of microorganisms and other foreign matter and also removes worn-out red blood cells (see p. 392). Table 10-1 summarizes the major functions of the lymphoid tissues.

Origins of B and T Cells Both types of lymphocytes, like all blood cells, are derived from common stem cells in the bone marrow (see p. 394). Whether a lymphocyte and all its progeny are destined to be B or T cells depends on the site of final differentiation and maturation of the original cell in the

FIGURE 10-10 Lymphoid tissues in a mammal. The lymphoid tissues, which are dispersed throughout the body, produce, store, or process lymphocytes.

© Cengage Learning, 2013

lineage (Figure 10-11). B cells differentiate and mature in the bone marrow in mammals, in the *bursa* (an offshoot of the cloaca) in birds. As for T cells, during fetal life and early childhood, some of the immature lymphocytes from the bone marrow migrate through the blood to the *thymus*, where they undergo further processing to become T-lymphocytes (named for their site of maturation). The **thymus** is a lymphoid tissue located midline within the chest cavity anterior to the heart in the space between the lungs (Figure 10-10). The thymus produces **thymosin**, a hormone that enhances proliferation of new T cells within the peripheral lymphoid tissues and augments the immune capabilities of existing T cells. Secretion of thymosin decreases in older mammals. This decline has been suggested as a contributing factor to the increased susceptibility to cancer and viruses with age.

On being released into the blood from either the bone marrow or the thymus, mature B and T cells take up residence and establish lymphocyte colonies in the peripheral lymphoid tissues. After the early developmental years of a mammal, most new lymphocytes are derived from these

TABLE 10-1 Functions of Lymphoid Tissues

Lymphoid Tissue	Functions
Bone Marrow	Origin of all blood cells Site of maturational processing for B lymphocytes
Lymph Nodes, Tonsils, Adenoids, Appendix, and Other Gut-Associated Lymphoid Tissue	Exchange lymphocytes with the lymph (remove, store, produce, and add them) Resident lymphocytes produce antibodies and activated T cells, which are released into the lymph Resident macrophages remove microbes and other particulate debris from the lymph
Spleen	Exchanges lymphocytes with the blood (removes, stores, produces, and adds them) Resident lymphocytes produce antibodies and activated T cells, which are released into the blood Resident macrophages remove microbes and other particulate debris, most notably worn-out red blood cells, from the blood Stores a small percentage of red blood cells, which can be added to the blood by splenic contraction as needed
Thymus	Site of maturational processing for T-lymphocytes Secretes the hormone thymosin

colonies (upon appropriate stimulation) rather than from the bone marrow.

An antigen induces an immune response against itself

Both B and T cells must be able to specifically recognize “self” from “nonself.” The presence of *antigens* enables them to make this distinction. An **antigen** is a large, complex, unique molecule that triggers a specific immune response against itself when it gains entry into the body. In general, the more complex a molecule, the greater its antigenicity, because it has multiple sites to which antibodies can be generated. Foreign proteins are the most common antigens because of their size and structural complexity, although other macromolecules, such as large polysaccharides, can also act as antigens. Antigens may exist as isolated molecules, such as bacterial toxins, or they may be an integral part of a multimolecular structure, such as being on the surface of an invading microbe.

We first examine the role of B cells, then T cells.

check your understanding 10.5

What are the basic differences between antibody- and cell-mediated responses?

Where do B and T cells originate and mature?

What is a lymphoid tissue? An antigen?

FIGURE 10-11 Origins of B and T cells. B cells are derived from lymphocytes that matured and differentiated in the bone marrow, whereas T cells are derived from lymphocytes that originated in the bone marrow but matured and differentiated in the thymus. After early childhood, new B and T cells are produced primarily by colonies of B and T cells established in peripheral lymphoid tissues during fetal life and early childhood.

10.6 Acquired Immunity in Mammals: B-Lymphocytes

The key to B- and T-cell specificity lies in their membrane PRRs that bind an antigen. We discuss how these receptors are generated later, but for now, keep in mind that B and T cells have unique PRRs—B-cell receptors (BCRs) and T-cell receptors (TCRs)—that can be thought of as the sensors of the acquired system; importantly, each receptor binds to only one particular type of the multitude of possible antigenic sites. This is in contrast to the TLRs (p. 460) of the innate system, which bind to numerous generic markers on many microorganisms.

The antigens to which B cells respond can be T-independent or T-dependent

B cells can bind with and be directly activated by polysaccharide antigens without any assistance from T cells. These antigens, known as **T-independent antigens**, stimulate production of antibody without any T cell involvement. By contrast, **T-dependent antigens**, which are typically protein antigens, do not directly stimulate the production of antibody without the assistance of a *helper T cell*. For now we will consider activation of B cells by binding with antigen without regard to whether or not helper T cells must be present. We will discuss how helper T cells are involved later.

Antigens stimulate B cells to convert into plasma cells that produce antibodies

When BCRs (Figure 10-12a) bind with antigen, signal transduction triggers the B cell to divide and differentiate into active *plasma cells* while others become dormant *memory cells*. We first examine plasma cells and their antibodies, then later look at memory cells.

Plasma Cells A plasma cell produces antibodies that can then combine with the specific type of antigen that stimulated activation of the plasma cell. During differentiation into a plasma cell, a B cell swells as the rough endoplasmic reticulum greatly expands (Figure 10-13). Because antibodies are proteins, plasma cells essentially become prolific protein factories, producing up to 2,000 antibody molecules per second. So great is the commitment of a plasma cell's protein-synthesizing machinery to antibody production that it cannot maintain protein synthesis for its own viability and growth. Consequently, it dies after a brief (five- to seven-day), highly productive life span.

Antibodies are secreted into the blood or lymph, depending on the location of the activated plasma cells, but all antibodies eventually gain access to the blood, where they are known as **gamma globulins**, or **immunoglobulins (Ig)**.

Antibodies are Y-shaped and classified according to properties of their tail portion

Antibodies are composed of four interlinked polypeptide chains—two long, *heavy chains* and two short, *light chains*—arranged in the shape of a Y (Figure 10-14). Characteristics of the arm regions of the Y determine the *specificity* of the antibody (that is, with what antigen the antibody can bind). Properties of the tail portion of the antibody determine the *functional properties* of the antibody (what the antibody does once it binds with an antigen).

An antibody has two identical antigen-binding sites, one at the tip of each arm. These **antigen-binding fragments (Fab)** are unique for each different antibody so that each antibody can interact only with an antigen that specifically matches it, much like a lock and key. The tremendous variation in Fabs of different antibodies leads to the extremely large number of unique antibodies that can bind specifically with millions of different antigens.

In contrast to these variable Fab regions at the arm tips, the tail portion of every antibody within each immunoglobulin subclass is identical. The tail, the antibody's so-

(a) B-cell receptor (BCR)

(b) T-cell receptor (TCR)

FIGURE 10-12 B-cell and T-cell receptors.

© Cengage Learning, 2013

called **constant region**, contains binding sites for particular mediators of antibody-induced activities, which vary among different subclasses, as follows.

Antibody Subclasses Antibodies are grouped into five subclasses; note that within each functional subclass are millions of different antibodies, each able to bind only with a specific antigen:

- **IgM** immunoglobulin serves as the B-cell receptor (BCR) for antigen attachment and is produced in the early stages of plasma cell response.
- **IgG**, the most abundant immunoglobulin, is produced copiously when the body is subsequently exposed to the same antigen. The constant tail region of IgG antibodies, when activated by antigen binding in the Fab region, binds with phagocytotic cells and serves as an opsonin to enhance phagocytosis. Together, IgM and IgG antibodies produce most specific immune responses against bacterial invaders and a few types of viruses.
- **IgE** immunoglobulins help protect against parasitic worms and is the antibody mediator for common allergic responses, such as hay fever, asthma, and hives. The constant tail region of IgE antibodies attaches to mast cells and basophils, even in the absence of antigen. Once the triggering antigen binds to the specific antibody (such as IgE in this case), this triggers the release of histamine from the affected mast cells and basophils. Histamine, in turn, induces the allergic manifestations that follow.
- **IgA** immunoglobulins are found in secretions of the digestive, respiratory, and genitourinary systems, as well as in milk and tears.

- **IgD** is present on the surface of many B cells, but its function is uncertain.

Antibodies largely amplify innate immune responses to promote antigen destruction

Antibodies generally do not destroy foreign organisms or other unwanted materials on binding with antigens on their surfaces (although there is some evidence that certain antibodies can catalyze the formation of ozone to kill microbes). Instead, they usually exert their protective influence by physically hindering antigens or, more commonly, by amplifying the innate immune responses (Figure 10-15).

Neutralization and Agglutination

Antibodies physically hinder some antigens from exerting their detrimental effects in two ways:

- In **neutralization**, antibodies combine with bacterial toxins and some types of viruses, preventing these harmful chemicals from interacting with susceptible cells (Figure 10-15a).
- In **agglutination**, multiple antibody molecules cross-link numerous antigen molecules into chains or lattices of antigen-antibody complexes (Figure 10-15b). Through this means foreign cells, such as bacteria or mismatched transfused red blood cells, bind together in a nonmotile clump.

Amplification of Innate Immune Responses These physical hindrance mechanisms play only a minor protective role. The most important function of antibodies by far is to profoundly augment the innate immune responses already initiated by the invaders. Antibodies do so by the following methods:

1. **Activating the complement system.** When an appropriate antigen binds with an antibody, receptors on the tail portion of the antibody bind with and activate C1, the first component of the complement system. This sets off the “classic pathway” of events leading to formation of the MAC, which is specifically directed at the membrane of the invading cell that bears the antigen that initiated the activation process (Figure 10-15c). By tagging the invading bacterium, the antibody initiates the most important attack mechanism by which it exerts its (indirect) protective influence.
2. **Enhancing phagocytosis.** As we noted earlier, IgG acts as an opsonin (Figure 10-15d).
3. **Stimulating natural killer (NK) cells.** Binding of antibody to antigen also induces attack of the antigen-bearing target cell by NK cells. NK cells have receptors for the constant tail region of antibodies. In this case, when the target cell is coated with antibodies, the tail

(a) Unactivated B cell

(b) Plasma cell

portions link the target cell to NK cells, which destroy the target (Figure 10-15e).

Note that each of these innate mechanisms is originally activated by innate means, with their actions being further enhanced by the acquired system’s antibodies.

Clonal selection accounts for the specificity of antibody production

Consider the remarkable diversity of foreign molecules a mammal can potentially encounter during a lifetime. Yet each B cell is preprogrammed to respond to only one of perhaps over 100 million different antigens. Other antigens cannot combine with the same B cell and induce it to secrete different antibodies. The astonishing implication is that each of us is equipped with about 100 million different kinds of preformed B-lymphocytes, at least one for every possible antigen that we might ever encounter—including those specific for synthetic substances that do not exist in nature. The clonal selection theory proposes how a “matching” B cell responds to its antigen.

Early researchers in immunologic theory believed antibodies were “made to order” whenever a foreign antigen gained entry to the body. In contrast, the currently accepted **clonal selection theory**, first proposed by the Danish immunologist Niels Jerne (who received the Nobel Prize), states that diverse B-lymphocytes are produced during fetal development, each capable of synthesizing an antibody against a particular antigen before ever being exposed to it. All offspring of a particular ancestral B-lymphocyte form a family of identical cells, or a **clone**, that is committed to producing the same specific antibody. B cells remain dormant—known as **naïve lymphocytes**—and low in number, not actually secreting their particular antibody product nor undergoing rapid division until (or unless) they come into contact with the appropriate antigen. When this antigen gains entry to the body, the particular clone of B cells that bear receptors (BCRs) on their surface uniquely specific for that antigen becomes activated or “selected” by antigen binding with the BCRs, hence the term **clonal selection theory** (Figure 10-16).

Selected clones differentiate into active plasma cells and dormant memory cells

Antigen also causes a small proportion of the activated B-cell clone to multiply and differentiate into another cell type—**B memory cells**. These do not participate in the current immune attack against the antigen but instead remain dormant. If the animal is ever reexposed to the same antigen, these memory cells remain primed and ready for immediate action.

Recently, evidence has accumulated for another type of B cell, a **B regulatory cell**, that helps suppress overactive immune responses. However, currently the **T-regulatory cell’s** role is better known, and we will describe that later.

Primary and Secondary Responses During initial contact with a foreign antigen, the response is delayed for several days as plasma cells are formed and antibody production increases until reaching a peak over a period of weeks. This

Structures are not drawn to scale.

FIGURE 10-15 How antibodies help eliminate invading microbes. Antibodies physically hinder antigens through (a) neutralization or (b) agglutination and precipitation. © Cengage Learning, 2013

response is known as the **primary response** (Figure 10-17a). Meanwhile, symptoms characteristic of the particular microbial invasion persist until either the invader succumbs to the mounting specific immune attack against it or the infected animal dies. After reaching the peak, the antibody levels gradually decline over a period of time, although some circulating antibody from this primary response may persist for a prolonged period, in some cases years after the initial triggering event. Long-term protection against the same antigen, however, is primarily attributable to the memory cells. If the same antigen ever reappears, memory cells launch a more rapid, more potent, and longer-lasting **secondary response** than occurred during the primary response (Figure 10-17b). This swifter, more powerful immune attack is frequently adequate to prevent or minimize overt infection on subsequent exposures to the same microbe, forming the basis of long-term immunity against a specific disease. **Vaccination (immunization)**, discovered by Jenner and now used widely on humans and domestic animals, is a powerful tool to prevent disease. It takes advantage of this process by deliberately exposing an animal to a pathogen that has been stripped of its disease-inducing capability but that can still induce antibody formation against itself. The mechanisms of long-term immunity induced by disease and vaccines are summarized in Figure 10-18.

FIGURE 10-17 Primary and secondary immune responses. (a) Primary response on first exposure to a microbial antigen. (b) Secondary response on subsequent exposure to the same microbial antigen. The primary response does not peak for a couple of weeks, whereas the secondary response peaks in a week. The magnitude of the secondary response is 100 times that of the primary response. (The relative antibody response is in the logarithmic scale.)

© Cengage Learning, 2013

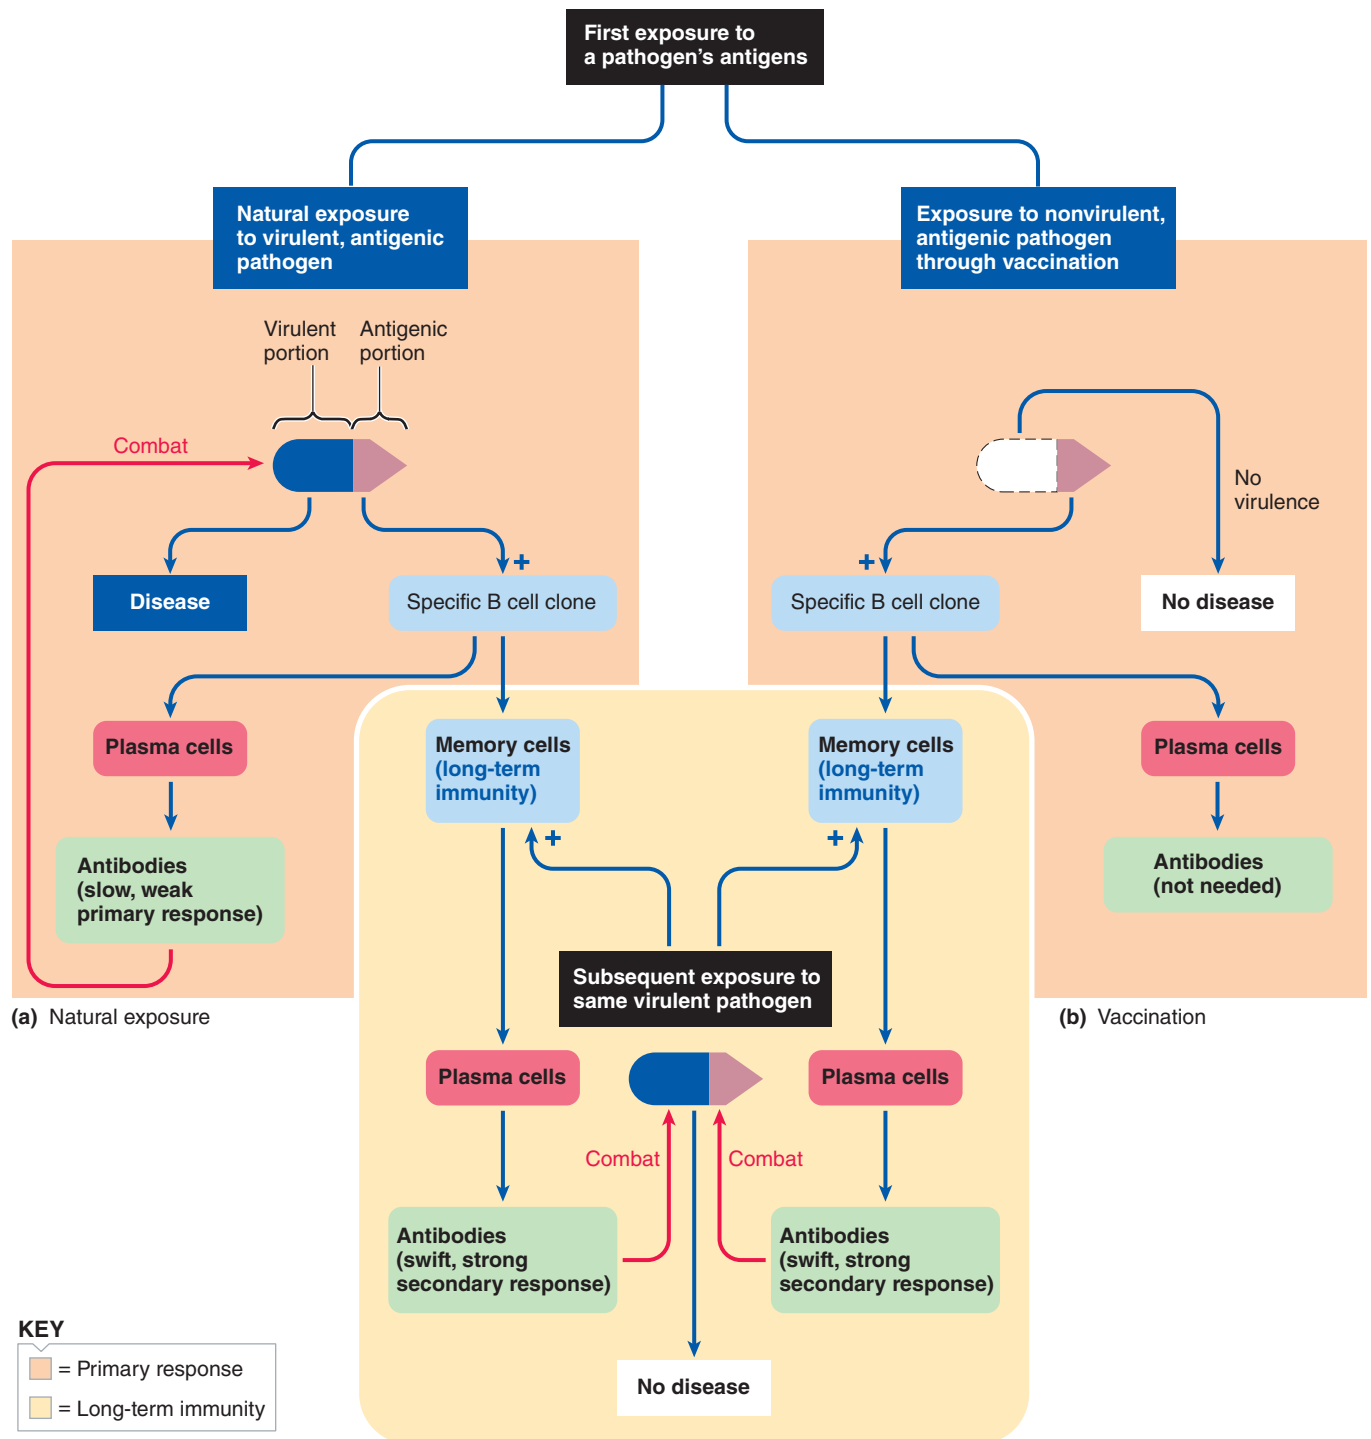

FIGURE 10-18 Means of acquiring long-term immunity. Long-term immunity against a pathogen can be acquired through having the disease or being vaccinated against it. (a) Exposure to a virulent (disease-producing) pathogen. (b) Vaccination with a modified pathogen that is no longer virulent (that is, can no longer produce disease) but is still antigenic. In both cases, long-term memory cells are produced that mount a swift, secondary response that prevents or minimizes symptoms on a subsequent natural exposure to the same virulent pathogen.

© Cengage Learning, 2013

The huge repertoire of B cells is built by recombination of a small set of gene fragments

Considering the millions of different antigens against which each mammal has the potential to actively produce antibodies, how is it possible for an individual to have such a tre-

mendous diversity of B cells and their corresponding antibodies? Antibodies as proteins require a nuclear DNA blueprint. Because all cells of the body, including the B cells, contain the same nuclear DNA, it is hard to imagine how enough DNA could be packaged within the nuclei of every cell to code for a 100 million different antibodies, along

with all the other genetic instructions used by other cells. Actually, only a relatively small number of gene fragments code for antibody synthesis, but during B cell development these fragments are cut, shuffled, and spliced in a vast number of different combinations. Each different combination gives rise to a unique B-cell clone. For example, to generate various *heavy chains* of IgG (Figure 10-14), humans have 51 different gene fragments that can code for the “V” (variable) section, 4 different gene fragments for the “C” (constant) section, and 27 different “D” (diversity) and “J” (joining) gene fragments (not shown in Figure 10-14). These can be cut and spliced into a large variety of V-D-J-C combinations. Diversity is further increased by some “slip” in D and J splicing, the addition of *light chains* that themselves are diversified by the same mechanisms, and *somatic mutation*: The antibody genes of already-formed B cells are highly prone to mutations in the region that codes for the variable antigen-binding sites on the antibodies. Each different mutant cell in turn gives rise to a new clone. In these ways, a huge antibody repertoire is made possible by using only a modest share of the genetic blueprint. You might recognize that this process is analogous to Darwinian natural selection: In both, random gene variants arise that are then subjected to a selection process that determines which variants thrive.

Active immunity is self-generated; passive immunity is “borrowed”

The production of antibodies as a result of exposure to an antigen is referred to as **active immunity** against that antigen. The direct transfer of preformed antibodies from one animal to another forms a second way in which an individual can acquire antibodies in a process known as **passive immunity**. Such transfer of antibodies of the IgG class normally occurs from the mother to the fetus in mammals across the placenta during intrauterine development. In addition, a lactating female’s colostrum (first milk) contains IgA antibodies that provide further protection for mammary-gland-fed infants. Passively transferred antibodies are usually broken down in less than a month, but meanwhile the newborn is provided important immune protection until it can begin actively mounting its own immune responses, which does not develop for about a month after birth in humans.

As you will see later, certain arthropods may also passively acquire immunity from their mothers.

We now turn to the other contributor to mammalian acquired immunity, the T cell.

How do specific B cells get selected to produce specific antibodies?

10.7 Acquired Immunity in Mammals: T-Lymphocytes

As important as B-lymphocytes and their antibody products are in specific defense against invading bacteria and other foreign material, they represent only half of the acquired immune defenses. The T cells are equally important in *cell-mediated* defense against most viral infections and also play a crucial regulatory role in both T and B cell responses.

T cells bind directly with their targets and effector cells via immunosynapses

Whereas B cells and antibodies defend against conspicuous invaders in the ECF, some T cells defend against covert invaders that hide inside cells where antibodies and the complement system cannot reach them. T cells do not secrete antibodies. Instead, they must directly come into contact with their targets, through receptors that form an immunosynapse. Cytotoxic T cells can then release chemicals that destroy targeted cells, especially virus-infected cells and cancer cells. Helper T cells must also directly contact effectors like B cells that they can also activate.

Like B cells, T cells undergo genetic recombination, are clonal, and are exquisitely antigen specific. On its plasma membrane, each T cell bears unique *T-cell receptors (TCRs)*, similar although not identical to BCRs (see Figure 10-12). Immature lymphocytes acquire their TCRs in the thymus during their differentiation into T cells. Unlike B cells, T cells are activated by foreign antigen only when it is on the surface of a cell that also carries a marker of the individual’s own identity; that is, both foreign antigens and **self-antigens** known as **major histocompatibility complex (MHC) molecules** must be on a cell’s surface before a T cell can bind with it. During *thymic education*, T cells learn to recognize foreign antigens only in combination with the animal’s own tissue antigens—a lesson passed on to all T cells’ future progeny. The importance of this dual antigen requirement and the nature of the MHC self-antigens will be described shortly.

As with B cells, activated T cells take several days to build up to therapeutic levels. Also like B cells, they form a *memory* pool and display both primary and secondary responses. During a few-week period after the infection is cleared, more than 90% of the huge number of effector T cells generated during the primary response die by means of *apoptosis* (cell suicide; see p. 101), triggered by the lack of stimulation by antigen. This is essential to prevent congestion in the lymphoid tissues. (B cells, recall, rapidly work themselves to death producing antibodies.) The remaining surviving effector T cells become long-lived memory T cells that migrate to all areas of the body, where they are poised for a swift secondary response to the same pathogen in the future.

The three types of T cells are cytotoxic T cells, helper T cells, and regulatory T cells

Recall that there are three subpopulations of T cells, which we’ll now examine in detail:

- **Cytotoxic T cells** destroy host cells harboring anything foreign and thus bearing foreign antigen, such as body

cells invaded by viruses, cancer cells that have mutated proteins resulting from malignant transformations, and transplanted cells. The T-cell receptors (TCRs) for cytotoxic T cells are associated with coreceptors designated CD8, which are inserted into the plasma membrane as these cells pass through the thymus. Therefore, these cells are also known as **CD8+ T cells**.

- **Helper T cells** do not directly participate in immune destruction of invading pathogens. Instead, they modulate activities of other immune cells. Because of the important role they play in “turning on” the full power of all the other activated lymphocytes and macrophages, helper T cells constitute the immune system’s “master integrator.” Helper T cells are by far the most numerous T cells, making up 60 to 80% of circulating T cells. The T-cell receptors for helper T cells are associated with coreceptors designated CD4. Accordingly, helper T cells are also called **CD4+ T cells**.
- **Regulatory T cells** (T_{regs}) are a recently identified small subset of CD4+ cells. They have the same CD4 coreceptors as the helper T cells, but in addition they also have CD25, a component of a receptor for IL-2, which promotes T_{reg} activities. Thus, these cells are also referred to as **CD4+CD25+ T cells**. Regulatory T cells, which represent 5 to 10% of CD4 cells, suppress immune responses. T_{regs} are specialized to inhibit both innate and acquired immune responses in a check-and-balance fashion to minimize harmful immune pathology. Researchers hope that the ability of T_{regs} to put the brakes on helper T cells, B cells, NK cells, and dendritic (macrophage-like) cells can be used therapeutically to curb autoimmune diseases and prevent rejection of transplanted organs.

We now examine the functions of the two most abundant and best known T cells, cytotoxic T cells and helper T cells, in further detail.

Cytotoxic T cells secrete chemicals that destroy target cells

Cytotoxic T cells are microscopic “hit men.” The most frequent targets of these destructive cells are host cells infected with viruses. When a virus invades a body cell, as it must to survive, the cell breaks down the envelope of proteins surrounding the virus and loads a fragment of this viral antigen piggyback onto a newly synthesized MHC self-antigen. This self-antigen and viral antigen complex is inserted into the host cell’s surface membrane, where it serves as a red flag indicating the cell is harboring the invader (Figure 10-19, steps 1 and 2). Cytotoxic T cells of the clone specific for this particular virus recognize and bind to the viral-antigen and self-antigen on the surface of an infected cell (Figure 10-19, step 3—the immunosynapse). Thus, activated by viral antigen, a cytotoxic T cell can kill the infected cell and its internal virus by either direct or indirect means, depending on the type of lethal chemicals the activated T cell releases:

- An activated cytotoxic T cell may directly kill the victim cell by releasing **perforins** that lyse the attacked cell before viral replication can begin (Figure 10-19, step 4) by the same hole-punching technique used by antimicrobial peptides (Figure 10-3) and the complement MAC (membrane attack complex, p. 470).

FIGURE 10-19 A cytotoxic T cell lysing a virus-invaded cell. The combination of the T cell receptors with the other cell’s membrane proteins is called an *immunosynapse*.

© Cengage Learning, 2013

- A cytotoxic T cell can also indirectly bring about death of an infected host cell by releasing **granzymes**, which are enzymes similar to digestive enzymes. Granzymes enter the target cell through the perforin channels. Once inside, these chemicals trigger the virus-infected cell to self-destruct through apoptosis.
- The virus released on destruction of the host cell by either of these methods is directly destroyed in the ECF by phagocytotic cells, antibodies, and the complement system. Meanwhile the cytotoxic T cell can move on to kill other infected host cells. Recall also that other nonspecific defense mechanisms also combat viral infections, most notably NK cells, interferon, macrophages, and the complement system. Thus, an intricate web of interplay exists among the defenses launched against viral invaders (Table 10-2).

Antiviral Defense in the Nervous System The previously described approach to destroying virus-infected host cells is not appropriate for the nervous system. If cytotoxic T cells destroyed virus-infected neurons, the lost cells could not be replaced, because neurons cannot reproduce. Fortunately, virus-infected neurons are spared from extermination by the immune system, but how, then, are neurons protected from viruses? Immunologists long thought that the only antiviral defenses for neurons were those aimed at free viruses in the ECF. Surprising new research has revealed, however, that antibodies not only target viruses in the ECF but can also eliminate viruses inside neurons. It is unclear whether antibodies can actually enter the neurons and interfere directly with viral replication (neurons have been shown to take up antibodies near their synaptic endings) or bind with the surface of nerve cells and trigger intracellular changes that stop viral replication.

Helper T cells secrete chemicals that amplify the activity of other immune cells

In contrast to cytotoxic T cells, helper T cells function as integrators, not effectors. They secrete cytokines that augment nearly all aspects of the immune response. B cells stimulated by T-dependent antigen cannot develop into antibody-secreting plasma cells without the help of a subset of helper T cells called **T helper 2 (T_H2)** cells. Additionally, the **T helper 1 (T_H1)** cells secrete cytokines that enhance actions of the cytotoxic T cells and activate macrophages. This is why **acquired immunodeficiency syndrome (AIDS)**, caused by the **human immunodeficiency virus (HIV)**, is so devastating to human immune defense system. The AIDS virus selectively invades helper T cells, destroying or incapacitating the cells that normally orchestrate much of the immune response.

The following are among the best known of helper T-cell cytokines, although the list is rapidly growing as researchers uncover more cytokines with other roles:

- B cell growth factors (IL-4, IL-5, and IL-6)** contribute to B cell function in concert with the IL-1 secreted by macrophages. Antibody production may be greatly reduced or absent without these.
- T cell growth factor (IL-2)** augments the activity of cytotoxic T cells and even of other helper T cells responsive to the invading antigen. In typical interplay fashion, IL-1 secreted by macrophages not only enhances the activity of both the appropriate B- and T-cell clones but also stimulates secretion of IL-2 by activated helper T cells.
- Macrophage-migration inhibition factor** keeps large phagocytotic cells in the affected region by inhibiting their outward migration. As a result, a great number of chemotactically attracted macrophages accumulate in the infected area. This factor also converts macrophages into **angry macrophages** that have more powerful phagocytotic ability.

We next examine how T cells are activated by antigen-presenting cells and the roles of MHC molecules.

T-lymphocytes respond only to antigens presented to them by antigen-presenting cells

Relevant T cells cannot recognize “raw” foreign antigens entering the body; before reacting to it, a T-cell clone must be formally “introduced” to the antigen. **Antigen-presenting**

FIGURE 10-20 Dendritic cell.

FIGURE 10-21 Generation of an antigen-presenting cell when a dendritic cell engulfs a bacterium.

© Cengage Learning, 2013

cells (APCs), which we have mentioned several times, handle the formal introduction; they process and present antigen, complexed with MHC molecules, on their surface to the T cells via an immunosynapse. APCs include (1) macrophages of innate defenses, (2) the closely related dendritic cells, and (3) B cells. The helper T cells in turn enhance antibody-mediated immunity. Let's examine how this works.

You are already familiar with macrophages. **Dendritic cells** are specialized APCs that act as sentinels in almost every tissue, but especially the linings of the barrier tissues where invasion is most likely (e.g., skin with its *Langerhans cells*; Figure 10-6). They are so named because they have many surface projections that resemble the dendrites of neurons (*dendros* means "tree") (Figure 10-20). After exposure to the appropriate antigen, dendritic cells leave their tissue home and migrate through the lymphatic system to nearby lymph nodes, where they cluster and activate T cells.

What triggers dendritic cells to begin their migration? There is evidence that, like macrophages, they use TLRs (p. 460) to sense unusual or foreign "patterns" (antigens). This concept of sensing nonself is sometimes called the "stranger" hypothesis. However, an alternative idea called the "danger" hypothesis proposes that immune sensing is based on chemicals released from damaged body cells. Recently, for example, researchers have found that *nucleotides* and crystals of *uric acid* (p. 558), released from damaged body cells, are potent activators of dendritic cells. Both "stranger" and "danger" signals may be at work in a complementary fashion; that is, tissue danger signals may prime dendritic cells so they more potently react to foreign materials.

How does a dendritic cell become an APC? As shown in Figure 10-21, invading bacteria are phagocytized by dendritic cells (step 1). Within the cell, the lysosome system enzymatically breaks down the bacterium's proteins into antigenic peptides (small protein fragments) (step 2). Each antigenic peptide then binds to an MHC molecule, which has been newly synthesized within the endoplasmic reticulum/Golgi complex (steps 3 and 4). Loading of the antigenic peptide onto an MHC molecule takes place on a specialized organelle within APCs, the **peptide-loading compartment**. An MHC molecule has a deep groove into which a variety of antigenic peptides can bind, depending on what the macrophage has engulfed. The MHC molecule then transports the bound antigen to the cell surface, where it is presented to passing T cells (step 5). The combined presentation of these self- and nonself antigens alerts the helper T cell—in particular, one with the appropriate receptor for the antigen—to the presence of an undesirable bacterium within the body.

Macrophages become APCs by a similar mechanism. B cells do not phagocytize antigenic particles like macrophages whereas dendritic cells do, but B cells can internalize antigens bound to their surface receptor by receptor-mediated endocytosis (see p. 44).

When the helper T cell binds to the APC, the APC secretes the cytokines IL-1 and TNF, which activate the associated T cell, among other effects. The activated T cell then secretes various cytokines, which act in an autocrine manner to stimulate that cell's clonal expansion and act in a paracrine manner on adjacent B cells, cytotoxic T cells, and NK cells to enhance their responses to the same antigen.

Next we will look at the role of MHCs in more detail.

The major histocompatibility complex (MHC) is the code for self-antigens

Self-antigens are plasma-membrane-bound glycoproteins arising from the MHC genes. This complex spans 4 million base pairs within the DNA molecule and contains 128 genes. The MHC genes are the most variable ones in mammals. For example, more than 100 different MHC molecules have been identified in human tissue, but each individual has

- 1 Class I MHC molecules are found on surface of all cells.
- 2 They are recognized only by cytotoxic (CD8+) T cells.
- 3 CD8 coreceptor links the two cells together.
- 4 Linked in this way, cytotoxic T cells can destroy body cells if invaded by foreign (viral) antigen.

(a) Class I MHC self-antigens

- 1 Class II MHC molecules are found on the surface of immune cells with which helper T cells interact: dendritic cells, macrophages, and B cells.
- 2 They are recognized only by helper (CD4+) T cells.
- 3 CD4 coreceptor links the two cells together.
- 4 To be activated, helper T cells must bind with a class II MHC-bearing APC (dendritic cell or macrophage). To activate B cells, helper T cell must bind with a class II MHC-bearing B cell with displayed foreign antigen.

(b) Class II MHC self-antigens

FIGURE 10-22 Distinctions between class I and class II major histocompatibility complex (MHC)

glycoproteins. Specific binding requirements for the two types of T cells ensure that these cells bind only with the target cells with which they can interact. Cytotoxic (CD8+) T cells can recognize and bind with foreign antigen only when the antigen is in association with class I MHC glycoproteins, which are found on the surface of all body cells. This requirement is met when a virus invades a body cell, whereupon the cell is destroyed by the cytotoxic T cells. Helper (CD4+) T cells, which are activated by and/or enhance the activities of dendritic cells, macrophages, and B cells, can recognize and bind with foreign antigen only when it is in association with class II MHC glycoproteins, which are found only on the surface of these other immune cells. The CD8+ or CD4+ T-cell's coreceptor CD8 or CD4 links these cells to the target cell's class I or class II MHC molecules, respectively, in an immunosynapse.

© Cengage Learning, 2013

a code for only three to six of these possible antigens. Because of the tremendous number of different combinations possible, the exact pattern of MHC molecules varies from one individual to another, much like a “biochemical fingerprint” or “molecular identification card,” except in identical twins (triplets, and so on), who have the same MHC self-antigens.

The major histocompatibility (*histo*, “tissue”) complex was so named because these genes and the self-antigens they encode were first discerned in relation to tissue typing (similar to blood typing), which is done to obtain the most compatible matches for tissue grafting and transplantation. However, the transfer of tissue from one individual to another does not normally occur in nature. The natural func-

tion of MHC antigens lies in their ability to direct the responses of T cells, not in their artificial role in rejecting transplanted tissue.

Each mammal has two main classes of MHC-encoded molecules that are differentially recognized by cytotoxic T and helper T cells—*class I* and *class II*, respectively (Figure 10-22). These markers serve as signposts to guide cytotoxic and helper T cells to the precise cellular locations where their immune capabilities are most effective. The coreceptors on the T cells bind with the MHC molecules on the target molecule, linking the two cells together in an immunosynapse. In addition to receptor–receptor binding shown in Figure 10-22, nanotubes (p. 91) may also join the two cells to increase the rate of communication signal transfer.

Class I MHC Glycoproteins Cytotoxic T cells (CD8+ T cells) can respond to foreign antigens only in association with **class I MHC glycoproteins**, which are found on the surface of all nucleated body cells, because the T cell's co-receptor CD8 can interact only with MHC class I. To carry out their role of dealing with pathogens that have invaded host cells, it is appropriate that cytotoxic T cells bind only with body cells that viruses have infected—that is, with foreign antigens in association with self-antigens. Furthermore, these deadly T cells can also link up with any cancerous body cell because class I MHC molecules may also display mutated (and thus appearing “foreign”) cellular proteins characteristic of these abnormal cells. Because any nucleated body cell can be invaded by viruses or become cancerous, essentially all cells display class I MHC glycoproteins, enabling cytotoxic T cells to attack any virus-invaded host cell or any cancer cell. Because cytotoxic T cells do not bind to MHC self-antigens in the absence of foreign antigen, normal body cells are protected from lethal immune attack.

Class II MHC Glycoproteins In contrast, **class II MHCs** are recognized by helper T cells (CD4+ T cells) and are restricted to the surface of APCs—macrophages, dendritic cells, and B cells. The CD4 coreceptor of helper cells can interact only with MHC class II glycoproteins. Thus, the specific binding requirements for cytotoxic T cells and helper T cells ensure the appropriate T-cell responses. For example, binding of the antigen-bearing B cell with the matching helper T cell causes the T cell to secrete cytokines that activate this specific B cell, leading to clonal expansion and conversion of this B cell clone into antibody-producing plasma cells and memory cells (Fig-

ure 10-23). This is the primary pathway by which the acquired immune system fights bacteria. Table 10-3 summarizes the innate and acquired immune strategies that defend against bacterial invasion.

You may have noticed a problem: Why doesn't the acquired immune system unleash its powerful defenses against an animal's own self-antigens? We examine this issue next.

The immune system is normally tolerant of self-antigens

The term **immune tolerance** refers to the phenomenon of preventing the immune system from attacking the animal's own tissues. During the genetic “cut, shuffle, and paste” process that goes on during lymphocyte development, some B and T cells are by chance formed that target the body's own antigens. If these lymphocyte clones were allowed to function, they would destroy the individual's own body. Fortunately, this rarely happens. At least eight different mechanisms are involved in tolerance; we will examine six of them:

1. **Clonal deletion.** In response to continuous exposure to body antigens early in development, B and T cell clones capable of attacking these self-antigens in most cases are permanently destroyed within the thymus. This **clonal deletion** is accomplished by triggering apoptosis of immature cells that would react with the body's own proteins. This physical elimination is the major mechanism by which tolerance is developed.
2. **Clonal anergy.** Recall that a T-lymphocyte must receive two specific simultaneous signals to be activated, one

Activation of helper T cells by antigen presentation

FIGURE 10-23 Interactions among large phagocytic cells (APCs), helper T cells, and B cells responsive to T-dependent antigen via immunosynapses.

© Cengage Learning, 2013

from its compatible antigen and a stimulatory cosignal found only on an APC. Both signals are present for foreign antigens introduced to T cells by APCs. In contrast, these dual signals are never present for self-antigens because these antigens are not handled by cosignal-bearing APCs. The first exposure to a single signal from a self-antigen turns *off* the compatible T cell, rendering the cell unresponsive to further exposure to the antigen, a reaction referred to as **clonal anergy** (*anergy* means “lack of energy”).

3. **Receptor editing.** A newly identified means of ridding the body of self-reactive B cells is **receptor editing**. With this mechanism, once a B cell that bears a receptor for one of the body's own antigens encounters the self-antigen, the B cell escapes death by swiftly changing its antigen receptor to a nonself version, in effect “rehabilitating” the self-reactive B cell.
4. **Active suppression by regulatory T cells.** T_{reg} cells play a role in tolerance by inhibiting throughout life some lymphocyte clones specific for the body's own tissues; the mechanism by which it accomplishes this feat is being actively studied.
5. **Immunological ignorance.** Some intracellular self-molecules are normally hidden from the immune system, since they are never in the ECF.
6. **Immune privilege.** A few tissues, most notably the testes and the eyes, have **immune privilege** because they escape immune attack even when they are transplanted in an unrelated individual. Scientists recently discovered that the plasma membranes in these immune-privileged tissues have a specific molecule that triggers apoptosis of approaching activated lymphocytes that could attack the tissues.

Autoimmunity Occasionally the immune system fails to distinguish self from nonself and begins to attack the body's own tissues, resulting in *autoimmune diseases*. Over 80 such diseases are known, including multiple sclerosis and Type I diabetes mellitus (the destruction of the insulin-producing beta cells; p. 316) in humans, and rheumatoid arthritis and systemic lupus erythematosus in humans and some dog breeds. Autoimmune diseases may arise from (1) exposure during injury of previously sequestered antigens; (2) modification of self-antigens by external chemicals, viruses or mutation; and (3) exposure of T cells to a foreign antigen almost identical to a self-antigen. Such foreign antigens may be bacterial, but may also be on fetal cells that accidentally enter a mother's bloodstream during the trauma of labor and birth.

Let's now look in more detail at the role of T cells in defending against cancer.

Immune surveillance against cancer cells involves an interplay among immune cells and interferon

Besides destroying virus-infected host cells, another important function of the T-cell system is a process known as **immune surveillance**: the recognition and destruction of new, potentially cancerous tumor cells before they have a chance to multiply and metastasize (spread through the body). At least once a day, on average, the human immune system destroys such cells. Any normal cell in an animal may be transformed into a tumor cell if mutations occur within its genes that govern cell division and growth. Such mutations may occur by chance alone or, more frequently, by

Activation of B cells responsive to T-dependent antigen

exposure to **carcinogenic** (cancer-causing) factors such as ionizing radiation, certain environmental chemicals, or physical irritants. Alternatively, a few cancers are caused by tumor viruses, which turn the cells they invade into cancer cells. The immune system recognizes cancer cells (Figure 10-24) because they bear new and different surface antigens alongside the cell's normal self-antigens, a consequence of either mutation or invasion by a tumor virus.

Fortunately, only a fraction of the mutations involve loss of control over the cell's growth and multiplication. A cell usually becomes cancerous only after an accumulation of multiple independent mutations. This requirement contributes at least in part to the much higher incidence of cancer in older individuals, in whom mutations have had more time to accumulate in a single cell lineage.

Effectors of Immune Surveillance Immune surveillance against cancer depends on an interplay among three types of cells—*cytotoxic T cells*, *macrophages*, and *NK cells*—as well as *interferon* (Figure 10-25). Not only can all three of these cell types attack and destroy cancer cells directly but all three also secrete interferon. Interferon, in turn, inhibits multiplication of cancer cells and increases the killing ability of the immune cells.

Because NK cells do not require prior exposure and activation in response to a cancer cell before being able to launch a lethal attack, they are the first line of defense against cancer. In addition, cytotoxic T cells take aim at cancer cells after being activated by mutated surface proteins alongside normal class I MHC molecules. On contacting a cancer cell, both these killer cells release perforin and other toxic chemicals that destroy the mutant cell (Figure 10-25). Macrophages can phagocytose cancer, as well as clear away debris.

FIGURE 10-24 Comparison of normal and cancerous cells in the large respiratory airways. The normal cells display specialized cilia, which constantly contract in whiplike motion to sweep debris and microorganisms from the respiratory airways so they do not gain entrance to the deeper portions of the lungs. The cancerous cells are not ciliated, so they are unable to perform this specialized defense task.

The fact that cancer does sometimes occur means that cancer cells occasionally escape immune surveillance. Some cancer cells are believed to survive by evading immune detection, for example, by failing to display identifying antigens. This is thought to be the case in Devil facial tumour disease, a lethal facial cancer of Tasmanian devils that can

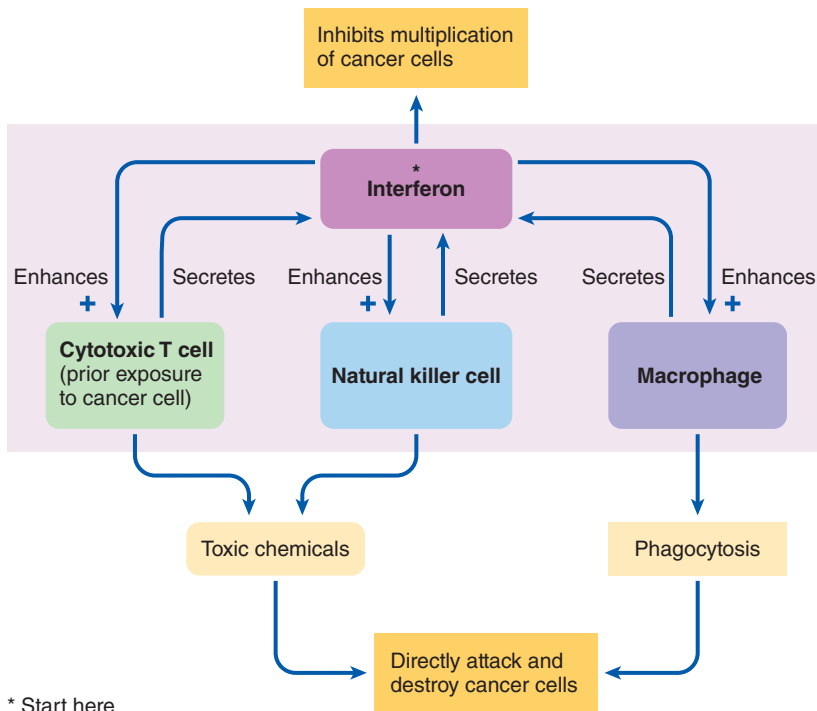

FIGURE 10-25 Immune surveillance against cancer. Anticancer interactions of cytotoxic T cells, natural killer cells, macrophages, and interferon.

© Cengage Learning, 2013

actually spread from one animal to another! Some cancer cells survive due to **blocking antibodies** that interfere with T-cell function. For unknown reasons, B cells occasionally make antibodies to the antigenic sites on the cancer cells, but instead of triggering complement, they “hide” these sites from recognition by cytotoxic T cells. A new finding reveals that other successful cancer cells thwart immune attack by inducing the cytotoxic T cells that bind with them to commit suicide. In addition, some cancer cells secrete large amounts of a chemical messenger that recruits regulatory T cells and programs them to suppress cytotoxic T cells.

A regulatory loop links the immune system with the nervous and endocrine systems

As you have seen, factors regulating the immune system are complex. Until recently, the immune system was believed to function independently of other control systems in animals. Investigations now indicate that the immune system both influences and is influenced by the two major whole-body regulatory systems, the nervous and endocrine systems. For example, IL-1 can turn on the stress response by activating a sequence of nervous and endocrine events that result in the secretion of cortisol, one of the major hormones released during stress. This linkage between a mediator of the immune response and a mediator of the stress response is appropriate. Cortisol mobilizes the body’s nutrient stores so that metabolic fuel is readily available to keep pace with the body’s energy demands at a time when the person is sick and may not be eating enough (or, in the case of a nonhuman animal, may not be able to search for food). Furthermore, cortisol mobilizes amino acids, which serve as building

blocks to repair any tissue damage sustained during the encounter that triggered the immune response.

In the reverse direction, lymphocytes and macrophages are responsive to bloodborne signals from the nervous system and from certain endocrine glands. These important immune cells possess receptors for a wide variety of neurotransmitters, hormones, and other chemical mediators. For example, epinephrine released in the short-term stress response (p. 308) can boost the activity of lymphocytes. In contrast, cortisol and other chemical mediators of the stress response have a profound immunosuppressive effect, as we have described (p. 470). Thus, negative-feedback loops appear to exist between the immune system and the nervous and endocrine systems. In large part because long-term stress suppresses the immune system, stressful physical, psychological, and social life events are linked with increased susceptibility to infections and cancer. Thus, the body’s resistance to disease can be influenced by an animal’s mental state. For example, infant monkeys separated from their mothers exhibit markedly suppressed immune responses.

There are other important links between the immune and nervous systems in addition to the stress connection. For example, many immune system organs, such as the thymus, spleen, and lymph nodes, are innervated by the sympathetic nervous system, the branch of the nervous system called into play during stress-related “fight-or-flight” situations (see p. 308). Also, the vagus nerve, the main nerve of the parasympathetic nervous system (p. 183), innervates the spleen and other sites where macrophages are abundant. Macrophages, the orchestrators of many aspects of the inflammatory process, have receptors for acetylcholine (ACh). As a parasympathetic postganglionic neurotransmitter, ACh suppresses inflammation. In the reverse direction, immune cytokines act on the brain to produce fever and other general symptoms that accompany infections. Furthermore, immune cells secrete some traditional hormones thought to be produced only by the endocrine system. For example, many of the hormones secreted by the pituitary gland are produced by lymphocytes as well. Scientists are only beginning to sort out the mechanisms and implications of the many complex neuro–endocrine–immune interactions.

10.8 Acquired Immunity in Other Animals

As we noted earlier, the acquired immune system has only been thoroughly documented in jawed vertebrates. In recent years, many interesting discoveries have been made in other animals.

unanswered Questions | How did the acquired immune system arise in jawed vertebrates?

The acquired immune system of higher vertebrates seems to have originated rather abruptly in evolutionary terms. How could this have happened by the known mechanisms of evolution? For a recent hypothesis, see the box, *Molecular Biology and Genomics: An Accidental Origin for Acquired Immunity?* <<

Sharks generate diverse B and T cells with a lower diversity but a greater number of gene fragments than mammals

Recent research on nonmammalian vertebrates and nonvertebrates has focused on understanding the genetic evolution of acquired immunity. Other jawed vertebrates appear to have B- and T-cell systems similar to mammals, most generating a comparable diversity of these cells in ways similar to mammals. But not all do. It is perhaps most instructive to compare mammals to chondrichthyes (sharks, skates, chimaeras, and rays), the most evolutionarily ancient jawed vertebrates to have acquired immunity. Like mammals, chondrichthyes have B and T cells and exhibit gene shuffling to make millions of different antibodies and receptors. However, shark antibodies differ in other ways from those of mammals. First, shark B cells make four different classes of antibodies, but only one of these—the IgM class—is the same as one of the five classes found in mammals. Second, they do not mutate to increase diversity with the result that they are theoretically limited in the scope of antigens that they can respond to (p. 480). Third, gene shuffling in sharks involves the recombination of a much lower diversity of gene fragments than in mammals. But shark genomes make up for this in ways not found in mammals. For example, the gene fragments that are recombined in mammals are found only in one cluster on one chromosome. Sharks, however, have hundreds of antibody-generating gene clusters on many chromosomes. Thus, although each cluster has a lower diversity of gene fragments to shuffle around, there are many more such clusters available. In addition, there are also hundreds of other gene clusters that already have the coding fragments joined together, so that they can rapidly produce antibodies without waiting for genetic recombination. Those gene combinations are fixed and heritable, so they do not generate more diversity than what the animal was born with. However, they work well (and much faster than mammalian counterparts) for common pathogens that sharks have encountered for millennia.

These studies on sharks reveal that the basic B- and T-cell system, with gene shuffling of receptor and antibody gene

clusters to increase diversity, evolved early on in the jawed vertebrates. But since the origin of acquired immunity, evolution has led to different uses of these gene clusters and the coding fragments within them. We cannot say that one version is better than the other. After all, the shark system, although somewhat different, has helped these animals survive successfully far longer than mammals have been on Earth.

Lamprey lymphocytes shuffle ancient PRR genes to generate variable receptors and antibody-like proteins

Recently, lampreys have been found to have a unique system of acquired immunity based on gene recombination that probably evolved independently of the jawed vertebrate system. These jawless fish have lymphocytes, which in 2009 were shown to be comparable to B or T cells. It is not clear whether these are related to the true B and T cells of jawed vertebrates. In any case, they also generate diverse proteins from relatively few genes, but their mechanism is clearly different: The cells make variable lymphocyte receptors (VLRs) by shuffling the genes of a class of PRRs, an ancient type different from the antibody-type. The T-like cells use these as membrane receptors, while the B-like cells secrete soluble versions of VLRs that may act like antibodies. The lamprey studies suggest that there may be many ways to evolve immune systems based on genetic recombination.

Some arthropods and mollusks have immunity mechanisms resembling vertebrate acquired processes

We end this chapter with a look at recent studies suggesting that some nonvertebrates may have independently evolved defenses with some similarities to the vertebrate acquired system.

First, research on the water flea (*Daphnia magna*) found that offspring are more resistant to a particular pathogenic bacterium (but not other bacteria) if their mother was exposed to it before she lays her eggs. It appears that the mother's immune system “learns” that a particular pathogen is present and passes on specific protective mechanisms to her eggs. How she does this is not yet known.

In another study, *Macrocyclus albidus*, a species of copepod (one of the most common animal groups on Earth; p. 128), was exposed to parasitic tapeworms twice. It was better able to resist the tapeworms during the second infection if the subsequent exposure used tapeworms closely related to those used in the first infection. This suggests that the copepod immune system somehow “learned” the antigenic markers of an individual tapeworm and later recognized those markers on its relatives. How this takes place is not yet known. Similarly, researchers found that giving *Drosophila* a sublethal dose of *Streptococcus pneumoniae* bacteria induces changes that subsequently protect them from an otherwise lethal dose of the same (but not other) bacteria.

How might specific immunity work in nonvertebrates? One possibility involves diversification of ancient PRR genes, as in lampreys. Research on the freshwater snail *Biomphalaria glabrata* (a host of the human schistosomiasis

Molecular Biology and Genomics

An Accidental Origin for Acquired Immunity?

All animals have innate immunity, but (as far as we know) only vertebrates with jaws have the acquired system based on generating millions of different receptors and antibodies (in T and B cells). For example, lancelets (nonvertebrates closely related to the first vertebrates) have genomes with codes that are similar to the gene fragments that give rise to antibody diversity in mammals. However, the functions of these lancelet genes are unknown, and they do not undergo the gene shuffling of acquired immunity. Lampreys appear to have lymphocyte-like cells, but their acquired system appears to be independently evolved. Thus, the system in jawed vertebrates seems to have appeared suddenly in evolutionary terms, with few precursors. How could this complex immunity innovation evolve so

quickly, and why only in jawed vertebrates? Recent genomic studies suggest that the initial event might have been an evolutionary accident involving a virus!

Recall that the acquired immune system can generate millions of different proteins by shuffling and joining a relatively small number of gene fragments. This process, called genetic recombination, is dependent on two genes called *RAG1* and *RAG2* (“recombinant-activating genes”). The genes code for a transposase, an enzyme that cuts out sections of DNA at one site in a chromosome, then inserts them at another location. Transposase activity has a partially random nature that is the key to generating millions of different B-cell antibodies and T-cell receptors.

Researchers used DNA probes to study other vertebrates and discovered a distinct divide: All jawed vertebrates have *RAG1* and *RAG2*, but hagfish and lamprey do not. Nor do those ancient fishes have any genes with similar coding that might provide a precursor. There seems to have been a sudden evolutionary transition, estimated at 450 million years ago. Transposase events have been well documented in other organisms (p. 34), where the genes have “jumped” from one species to another, causing a sudden genetic leap. The jumping transposase genes were most likely carried by viruses. If this mechanism is indeed the origin of the *RAG* genes in higher vertebrates, we may owe our complex immune systems to an ancestral fish that survived a viral infection!

parasite) found that these molluscs’ circulating defense cells (hemocytes) generate a wide diversity of *lectin* defense proteins (p. 463). The diversity appears to arise from both increased mutation and gene shuffling (recombination).

Arthropods also appear to diversify their *Ig-like* PRRs (p. 463) called *Dscam* (Down syndrome cell-adhesion molecules) by *alternative splicing* (p. 32), which generates over 30,000 variants from very few genes. (In contrast, an antibody system might have evolved from gene recombination of ancient *Ig-like* PRRs.) Much like B cells, arthropod hemocytes use *Dscam* proteins as receptors and secrete smaller versions that act much like antibodies (Figure 10-26). A possible learning aspect of this system has been found in some insects. In mosquitoes, specific *Dscam* proteins were produced after infection that enhanced survival upon later infection. Moreover, when those particular *Dscam*’s mRNAs were blocked by RNA interference (p. 33) to prevent translation, survival during a specific infection was impaired.

However, it is not clear if the snail or insect system has the ability to learn in the vertebrate sense, that is, to selectively amplify receptors that have encountered a specific antigen and to retain a lifelong memory. Still, this and the other nonvertebrate discoveries indicate a need for more study in all types of animals for possible acquired immunity.

FIGURE 10-26 *Dscam* (Down syndrome cell-adhesion molecule) receptors in *Drosophila melanogaster* (fruit fly) immunity. *Dscams* are pattern-recognition receptors that bind to foreign molecules on invaders. Hemocytes can make many diverse *Dscams* by alternative RNA splicing, and secrete them to act as opsonins in antibody-like fashion, enhancing phagocytosis, using *Dscam* receptors that have not been fully characterized.

How Defense Systems Contribute to the Body as a Whole

Animals could not survive beyond early infancy were it not for defense mechanisms. Homeostasis can be optimally maintained only if body cells are not physically injured or

functionally disrupted by pathogens or are not replaced by cancer cells. Immune defense systems—complex, multifaceted, interactive networks of barrier tissues, defense proteins, and specialized cells for sensing, integrating, and effecting defenses—keep cells alive so that they can perform their specialized activities to maintain a stable internal environment. Immune systems protect from foreign agents, eliminate newly arisen cancer cells, and clear away debris to pave the way for replacement with healthy new cells. These defenses involve both positive- and negative-feedback loops, interacting with neural and endocrine systems in ways that are still being explored.

Chapter Summary

- Animal survival depends on immune systems that fight external as well as internal threats including pathogenic bacteria, viruses, parasites, and cancerous cells. Immune responses can be either “ready-to-go” innate ones or “learning” acquired ones that must be first exposed to a pathogen. Immunity uses pattern-recognition receptors (PRRs) to distinguish “self” from “nonself” by having binding sites for foreign molecules. Immune cells coordinate their actions with external signals called cytokines.
- Innate barrier tissues—integumentary, digestive, respiratory, genitourinary—are the first line of defense. They form passive walls and have active glands to aid defense. If barriers are breached, the second lines of defense are (1) phagocytotic cells, with PRRs to sense common foreign molecules such as bacterial cell wall components, that engulf and digest invaders; (2) inflammatory signals to draw phagocytotic cells to an invasion site; (3) antimicrobial peptides, many of which punch holes in bacterial membranes; and (4) opsonin proteins, which bind to common foreign molecules and “tag” them for phagocytotic ingestion. Arthropods can also “wall off” large invaders with a polymerized capsule.
- Vertebrate active immune responses are regulated by feedback systems with sensors, integrators, and effectors that are primarily leukocytes and proteins. Circulating leukocytes include phagocytotic neutrophils, macrophages, and natural killer (NK) cells of innate immunity and lymphocytes of acquired immunity. Localized leukocytes include mast cells and dendritic cells in barrier tissues.
- Mammalian barrier tissues have active defenses; for example, skin glands release antimicrobial peptides, stomachs produce acid, respiratory systems use mucus, cilia, and sneezing and coughing to transport foreign materials out.
- In mammalian inflammation, mast cells detect damage and release histamine, which promotes fluid accumulation. Chemotaxins draw in phagocytes, which also release other cytokines that can promote fever. The complement protein system (among other things) punches holes in microbes and acts as opsonins to enhance phagocytosis.
- NK cells destroy virus-infected cells and cancer cells on first exposure to them by uncertain mechanisms. Interferon transiently inhibits multiplication of viruses in most cells and warns other cells of potential viral attack.
- Acquired immunity includes B-cell antibody-mediated and T-cell cell-mediated responses, both aided by integrating helper and regulatory T cells. Both cells are produced and mature in lymphoid tissues and organs including bone marrow and thymus. B cells react to antigens, foreign molecules that induce an immune response against itself.
- Antigens stimulate B cells to convert into plasma cells that produce antibodies, Y-shaped proteins classified according to properties of their tail portion. They amplify innate immunity (e.g., becoming opsonins) to promote antigen destruction. The huge variety of B cells results from shuffling a small set of gene fragments. Via clonal selection, only the B cell with a receptor for a particular antigen will multiply and produce specific antibodies. Some B cells become memory cells to mount a much faster defense upon second exposure to an antigen.
- T cells make diverse receptors by the same shuffling mechanism, and also form memory cells. To be activated, they must bind other body cells through immunosynapses. Cytotoxic T cells secrete chemicals that destroy virus-infected or cancerous body cells that “present” improper proteins on their major histocompatibility complexes (MHCs). Helper T cells secrete chemicals that amplify the activity of other immune cells, for example, B cells. Helper T cells are activated by antigen-presenting cells (APCs), for example, macrophages and dendritic cells that ingest and present antigens on their MHCs.
- The MHC is the code for self-antigens: MHC I is found on all cells and can present viral or cancerous proteins to T cells; MHC II is found on APCs and presents foreign antigens. The immune system is normally tolerant of self-antigens; among other mechanisms, B and T clones specifically capable of attacking self-antigens in most cases are permanently destroyed within the thymus.
- Immune surveillance, a constant search-and-destroy mission against cancer cells, involves an interplay among cytotoxic T cells, NK cells, and interferon.
- A regulatory loop links the immune system with the nervous and endocrine systems. Cortisol, for example, released in long-term stress, can suppress overactive immunity.
- Sharks generate diverse B and T cells with a lower diversity but a greater number of gene fragments than mammals. Lamprey lymphocytes shuffle PRR genes to generate variable receptors and antibody-like proteins. Some arthropods and mollusks have alternative-RNA splicing mechanisms to make diverse defense proteins from a limited gene set.

Review, Synthesize, and Analyze

1. In what ways is the innate immune system of mammals similar to that of insects?
2. Both mast and dendritic cells reside in mammalian barrier tissues. Compare their functions.
3. Dendritic cells, helper T cells, and B cells with their antibodies can be considered as sensors, integrators, and effectors, respectively, of a negative-feedback system. Explain.
4. Explain the events that occur in mammalian skin following a mosquito bite.
5. Explain how the mammalian body and its acquired immune system respond when the body is invaded by an influenza virus that has evolved new antigens.
6. Antimicrobial peptides, hemolin, complement, perforins, and antibodies are all extracellular defensive proteins. Compare how they work.
7. Cheetahs are highly susceptible to diseases such as feline infectious peritonitis (FIP), which kills less than 10% of other cats but 50% of cheetahs. Cheetahs are nearly identical genetically, apparently due to a crash in population numbers perhaps 10,000 years ago. Explain why low genetic diversity in these cheetahs and also in inbred domestic animals makes acquired immunity less effective.
8. Feline immunodeficiency virus (FIV) is a common and ultimately fatal disease of cats; much like HIV, FIV damages T cells. Explain all the possible problems that could result from this. Also, like HIV, FIV mutates rapidly into new strains. Veterinarians can give cats an FIV vaccine; explain how it might work to protect the cat and why it might not work.

Respiratory Systems

11.1 Gas Demands: General Problems and Evolutionary Solutions

Energy is essential for sustaining all life-supporting cellular activities. For most animals to survive for extended periods of time, **aerobic** (oxygen-using) **metabolism** (p. 47) is necessary. In fact, most (though not all) scientists believe that the first nonmicroscopic animals did not evolve until the O_2 content of Earth's atmosphere reached a critical point some 550–600 million years ago. In addition to obtaining O_2 , animals must eliminate the CO_2 produced as a by-product of aerobic metabolism at the same rate it is produced to prevent dangerous fluctuations in pH (that is, to maintain the acid–base balance), because CO_2 generates carbonic acid. The term **respiration** refers to all of the processes of gas movement and metabolism, with two distinct components:

- The term **internal** or **cellular respiration** refers to the intracellular metabolic processes carried out within the mitochondria, which use O_2 and produce CO_2 during the derivation of en-

ergy from nutrient molecules (see pp. 47–53).

- The term **external respiration** refers to the sequence of events involved in the exchange of O_2 and CO_2 between the external environment and cellular mitochondria.

External, not cellular, respiration is the topic of this chapter. We begin with an overview.

External respiration involves up to four major steps of transport and exchange

For the most part, gases in the external-respiration sequence move by two methods:

1. *Exchange* (i.e., O_2 and CO_2 moving oppositely) across membranes by the relatively slow process of *diffusion*, and
2. *Bulk transport*—the movement of the medium that contains the O_2 and CO_2 , which (as discussed in Chapter 9 for circulation):
 - a. bypasses diffusion altogether to move gases much more quickly than diffusion; and

- b. enhances diffusion gradients (as we will explore in detail in this chapter)

These two processes can occur in up to four steps, summarized in Figure 11-1:

Step 1. *Ventilation*: bulk transport of external media across a gas exchange surface. This motion, called **ventilation**, arises from environmental movements (e.g., winds or currents), an animal's locomotion, and/or **breathing** if it is actively and specifically produced.

Step 2. *Respiratory exchange*: gas diffusion between the environmental medium and internal body fluids. This occurs at a *respiratory surface*, which may be a dedicated organ such as a lung or gill, and the internal fluid may be the ECF in a circulatory system. The gases move through membranes without the need of protein carriers; however, CO_2 in the form of bicarbonate (HCO_3^-) may also be moved via facilitated diffusion carriers (p. 84) into an aquatic environment. (In

FIGURE 11-1 The four steps of external respiration, shown for an air-breathing vertebrate. External respiration encompasses the steps involved in the exchange of O_2 and CO_2 between the external environment and the tissue cells (steps 1 through 4). Gases flow from areas of high (P_1) to low (P_2) partial pressures (defined in Figure 11-2). Internal respiration, shown at the bottom, encompasses the intracellular metabolic reactions involving the use of O_2 to derive ATP from food, producing CO_2 as a by-product.

© Cengage Learning, 2013

general, gases are not moved by membrane active transport.)

Step 3. *Circulation*: bulk transport of the ECF (Chapter 9).

Step 4. *Cellular exchange*: gas diffusion between the outside (typically in the ECF, but sometimes the external environment) and the ICF. This is the ultimate goal of external respiration: exchange of gases between the cell's immediate surroundings and its mitochondria.

All animals have gas exchange with their cells (step 4) but not necessarily all other steps; for example, vertebrates have all four steps, but insects have steps 1, 2, and 4. When we refer to an animal's **respiratory system**, we are not talking about all these steps of external respiration, rather only steps 1 and 2. We will examine respiratory systems in detail later, but first, we begin with general problems and principles of gas exchange and transport.

Gas diffusion follows Fick's law for partial pressure gradients

Since two of the four steps involve diffusion, we begin by revisiting the physics of that process. In Chapter 3, you learned that diffusion follows **Fick's law**, in which solutes move down a concentration gradient. For gases, the term C (concentration) is replaced with the *partial pressure* P as follows (compare this version to that in Table 3-1, p. 76):

$$\text{Rate of diffusion } (Q) = \frac{\Delta P \cdot A \cdot D}{\Delta X}$$

where:

D = the *diffusion coefficient* (which depends on, among other things, molecular weight, temperature, and the permeability of any barrier between two points)

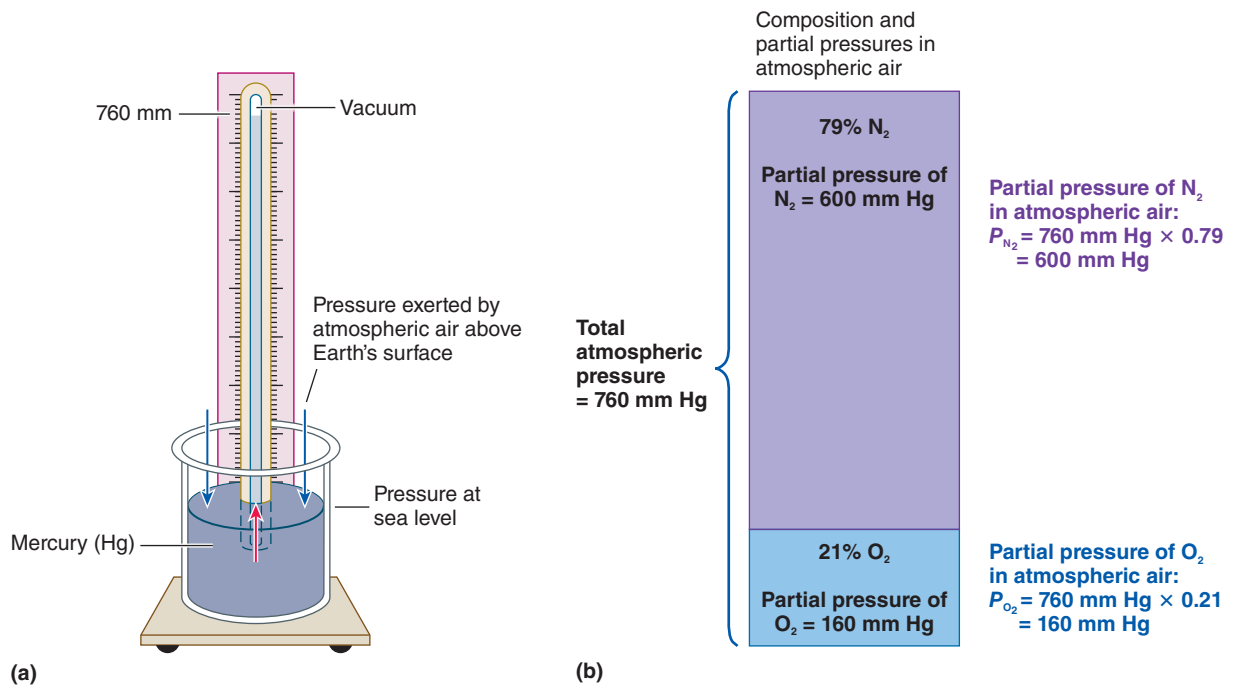

FIGURE 11-2 Gas Pressures. (a) Atmospheric pressure. The pressure exerted on objects by the atmospheric air above Earth's surface at sea level can push a column of mercury to a height of 760 mm. Therefore, atmospheric pressure at sea level is 760 mm Hg. The International System of Units (SI system) uses the pascal (Pa) unit, with 1 atm being equivalent to 101.3 kPa. (b) Concept of partial pressures. The partial pressure exerted by each gas in a mixture equals the total pressure times the fractional composition of the gas in the mixture. (c) A comparison of concentration and partial pressures between air and liquid. On the left side, air (sea level) has a concentration of 210 mL/L O_2 , and due to poor solubility, only about 5 mL/L can dissolve in seawater at 25°C. Thus, the air and water here are in equilibrium; but if we plug the values into Fick's law for concentration, we would erroneously think there is a gradient of 205 (210 – 5) and, thus, that diffusion into the water is still occurring. To prevent this error, we convert concentrations to partial pressures (*right side*). Air has 158 mm Hg of O_2 (21% of 760 mm Hg). The O_2 concentration (5 mL/L) is converted by dividing it by its *solubility* (a physical constant). At 25°C in seawater, the solubility is 0.0316 mL/L per mm Hg air pressure. So, dividing 5 mL/L gives 158 mm Hg, showing there is an equilibrium.

A = the *surface area* for gas exchange
 ΔP = the *gas gradient* (in *partial pressure*) = $P_1 - P_2$,
 where P_1 is the partial pressure in one compartment and P_2 is the pressure in the other (do not confuse this with blood pressure)
 ΔX = the *distance* the gas must cover

Partial Pressures Before we proceed, it is important to understand the term *partial pressure*. Atmospheric air is a mixture of gases that contains about 79% nitrogen (N_2) and 20.9% O_2 or 209 mL per liter of air, with very small percentages of CO_2 , H_2O vapor, other gases, and pollutants in dry air. Altogether, these gases exert a total atmospheric pressure of 760 mm Hg at sea level (Figure 11-2a). This total pressure is equal to the sum of the pressures that each gas in the mixture partially contributes. The pressure exerted by a particular gas is directly proportional to the percentage of that gas in the total air mixture. Every gas molecule, no matter what its size, exerts the same amount of pressure; for example, an

N_2 molecule exerts the same pressure as an O_2 molecule. Because 79% of the air consists of N_2 molecules, 79% of the 760 mm Hg atmospheric pressure, or 600 mm Hg, is exerted by the N_2 molecules. Similarly, because O_2 represents about 21% of the atmosphere, 21% of the 760 mm Hg atmospheric pressure, or about 160 mm Hg, is exerted by O_2 (Figure 11-2b). The individual pressure exerted independently by a particular gas within a mixture of gases is known as its **partial pressure**, designated by P_{gas} . Thus, the partial pressure of O_2 in dry atmospheric air, P_{O_2} , is normally about 160 mm Hg. The atmospheric partial pressure of CO_2 , P_{CO_2} , is negligible at 0.2 mm Hg.

Gases dissolved in water or blood are also considered to exert a partial pressure. Water that is in equilibrium with air will have the same gas partial pressures as in the air, *but the actual concentrations can be very different*. The amount of a gas that will dissolve in the blood depends on the gas's solubility in water and on the partial pressure of the gas in the environment (alveolar air or water) to which the blood is

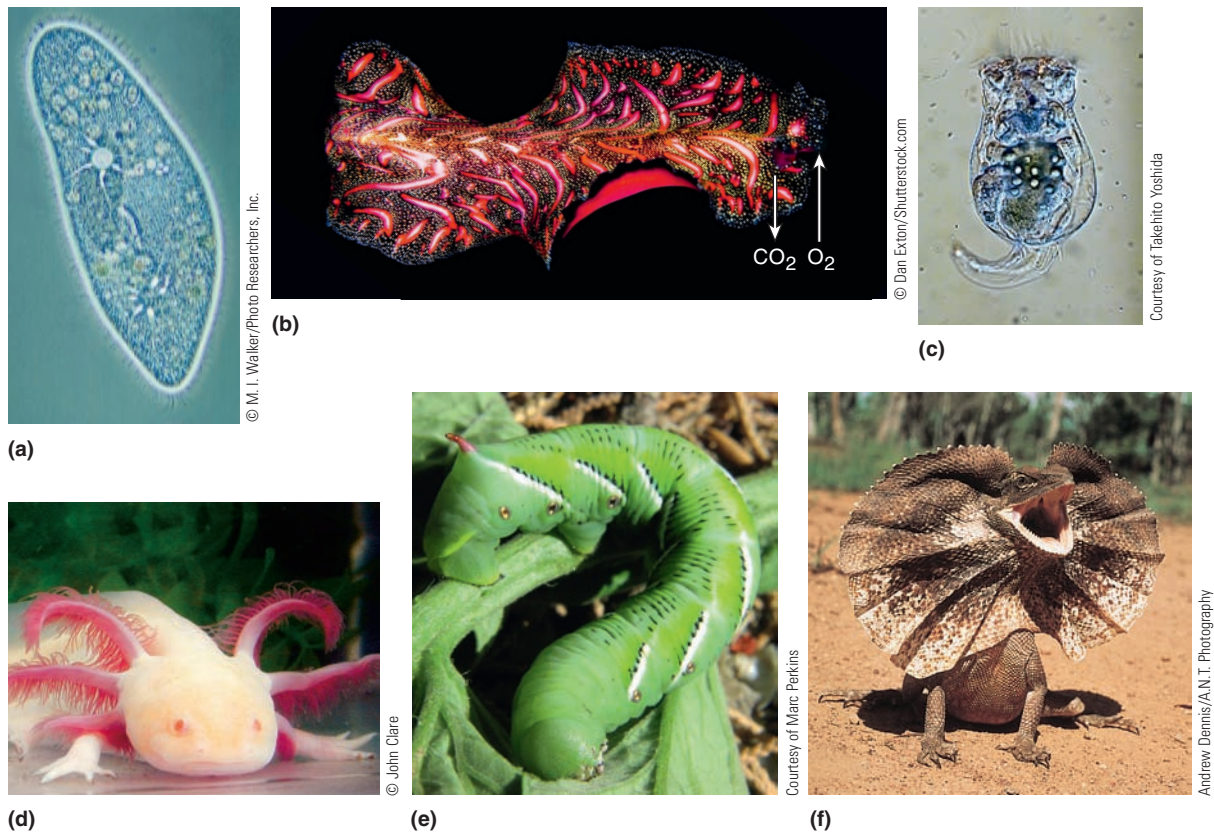

FIGURE 11-3 Diversity of gas exchange structures. (a) Respiratory gases diffuse across the plasma membrane of single-celled organisms, such as *Paramecium*. (b) In small multicellular animals, such as this flatworm, gas exchange occurs through the skin or integument; the distance from the integument to the tissues is small enough that gases can diffuse down concentration gradients in adequate time. (c) Some small aquatic animals, such as this rotifer, have cilia that create both feeding and breathing currents. (d) Most large aquatic animals, such as this axolotl, exchange gases at gills, evaginations of the respiratory surface. (e) The respiratory surface of terrestrial animals is invaginated, such as the tracheae of insects, with openings called spiracles (the brass-colored pores on this caterpillar). (f) Air-breathing vertebrates have lungs, with noses and mouths for air entry, as seen in this frilled lizard.

exposed. Because O_2 is nonpolar, it is very poorly soluble in water. So even if air and water have the same P_{O_2} , the actual concentration is much higher in air than water. You'll see the consequences of this later; for now, examine Figure 11-2c to make sure you understand why we rarely use gas concentrations.

In summary, keep in mind that *gas diffusion follows partial pressure ΔP gradients and changes linearly with surface area A , coefficient D , and inversely with distance ΔX .*

External respiratory processes must meet the demands of size, metabolism, and habitat

Recall that diffusion is quite slow except over very small distances (p. 385). Indeed, August Krogh (p. 3) calculated that diffusion can supply the energy demands of a typical cell only over distances of 1mm or less. For very small organisms, simple diffusion using steps 2 and 4, or step 4 only (Figure 11-1), can be sufficient. However, some larger organisms rely primarily on diffusion by having morphological adaptations that enhance it. As indicated by the ΔX compo-

nent of Fick's law, flattened and thin shapes (which reduce distances compared to more spherical shapes) are the most efficient for exchange of O_2 and CO_2 . This can be seen even in unicellular organisms: While very small ones are often spherical, larger unicellular protists are often elongated and narrow (such as *Paramecium*, Figure 11-3a), a shape that reduces ΔX between the environment and the mitochondria (step 4).

In animals, exchange occurs across **respiratory surfaces**—tissues that are exposed to the environment and across which O_2 and CO_2 diffuse, either directly to internal cells (step 4) or first into an ECF (step 2). The site of gas exchange in the first animals was presumably through the relatively unspecialized body surface or integument. This has persisted to the present in many small, thin, and/or sluggish animals such as Cnidaria (e.g., Figure 9-1b, p. 386), which have thin tissues close to external water, and thin-bodied flatworms (Figure 11-3b), which rely substantially on this **integumentary** (or **cutaneous**) **exchange**. Both can also exchange gases with digestive tract fluid, often highly branched to increase A .

Even in such organisms, there can be forms of bulk transport. For example, the cytoplasm of many protists such as *Paramecium* (Figure 11-3a) exhibits a cyclical cytoskeletal-powered movement called *cytoplasmic streaming*. Ventilation may also occur: The cilia of *Paramecium*, for example, produce not only locomotion but also a flow of fresh oxygenated water across the membrane. Many small animals such as rotifers and aquatic larvae have similar dual-purpose integumentary cilia (Figure 11-3c). In Cnidaria, ciliary movements that move fluid into the digestive tract bring in O_2 , while some sea anemones have cilia on their tentacles that move water for both feeding and respiration.

However, three major factors in the evolution of many animals groups have favored enhancements in gas exchange—for every component of Fick's law—and more advanced forms of bulk transport:

1. Animal *size* has increased in many phyla since the first animals evolved. As this occurred, diffusion became too slow to cover internal distances in a reasonable time.
 2. Animal *habitats* vary in their availability of O_2 , from anoxic (“no oxygen”) aquatic mud to sea level air. Table 11-1 shows the wide range of availability of O_2 among various habitats. The most distinctive difference is found when comparing aquatic to terrestrial habitats. Note in particular that in water, *gas solubility decreases as temperature increases*, such that oxygen can be much more available in a cold-water habitat. Note also that aquatic habitats, even at their highest O_2 content, hold only a fraction of the content of air. And levels can get much lower in mud (which impedes diffusion much more than sand) and in waters such as the Oxygen Minimum Zones found at intermediate depths in many areas of the oceans (Table 11-1). These occur where it is too dark for photosynthetic O_2 production; bacteria use up the available O_2 , and there are no O_2 -rich surface waters sinking down to freshen the zones. (The deepest waters of most oceans, however, are adequately oxygenated by the sinking of cold surface waters in polar regions.) The bottoms of some ponds, lakes, and ocean basins also have low concentrations of O_2 when there are no vertical currents to mix surface with deeper water.
- Animal lifestyles also come into play regarding habitat O_2 ; for example, air-breathing aquatic divers like sperm whales may need to survive over an hour without O_2 intake.
3. Animal *metabolisms* vary in their demand for O_2 , with the highest demands arising in birds, mammals, some fishes, some cephalopods, and flying insects.

Let's now look at the general ways that external respiration has been enhanced in animals that are larger, live in lower-oxygen environments, and/or have more active metabolisms.

Gas exchange may be increased by respiratory organs, bulk transport, and diffusion-enhancing proteins

Diffusion at steps 2 and/or 4 can be enhanced, beyond the basic ways found in flatworms, by four broad adaptations at the cellular, organ, and system levels, as follows:

TABLE 11-1 Oxygen Concentration in Various Habitats, in mL per Liter of Medium

Air at sea level	209
Air at Mount Everest (8,848 m)	59
Fresh water at 0°C (maximum)	10.3
Fresh water at 30°C (maximum)	5.6
Seawater at 0°C (maximum)	8.0
Seawater at 30°C (maximum)	4.5
Seawater in Oxygen Minimum Zones, 200–1,000 m depths	0–0.7

© Cengage Learning, 2013

1. **Ventilation** (step 1). For diffusion between two nonmoving fluids, a gas gradient can quickly become equilibrated (thus, $\Delta P = 0$), and no further net gas movement can occur. Bulk transport delays this equilibration. In the case of ventilation, respiratory surfaces are provided with a continuous fresh supply of external medium with a high P_1 for O_2 (accompanied by a low P_2 for CO_2), keeping gas gradients high in the appropriate directions at step 2.
2. **Respiratory organs** (step 2). The integument may not provide enough surface area for gas exchange, and it may also have a low D and large diffusion ΔX , because of protective layers. Thus, many animal groups have evolved dedicated gas-exchange organs such as *gills*, *tracheae*, and *lungs* (Figure 11-3d, e, and f), which enhance step 2 as follows:
 - a. A high D value due to high permeability; for example, a fish gill epithelium is much more permeable to gases than mucus- and scale-covered skin;
 - b. A low ΔX (distance), using very thin epithelia;
 - c. A high A value, through specialized *folds* (*evaginations*, or “outpockets,” and *invaginations*, or “inpockets”) that increase surface area for gas diffusion. Surface areas are generally higher in animals with higher metabolisms. For example, the lungs of some amphibians are relatively simple sacs, but in more active (non-avian) reptiles and all mammals, the tubes branch into numerous tiny blind-end sacs (*alveoli*, which we explore later) to provide a much higher surface area.
3. **Circulation** (step 3). Internal bulk transport aids diffusion in the same way as ventilation. At the respiratory surface (step 2), ventilation may be complemented by circulatory *perfusion*, which brings to the exchange surface a continuous supply (P_2) of low- O_2 body fluid (with a high P_1 for CO_2). At internal tissues (step 4), which are consuming O_2 and producing CO_2 , the circulatory fluid—re-oxygenated at the respiratory surface—provides a fresh supply (P_1) of high O_2 (accompanied by a low P_2 for CO_2).

An internal circulatory system may also enhance diffusion at steps 2 and 4 by increasing D (e.g., permeable capillaries), increasing A (e.g., high vascularization), and reducing ΔX (e.g., narrow capillaries in closed circulations, or direct bathing of cells by circulatory fluids in open circulations).

4. *Proteins* in the circulatory fluid and inside some cells that convert gases between *diffusible* and *nondiffusible* forms (at steps 2 and 4). In its *nondiffusible* form, a molecule does not contribute to ΔP , and so the gas gradient ($P_1 - P_2$) is not equilibrated nearly as quickly. Think of the gas as being “trapped” so that it cannot diffuse backward once it has reached a certain location, keeping P_2 low. Conversely, when a “trapped” gas is released back into a *diffusible* form, P_1 increases. This greatly increases the amount of gas that the circulation can carry. For O_2 , this mechanism typically involves special *respiratory pigments* (p. 391) such as *hemoglobin* and *myoglobin*. For CO_2 , this involves both binding to hemoglobin and enzymatic conversion to and from *bicarbonate* HCO_3^- ion, which unlike the free gas cannot diffuse through membranes without a membrane transporter.

Breathing as a form of bulk transport can be tidal or flow-through

Now let's look at bulk transport itself for moving gases rapidly. As we noted earlier, ventilation may occur by environmental movements, for example, a water current flowing over the gills of the axolotl in Figure 11-3d. True breathing, however, requires energy-using devices to move the external medium. Typically, these devices are either flagella or cilia that line the surfaces themselves, or separate muscular pumps that create negative and positive pressures to move the medium (as with the respiratory muscles of the lizard in Figure 11-3f). You will later see how these work, but for now, understand that there are two distinct designs to consider in terms of the type of flow created by the pumps:

1. In **tidal breathing**, the external medium is moved in and out of the same opening, in two distinct steps termed **inhalation** (or **inspiration**) and **exhalation** (or **expiration**). It is relatively inefficient because fresh medium typically mixes with depleted medium, and because fresh medium can only be brought in about half the time.
2. In **flow-through breathing**, the external medium enters one opening and leaves through a separate opening. Fresh and depleted medium need not mix much in this process, and flow of fresh medium can be nearly or fully continuous. This also allows for *countercurrent flow*, a process we will explore later that increases gas exchange efficiency. Thus, flow-through systems can be much more effective at gas exchange than tidal ones.

We will examine how all these adaptations and processes work in detail in this chapter, except for some details of circulatory covered in Chapter 9. We first turn to specific respiratory systems (that is, steps 1 and 2 in Figure 11-1).

What are the four possible steps in external respiration?

How have body size, metabolism, and habitat affected the evolution of external respiration?

How do respiratory adaptations enhance the limits of diffusion?

Compare tidal and flow-through ventilation.

11.2 Water Respirers

Let us begin our examination of respiratory systems by focusing on the most distinctive adaptational contrasts: water respirers and air respirers.

Water is a more difficult medium than air for gas exchange

Though life began in water, it contains much less O_2 than air (Table 11-1). It is also problematic for gas exchange in other ways. A comparison of air and water reveals the following points:

1. **Viscosity:** Water has a higher viscosity than air (approximately 850-fold) that necessitates a higher energy output to maintain flow over the respiratory surface. The higher density of water (60-fold greater than air) also entails a higher cost of acceleration.
2. **Solubility:** CO_2 is and its product, bicarbonate, being polar, are in much higher concentrations than in air. However, as we noted earlier, O_2 concentration of water is considerably smaller than in the gas phase: 1 L of water at $15^\circ C$ contains 7 mL of O_2 , whereas 1 L of air contains 209 mL of O_2 . For this reason approximately 30 times more water than air must be moved to achieve the same ventilatory transport of O_2 .
3. **Diffusion:** The rate of diffusion of gases in water is about 10,000-fold slower than in air.
4. **Salinity:** The solubility of O_2 and CO_2 decrease with increases in salinity; no comparable effect occurs in air.
5. **Temperature:** Diffusion rates for gases increase with temperature in both air and water; however, solubility of O_2 and CO_2 are *decreased* as ambient temperature *increases*. No comparable effect occurs in air. These changes in solubility are critical; as temperature is raised from 0 to $35^\circ C$, O_2 concentration is reduced by 50% at constant P_{O_2} . Because an increase in temperature raises the metabolic rate in ectotherms (animals whose body temperatures depend on the environment; Chapter 15), the associated reduction in O_2 solubility in water exerts an ecological pressure for aquatic species to obtain access to air.
6. **Habitat variation:** As we noted earlier, the O_2 content of water is subject to greater variation than that of air. In addition to areas with permanently low O_2 (muddy sediments, warm areas, and Oxygen Minimum Zones; Table 11-1), bays, swamps, and intertidal pools can have large swings in P_{O_2} , which rise during daylight hours as a result of photosynthesis and decline at night as a result of biological O_2 demand. The P_{O_2} values vary from 0 to 450 mm Hg in these shallow habitats, whereas the surface waters of the open ocean have O_2 levels at close to that of air, about 155 mm Hg.
7. **Composition:** Unlike air, water can contain many life-sustaining components other than gases. These include dissolved ions and organic matter, and, of course, water itself (although air can have water vapor).

The limitations of diffusion in water are overcome with gills and other external thin, high-surface-area structures, internal circulation, and flow-through breathing

Enhancements to the components of the diffusion equation are critical for water respirers. Bulk transport is similarly important, with the more effective flow-through arrangements being more common than tidal ones. Earlier we saw how cell shape, cytoplasmic streaming, and cilia aid gas exchange in *Paramecium* (Figure 11-3a). In addition, cilia of *Paramecium* and many animals such as sea anemones often beat in synchrony in one direction, essentially creating a “flow-across” process akin to a flow-through organ system.

Integument We have already noted integumentary respiration in flatworms and Cnidaria. It also occurs to some extent in many larger and less thin aquatic animals and is sufficient to maintain a normal resting metabolic rate, even in some gill-bearing vertebrates such as certain eels and catfish. However, unlike flatworms and Cnidaria, internal circulation (step 3, Figure 11-1) enhances this process. For example, in the earthworm (an annelid) a single, thin layer of mucus-coated epidermal cells covers a dense network of capillaries. (O_2 and CO_2 can cross cell membranes only when they are dissolved in water, so this “terrestrial” animal is effectively a water respirer.)

Integumentary respiration is important in virtually all amphibians and aquatic reptiles and in most fishes. During hibernation, for example, frogs and turtles exchange all their respiratory gases through this route while submerged in ponds or buried beneath the bank of a stream. Eels normally exchange 60% of their CO_2 and O_2 through their highly vascular skins. Of particular note are the lungless salamanders of the family *Plethodontidae*. Because the skin of these animals is also important for protection against the environment, the efficiency of gas exchange is compromised.

Gills Nonintegumentary structures for gas exchange evolved in most water breathers with larger and/or less-thin bodies and higher metabolisms. Most of these specialized respiratory organs are called **gills** (Figure 11-3d and Figures 11-4 to 11-6), evaginations of tissue protruding into the external medium. Gills range from simple integumentary bulges, to branched

filaments, to stacks of **lamellae** (flat platelets on filaments). Filaments and lamellae greatly increase surface area A .

Typically, gills are delicate structures because, as we noted earlier, they are composed of thin cell layers for a small ΔX as well as a high A . They are also highly perfused by a circulatory system and may have associated

flow-through breathing mechanisms. For example, gill filaments of mollusks (Figure 11-4a) have cilia that create unidirectional respiratory currents across the filament surfaces.

Due to the fragile composition of gills, some form of protection is generally required. Often the organs are internal in the sense of being protected by a hard cover like a mollusk's shell (thus, the gills are not externally visible; Figure 11-4a). But even then, the respiratory surfaces evaginate to form delicate structures in direct contact with the external medium through openings to the environment. Protection of a different kind is found in the specialized elaborate filaments of shell-less sea slugs called *nudibranchs* ("naked gills") (Figure 11-4b). Although their gills are fully external, they are not unprotected. The integuments and gills of most nudibranchs contain noxious substances, or unfired nematocysts (stinging capsules, p. 42) "stolen" from the tentacles of sea anemones they have consumed! The (somehow) unfired nematocysts are absorbed by the digestive tract and move into the gill filaments. These animals are usually brightly colored to advertise their invisible defenses.

In some annelids, gills are simply evaginated, folded extensions of the body surface, without protection; but in other annelids such as tube-dwelling polychaetes, the extensions form dense filaments with a large surface area (also used for feeding; Figure 11-5a). Though unprotected when in use, these filaments can be quickly withdrawn into the animal's hard tube when threatened.

The gills of arthropods such as crabs and lobsters (Figure 11-5b) are protected by their exoskeletons. Those of fishes (Figure 11-6) are also protected with hard parts. Let's look at fish in more detail. The gill system of fish consists of **gill arches**, the tissue that provides skeletal support for a double series of gill filaments, each of which carries a row of lamellae on either side (Figure 11-6a–c). Normally there are five separate pairs of these arches, covered with a protective bony plate called the **operculum**, which opens on one side to the outside world. The basic unit of gas exchange in the gill is the lamella, not the arch or filament. Lamellae form a sieve-like structure which minimizes diffusion distances for gas exchange between water and the extensive blood supply found in each lamella. The thickness of each lamella ranges from 10

to 25 μm . Each is comprised of two epithelial cells, separated by a series of *pillar cells* between which blood can flow. The degree of activity of a fish species is correlated with the amount of spacing between subsequent lamellae, which can vary from 10 to 60 per mm. Depending on the species, total lamellar numbers can also vary. Generally, to accommodate the metabolic requirements of fast-swimming species, the size of the lamella is larger and the interlamellar spacing is smaller. For example, in an inactive bottom dweller such as the toadfish the number of lamellae is approximately 0.5 million, whereas in a comparably sized active species such as the bluefin tuna, lamellar number is over 6 million.

Exposure to the environment has its risks. **Environmental gill disease (EGD)** is a syndrome that commonly affects fish reared using aquaculture technology. The initial stages are characterized by inflammation of the gill lamellae. It is believed that stress as well as environmental factors triggers the disease process. If exposure to the irritant (such as bacteria, amoebas, fungi) is short-lived, damage to the gill lamellae is minimal. However, if the irritant exposure continues, a serous (blood plasma) exudate accumulates around the capillary endothelium, which reduces gas exchange. Fish with *epithelial-capillary endothelial separation (ECS)* exhibit symptoms of respiratory distress that ultimately becomes fatal if left untreated.

Other Respiratory Tissues Integuments and gills are not the only respiratory surfaces in aquatic animals. For example, in water-breathing mollusks, the **mantle** (Figure 11-4a) as well as the gill is highly vascularized and can take up O_2 from ventilatory currents flowing over these surfaces. In shelled mollusks, the ventilatory current also flushes the **visceral mass** (main body) with oxygenated water. A comparatively large sinus lying beneath the visceral mass can actually be inflated, increasing the amount of surface area exposed to the ventilatory current.

Sea cucumbers (soft-bodied echinoderms) are animals with a unique respiratory structure. Echinoderms are not typically high-metabolism animals, and most (such as sea stars and sea urchins) exchange gases through small body-wall evaginations and/or tube feet. But a sea cucumber

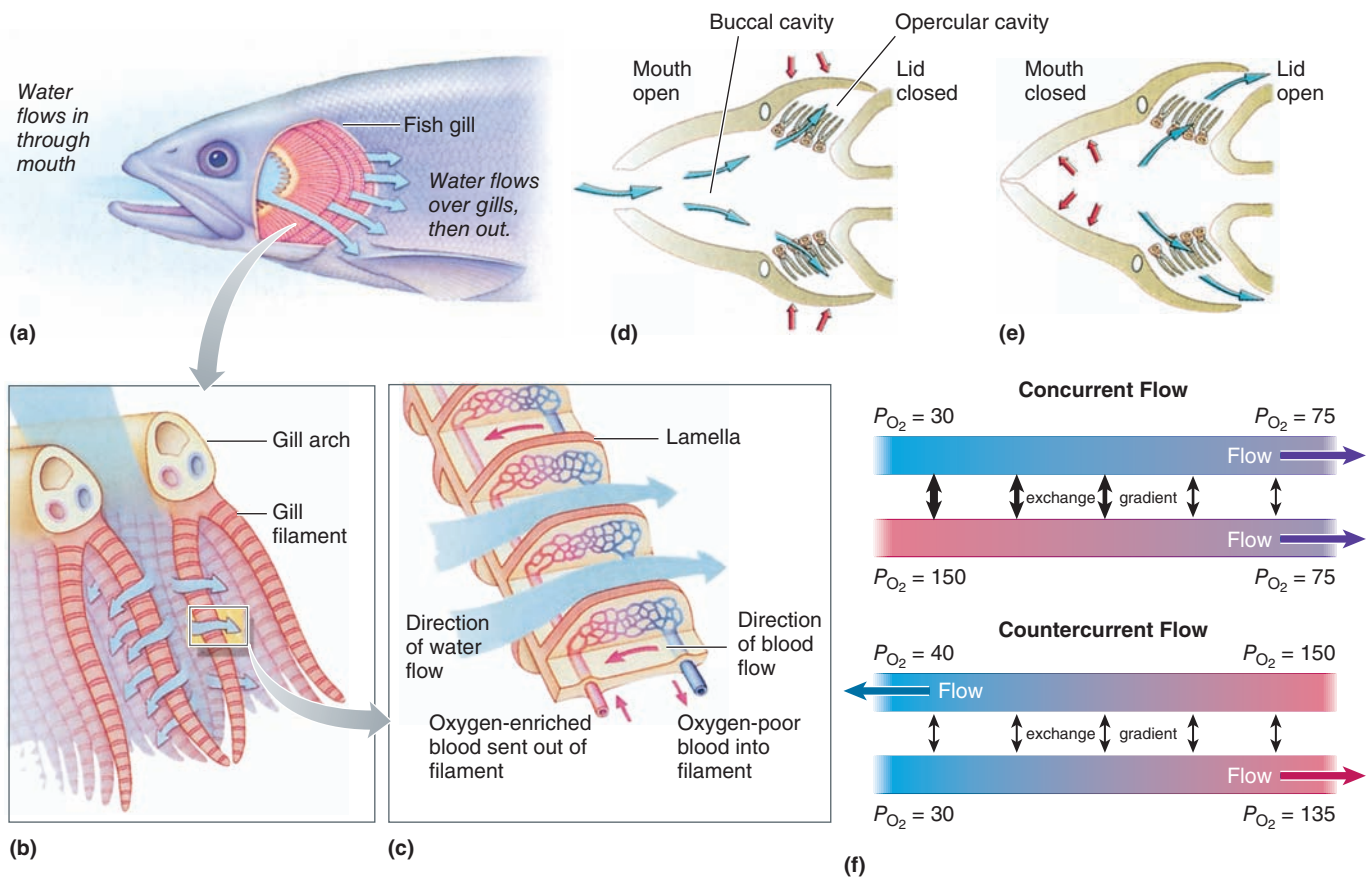

FIGURE 11-6 Respiratory system of a teleost (bony fish). (a) One of a pair of gills. The gill cover or operculum has been removed for this sketch. Water drawn into the fish's mouth is forced across the gills. (b) Each gill has filaments bearing lamellae, which are richly vascularized respiratory surfaces. (c) The flow of oxygen-rich water is countercurrent to the flow of oxygen-depleted blood entering the lamellae. (d) Opening the mouth and closing the lid forces water into the buccal cavity and across the gill. (e) Closing the mouth and opening the lid forces the water to exit through the opercular cavity. (f) In concurrent flow (top), gases reach a 50:50 equilibrium in the two tubes. However, in countercurrent flow (bottom) as in a gill, up to 90% of a gas can be transferred because blood moving through the one tube continually encounters water whose O_2 content is higher than what is present in the blood. Thus, there is a positive ΔP at every point, keeping gases diffusing into the blood.

draws in seawater through its anus into a branching structure called a **respiratory tree** that protrudes into its coelomic (body cavity) fluid, not into the environment. Pumping involves muscles in the tree, but it is relatively slow and involves a low-efficiency tidal flow, so it cannot be used to support a high metabolism. This outgrowth of the digestive tract is structurally more like a lung than a classic gill!

Breathing muscles in water provide rapid and often flow-through transport

Gas exchange in the most active aquatic species requires the aid of a dedicated muscle-driven form of breathing. The most active of the mollusks—cephalopods—exemplify this: They have abandoned ciliary-driven bulk transport on their gills and instead rely on a muscular pumping mechanism. This involves the muscular walls of their mantle cavity and funnel (Figure 11-4c). During inhalation, the funnel closes and the mantle cavity expands, drawing in large amounts of water to

ventilate the gills rapidly. To exhale, the mantle opening seals up and the funnel opens, whereupon the mantle contracts and squirts the water out the siphon. This can also be used as a means of rapid **jet propulsion** when the animal needs to move quickly. Note that, because the intake and exit paths are different, this is largely a flow-through process (Figure 11-4c).

Another flow-through type of muscular pump is readily seen in fishes (Figure 11-6d, e). Water is pumped over the gills of bony fish by skeletal muscle pumps in the **buccal** (mouth) and **opercular cavities**. Ventilation of the gills operates by a cycle of negative and positive pressure gradients. As the mouth opens, the opercula are shut, which leads to a negative pressure gradient in the buccal and opercular cavities, resulting in the inward movement of O_2 -rich water. The mouth is then closed and the opercular cavity constricts, forcing water through the gills. At this point the water that is trapped in the gills is under higher pressure than outside. When the opercula open, the positive pressure gradient forces water outward across the gills and through the

opercular exit. Note again that this is a flow-through system, whose efficiency we explore later.

Paradoxically (it seems at first), the most active fish of all—tuna—have lost their breathing muscles! They instead rely on a flow-through process called **ram ventilation**, in which bulk transport is created by the animal's own motion, along with keeping the mouth and opercula slightly open. However, the principle—that high metabolisms require muscular-driven bulk transport—remains the same, but the muscles are those of swimming, not the traditional respiratory muscles. Large masses of external medium are moved over the gills rapidly and continuously because these animals never stop swimming. Although the open mouth increases drag, the continuous flow of water is more economical than the costs associated with pumping water over the gills and the drag of the turbulence that would be caused by flapping opercula. In addition, the faster the fish swims, the greater the supply of O₂-rich water that flows over the gills to meet the increased tissue requirements for O₂. Because tunas must swim to breathe, they are *obligate* ram ventilators. So are many open-ocean sharks such as white sharks. Because of their need for constant swimming, captive tunas and open-ocean sharks must be kept in special large aquarium tanks that are round (that is, lacking corners to bump into) with circular water flow.

Many other fish, in contrast, are *facultative* ram ventilators, that is, they switch from active buccal-opercular breathing to ram ventilation when swimming above certain velocities, presumably to save energy. Rainbow trout, for example, switch as they reach a speed of about 24 cm/sec, at which point their total body O₂ consumption drops by 10%.

Countercurrent blood flow enhances gas pressure gradients in fishes

Another way to maximize gas exchange relies on the arrangement of blood flow. To be able to extract the maximum amount of O₂ from the water flowing through the gills, blood flows in a direction opposite or **countercurrent** to that of water flow (Figure 11-6c and f); that is, blood flow through the capillaries is opposite to the stream of water flowing through the gill lamellae, such that blood moving through the lamellae continually encounters water whose O₂ content is higher than what is present in the capillary. Thus, there is a positive ΔP at every point, keeping gases diffusing into the blood. This anatomical arrangement permits the O₂ content of arterial blood to exceed that in the respired water. As you will see later when we compare water and air respirers, this yields a much greater efficiency of gas exchange than other forms of flow.

Interestingly, some species of fish use *retrograde flow* of water from the opercular opening into the buccal chamber to ventilate their gills. Lampreys, for example, use this unusual adaptation because, while feeding, the lamprey's mouth remains attached to a host fish. Thus, the gills must be ventilated by this tidal flow of water generated by cyclic contraction of the muscular walls lining the gill pouches.

Aquatic respiratory systems can perform numerous nonrespiratory functions

In water respirers the respiratory system (such as gills) provides the greatest exposure between internal and external environments. Therefore, the system often performs several important nonrespiratory functions related to its high exchange capacity:

1. **Feeding**—many gills are also feeding structures, as in bivalve mollusks, many polychaetes (Figure 11-5a), brachiopods, and so on. These animals have ciliated filaments that create flow-through currents for obtaining plankton as well as for exchanging gases.
2. **Fluid and solute balance**—the regulation of osmotic and ionic balance. Gills in crustaceans, fishes, and other groups continually adjust wastes, ions, and water levels in blood (Chapter 13), and so any increase in ventilation can be accompanied by a marked increase in ionic loss (Na⁺) and water influx. Marine bony fish, however, gain ions and potentially lose body water to the environment. Generally more active species rely on an increase in the functional surface area of the gills to accommodate an increase in O₂ needs, whereas sedentary species increase blood flow to the gills during increased activity. Because these fish rarely require maximal O₂ ventilation, they are better able to tolerate the resulting ion losses.
3. **Acid-base balance**—the maintenance of normal acid-base balance by transporting H⁺ or HCO₃⁻ through the gills into the aqueous media (Chapter 13).
4. **Excretion**—for example, removing the toxic waste product ammonia (Chapter 12).
5. **Nutrient and mineral uptake**—for example, calcium intake from the environment through the gills.

Another process affected by gills, one that is not always adaptive, is heat transfer. The vast majority of aquatic animals have body temperatures within 1 to 2°C of the surrounding environment because of heat loss through the high surface area of respiratory structure. Endothermic water respirers such as tuna require special adaptations to minimize heat loss (Chapter 15).

What are some nongill methods of gas exchange in aquatic animals?

Describe three examples of gills in different nonvertebrate phyla.

How do fish create flow-through breathing, and how does gill countercurrent flow aid gas exchange?

11.3 Air Respirers: Overview and Nonvertebrates

The evolutionary transition to land involved new challenges for external respiration.

Air breathers may have less efficient exchange surfaces and breathing mechanisms, and their exchange surfaces must be protected from drying out

Firstly, recall that air is much less viscous than water and that it contains much more O₂ than any body of water (Table 11-1). These facts have two implications for diffusion and bulk transport:

- Surface area need not be as high as in water. For example, one remarkable animal, the land crab *Scopimera*, can take up O_2 from special “thigh windows,” thinned areas of the cuticle located in its walking legs. These have much less surface area than gills of aquatic crabs but are just as effective in total gas exchange. Nevertheless, the most active air breathers do require high surface areas, as you will see.
- Efficient external bulk transport (which has a potentially significant metabolic cost) is less necessary for air respirers. For example, small insects rely partly on diffusion for gas movement in and out of their tracheae. Also, simple tidal breathing is more common among terrestrial animals than the (often more complex) more efficient flow-through systems. For example, mammals (which have among the highest known metabolic rates) have relatively inefficient tidal breathing. However, birds, with their even higher metabolic rates, have partial flow-through arrangements (as you will see later).

Secondly, because respiratory surfaces are typically thin for diffusion, they can potentially collapse in air under gravity and, more importantly, dry out rapidly if exposed to air. Therefore, in air respirers the respiratory surfaces must be kept moist to maintain the integrity of the respiratory surface. There are two broad ways to do so:

- *Remain in moist conditions.* Such land animals closely resemble small aquatic animals in respiratory features; for example, many rely on integumentary exchange. But because air with its high O_2 content is close at hand, this type of exchange can work well in larger animals. Earlier, you saw how the earthworm can be considered aquatic in this regard. Sometimes certain regions of the skin are enhanced for respiration. For example, the East African annelid swamp worm, *Alma emini*, spends the dry season burrowed in decomposing plant material, where it breathes moist air. During the rainy season, the local environment becomes anoxic, so the swamp worm extends its highly vascularized, flattened tail out of its burrow into the air. The tail is even more versatile than this, however. When the animal withdraws into its burrow (to avoid predation or drying out), its tail can roll up into a covered cylinder that takes a bubble of air down with it underground. The tail then slowly absorbs the O_2 from this “scuba tank” of gas!
- *Have covered or fully internal structures* for gas exchange, with secretions to moisten the surface. Structures include internal air tubes called **tracheae**, which take air directly to tissues (insects, some spiders), gill-like **book lungs** (scorpions and some spiders), **mantle cavities** (some snails), or vascularized sacs called **lungs**, which provide air for internal circulation (some snails, and land vertebrates, including those such as penguins and whales that have reevolved into aquatic habitats). Some of these form as invaginations rather than the evaginations; others form as evaginations off of digestive tracts, but are fully internal.

Let’s now examine these internal structures in more detail.

Land slugs and snails use skin, mantle tissue, or lungs

Mollusks are primarily aquatic. Some species such as many bivalves are semiterrestrial in the intertidal zone, where they are exposed alternately to water and air. They generally use the same (gill) structures for gas exchange with air or water. However, these animals limit exposure of their epithelial surfaces to the atmosphere because of desiccation risk, so they typically close up to minimize water loss and then depend on anaerobic metabolism.

Only in certain groups of gastropods (snails, slugs) have any mollusks become terrestrial. Land slugs require moist habitats, relying on integumentary exchange through a moistened skin, whereas one group of snails (the *prosobranchs*) uses its mantle tissue under its shell. The most successful groups are the pulmonate (“lung-bearing”) snails, some of which have adapted to deserts. They have an actual lung in which a well-perfused mantle tissue forms a complete chamber with a small opening to the outside to reduce water loss. Gases move primarily by diffusion, although some tidal transport may occur from body movements.

Arachnids use book lungs or tracheae

The first animals to venture onto land were probably arthropods, over 400 million years ago. Recent fossil evidence suggests that these were scorpion-like animals that lived in empty mollusk shells to keep their gills from drying out (much like modern hermit crabs do; see photograph below). The gills eventually became invaginated into an internal chamber to become the first lungs. We see these in modern scorpions and some spiders (arachnids) in the form of **book lungs**, called this because they consist of stacked lamellae appearing like pages of a book, with air spaces between the folds for gas exchange (Figure 11-7). These stacks of lamellae invaginate from the cuticle into the abdomen, forming numerous thin air chambers. In more advanced spiders, these have evolved into tubular extensions into the tissues and thus form a true *tracheal* system (which, however, evolved independently of the insect system, which we examine next).

A land hermit crab in Costa Rica. It protects its gills from drying out by entering the shell of a dead snail, much like the first land animals were thought to have done some 400 million years ago.

FIGURE 11-7 Book lung of a spider. Scorpions also have this type of respiratory organ.

sacs, which are actually regions where the tracheae are enlarged (for example, in honey bees). Because they are thin walled, the sacs collapse and expand from external muscle action. This provides some bulk transport to the process. The other method—which may also use air sacs—uses rhythmic muscle contractions of the abdomen and movements of the head and prothorax to force air through the tracheae. The action of the flight muscles to compress the thorax further enhances ventilation. In some cases, actual flow-through movement is achieved as air is drawn in certain spiracles and forced out through separate ones (Figure 11-8a). However, air movement in the final tracheoles cannot be flow-through, because of their blind-end design.

In insects, internal air-filled tubes—tracheae—supply oxygen directly to the tissues

In insects (as well as centipedes, millipedes, onychophorans, and most spiders), gas exchange occurs through a system of internal air-filled tubes, the tracheae (Latin *trachea*, “wind-pipe”), which directly supply O_2 to the tissues (Figure 11-8). It is not known how these evolved, but regulatory genes that induce their formation in insects are related to genes of crustacean gill development, so tracheae may have started as invaginated gill folds. Tracheae have been found in fossilized millipedes from about 400 million years ago.

Most insect tracheae are reinforced with rings of chitin. The circulatory system is thus important *only* for the transport of nutrients and not respiratory gases to the respiring cells. The tracheae connect to the outside through openings called **spiracles** (Latin *spiraculum*, “airhole”) that are pores or openings through the exoskeleton (Figures 11-3e and 11-8). These can be closed by processes we will discuss later (see p. 546). Most species have three pairs of spiracles above the legs and on the first seven abdominal segments. The tracheae ultimately break up into finer branches, the **tracheoles**, which are about $0.2\ \mu\text{m}$ in diameter. Tracheoles can actually indent the surface of target cells such as muscle fibers and are “functionally internalized,” although they never become intracellular. Thus, insects use steps 2 and 4 of Figure 11-1, bypassing step 3. The distribution of tracheae reflects the O_2 demands of particular tissues. For this reason, the brain, sense organs, and flight muscles of insects contain an abundant supply.

Insects can also have step 1. Both larger and flying insects have long been known to rely on active tidal pumping of gas through the tracheal system. One method uses air

It used to be thought that simple diffusion was sufficient for gas movement in and out of tracheae in small insects. This is probably true in some cases. However, in 2003, Mark Westneat and colleagues observed tracheae alternately compressing and expanding in head and thorax regions of many insects, including very small ones such as carpenter ants. Compression, which forces air out of the tracheae, is thought to be due to body muscles contracting around the tracheae. Expansion, which creates suction to draw air into the tracheae (in tidal fashion), is due to elastic rings in the tracheae walls that expand like springs after being compressed.

check your understanding 11.3

Compare how ventilation and gas exchange work in a land snail, spider, and insect.

11.4 Air Respirers: Vertebrates

The respiratory system of vertebrate lung breathers includes the respiratory structures leading into the lungs, the lungs themselves, and the structures of the thorax (chest) involved in moving air through the airways into and out of the lungs. The **respiratory airways** are tubes that carry air between the atmosphere and the lung surfaces such as **alveoli** (small sacs in grapelike clusters). In some cases, these airways can also function in gas exchange. An unusual solution to gas exchange observed in submerged turtles are the well-vascularized membranes lining the mouth, which take up O_2 from water as well as from the air. The tortuous nasal passages of some birds also

Challenges and Controversies

Why Are There No Large Insects?

Watch a bee or dragonfly accelerate and zoom—those feats of flight rely on muscles that receive the most O_2 per second of any known animal muscle—up to 200 times faster than in mammals. How can they do this? As a result of pumping air directly to muscles, tracheae are actually much more effective at delivering O_2 than the vertebrate blood system, which requires many more stages and the relatively slow pumping of a liquid. Insect flight muscle can elevate its metabolism 100-fold, but mammals rarely increase muscle metabolism more than 20-fold. And yet, tracheae may explain why insects are so small. Careful *scaling* analysis of small to large beetles, done by Alexander

Kaiser and colleagues in 2006 with intense X-rays, found that tracheae take up a proportionally greater part of an insect body as body size increases. That is, the tubes must increase in width more than body size increases in order to deliver enough O_2 , and the researchers calculate that at above a 15 cm body size—interestingly, the size of the largest insects (rhinoceros beetles)—spiracles and tubes begin to take up too much space, particularly in legs. This idea is supported by the fossil record. Some 300 million years ago, Earth's atmosphere was about 35% O_2 (instead of the 21% today), which would have boosted tracheal O_2 deliv-

ery. At that time, there were large insects including giant dragonflies with wingspans of almost a meter!

represent an additional site of O_2 pickup. Let's examine the evolution of these airways and lungs in more detail.

The first air-breathing vertebrates were bimodal

Vertebrate air breathing is believed to have been favored among those animals living in habitats similar to modern tropical lowlands, where warm water and seasonal drought

results in stagnation of ponds leading to aquatic *hypoxia* (low oxygen), and even desiccation. The first evolutionary transition from aquatic to terrestrial life produced distinct fishes with a unique set of adaptations to respiring in both media. Some had modified gills (such as air-breathing catfish, with more arch support to prevent gill collapse), but others were **bimodal breathers** with, in addition to gills in water, the ability to breathe air by integumentary exchange

(such as some eels), parts of the digestive system including oral or stomach linings, or separate air sacs called *lungs*. Bimodal breathing is used by some fishes in waters that become anoxic (such as stagnant swamps) or in ponds that dry out seasonally. In fact, the mangrove rivulus (*Rivulus marmoratus*) a tropical killifish, can survive for over two months without water and food. When their habitat dries up, they seek refuge in logs hollowed out by insects as they await a subsequent rainfall. In addition, some have gills, lungs, *and* some integumentary (skin) gas exchange with the result that they are actually **trimodal breathers** (such as the reedfish *Calamoichthys calabaricus*).

The most successful vertebrate groups in terms of terrestrial adaptation are those that evolved true lungs. Lungs in fishes originally evolved as a simple ventral (internal) evagination of the pharynx, and in some groups evolved into a dorsal gas bladder (see p. 539 and Figure 11-32). Eventually the gas bladder transformed into a structure specialized for both sound reception and buoyancy control and in many cases lost its respiratory function. In at least one group of fishes, however, the air sac became paired and ventrally oriented, leading eventually to the lungs of terrestrial amphibians, reptiles, birds, and mammals. The tube connecting the pharynx to the lungs became the **trachea** (windpipe), splitting into two primary **bronchi** for the paired lungs (the anatomy found in most terrestrial vertebrates).

Frog lungs may be simple or moderately folded and are inflated by positive pressure

Amphibians, the first class of vertebrates to evolve from lung-bearing fishes, are noted for their bimodal lifestyles, living both in the water and air. Aquatic and terrestrial amphibians rely to varying degrees on integuments, gills, and lungs for gas exchange. For example, some species of salamanders are without lungs and are solely dependent on cutaneous gas exchange. In these animals the skin is moist and well vascularized. At the other extreme, one salamander (*Siren lacertina*) has trimodal breathing.

In frogs, most larval stages have gills, whereas most adults have lungs that are comparatively simple and non-compartmentalized (Figure 11-9a). Air enters these lungs from the pharynx via the trachea and bronchi; note that the pharynx also branches into the **esophagus**, the tube through which food passes to the stomach, reflecting the way that lungs first evolved. In larger species needing greater surface area because of scaling problems, the lung is folded into alveoli. However, alveoli are larger and less numerous than in vertebrates with higher metabolisms. Air is forced by *positive pressure* into their lungs by a **buccal pump** (originating in the mouth) that is similar in function to that used in fish (Figure 11-10a–d). Normally, several inspiratory oscillations are required to completely fill the lungs, whereas one long exhalation empties the lungs. These animals are bi-

FIGURE 11-9 Comparative lung structure of amphibians, reptiles, and mammals.

(a) Amphibian lungs range from comparatively simple sacs surrounded by few blood vessels to pouches divided into many large compartments with dense vascularization. The latter is helpful for terrestrial amphibians that spend more time on land to reduce the use of integumentary exchange. (b) Lungs of a typical reptile rely on a bellowslike pumping of posterior air sacs that help airflow into and out of the lungs. Gas exchange occurs in a forward, spongy region of each lung. (c) Highly compliant mammalian lungs rely on gas-exchanging alveoli (lower right-hand box). t = trachea, b = bronchus

Source: C. Starr & R. Taggart. (2004). *Biology: The Unity and Diversity of Life*, 10th ed., Belmont, CA: Brooks/Cole, p. 711, Figure 40.8.

modal skin-lung breathers (Figure 11-10e), but O_2 uptake is primarily through the lung, whereas CO_2 elimination is almost exclusively cutaneous. Terrestrial caecilians (tropical, legless amphibians), which spend most of their time in burrows, have single, elongate lungs that extend almost 70% of their body length. Structurally, caecilian lungs have a high degree of internal compartmentalization, forming numerous alveoli that markedly increase the available surface area for gas exchange.

In bimodal gill–lung breathers, branchial (gill) contractions alternate between periods of pumping water through the gills to pumping air into the lung. In the ancestors of the first exclusively air breathers, water pumping was completely abandoned with the buccal muscles exclusively functioning as a positive-pressure air pump to inflate the lungs. As the dependence on branchial O_2 uptake decreased, the gills and branchial arteries became reduced and internalized. The diffuse, externally oriented chemoreceptors for monitoring gas concentrations located in the gills evolved into discrete arterial chemoreceptors located near the carotid artery and in the aortic arch (see the section on breathing regulation later). Adaptations to air breathing also included a decrease in the affinity of *hemoglobin* for O_2 that reflected the much greater O_2 availability in air (see Section 11.9 later).

FIGURE 11-10 Respiration in a frog. (a) During inspiration, the frog lowers the floor of its mouth and inhales air through its nostrils into the buccal cavity. (b) The frog then closes its nostrils, opens the glottis, and raises the mouth's floor. This action forces air into the lungs. (c) Gas exchange occurs in the lungs. The nostrils open at the end of this phase. (d) Air is forced out of the lungs when muscles in the body wall above the lungs contract and the lungs elastically recoil. Lung filling generally requires several successive active inflation cycles, whereas lung deflation is usually accomplished by a single passive expiration. (e) Integumentary "open" exchange in a frog, showing blood flowing in capillaries underneath the skin.

Reptiles and mammals have respiratory systems ranging from simple to elaborately folded chambers inflated by negative pressure

Compartmentalized lungs are an important adaptation in some reptiles as well as birds and mammals, but what separates these groups from all others is their mechanism of ventilation. Instead of forcing air from the buccal cavity into the lungs (amphibians and some reptiles), air flows into the lungs because of a *negative pressure*. Various muscles forcefully *expand* the lungs creating a subatmospheric pressure that draws air inward. You will later see how negative pressure and these muscles work, but note that all work indirectly, that is, they do not connect directly to the lungs themselves.

Most Reptiles Except for birds and crocodilians, reptile lungs are expandable tidally ventilated sacs, which may be simple or with several large sacs and even some alveoli (Figure 11-9b). The simplest reptilian lung is somewhat analogous to a single, oversized alveolus. Vascularized ingrowths, or *septa* (dividing walls or partitions), penetrate centrally from the lung's perimeter and subdivide the pulmonary lu-

men into a series of spatial units called *edicolae* (if they are as wide as they are deep, as in tortoises, chameleons, and geckos) or *faveoli* (if they are deeper than they are wide, as in snakes and iguanids). Gas exchange occurs principally on the septae, although they are poorly vascularized compared to alveoli. Unlike mammalian alveoli, edicolae are relatively passive participants during ventilation and do not contribute to the movement of air during inhalation and exhalation. Airflow during ventilation is tidal and bellowslike, as you will see for mammals later.

Lizards and snakes rely solely on *costal* (rib muscle) ventilation resulting from simple rib-cage expansion to create negative pressure for inhalation, and contraction for exhalation. They work indirectly in ways similar to the mammalian system, to be described shortly. Animals whose rib cage is fixed rely on alternative solutions to expand their lungs. Tortoises, for example, must extend their limbs to expand the thoracic cavity.

Crocodilians Crocodiles, caymans, and alligators were long thought to have a tidally ventilated lung, but a recent study by C. G. Farmer and K. Sanders reveals that alligators, at least, have a birdlike *flow-through* system! Inhaled air enters the lungs via the trachea and bronchi, but instead of becoming a dead-end sac, each bronchus branches into secondary bronchi and then into very small tertiary or *parabronchi*, where gas exchange takes place. Importantly, the air continues in one direction into other secondary bronchi that reenter the original bronchus for exhalation. Though tidal in the initial airways, flow is unidirectional at the gas-exchange sites. We will explore the similar but more elaborate flow-through parabronchi of birds later.

For ventilation in crocodilians, contraction of a **diaphragmaticus muscle** (attached between the liver and a distinctive elongated region of the pubis bone) pulls the liver away from the lungs in a pistonlike manner that results in expansion of the lungs. The crocodilian **diaphragm** consists of a sheet of nonmuscular connective tissue that adheres tightly to the dome-shaped anterior surface of the liver. Exhalation is accomplished by abdominal muscles, which push the liver against the lungs. You will see how similar muscles work in mammals shortly.

Birds and Mammals To meet the energy demands of birds and mammals with their increased metabolic rates, the surface area of the lung available for gas exchange had to markedly increase. The mammalian solution was the elaboration of numerous very small alveoli (Figures 11-9c and 11-11), whereas the avian respiratory system, which is the most complex of the vertebrates, evolved parabronchi with *air capillaries*. The cardiovascular system became increasingly modified to perfuse the gas exchange organ. Oxygenated blood from the lung achieved complete separation from systemic venous blood with a four-chambered heart (also found in crocodilians; Chapter 9). With the evolution of these two adaptations both groups were now able to exploit lifestyles that could make use of their high metabolic rates.

Most mammals are bimodal due to integumentary gas exchange, as exemplified by bats: in flight they are capable of eliminating almost 12% of their CO₂ across the surface of their wings. Approximately 1 to 2% of the total CO₂ and O₂ in many other mammals can be exchanged directly through the skin. This one signal by which a mosquito finds

FIGURE 11-11 Anatomy of the respiratory system in a mammal.

its victims, and a tick detects a potential host, including humans. Carbon dioxide release serves as the primary attractant as the tick scuttles its way up the concentration gradient. A greater CO_2 production rate increases the likelihood of a particular individual becoming the tick's next meal!

Mammalian airways terminate in alveoli, which are involved in both ventilation and gas exchange

Mammalian airways begin with the **nasal passages** (in a nose or blowhole) (Figure 11-11a). Adaptations for running in the horse and cheetah include nostrils that are pliable and easily dilated to increase the volume of air inspired. Concomitantly with the evolution of endothermy, the evolution of **maxilloturbinals**, thin curls of bone deep within the nasal cavity, was favored to retain heat and water (see Chapter 15). The nasal passages open into the **pharynx** (throat), which serves as a common passageway for both the respiratory and digestive systems. Again, reflecting evolutionary

ancestry, two tubes lead from the pharynx—the trachea and the esophagus. Because the pharynx serves as a common passageway for food and air, reflex mechanisms exist to close off the trachea during swallowing so that food enters the esophagus and not the airways. The esophagus remains closed except during swallowing to prevent air from entering the stomach during breathing. The trachea is lined with two kinds of cells: mucus-secreting cells, which lubricate it, and ciliated cells lined with tiny hairs that continually beat upward, pushing impurities such as inhaled particles and dust, up and out of the trachea.

Again, the trachea divides into right and left bronchi, each entering one lung. Within each lung, the bronchus continues to branch into progressively narrower, shorter, and more numerous airways called **bronchioles**, much like the branching of a tree. Clustered at the ends of the terminal bronchioles in mammals are the alveoli (Figure 11-11b).

To permit airflow in and out of the gas-exchanging portions of the lungs, the continuum of conducting airways, from the entrance through the terminal bronchioles to the

alveoli, must remain open most or all of the time. The trachea and larger bronchi in most mammals are fairly rigid, nonmuscular tubes encircled by a series of cartilaginous rings that prevent the tubes' compression. For example, the trachea of a giraffe is supported along its length by more than a hundred of these tracheal rings. The smaller bronchioles have no cartilage to hold them open. Their walls contain smooth muscle that is innervated by the autonomic nervous system and is sensitive to certain hormones and local chemicals. These factors, by varying the degree of contraction of bronchiolar smooth muscle and hence the caliber of these small terminal airways, are able to regulate the amount of air passing between the atmosphere and each cluster of alveoli. We'll examine their regulation later.

Alveoli These tidally ventilated sacs cannot have counter-current exchange with blood, so they can only achieve equal partial pressures of gases in air and blood P_{O_2} (compare Figure 11-11c to the gill countercurrent in Figure 11-6f, in which arterial gas pressure is *higher* than exhaled water's gas pressure). However, in other ways, alveoli are well-adapted for gas exchange. Recall that, according to Fick's law, enhancements arise by decreasing the distance for diffusion (ΔX), and increasing the surface area (A). The alveoli accomplish both of these enhancements well, as readily visible in Figure 11-12. The alveolar walls consist of a single layer of highly flattened **Type I alveolar cells** (Figure 11-12a). The linings of the dense network of pulmonary capillaries encircling each alveolus also consist of a single layer of very thin cells. The interstitial space between an alveolus and the surrounding capillary network is also an extremely thin barrier, with only $0.25\ \mu\text{m}$ separating the air in the alveoli from the blood in the pulmonary capillaries. (A sheet of tracing paper is about 50 times thicker than this air-to-blood barrier.)

Furthermore, the alveolar air–blood interface presents a tremendous surface area for exchange. The lungs of a human contain about 300 million alveoli in the lungs, each about $300\ \mu\text{m}$ (11 mm) in diameter. So dense are the pulmonary capillary networks that each alveolus is encircled by an almost continuous sheet of blood (Figure 11-12b). The total surface area thus exposed between alveolar air and pulmonary capillary blood is about $75\ \text{m}^2$ (about the size of a tennis court). In contrast, if the lungs consisted of a single, hollow chamber of the same dimensions instead of being divided into myriad alveolar units, the total surface area would be only about $0.01\ \text{m}^2$.

The alveolar surface area varies among mammals. One of the hallmarks of *scaling* (p. 10) in animals is that smaller species have higher basal metabolic rates, that is, they require more energy per unit mass. As you will see in Chapter 15, this phenomenon in birds and mammals is traditionally attributed to the higher surface-area-to-volume ratio of small species, with concomitant high rate of heat loss. To

FIGURE 11-12 Alveolus and associated pulmonary capillaries (mammalian lung). (a) A schematic representation of a detailed electron microscope view of an alveolus and surrounding capillaries. A single layer of flattened Type I alveolar cells forms the alveolar walls. Type II alveolar cells embedded within the alveolar wall secrete pulmonary surfactant. Wandering alveolar macrophages are found within the alveolar lumen. (The size of the cells and respiratory membrane is exaggerated compared to the size of the alveolar and pulmonary capillary lumens. The diameter of an alveolus is actually about 600 times larger than the intervening space between air and blood.) (b) Each alveolus is encircled with a dense network of pulmonary capillaries and therefore surrounded by an almost continuous sheet of blood.

compensate, smaller mammals can take up proportionately more O_2 per unit of body weight than large mammals by (1) reducing the size of each alveolus with a concomitant increase in the density (and thus total surface area) of alveoli, and (2) increasing the density of capillaries for gas exchange. You can see the result in *scaling relationships* that

(a) Analogy of relationship between lung and pleural sac

(b) Relationship of lungs to pleural sacs, thoracic wall, and diaphragm

FIGURE 11-13 Pleural sac. (a) Pushing a lollipop into a water-filled balloon produces a relationship analogous to that between each double-walled, closed pleural sac and the lung that it surrounds and separates from the thoracic wall. (b) Schematic representation of the relationship of the pleural sac to the lungs and thorax. One layer of the pleural sac, the *visceral pleura*, closely adheres to the surface of the lung (*viscus* means “organ”), then reflects back on itself to form another layer, the *parietal pleura*, which lines the interior surface of the thoracic wall (*paries* means “wall”). The relative size of the pleural cavity between these two layers is grossly exaggerated for the purpose of visualization.

© Cengage Learning, 2013

have been determined by actual measurements of lungs. Among mammals, lung volume (V_l , in liters) is directly related to body weight by the equation

$$V_l = 0.035m_b^{1.06}$$

where m_b = body mass (kilograms). The exponent 1.06 tells us that larger mammals actually have slightly *larger* lung volumes per unit mass than do smaller species. However, alveolar surface area (A_a , in cm^2) follows the following relationship:

$$A_a = 119m_b^{0.75}$$

This exponent of 0.75 (3/4) tells us that larger animals have comparably reduced surface areas for gas exchange. This value is also essentially identical to the exponent for basal metabolic rate (as you will see in Chapter 15), showing that gas exchange ability precisely matches metabolic needs.

In addition to the thin, wall-forming Type I cells, the alveolar epithelium also contains **Type II alveolar cells** (Figure 11-12a), which secrete **pulmonary surfactant**, a phospholipoprotein complex that facilitates alveolar expansion (described later). Surfactant can be found in the lungs of amphibians, reptiles, birds, and mammals as well as the gas bladders of fish. Also present within the air sac lumen are defensive *macrophages* (p. 465).

Minute **pores of Kohn** (Figure 11-11b) present in the alveolar walls permit airflow between adjacent alveoli, a process known as **collateral ventilation**. These passageways are especially important in allowing fresh air to enter an alveolus whose terminal conducting airway is blocked because of disease.

A pleural sac separates each lung from the thoracic wall

Mammalian lungs occupy most of the volume of the **thoracic (chest) cavity**, the only other structures in the chest being the heart and associated vessels, the esophagus, the thymus, and some nerves. Separating each lung from the thoracic wall and other surrounding structures is a double-walled, closed sac called the **pleural sac** (Figure 11-13). The interior of the pleural sac is known as the **pleural cavity**. Its size is greatly exaggerated in the illustration to aid visualization; in reality the layers of the sac are in close contact with one another. The surfaces of the pleura secrete a thin **intrapleural fluid**, which lubricates the pleural surfaces as they slide past each other during respiratory movements. The pleural cavity plays a crucial role in the flow of air, as you will see shortly.

Surprisingly, elephants are without a pleural cavity and instead their lungs are surrounded by loose connective tissue. A clue to explain this mystery arises from the chapter opener photograph of the “snorkeling” elephant. Elephants are the only mammal that can remain underwater while breathing at depth, using their trunks as

snorkels. The presence of a pleural cavity would create a significant pressure difference between the interior of the lungs and the blood vessels lining the cavity. Because the vessels would also be exposed to the higher pressures from the surrounding water, the pressure gradient could be sufficient to cause rupture of the vessels (at 2 meters under water, pressure would be about 20% greater than in the lungs). By replacing the pleural membranes with layers of connective tissue minus a vascular component, the loose tissue permits the lung to expand against the chest wall while swimming. Molecular evidence reveals that elephants are related to manatees, while paleontology studies suggest that elephants evolved from an aquatic ancestor to a land animal.

Mammalian lungs are inflated and deflated tidally by cyclical changes in intra-alveolar pressure generated indirectly by respiratory muscles

Now let’s see how ventilatory bulk transport works in mammalian lungs. Alveoli have no muscles to help them inflate and deflate during the breathing process. Moreover, respira-

tory muscles that accomplish breathing do not act directly on the alveoli or even the lung organ to change their volume. Instead, these muscles change the volume of the thoracic cavity, causing a corresponding change in lung volume because the thoracic wall and lungs are linked together by the pleural sac.

Let's follow the changes that occur in a mammal during one respiratory cycle—that is, one breath in (*inspiration*) and out (*expiration*).

Inspiration: Contraction of Inspiratory Muscles Before the beginning of inspiration, the respiratory muscles are relaxed (Figure 11-14a), no air is flowing, and **intra-alveolar pressure** (pressure inside the alveoli) is equal to atmospheric pressure. At the onset of inspiration, these muscles are stimulated to contract, resulting in enlargement of the thoracic cavity. The major *inspiratory muscles* are the *diaphragm* and *external intercostal muscles* (Figure 11-14b):

1. The relaxed **diaphragm** assumes a dome shape that protrudes into the thoracic cavity. When the diaphragm contracts on stimulation by the phrenic nerve, it contracts downward, thereby enlarging the volume of the thoracic cavity (Figure 11-14b). Contraction of the muscular diaphragm can account for up to two thirds of the increase in pulmonary volume in mammals.
2. Whereas contraction of the diaphragm enlarges the thoracic cavity in the vertical dimension, contraction of the **external intercostal muscles**, whose fibers run downward and forward between adjacent ribs, enlarges the thoracic cavity in both the lateral (side-to-side) and anteroposterior (front-to-back) dimensions (Figure 11-14b). They do so by expanding the ribs and subsequently the sternum outward.

Exhalation: Elastic Recoil and Relaxation of Inspiratory Muscles At the end of inspiration (Figure 11-14c), the inspiratory muscles relax. The diaphragm rebounds to its original dome-shaped position as it relaxes; the expanded rib cage contracts when the external intercostals relax; and the chest wall and stretched lungs recoil to their pre-inspiratory size because of their elastic properties, much as a stretched balloon would on release (we will examine recoil properties on p. 520). As the lungs become smaller in volume, the intra-alveolar pressure rises because the greater number of air molecules contained within the larger lung volume at the end of inspiration are now compressed into a smaller volume. Air now leaves the lungs down its pressure gradient. Outward flow of air ceases when intra-alveolar pressure becomes equal to atmospheric pressure.

Exhalation: Contraction of Expiratory Muscles In most mammals, the inspiratory and expiratory phases are cyclical and smooth. Expiration in humans is normally a *passive* process during quiet breathing because it is accomplished by elastic recoil of the lungs on relaxation of the inspiratory muscles, with no muscular exertion or energy expenditure required. In contrast, inspiration is *active* because it is brought about by contraction of inspiratory muscles at the expense of energy use. To empty the lungs more completely and more rapidly than is accomplished during quiet breathing, as during the deeper breaths accompanying locomotory activity, expiration does become active in mammals. The intra-alveolar pressure

must be increased even further above atmospheric pressure than can be accomplished by simple relaxation of the inspiratory muscles and elastic recoil of the lungs. To produce such a **forced**, or **active expiration**, two sets of **expiratory muscles** must contract to further reduce the volume of the thoracic cavity and lungs (Figure 11-14d):

1. The most important expiratory muscles are the **abdominal wall muscles**. As the abdominal muscles contract, the resultant increase in intra-abdominal pressure exerts a force on the diaphragm, pushing it further into the thoracic cavity than in its relaxed position, thus decreasing the vertical dimension of the thoracic cavity even more.
2. The other expiratory muscles are the **internal intercostal muscles**, whose contraction pulls the ribs inward, flattening the chest wall and further decreasing the size of the thoracic cavity; this action is antagonistic to that of the external intercostal muscles (Figure 11-14b, c). These muscles increase the differential between intra-alveolar and atmospheric pressure above that of passive expiration, so more air leaves down the pressure gradient before equilibration is achieved. In this way, the lungs are emptied more completely during forceful, active expiration than during quiet, passive expiration.

This general pattern of respiration is somewhat different in the horse, where both the inspiratory and expiratory phases have two separate components even at rest. Inspiration begins from passive recoil but rapidly becomes an active process with contributions from the diaphragm, external intercostals, and (again in horses) the *triangularis sterni* connected to the sternum. Similarly expiration begins passively by recoil and rapidly becomes active as the internal intercostals and abdominal muscles become involved. This pattern of respiration occurs because a portion of the energy spent during both active inspiration and expiration is stored and used as passive recoil energy to initiate the subsequent breathing cycle. Both inspiration and expiration thus have an active as well as a passive component.

Ventilation and gas exchange are separated in avian respiratory systems due to air sacs and parabronchi with air capillaries

Finally, let's see how the most complex vertebrate lung works. A greater efficiency is achieved in birds compared to mammals due to a complete *separation of ventilation and gas-exchange functions*. In contrast to those of mammals, the lungs of birds only perform gas exchange and are comparatively small and inelastic (and thus do not change in volume during the respiratory cycle). Instead, ventilation arises from expandable **air sacs** (Figure 11-15a, b) that perform a bellowslike tidal function comparable to the mammalian lung but without gas exchange. As you will see, this separation of function allows tidal flow to be converted into a flow-through pattern in the lungs, which results in an increase in exchange efficiency.

Again, air enters the nasal passages, the trachea, and bronchi. The tracheal volume of a bird is considerably larger than that of a comparably sized mammal. To perform some functions assigned to forelimbs, birds can have necks up to threefold longer than mammals of comparable body size.

(a) Before inspiration

(b) Inspiration

(c) Passive expiration

(d) Active expiration

FIGURE 11-14 Respiratory muscle activity during inspiration and expiration in a human. (a) Before inspiration, all respiratory muscles are relaxed. (b) During *inspiration*, the diaphragm descends on contraction, increasing the vertical dimension of the thoracic cavity. Contraction of the external intercostal muscles elevates the ribs and subsequently the sternum to enlarge the thoracic cavity from front to back and from side to side. (c) During *quiet passive expiration*, the diaphragm relaxes, reducing the volume of the thoracic cavity from its peak inspiratory size. As the external intercostal muscles relax, the elevated rib cage falls because of the force of gravity. This also reduces the volume of the thoracic cavity. (d) During *active expiration*, contraction of the abdominal muscles increases the intra-abdominal pressure, exerting an upward force on the diaphragm. This reduces the vertical dimension of the thoracic cavity further than it is reduced during quiet passive expiration. Contraction of the internal intercostal muscles decreases the front-to-back and side-to-side dimensions by flattening the ribs and sternum.

Wang, R. B. Banzett, C. S. Nations, & F. A. Jenkins, Jr. (1992). An aerodynamic valve in the avian primary bronchus. *J. Exp. Zool.* 262: 441–445.

The longer trachea increases the resistance to airflow, but this is compensated, in part, by an increase in the radius of the trachea. For this reason the resistance to tracheal airflow in birds is similar to a mammal of similar body weight.

Within each lung a bronchus gives rise to several sets of secondary bronchi, named according to the regions of the lung that they supply. The most important groups include the *ventrobronchi* and the *dorsobronchi*. As in alligators, the secondary bronchi are connected to each other by a number of *parabronchi* from which the **air capillaries** (gas exchange surface) originate (Figure 11-15c). Parabronchi interconnect freely with each other and tend to have a constant internal diameter, ranging from 0.5 mm in hummingbirds to approximately 2 mm in chickens. Parabronchi are cylindrical and run in parallel with each other (shown schematically in Figure 11-15b). Comparable to the bronchial muscles of mammals, smooth muscles lining the parabronchus are innervated and regulate the diameter of the parabronchi.

Together, the secondary bronchi and their interconnecting parabronchi form an integrated unit that enables flow-through air movement. Airflow is from the dorsobronchi, through the parabronchi and air capillaries, to the ventrobronchi. Recall that flow-through systems are more efficient; in-

deed, in birds air is not diluted with “old” air as in mammalian alveoli. Shortly you will see how the airflow is achieved.

Air Capillaries In birds, the air capillaries form an extensive network of air-carrying tubules jacketed with a profuse network of blood capillaries. A comparison of the gas exchange surfaces between birds (Figure 11-15c) and mammals (Figure 11-11a) reveals the following:

1. **Narrow size:** The diameter of an air capillary varies from only 3 μm in songbirds to 10 μm in swans and penguins, compared to the 35 μm of alveoli in the smallest mammals. The mean thickness of the epithelial cells lining the air capillaries is also lower than in alveoli. Thus, the diffusion distance ΔX is at least 30% less than in mammals.
2. **Flow-through:** Air capillaries are not blind ending; rather, they freely anastomose (connect) with each other. This allows air to flow through in one direction.
3. **Rigidity:** Unlike alveoli, the diameter of air capillaries does not change significantly during the respiratory cycle. This allows them to be rigid and thus to resist damage more effectively than alveoli can. Galloping horses,

FIGURE 11-16 The movement of pure nitrogen (N_2 ; shaded) through the avian lung. N_2 is used as an inert tracer. Two complete cycles of inspiration and expiration are required to move a specific volume of air through the avian respiratory system. (a) During the first inspiration most of the N_2 flows directly to the abdominal air sacs. Although the cranial sacs also expand on inhalation, they do not receive any of the inhaled N_2 . (b) On the first exhalation, nitrogen from the abdominal air sacs flows into the gas-exchanging parabronchi. (c) On the subsequent inhalation, N_2 from the lung now moves into the cranial air sacs. (d) Finally, on the second exhalation, N_2 from the cranial air sacs flows through the trachea to the outside.

Source: K. Liem, W. Bemis, W. F. Walker, & L. Grande. (2001). *Functional Anatomy of the Vertebrates: An Evolutionary Perspective*, 3rd ed. Belmont, CA: Brooks/Cole, p. 594, Figure 18-18.

for example, often suffer ruptured alveolar blood capillaries due to the stretch-recoil action of alveoli, but birds do not have such problems.

4. **Greater blood volume:** The volume of the pulmonary-capillary blood per gram of body weight is approximately 20% greater in birds.

Air Sacs In most birds the air sacs arise in the embryo from six primordial pairs of sacs, two of which fuse at the time around hatch. Thus, there are eight air sacs in the adult domestic fowl: one cervical and one clavicular sac, two cranial thoracic and two caudal thoracic sacs in addition to the two abdominal sacs. Functionally, though, there are two groups of air sacs (Figure 11-15a, b), an *anterior* (or *cranial*) group and a *posterior* (or *caudal*) group. The anterior group consists of several smaller sacs that connect with the ventrobronchi and receive expelled air from the lungs, whereas the posterior group, which includes the comparatively large abdominal sacs, connects to the caudal end of the main bronchus and receives relatively fresh air from the trachea. Because the blood supply to the air sacs is essentially negligible, no gas exchange occurs across this surface (as we noted earlier). Air sacs are held open by their attachment to the structures that surround them and occasionally even penetrate the medullary (inner portion) cavities of some bones. The air sacs are also a common site of disease in birds. Generally, inspired pathogens lodge in the posterior air sacs because of their role in receiving freshly inspired air.

Flow-through breathing plus crosscurrent blood flow enhances gas exchange in birds

Now let us see how these structures achieve efficient gas exchange. First, the sacs must inflate and deflate tidally, much like mammalian lungs. Birds do not have a muscular diaphragm but instead have a **membranous diaphragm** that is attached to the body wall by muscles. Birds rely primarily

on a highly modified costal (rib) movement in association with a well-developed sternum (the long, flat breastbone) to power air-sac ventilation. In addition, in some species of birds the joints of the ribs permits fore-aft movement of the rib cage during ventilation. As a result, avian ribs rotate such that the posterior end of the sternum is depressed on inhalation and generates negative intra-abdominal pressures that helps fill the comparatively large abdominal air sacs.

Although they do not need to be as efficient as fishes because air is a much better medium for oxygen uptake, birds do require greater efficiency than mammals because of their higher metabolisms. This occurs at three levels:

1. **Narrower diffusion distance between air and blood capillaries**, as described earlier.
2. **Flow-through movement in the parabronchi and air capillaries.** What is particularly intriguing about bird respiration is precisely how the ventilatory muscles and air sacs are coordinated in order to achieve this highly efficient means of gas exchange. To comprehend this process, let's follow the passage of an inert component such as N_2 through the avian respiratory system (Figure 11-16). The inhaled N_2 gas is initially mixed with gases present in the dead air space of the trachea and primary bronchus of each lung. Then the posterior air sacs inflate for the first inspiration, and the N_2 flows into these air sacs (Figure 11-16a). Gases in these air sacs are rich in O_2 and relatively low in CO_2 . The posterior sacs initiate the first expiration, with valving that directs the flow with the N_2 into the gas-exchanging parabronchi region of the lung (Figure 11-16b). Here the composition of the respiratory gases is modified to suit the metabolic needs of the bird. Next, the anterior sacs inflate to create a second inspiration, with the N_2 gas now drawn into those air sacs (Figure 11-16c). Finally, with second expiration resulting from the anterior sacs and valving control, the gas is expelled to the outside atmosphere (Figure 11-16d). Thus,

FIGURE 11-17 Crosscurrent flow in the avian parabronchus. Air (in turquoise) enters a parabronchus with a high P_{O_2} at the inhalation side on the right (P_i), and is exhaled with a low P_{O_2} (P_E). Blood enters on the left with low P_{O_2} (blue color at P_v) then branches to run along air capillaries at a right angle to the parabronchus. Each successive branch picks up more gas because the air capillaries have successively increasing P_{O_2} levels, much as in the fish countercurrent system. Blood then leaves with a relatively high P_{O_2} (red color at P_a).

Source: Modified from P. Scheid, (1979). Mechanisms of gas exchange in bird lungs. *Rev. Physiol. Biochem. Pharmacol.* 86:137–186.

in birds, it requires two complete respiratory cycles to move air through the entire system. This remarkable pattern of gas flow through the avian lung is achieved through both aerodynamic mechanisms and valving properties of the air sacs. The end result is that gas flow is continuous and unidirectional from the mediadorsals through the parabronchi to the medioventrals.

The nature of the valving that ensures unidirectional flow is still not fully understood. There are no muscular sphincter valves that shut off flow. However there is evidence for *aerodynamic valving*, in which a bronchial constriction before a junction increases air velocity, much as narrowing a nozzle increases the speed of water out of a garden hose (see the *segmentum accelerans* (Figure 11-15b). The higher velocity air then jets past the inappropriate joining tubes without entering them.

3. **Crosscurrent blood flow at the parabronchus.** The anatomic arrangement of airflow through the gas-exchanging air capillaries in concert with the surrounding blood capillary network is such that blood flow approaches the parabronchus at approximately right angles, providing a **crosscurrent** system of gas exchange (Figure 11-17). Blood in the capillaries becomes oxygenated to varying degrees depending on how far along the parabronchus the blood capillary is located. As in fish gills (Figure 11-6f), and in contrast to alveoli (Figure 11-11c), the arterial blood P_{O_2} is actually *higher* than expired P_{O_2} because arterial blood P_{O_2} results from the mixing of the blood from the differently oxygenated blood capillaries (Figure 11-17).

unanswered Questions | Soaring birds from Saurischian dinosaurs?

The unique bird respiratory system has traditionally been thought to have evolved in concert with the energetic demands of flight. However, the recent finding of birdlike lungs in alligators (p. 507)

and recent fossil evidence suggest a different origin. Certain bones of flightless Saurischian dinosaurs such as *Haplocanthosaurus* had large holes very similar to the ones in bird bones that house their air sacs. Jonathan Codd, Phil Manning, and colleagues have also found that carnivorous Saurischians called *theropods*—from which birds are descended—had small birdlike bones that moved the ribs and sternum for breathing (an example was the feathered cheetah-like *theropod Velociraptor*).

Theropods also had a diaphragmaticus muscle for respiration like crocodiles. Moreover, Saurischians first evolved during a period (175–275 million years ago) when atmospheric O_2 levels were at about half of that found today. Paleontologist Peter Ward has hypothesized that Saurischians had birdlike flow-through ventilation, making them better adapted than mammals at gas exchange in that low- O_2 world. Perhaps birds owe their ability to soar over mountaintops in our current high O_2 era to these flightless progenitors who lived at sea level with O_2 levels equivalent to today's mountaintops. <<

Aerial respiratory systems can perform numerous nonrespiratory functions

As with gills, lungs and other respiratory structures can have nonrespiratory functions:

1. **Regulation of water loss and heat exchange.** Venous blood originating from the walls of the nasal passages can cool the arteries that supply the brain during intense activity. Inspired atmospheric air is humidified and warmed by the respiratory airways. Moistening of inspired air is essential to prevent the respiratory surfaces from drying out. O_2 and CO_2 cannot diffuse through dry membranes. The *maxilloturbinals* are especially effective for both purposes (Chapter 15, p. 745).

(a) Mammalian larynx (dog)

FIGURE 11-18 The mammalian larynx and avian syrinx. (a) The mammalian larynx sits at the junction of the pharynx and trachea, where it keeps food from entering the latter, and has folds for sound production. (b) The avian syrinx sits at the trachea–bronchi junction, and is also involved in sound production.

(b) Bird syrinx

2. *Circulation*—enhancement of venous return (see the “respiratory pump,” p. 448).
3. *Acid–base balance*—the maintenance of normal acid–base balance by altering the amount of H^+ -generating CO_2 exhaled (Chapter 13, p. 642).
4. *Defense* against inhaled foreign matter (Chapter 10, p. 467).
5. *Removal, modification, activation, or inactivation of various materials* passing through the pulmonary circulation. All blood returning to the heart from the tissues must pass through the avian and mammalian lungs before being returned to the systemic circulation. The lungs, therefore, are uniquely situated to partially or completely remove specific materials that have been added to the blood at the tissue level before they have a chance to reach other parts of the body. For example, *prostaglandins*, a collection of chemical messengers released in numerous tissues to mediate particular local responses, may spill into the blood, but they are inactivated during passage through the lungs so that they cannot exert systemic effects. In contrast, the lungs generate *angiotensin II*, a hormone that plays an important role in regulating both blood pressure as well as the concentration of Na^+ in the extracellular fluid (p. 587).

6. **Olfaction.** The nose has chemoreceptors for airborne odorants (Chapter 6, p. 236).
7. **Sounds: Vocalization, warning and mating calls, and so on.** In mammals, the **larynx** (or **voicebox**) at the tracheal entrance (Figure 11-18a) is a set of cartilage folds that helps prevent food from entering the trachea (though not as effectively in a few species, including many aquatic mammals, red deer, and adult humans, in which the larynx descends down the trachea). The larynx also has vibrating **vocal folds or cords** that allow for modulation of air flow for the production of sounds. The **laryngeal nerve**, which controls the larynx, illustrates the historical and often illogical nature of evolution. This nerve evolved as a branch from a fish vagus nerve running from the brain directly to the gills. As a branch evolved to the larynx in an early terrestrial vertebrate, it turned back up to the neck. In a giraffe, this illogical feature results in a looping 6-meter (20-foot) nerve from the brain down to near the lungs and then nearly all the way back up!

Unlike the larynx, the **syrix** of birds lies at the exit of the trachea (Figure 11-15b) and generally consists of both tracheal and bronchial contributions (Figure 11-18b). Normally, three to six rings at the base of the trachea are enlarged and form a rigid structure termed the **tympanum**. The upper three rings of each bronchus are also enlarged, and together the composite structure is supplied with muscles, air sacs, and vibrating membranes. The entrance to each bronchus is constricted by a narrow slit, the so-called **tympanic membrane**, and the extent of opening is subject to variable muscle tension from the **syrixal muscles**. Air pressure generated from the lungs and air sacs sets the tympanic membrane in motion, and the syrix operates as a valve that regulates both pitch and volume. The complexity of a bird's song is closely related to the number of syrixal muscles that connect with the various rings and assorted membranes. Several species of birds, including vultures, storks, and ostriches, lack any syrixal muscles, whereas true songbirds have around five pairs. Because each bronchus has its own tympanic membrane and the muscles are innervated separately, it is possible for some species, such as the wood thrush (*Hylocichla mustelina*), to simultaneously sing notes of separate frequencies. Contributing to vocalization in some species (swans, geese, and cranes) are tracheae of exceptional length. In the whooping crane (*Gus americana*), the trachea is almost as long as the bird itself and serves as a resonating tube to amplify its vocalization. More powerful vocalizations are evidence of "fitness," which increase the male's likelihood of attracting a mate and passing on its genes.

This completes our overview of respiratory systems. In the following sections, we delve into each of the steps of Figure 11-1 in greater detail, beginning with breathing.

11.5 Breathing: Respiratory Mechanics in Mammals

In this section, we examine details of the mechanics involved in breathing (step 1, Figure 11-1) in more depth, focusing primarily on mammals.

Interrelationships among atmospheric, intra-alveolar, and intrapleural pressures are important in respiratory mechanics of mammals

Recall that air flows in and out of mammalian lungs during the act of breathing by moving down alternately reversing pressure gradients, established between the lungs and the atmosphere by cyclical respiratory-muscle activity. Let's look at this more closely. Three different pressure considerations are important in ventilation (Figure 11-19a):

1. **Atmospheric (barometric) pressure** is the pressure exerted by the weight of the air in the atmosphere on objects on Earth's surface. At sea level it equals 760 mm Hg or 1 atmosphere (atm) or 101.3 kilopascals (Figure 11-2a). Atmospheric pressure diminishes with increasing altitude above sea level (Table 11-1), and minor fluctuations occur at any height because of changing weather conditions (as you can see using a barometer).
2. **Intra-alveolar pressure** was defined earlier (p. 511). Because the lung communicates with the atmosphere through the conducting airways, air quickly flows down its pressure gradient any time this pressure differs from atmospheric pressure; the airflow continues until the two pressures equilibrate.
3. **Intrapleural pressure** is the pressure exerted outside the lungs within the thoracic cavity, that is, within the pleural sac. This pressure is usually less than atmospheric pressure, averaging 756 mm Hg at rest (4 mm Hg less). Intrapleural pressure does not equilibrate with atmospheric or intra-alveolar pressure, because there is no direct communication between the pleural cavity and either the atmosphere or the lungs.

The lungs are normally stretched to fill the larger thorax

The thoracic cavity is larger than the unstretched lungs because the thoracic wall grows more rapidly than the lungs during development. However, two forces—the intrapleural fluid's cohesiveness and the **transmural pressure gradient**—hold the thoracic wall and lungs in close apposition, stretching the lungs to fill the larger thoracic cavity:

1. **Intrapleural fluid's cohesiveness:** The polar water molecules in the intrapleural fluid resist being pulled apart because of their attraction to each other. The resultant cohesiveness of the intrapleural fluid tends to hold the pleural surfaces together. Thus, the intrapleural fluid can be considered very loosely as a "glue" between the lining of the thoracic wall and the lung. If you ever tried to pull apart two glass slides held together by a thin layer of liquid, you know that the two surfaces act as if the thin layer of water sticks them together. Even though you can easily slip the slides back and forth relative to each other

Numbers are mm Hg pressure.

(b) Transmural pressure gradient

FIGURE 11-19 Pressure and mammalian lung inflation.

(a) Atmospheric, intra-alveolar and intrapleural pressures. (b) Across the lung wall, the intra-alveolar pressure of 760 mm Hg pushes outward, while the intrapleural pressure of 756 mm Hg pushes inward. This 4-mm Hg difference in pressure constitutes a transmural pressure gradient that pushes out on the lungs, stretching them to fill the larger thoracic cavity. Across the thoracic wall, the atmospheric pressure of 760 mm Hg pushes inward, while the intrapleural pressure of 756 mm Hg pushes outward. This 4-mm Hg difference in pressure constitutes a transmural pressure gradient that pushes inward and compresses the thoracic wall.

© Cengage Learning, 2013

(just as the intrapleural fluid facilitates movement of the lungs against the interior surface of the chest wall), you can pull the slides apart only with great difficulty because the molecules within the intervening liquid resist being separated. This relationship is partly responsible for the fact that changes in thoracic dimension are always accompanied by corresponding changes in lung dimension; that is, when the thorax expands, the lungs, being stuck

to the thoracic wall by virtue of the intrapleural fluid's cohesiveness, do likewise.

2. **Transmural pressure gradient:** An even more important reason that the lungs follow the movements of the chest wall are the **transmural pressure gradient** that exists across the lung and thoracic walls (*trans*, “across”; *mural*, “wall”) (Figure 11-19b). First, intra-alveolar pressure at 760 mm Hg is greater than the intrapleural

FIGURE 11-20 Boyle's law. Each container has the same number of gas molecules. Given the random motion of gas molecules, the likelihood of a gas molecule striking the interior wall of the container and exerting pressure varies inversely with the volume of the container at any constant temperature. The gas in container B exerts more pressure than the same gas in larger container C but less pressure than the same gas in smaller container A. This relationship is stated as Boyle's law: $P_1V_1 = P_2V_2$. As the volume of gas increases, the pressure of the gas decreases proportionately; conversely, the pressure increases proportionately as the volume decreases.

© Cengage Learning, 2013

pressure of 756 mm Hg, so a greater pressure is pushing outward than is pushing inward across the lung wall. This net outward pressure differential, the lung-wall transmural pressure gradient, pushes out on the lungs, stretching or distending them (Figure 11-19b). Because of this pressure gradient, the lungs are always forced to expand to fill the thoracic cavity.

Second, external atmospheric pressure pushing inward on the thoracic wall is again greater than the intrapleural pressure of 756 mm Hg, creating a thoracic-wall transmural pressure that tend to “squeeze in” or compress the chest wall compared to what it would be in an unrestricted state. The effect of the lung-wall transmural pressure gradient is much more pronounced, however, because the highly distensible lungs are influenced by this modest pressure differential to a much greater extent than is the more rigid thoracic wall.

Because neither the lungs nor the thoracic wall are in their natural position when they are held in apposition to each other, they constantly try to assume their own inherent dimensions. The stretched lungs have a tendency to pull inward away from the thoracic wall, whereas the compressed thoracic wall tends to move outward away from the lungs. The transmural pressure gradient and intrapleural fluid's cohesiveness, however, prevent these structures from pulling away from each other except to the slightest degree. Even so, the resultant ever-so-slight expansion of the pleural cavity is sufficient to drop the pressure in this cavity by 4 mm Hg to the subatmospheric value of 756 mm Hg.

In summary, the lungs are stretched and the thorax is compressed because a transmural pressure gradient exists across their walls as a result of the presence of a subatmospheric intrapleural pressure. The intrapleural pressure, in turn, is subatmospheric because the stretched lungs and

compressed thorax tend to pull away from each other, slightly expanding the pleural cavity.

Intrapleural and lung pressures decrease during inhalation and increase during exhalation

Because air flows down a pressure gradient, for air to flow into the lungs during inspiration the intra-alveolar pressure must be less than atmospheric pressure. Similarly, the pressure gradient must reverse during expiration. Altering the volume of the lungs, in accordance with Boyle's law, can change intra-alveolar pressure. Boyle's law states that at any constant temperature, the pressure exerted by a gas varies inversely with the volume of the gas (Figure 11-20).

Just before inspiration, intra-alveolar pressure is equal to atmospheric pressure so no air is flowing into or out of the lungs (Figure 11-21a). As the thoracic cavity expands, the intrapleural pressure falls from 756 to 754 mm Hg because the same number of air molecules now occupy a larger lung volume. Thus, the lungs are forced to expand to fill the larger thoracic cavity, typically causing the intra-alveolar pressure to drop 1 mm Hg to 759 mm Hg (Figure 11-21b). Because this is now less than atmospheric pressure, air flows into the lungs until intra-alveolar pressure equals atmospheric pressure.

In a resting expiration, as the lungs and diaphragm recoil, the intra-alveolar pressure increases about 1 mm Hg above atmospheric level to 761 mm Hg (Figure 11-21c). Now air flows outwards from the lungs to the environment.

Respiratory diseases often increase airway resistance

In Chapter 9, we discussed how fluid flow depends on both the pressure gradient and resistance ($\text{flow} = \Delta P/R$; see p. 419). This is true of airflow as well as blood flow. In a

FIGURE 11-21 Changes in lung volume and intra-alveolar pressure during inspiration and expiration (mammalian lung). (a) Before inspiration, at the end of the preceding expiration. Intra-alveolar pressure is equilibrated with atmospheric pressure and no air is flowing. (b) Inspiration. As the lungs increase in volume during inspiration, the intra-alveolar pressure decreases, establishing a pressure gradient that favors the flow of air into the alveoli from the atmosphere; that is, an inspiration occurs. (c) Expiration. As the lungs recoil to their pre-inspiratory size on relaxation of the inspiratory muscles, the intra-alveolar pressure increases, establishing a pressure gradient that favors the flow of air out of the alveoli into the atmosphere; that is, an expiration occurs.

© Cengage Learning, 2013

healthy respiratory system, the radius of the conducting system is sufficiently large that resistance remains extremely low. Therefore, the pressure gradient between the alveoli and the atmosphere is usually the primary factor determining the airflow rate. Indeed, the airways normally offer such low resistance that only very small pressure gradients of 1 to 2 mm Hg need be created to achieve adequate rates of airflow in and out of the lungs. However, various respiratory diseases can narrow the airways such that resistance becomes a limiting factor. For example, **chronic obstructive pulmonary disease (COPD)** is a group of human lung diseases (including *chronic bronchitis*, *asthma*, and *emphysema*) characterized by increased airway resistance resulting from the narrowing of the lumen of the lower airways. Other mammals can develop similar diseases, such as *equine restrictive lung diseases* in horses. When airway resistance increases, a larger pressure gradient must be established to maintain even a normal airflow rate. Accordingly, mammals with such diseases must work harder to breathe.

Elasticity in mammalian lungs depends on connective tissue and alveolar surface tension, which is reduced by surfactant

The term **elastic recoil** refers to how readily the lungs rebound after having been stretched. It is responsible for the lungs returning to their pre-inspiratory volume when the inspiratory muscles relax at the end of inspiration. Elastic recoil depends mainly on two factors: highly elastic connective tissue in the lungs and alveolar surface tension:

1. **Elastin:** Pulmonary connective tissue contains large quantities of *elastin* fibers (see p. 65). Not only do these fibers exhibit elastic properties themselves, but they are

arranged into a meshwork that amplifies their elastic behavior, much like the threads in a piece of stretch-knit fabric. These rebound to a smaller length after being stretched.

2. **Alveolar surface tension:** An even more important factor influencing elastic behavior of the lungs is the **alveolar surface tension** displayed by the thin liquid film that lines each alveolus. At an air–water interface, the water molecules at the surface are more strongly attracted to other surrounding water molecules than to the air above the surface. This unequal attraction produces a force known as *surface tension* at the surface of the liquid. Surface tension is responsible for a twofold effect. First, the liquid layer resists any force that increases its surface area; that is, it opposes expansion of the alveolus because the surface water molecules oppose being pulled apart. Accordingly, the greater the surface tension, the less compliant the lungs. Second, the liquid surface area tends to become as small as possible because the surface water molecules, being preferentially attracted to each other, try to get as close together as possible. Thus, the surface tension of the liquid lining an alveolus tends to reduce the size of the alveolus, squeezing in on the air within it (Figure 11-22). This property, along with the rebound of the stretched elastin fibers, is responsible for the lungs' elastic recoil back to their pre-inspiratory size after inspiration.

However, there is a problem. The cohesive forces between water molecules are so strong that if the alveoli were lined with water alone, the surface tension would be so great that the lungs would collapse; the recoil force attributable to the elastin fibers and high surface tension would exceed the opposing stretching force of the transmural pressure gradient. Furthermore, the lungs would be very poorly compliant, so exhausting

FIGURE 11-22 Alveolar surface tension (mammalian lung). The attractive forces between the water (H_2O) molecules in the liquid film that lines the alveolus are responsible for surface tension. Because of its surface tension, an alveolus (1) resists being stretched, (2) tends to be reduced in surface area or size, and (3) tends to recoil after being stretched.

© Cengage Learning, 2013

muscular efforts would be required to accomplish stretching and inflation of the alveoli.

Pulmonary Surfactant The tremendous surface tension of pure water is normally counteracted by pulmonary surfactant, a detergent-like mixture of lipids and proteins secreted by the Type II alveolar cells (Figure 11-12a) in response to mechanical stimulation and autonomic nerves. Pulmonary surfactant intersperses between the water molecules in the fluid lining the alveoli and lowers the alveolar surface tension because the cohesive force between a water molecule and an adjacent pulmonary surfactant molecule is very low. This provides two important benefits: (1) It increases pulmonary compliance, thus reducing the work of inflating the lungs; and (2) it reduces (but does not eliminate) the lungs' tendency to recoil so that they do not collapse as readily.

Pulmonary surfactant's role in reducing the alveoli's tendency to recoil, thereby discouraging alveolar collapse, is important in helping maintain lung stability. The division of the lung into a myriad of tiny air sacs provides the advantage of a tremendously increased surface area for the exchange of O_2 and CO_2 , but it also presents the problem of maintaining the stability of all these alveoli. Recall that the pressure generated by alveolar surface tension is directed inward, squeezing in on the air in the alveoli. If the alveoli are visualized as spherical bubbles, according to **LaPlace's law**, the magnitude of the inward-directed collapsing pressure is directly proportional to the surface tension and inversely proportional to the radius of the bubble:

$$P = 2T/r$$

where P is the inward-directed collapsing pressure; T is the surface tension; and r is the radius of bubble (alveolus) (Figure 11-23). Because the collapsing pressure is inversely pro-

portional to the radius, the smaller the alveolus, the greater its tendency to collapse at a given T . Accordingly, if two alveoli of unequal size but the same T are connected by the same terminal airway, the smaller alveolus—because it generates a larger collapsing pressure—has a tendency to collapse and empty its air into the larger alveolus (Figure 11-23a). This does not normally happen, however, because pulmonary surfactant reduces the surface tension of small alveoli more than it reduces it in larger ones. This is because the surfactant molecules are more densely packed together in the smaller alveoli. The surfactant-induced lower T of small alveoli offsets the effect of their smaller radii in determining the inward-directed pressure. Therefore, the presence of surfactant causes the collapsing pressure of small alveoli to become comparable to that of larger alveoli and minimizes the tendency for small alveoli to collapse (Figure 11-23b).

In nonmammals surfactant functions as an “antiglue” that prevents adhesion of adjacent respiratory surfaces close to each other. Complete collapse of the lung occurs at the end of expiration in a variety of species including sea snakes and some small frogs. Without surfactant, inspiration after lung collapse would be costly in terms of energy expenditure. Moreover, as body temperature decreases, lung volumes in a lizard are reduced and contact of the respiratory surfaces within the lung are increased. Surfactant is thus essential in this situation to prevent adhesion of the surfaces. The cooler ambient temperatures trigger the release of surfactant via cholinergic stimulation of the Type II cells.

11.6 Breathing: Lung Volumes in Mammals

Next we turn to details of lung dynamics and volume changes that occur in mammalian respiratory cycles.

Changes in lung volumes are important for analyzing different respiratory efforts, disease states, aerobic activity capacities, and species differences

Let's begin with key volume measurements that are often made for a respiratory cycle.

Methodology: The Spirometer Lung volumes have traditionally been measured with a **spirometer**. Spirometric measurements can be obtained from trained or anesthetized animals wearing a mouthpiece appropriate to their anatomy. Basically, a spirometer consists of an air-filled inverted drum

Law of LaPlace:
Magnitude of inward-directed pressure (P) in a bubble (alveolus) = $\frac{2 \times \text{Surface tension } (T)}{\text{Radius } (r) \text{ of bubble (alveolus)}}$

FIGURE 11-23 Role of pulmonary surfactant in counteracting the tendency for small alveoli to collapse into larger alveoli. (a) According to the law of LaPlace, if two alveoli of unequal size but the same surface tension are connected by the same terminal airway, the smaller alveolus—because it generates a larger inward-directed collapsing pressure—has a tendency (without pulmonary surfactant) to collapse and empty its air into the larger alveolus. (b) Pulmonary surfactant reduces the surface tension of a smaller alveolus more than that of a larger alveolus. This reduction in surface tension offsets the effect of the smaller radius in determining the inward-directed pressure. Consequently, the collapsing pressures of the small and large alveoli are comparable. Therefore, in the presence of pulmonary surfactant, a small alveolus does not collapse and empty its air into the larger alveolus.

floating in a water-filled chamber. As the animal breathes air in and out of the drum through a tube connecting the mouth to the air chamber, the drum rises and falls in the water chamber (Figure 11-24). This rise and fall can be recorded as a **spirogram**, which is calibrated to volume changes (typically analysed by a computer). Spirograms yield several lung volumes and **capacities** (sums of two or more lung volumes), as shown in Figure 11-25 and defined below. Figure 11-25a shows total capacity and resting volume for an average human male (generally the values are lower for females). Let's now look at the significances of these and other volumes and capacities.

Volumes and Capacities Most mammals have similar respiratory cycles, although the volumes and capacities can differ greatly among species. Figure 11-25b is a hypothetical example of a spirogram and a table of values for a healthy young human compared a healthy young horse. Let us compare them:

1. **Total lung capacity, or TLC**—the maximum amount of air that the lungs can hold. On average, in healthy young horses this is about 42 L, whereas it is only about 5.7 L in humans. Within a species, anatomic build, age, distensibility of the lungs, and presence or absence of

FIGURE 11-24 Spirometry in animals. A spirometer is a device that measures the volume of air breathed in and out; it consists of an air-filled drum floating in a water-filled chamber. A tracheal catheter is placed in an anesthetized animal (or trained animals are fitted with an appropriately sized mask). Initially, the animal breathes outside air until adapted to the procedure. A valve is closed, and breathing continues into an oxygen-filled reservoir. Carbon dioxide is absorbed, and the amount of O₂ consumed is computed from the recording. As the animal breathes in and out of the drum, the resultant rise and fall of the drum are recorded as a spirogram, which is calibrated to the magnitude of the volume change. Modern spirometers record the output on a computer.

respiratory disease all affect TLC. However, not all this air can be exchanged.

2. **Tidal volume, or TV**—the volume of air entering or leaving the lungs during a single breath. The resting TV (**rTV**) is a common measurement. During each typical breath at rest, a horse inspires about 4 to 6 L (0.4 to 0.5 L in humans) of air, and the same quantity is expired, so during quiet breathing the lung volume varies between 24 L (2.2 L in humans) at the end of expiration to 30 L (2.7 L in humans) at the end of inspiration. In most mammals, rTV is about 10 to 14% of TLC.
3. **Functional residual reserve, or FRC**—the volume of air in the lungs at the end of a normal passive expiration. Normally, during quiet breathing, the lungs are not close to maximal inflation, nor are they deflated to their minimum volume. Thus, the lungs normally remain moderately inflated throughout the respiratory cycle. At the end of a normal quiet expiration, the lungs still contain about 24 L (2.2 L in humans) of air.
4. **Residual volume, or RV**—the minimum volume of air remaining in the lungs even after a maximal expiration. During maximal expiration, lung volume can be decreased to 12 L (1.2 L in humans), but the lungs can never be completely deflated because the small airways collapse during forced expirations at low lung volumes, blocking further outflow of air. This results in:
5. **Vital capacity, or VC**—the maximum volume of air that can be moved out during a single breath following a maximal inspiration. It is rarely used because the maximal muscle contractions involved become exhausting, but it is useful in ascertaining the functional capacity of the lungs. For the average horse it is 30 L (4.5 L in hu-

mans). VC declines in many lung diseases such as asthma.

The inability to empty the lungs completely is a drawback because fresh inspired air is mixed with the large volume of old air remaining in the lungs (FRC during rest, RV during maximal activity), reducing the O₂ partial pressure. However, as we will explain later (p. 528), this does have the benefit of preventing wide fluctuations in gas exchange. Furthermore, recall that it takes less effort to inflate a partially inflated alveolus than a totally collapsed one.

Alveolar ventilation is less than pulmonary ventilation because of the presence of dead space

Various changes in lung volume represent only one factor in the determination of **pulmonary** or **minute ventilation**, which is the volume of air breathed in and out in one minute. The other important factor is **respiratory rate**, which averages 12 breaths per minute in both humans and horses. The *pulmonary ventilation equation* parallels that of cardiac output (cardiac output = stroke volume × beat rate; p. 414):

$$\text{Pulmonary ventilation} = \text{tidal volume} \times \text{respiratory rate}$$

$$(\text{L/ breath}) \quad (\text{L/min}) \quad (\text{breaths/min})$$

Pulmonary ventilation *scales* with mammalian body size. Tidal volume does not; that is, it is almost exactly proportional to body mass (m_b in kg):

$$TV = 0.0062m_b^{1.01}$$

(a) Values are average for a healthy young adult male; values for females are somewhat lower.

(b) Spirogram and table of values for adult male human and horse

FIGURE 11-25 Variations in lung volume. (a) Normal range and extremes of lung volume in a human (healthy young adult male). (b) Normal spirogram of a human (healthy young adult male) compared to a horse. See main text for details on the various volumes (such as tidal volume, TV) and capacities (such as vital capacity, VC). (The residual volume cannot be measured with a spirometer but must be determined by another means.)

However, resting respiratory rate RR follows the equation:

$$RR = 53.5m_b^{-0.26}$$

The negative exponent, -0.26 , means that larger animals have slower rates. (Recall that alveolar area scaled to 0.75 or $3/4$ power (p. 510), while here we see an approximate negative $1/4$ power; the significance of these will be explored in Chapter 15.) On the next page are some average examples

for resting and active mammals (differing slightly for humans compared to Figure 11-25b due to different studies). Among the resting animals, note that the giraffe's respiratory rate of $9/\text{min}$ is 20% less than the scaling relationship predicts ($11/\text{min}$), perhaps because of the high friction in its long trachea. Also, compare the resting and active human and horse. Note that both can increase ventilation over 20-fold during high activity, and that TV increases about as much as respiratory rate. We explore why this is important next.

Animal at Rest	Pulmonary Ventilation (PV)	=	Resting Tidal Volume (rTV)	×	Respiratory Rate
Rat (0.22 kg)	0.12 L/min	=	0.001 L/breath	×	120 breaths/min
Human (70 kg)	6.0 L/min	=	0.4 L/breath	×	15 breaths/min
Giraffe (400 kg)	30 L/min	=	3.3 L/breath	×	9 breaths/min
Horse (450 kg)	72 L/min	=	6 L/breath	×	12 breaths/min
Elephant (7,000 kg)	235 L/min	=	47 L/breath	×	5 breaths/min
Active Animals			Active TV		
Human, fast run:	150 L/min	=	2.5 L/breath	×	60 breaths/min
Horse, fast trot:	1,500 L/min	=	25 L/breath	×	60 breaths/min

Anatomic Dead Space Pulmonary ventilation does not give a proper estimate of gas delivery. When increasing pulmonary ventilation, *it is usually more advantageous to have a greater increase in tidal volume* than in respiratory rate because of the presence of **anatomic dead space**, which results from the fact that not all the inspired air gets down to the site of gas exchange in the alveoli. Part of it remains in the conducting airways, where it is not available for gas exchange. The volume of the conducting passages in an adult human averages about 0.15 L, whereas it is about 1.8 L in the horse. This volume is considered anatomic dead space (Figure 11-26) because air within these conducting airways is useless for exchange purposes. Anatomic dead space has a pronounced effect on the efficiency of pulmonary ventilation. In horses, even if 6 L of air are moved in and out with each breath, only 4.2 L are actually exchanged between the atmosphere and alveoli because of the 1.8 L occupying the anatomic dead space.

Alveolar Ventilation and Breathing Patterns Because the amount of atmospheric air that reaches the alveoli and is actually available for exchange with the blood is more important than the total amount breathed in and out, **alveolar ventilation (AV)**—the volume of air exchanged between the atmosphere and alveoli per minute—is more important than pulmonary ventilation (PV). In determining AV, the amount of wasted air in the anatomic dead space must be taken into account, as follows:

$$AV = (TV - \text{dead-space volume/breath}) \times \text{respiratory rate}$$

If we use this for average resting values for a horse, we get:

$$AV = (6 \text{ L/breath} - 1.8 \text{ L/breath}) \times 12 \text{ breaths/min} = 50.4 \text{ L/min}$$

Since pulmonary ventilation is 72 L/min, this is a loss of 21.6 L/min (30%).

To understand how important dead-space volume is in determining the magnitude of AV, let's examine the effect of various breathing patterns on human AV when pulmonary ventilation (PV) is constant at 6.0 L/min. The values for normal resting yield an AV of 4.2 L/min, also a 30% loss:

$$AV, \text{ normal rest} = (0.5 \text{ TV} - 0.15 \text{ dead-space L/breath}) \times 12 \text{ breaths/min} = 4.2 \text{ L/min}$$

Now suppose a human deliberately breathes deeply (for example, a TV of 1.2 L) and slowly (e.g., at 5 breaths/min). PV is still 6.0 L/min, but AV *increases*:

$$AV, \text{ deep/slow} = (1.2 \text{ TV} - 0.15 \text{ dead-space L/breath}) \times 5 \text{ breaths/min} = 5.25 \text{ L/min}$$

In contrast, if a person deliberately breathes shallowly (for example, a TV of 0.15 L) and rapidly (at 40 breaths/min), PV is still 6.0 L/min; however, AV would be *zero*!

$$AV, \text{ shallow/rapid} = (0.15 \text{ TV} - 0.15 \text{ dead-space L/breath}) \times 40 \text{ breaths/min} = 0 \text{ L/min}$$

In effect, the person would only be drawing air in and out of the anatomic dead space without any atmospheric air being exchanged with the alveoli, where it could be useful. The individual could voluntarily maintain such a breathing pattern for only a few minutes before losing consciousness, at which time normal breathing would resume.

The value of reflexively bringing about a large increase in depth of breathing (TV) as well as in rate of breathing when PV is increased during activity should now be apparent. When TV is increased, the entire increase goes toward elevating AV, whereas an increase in respiratory rate does not entirely do so. When respiratory rate is increased, the frequency with which air is wasted in the dead space is also increased because a portion of *each* breath must move in and out of the dead space. Here are human values for high activity yielding a PV of 150 mL/min; note that AV is only 7% less:

$$AV, \text{ high activity} = (2.5 \text{ TV} - 0.15 \text{ dead-space L/breath}) \times 60 \text{ breaths/min} = 141 \text{ L/min}$$

In trotter horses at a maximal trot with a PV of 1,500 L/min, we get a similar 8% drop:

$$AV, \text{ maximal trot} = (25 \text{ TV} - 1.8 \text{ dead-space L/breath}) \times 60 \text{ breaths/min} = 1,392 \text{ L/min}$$

However, trotters forced to gallop at maximum are only able to manage a TV of 12 L/min, so are forced to breathe at a much faster rate of 140! This yields an impressive PV of 1,680 L/min, but the AV is 15% less in this case:

$$AV, \text{ maximal trot} = (12 \text{ TV} - 1.8 \text{ dead-space L/breath}) \times 140 \text{ breaths/min} = 1,428 \text{ L/min}$$

The numbers in the figure represent ml of air.

KEY

- "Old" alveolar air that has exchanged O_2 and CO_2 with the blood
- Fresh atmospheric air that has not exchanged O_2 and CO_2 with the blood

FIGURE 11-26 Effect of dead-space volume on exchange of tidal volume between the atmosphere and the alveoli for humans. Even though 500 mL of air move in and out between the atmosphere and the respiratory system and 500 mL move in and out of the alveoli with each breath, only 350 mL are actually exchanged between the atmosphere and the alveoli because of the anatomic dead space (the volume of air in the respiratory airways).

Compare pulmonary ventilation and alveolar ventilation. What is the consequence of anatomic and alveolar dead space? Give some examples with actual animal data.

11.7 Breathing: Flow-Through versus Tidal Respirers

We temporarily end our examination of ventilation and breathing (step 1, Figure 11-1) with comparisons between

flow-through and tidal respirers. (We will return to breathing at the end of the chapter when we examine neural, hormonal and local regulation.)

Dead-space volumes are lower in fishes but higher in birds compared to mammals

The dead-space problem we just discussed also occurs in animals with gills. Not all the water entering the buccal cavity perfuses through the gill lamellae and is, instead, lost through the spaces between the gill arches. This fraction of the water unavailable for gas exchange is also termed the **anatomical dead space**. However, flow-through systems have much lower dead-space volumes because of unidirectional flow.

However, the same does not hold true for the partial flow-through systems of birds, but this is because their tracheae are longer and wider than mammals'. In fact, bird tracheae—which have tidal, not flow-through, ventilation—have an average 4.5 greater dead-space volume than mammals (when comparing animals of the same size). To compensate, a bird has a much higher TV and a much lower respiratory rate than a mammal of the same size. For example, compare a bird and a mammal, both weighing 2.6 kg:

$$\begin{aligned}\text{Mammal's PV} &= 0.02 \text{ TV L/breath} \times 42 \text{ breaths/min} \\ &= 0.84 \text{ L/min} \\ \text{Duck's PV} &= 0.07 \text{ TV L/breath} \times 16 \text{ breaths/sec} \\ &= 1.12 \text{ L/min}\end{aligned}$$

The work of normal breathing requires as little as 2% of total energy expenditure in some mammals to as much as 50% in some fishes

During normal quiet breathing, the respiratory muscles must work during inspiration to expand the lungs against their elastic forces and to overcome airway resistance, whereas expiration is a passive process. Normally, the mammalian lung is highly compliant and airway resistance is low, so only about 2% of the total energy expended by the body is used to accomplish quiet breathing.

During strenuous activity, the amount of energy required to power pulmonary ventilation may increase up to 25-fold. However, because total energy expenditure by the body is increased up to 15- to 20-fold during heavy activity, the energy used to accomplish the increased ventilation still represents only about 5% of total energy expended. There is an exception to this: Animals with chronic lung disease require considerably more energy for respiration, which may increase to 30% of total energy expenditure.

In contrast, respiration in water assumes a greater metabolic cost because of the fluid properties of water, which resist movement as compared to air. Estimates of the metabolic cost of respiration in a resting fish vary from 5 to 50% (normally approximately 20%) of the resting metabolic rate. However, were it not for the efficiencies of flow-through ventilation—including the switch from active breathing to ram ventilation at high speeds—the costs would presumably be even higher.

Flow-through ventilation yields a greater oxygen uptake than tidal breathing

Recall that flow-through ventilation allows for counter- or crosscurrent blood flow. Consequently, the P_{O_2} in outgoing blood of fish and birds is distinctly higher than in the expired medium from the respiratory organ (Figures 11-6f and 11-17), unlike the case for alveoli. However, as we noted earlier, the tidal lung of mammals can only yield an outgoing blood P_{O_2} that is equal to that of expired air (Figure 11-11c). In terms of the total O_2 extracted from the incoming medium, efficiency from the water can be as high as 90% in some species of fish, crustaceans, and amphibians. In birds, because they are partially tidal with dead spaces, efficiency of extraction from air ranges from only 30 to 40%. But in mammals, it averages a mere 25%. (In taking to the air, bats—while retaining the basic mammalian tidal system—

do somewhat better, having evolved the highest capacity gas exchange system among mammals with relatively larger lungs and thinner alveolar barriers to diffusion. A flying bat can maintain metabolic rates 2.5 to 3 times the maximal rates attainable by comparably sized nonflying rodents.) Recall, however, that, the low O_2 content of water relative to air requires a greater expenditure of energy for water breathers compared to air breathers with similar metabolisms.

Oxygen uptake—actually, O_2/CO_2 exchange—at respiratory surfaces is step 2 of external respiration, to which we now turn our focus.

Compare vertebrate tidal and flow-through breathers in terms of dead space, energy costs, and oxygen uptake efficiency.

11.8 Gas Exchange at Vertebrate Respiratory Organs and Body Tissues

Having examined the details of ventilatory bulk transport (step 1, Figure 11-1), we now turn to gas exchange in depth, focusing on vertebrates. The ultimate purpose of step 1 is to provide a continual supply of fresh O_2 for pickup by the blood and to constantly remove CO_2 unloaded from the circulation. This is the gas exchange step 2 of Figure 11-1. In turn, circulation serves the same purpose at the blood-tissue exchange step 4. Since both of these involve Fick's law and its gas gradients (ΔP), will examine them together, starting with step 2.

Lung air has a lower partial pressure of oxygen than atmospheric air

Let's begin with the gas gradients in air breathers. In tidal systems, there is a drawback: Generally, lung air (alveolar air in mammals) is not of the same composition as inspired atmospheric air, for two reasons. First, as soon as atmospheric air enters the respiratory passages, it becomes saturated with H_2O by exposure to the moist airways. Water vapor exerts a partial pressure just like any other gas. At mammalian body temperature, the partial pressure of H_2O vapor is 47 mm Hg. Humidification of inspired air in effect "dilutes" the partial pressure of the inspired gases by 47 mm Hg because the sum of the partial pressures approximates the atmospheric pressure of 760 mm Hg. In moist air, $P_{H_2O} = 47$ mm Hg, $P_{N_2} = 563$ mm Hg, $P_{O_2} = 150$ mm Hg, and $P_{CO_2} = 0.2$ mm Hg.

Second, compared to air, alveolar P_{O_2} is lower and P_{CO_2} is much higher because fresh inspired air is mixed with the large volume of old air that remained in the lungs and dead space at the end of the preceding expiration (the FRC—functional residual capacity, Figure 11-25b). In a human, only about one seventh of the total alveolar air is replaced by fresh atmospheric air with each normal breath. Thus, at the end of inspiration, less than 15% of the air in the alveoli is

FIGURE 11-27 O_2 and CO_2 exchange across pulmonary and systemic capillaries caused by partial pressure gradients (shown for a mammal).

© Cengage Learning, 2013

fresh air. As a result of humidification and the small turnover of alveolar air, the average alveolar P_{O_2} is 100 mm Hg, compared to (nonmoist) atmospheric P_{O_2} of about 160 mm Hg (Figures 11-11c and 11-27). P_{CO_2} is even worse at 40 mm Hg in the lungs compared to atmospheric level of 0.2 mm Hg (Figure 11-27).

It is logical to think that alveolar P_{O_2} and P_{CO_2} would change during inspiration with the arrival of fresh air during expiration. Only small fluctuations of a few mm Hg occur, however, for two reasons. First, because only a small proportion of the total alveolar air is exchanged with each breath, the relatively small volume of high- P_{O_2} low- P_{CO_2} air that is inspired is quickly mixed with the much larger volume of retained alveolar air, which has a lower P_{O_2} and

higher P_{CO_2} . Thus, the gases in the inspired air can only slightly change the total alveolar gas pressures. Even a potentially small elevation of P_{O_2} is diminished for another reason. Oxygen is continually moving by passive diffusion down its partial pressure gradient from the alveoli into the blood. The O_2 arriving in the alveoli in the newly inspired air simply replaces the O_2 diffusing out of the alveoli into the pulmonary capillaries. Therefore, the alveolar P_{O_2} remains relatively constant at about 100 mm Hg throughout the respiratory cycle. Because the pulmonary blood P_{O_2} equilibrates with the alveolar P_{O_2} , the P_{O_2} of the blood leaving the alveoli likewise remains fairly constant at this same value. Similar events occur for CO_2 but in reverse (Figure 11-27).

O₂ enters and CO₂/HCO₃⁻ leaves the capillaries in the lungs or gills passively down partial pressure or concentration gradients

Now let's look at the specific gradients, starting with mammals. The blood entering the pulmonary capillaries is systemic venous blood pumped to the lungs through the pulmonary arteries (Chapter 9). This blood, having just returned from the body tissues, is relatively low in O₂, with a P_{O_2} of 40 mm Hg, and is relatively high in CO₂, with a P_{CO_2} of 46 mm Hg. As this blood flows through the pulmonary capillaries, it is exposed to alveolar air with a higher P_{O_2} at 100 mm Hg (Figure 11-27). Therefore O₂ diffuses down its partial pressure gradient ($\Delta P = 60$ mm Hg) into the blood until no further gradient exists. As the blood leaves the pulmonary capillaries, it has a P_{O_2} equal to alveolar P_{O_2} at 100 mm Hg. The partial pressure gradient for CO₂ is in the opposite direction. Alveolar P_{CO_2} is only 40 mm Hg, 6 mm Hg less than the blood. Thus, CO₂ diffuses from the blood into the alveoli until blood P_{CO_2} equilibrates with alveolar P_{CO_2} , so the blood leaving the pulmonary capillaries has a P_{CO_2} of 40 mm Hg. After leaving the lungs, the blood is returned to the heart to be subsequently pumped out to the body tissues as systemic arterial blood (Chapter 9).

Note that blood returning to the lungs from the tissues still contains O₂ at an average P_{O_2} of 40 mm Hg. However, that value varies. The amount of O₂ picked up in the lungs matches the amount extracted and used by the tissues. When the tissues metabolize more actively (for example, during strenuous activity), more O₂ is extracted from the blood at the tissue level, reducing the systemic venous P_{O_2} even lower—for example, to a P_{O_2} of 30 mm Hg. At the lungs, a larger-than-normal P_{O_2} gradient exists, now at 70 mm Hg (100 mm Hg vs 30 mm Hg), compared to the normal gradient of 60 mm Hg. Therefore, more O₂ diffuses from the alveoli into the blood down the larger partial-pressure gradient before blood P_{O_2} equals alveolar P_{O_2} . This additional transfer of O₂ into the blood replaces the increased amount of O₂ consumed, so O₂ uptake matches O₂ use even when O₂ consumption increases. At the same time, ventilation is stimulated so that O₂ enters the alveoli more rapidly from the atmosphere to replace the O₂ diffusing into the blood.

Similarly, blood leaving the lungs still contains CO₂ at an average P_{CO_2} of 40 mm Hg. The CO₂ remaining in the blood even after passage through the lungs plays an important role in the acid–base balance of the body, because CO₂ generates carbonic acid (Chapter 13). Furthermore, arterial P_{CO_2} is important in driving respiration. This mechanism is described later. As with O₂, the amount of CO₂ given up to the alveoli from the blood matches the amount of CO₂ picked up at the tissues. Once again, an increase in ventilation associated with increased activity assures that increased amounts of CO₂ delivered to the alveoli are blown off to the atmosphere.

Water breathers are exposed to very low concentrations of CO₂, with in-current water having only about 0.2 mm Hg, the same as atmospheric P_{CO_2} (in contrast to the 30 to 40 mm Hg in most air breathing vertebrates). This is because flow-through ventilation prevents buildup of the gas in the gill chamber. The P_{CO_2} in expired water and in arterial blood of fish is also remarkably low, around 1 to 4 mm Hg, but higher than the incoming water. The low arterial level arises because much of the gas in the blood is actually in the

form of *bicarbonate*, HCO₃⁻, which is highly soluble and higher than in most external waters:

$$\begin{aligned}\text{Venous blood (tuna) } \text{HCO}_3^- &= 12 \text{ mmol/L;} \\ \text{seawater } \text{HCO}_3^- &= 2 \text{ mmol/L}\end{aligned}$$

Thus, the ion can readily diffuse (through facilitated transporters) out of the gills into the external water (down a concentration rather than a partial pressure gradient). Air breathers, in contrast, cannot excrete bicarbonate into the air. Conversion of CO₂ into HCO₃⁻ is primarily due to the enzyme *carbonic anhydrase* in erythrocytes. We'll explore how this enzyme works in mammalian erythrocytes later.

Factors other than the partial pressure gradient influence the rate of gas transfer

We have been discussing diffusion of O₂ and CO₂ between the blood and the environment in terms of the gases' partial pressure (ΔP) gradients. Recall that, according to Fick's law of diffusion, the rate of diffusion of a gas through a sheet of tissue also depends on the surface area (A) and thickness of the membrane (ΔX) through which the gas is diffusing and on the diffusion coefficient (D). Let's examine these factors more closely.

In an individual animal, D is not typically alterable, except that it increases somewhat as temperature increases. However, during intense activity, A and ΔX can be physiologically altered to enhance the rate of gas transfer. During resting conditions in mammals, some of the pulmonary capillaries are typically closed because the normally low pressure of the pulmonary circulation is inadequate to keep all the capillaries open. During activity, when the pulmonary blood pressure is raised as a result of increased cardiac output, many of the previously closed pulmonary capillaries are forced open. This increases the surface area of blood available for exchange. Furthermore, the alveolar membranes are stretched further than normal during activity because of the larger tidal volumes (deeper breathing). Such stretching increases the alveolar surface area and decreases the thickness (ΔX) of the alveolar membrane.

Similarly, in resting fishes the functional surface area is the total surface area available for gas exchange. For example, during quiet breathing of water in trout only 60% of the available lamellae are perfused with water. As the level of activity increases, more water channels are recruited for ventilation.

Inadequate gas exchange can occur when the thickness of the barrier separating the air or water from the blood is pathologically increased. As the thickness increases, the rate of gas transfer decreases because a gas takes longer to diffuse through the greater thickness. Thickness increases because of (1) *low or high environmental pH* in water breathers: Acute exposure of freshwater fish to pH values between 4.0 to 5.5 or between 8.5 to 10.5 results in mucification and inflammatory swelling of the gill epithelium; (2) *pulmonary edema* in air breathers, an excess accumulation of interstitial fluid between the alveoli and pulmonary capillaries, caused by pulmonary inflammation or left-sided congestive heart failure; (3) *pulmonary fibrosis* in air breathers involving replacement of delicate lung tissue with thick fibrous tissue in response to certain chronic irritants; and (4) *pneumonia* in air breathers, which is characterized by inflammatory fluid accumulation within or around the

alveoli. Most commonly, pneumonia is due to bacterial or viral infection of the lungs, but it may also arise from accidental aspiration (breathing in) of food, vomitus, or chemical agents.

The preceding discussion focused on individual animals. As we have touched on earlier, all the components of Fick's law can be evolutionarily adapted over generations if not always within an individual. For example, the area of the gill surface available for gas exchange and the diffusion distance have evolved to match the lifestyles of different fish species. At one extreme are the air-breathing fish that have comparatively small gill surface areas and thick lamellae, so much so that in some cases the gills are virtually functionless in terms of gas exchange. Alternatively, fast-swimming fishes such as tuna and mackerel have particularly thin lamellae and a comparatively large surface area available for gas exchange.

Gas exchange across the systemic capillaries also occurs down partial pressure gradients

Just as they do at the pulmonary and branchial (gill) capillaries, O_2 and CO_2 move between the systemic capillary blood and the tissue cells by simple passive diffusion down partial pressure gradients. Refer again to Figure 11-27 for a mammal. The arterial blood that reaches the systemic capillaries is essentially the same blood that left the lungs by means of the pulmonary veins—that is, arterial P_{O_2} is 100 mm Hg and P_{CO_2} is 40 mm Hg—because the only two places in the entire circulatory system at which gas exchange can take place are the pulmonary capillaries and the systemic capillaries.

Cells constantly consume O_2 and produce CO_2 through oxidative metabolism (Chapter 2). Cellular P_{O_2} in a mammal averages about 40 mm Hg and P_{CO_2} about 46 mm Hg, although these values are highly variable, depending on the level of cellular metabolic activity. Oxygen moves by diffusion down its partial pressure gradient from the entering systemic capillary blood ($P_{1O_2} = 100$ mm Hg) into the adjacent cells ($P_{2O_2} = 40$ mm Hg) until equilibrium is reached with the P_{O_2} of venous blood leaving the systemic capillaries equal to the tissue P_{O_2} at an average of 40 mm Hg. The reverse situation exists for CO_2 . Carbon dioxide rapidly diffuses out of the cells ($P_{1CO_2} = 46$ mm Hg) into the entering capillary blood ($P_{2CO_2} = 40$ mm Hg) down the gradient created by the ongoing production of CO_2 , until blood P_{CO_2} equilibrates with tissue P_{CO_2} . Accordingly, the blood leaving the systemic capillaries has an average P_{CO_2} of 46 mm Hg. This systemic venous blood returns to the heart and is subsequently pumped to the lungs as the cycle repeats itself (Figure 11-27).

The more actively a tissue is metabolizing, the lower the cellular P_{O_2} falls and the higher the cellular P_{CO_2} rises. As a consequence of the larger blood-to-cell partial pressure gradients, more O_2 diffuses from the blood into the cells and more CO_2 moves in the opposite direction before blood P_{O_2} and P_{CO_2} achieve equilibrium with the surrounding cells. Thus, the amount of O_2 transferred to the cells and the amount of CO_2 carried away from the cells depend on the rate of cellular metabolism.

This ends our examination of the detailed gas-exchange gradients at steps 2 and 4 of Figure 11-1. Next we look in depth at the effects of the bulk transport step 3.

check your understanding 11.8

Describe how all the gas gradients of Figure 11-27 arise; apply them to fish.

11.9 Circulatory Transport and Gas Exchange

Oxygen picked up by the circulation at the respiratory organs must be transported to the tissues for cell use. Conversely, CO_2 produced at the cellular level must be transported to the respiratory organs for elimination. In theory, this could be done by simply dissolving the gases in the circulatory water—and in some animals that is the case. However, in most circulatory systems, there is another way.

Most O_2 in many animal circulatory systems is transported bound to hemoglobins, hemocyanins, and other metal-containing respiratory pigments

Oxygen can present in the blood in two forms: physically dissolved as *free gas*, and chemically bound to a *respiratory protein or pigment*. As you saw in Chapter 9 (p. 391), for vertebrate *hemoglobin*, the pigment may be carried in circulating cells such as erythrocytes. However in some animals, the pigments are extracellular. There is a wide diversity of these pigments, but all use a *metal ion* to bind and release O_2 :

1. **Hemoglobins (Hb)**, which have two parts: (1) the **globin** portion, a protein made up of a highly folded polypeptide chain, and (2) one iron-containing, nonprotein group known as **heme** bound to each of the polypeptides (Figure 11-28a, b). It appears blue when deoxygenated and red when oxygenated. Hemoglobins are the most common respiratory pigments, found not only in vertebrates but in many annelids, and some mollusks and crustaceans. They are usually intracellular. Most consist of two or more subunits; for example, mammalian Hb is called a **tetramer** because it has four subunits (Figure 11-28a).
Hemoglobins are found in some species of plants, fungi, protists, and even bacteria; and related proteins called *protoglobins* are found in some archaea. The protein-heme-iron complex may have originally evolved to detoxify toxic gases like H_2S , only later becoming adapted for O_2 transport.
2. **Hemocyanins (Hc)**, which use a pair of *copper* ions directly bound to amino acid side chains to bind O_2 . As a result of the copper atoms, the blood of these animals appears blue (colorless when deoxygenated). Hemocyanins are the second most common type of respiratory pigment. They are usually extracellular and are therefore very large proteins that will not leak out in excretory organs, and fall into two groups with very different structures:
 - (i) Arthropods (in the Ecdysozoa branch of the animal kingdom, Figure 1-1) have **hexameric** (six-unit) Hc complexes akin to hemoglobin, but several hexamers can join together. For example, spider Hc forms

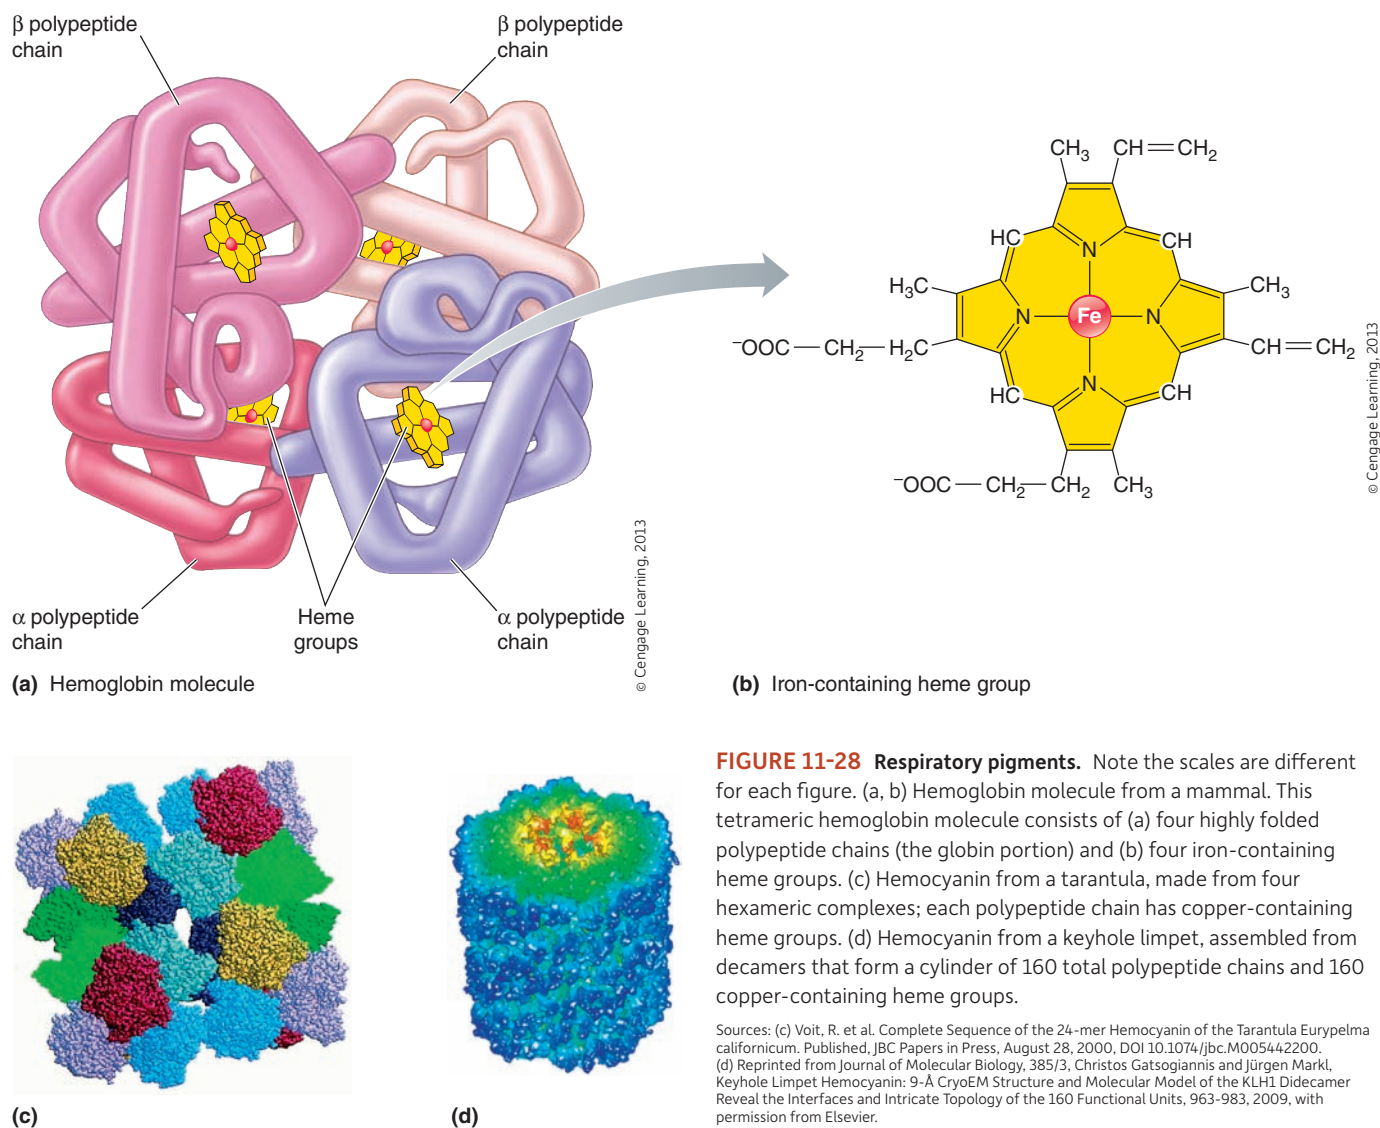

FIGURE 11-28 Respiratory pigments. Note the scales are different for each figure. (a, b) Hemoglobin molecule from a mammal. This tetrameric hemoglobin molecule consists of (a) four highly folded polypeptide chains (the globin portion) and (b) four iron-containing heme groups. (c) Hemocyanin from a tarantula, made from four hexameric complexes; each polypeptide chain has copper-containing heme groups. (d) Hemocyanin from a keyhole limpet, assembled from decamers that form a cylinder of 160 total polypeptide chains and 160 copper-containing heme groups.

- by four hexamers joining (24 total proteins) (Figure 11-28c).
- (ii) Annelids and mollusks (in the Lophotrochozoan branch, Figure 1-1) have very different hemocyanins based on **decamers** (10-protein) clusters that form hollow rings. Two or more decamers, in turn, may assemble into huge cylinders (Figure 11-28d) containing up to 160 copper ions, each of which can bind one O_2 !
 3. *Hemerythrin* also uses iron and is red, but the iron is not in a heme complex. This pigment is found intracellularly in certain groups of marine brachiopods (lamp shells) and some worm groups such as sipunculids (peanut worms) and one known annelid.
 4. *Chlorocruorin* and *erythrocrucorin* are pigments found only in some annelids. Both are iron/heme proteins like hemoglobin, but are much larger and found extracellularly. Chlorocruorin appears green to red when oxygenated, while erythrocrucorin is red.

Annelids are the perhaps most remarkable group: In this one phylum can be found *five* different respiratory pig-

ments: hemoglobin, hemocyanin, chlorocruorin, erythrocrucorin, and hemerythrin.

Insects, as air breathers with direct tracheal input to their tissues, normally lack a respiratory pigment. However, in the aquatic larvae of the caddis fly (*Chironomus*) and the water bugs *Anisops* and *Buenoa*, hemocyanin plays a role in O_2 uptake. Recall that O_2 uptake is more difficult in water than in air (p. 498).

For the rest of this section, we focus primarily on vertebrate respiratory pigments. In a mammal, very little O_2 is physically dissolved in plasma because O_2 is poorly soluble in warm fluids (Table 1-1). The amount dissolved is directly proportional to the P_{O_2} of the blood; the higher the P_{O_2} , the more O_2 dissolved. At a normal arterial P_{O_2} of 100 mm Hg and body temperature of $37^\circ C$, only 3 mL of O_2 can dissolve in 1 liter of blood. Thus, in a human, only 15 mL of O_2 /min can be dissolved in the normal pulmonary blood flow of 5 L/min (the resting cardiac output in a human). Even under resting conditions, human cells consume 250 mL of O_2 /min in total, and this may increase up to 25-fold during strenuous activity. To deliver the O_2 required by the tissues

A Closer Look at Adaptation

Life in the Cold: The Hemoglobinless Icefish

Antarctic icefish (Channichthyidae) are noted for having a low metabolic rate and sluggish lifestyle. They are unique among vertebrates in that they completely lack erythrocytes and hemoglobin. Genome analysis shows that they have completely lost the β -globin gene, whereas the α -globin gene is still present but mutated into a transcriptionally inactive pseudogene (p. 33). In the absence of red blood cells, these fish appear whitish and translucent—hence their common name. Icefish are sizable: They can weigh over 2 kg and reach a length of approximately 0.6 m.

Icefish are ectotherms with body temperatures essentially equal to that of the environment. A lack of hemoglobin in this species represents an adaptation to a stable environmental condition of cold (-2°C) as well as water with a relatively high O_2 content (recall that cold water dissolves gases better than warm water). In the low ambient temperatures, the viscosity of the

blood is increased. Elimination of red blood cells helps to offset the decrease in blood flow. However, in the absence of hemoglobin, only O_2 , which is physically dissolved in solution, can be transported in the blood. Because icefish live in cold, well-oxygenated waters, the arterial P_{O_2} is a relatively high 110 mm Hg. Cardiac output is also remarkably elevated in icefish, which helps ensure that sufficient quantities of O_2 can be taken up at the gill and delivered to the tissues despite a low arterial–venous O_2 difference. Relative heart size and blood volume are also increased in these animals. The increased cardiac output is maintained by an increase in stroke volume and not heart rate, which is a relatively slow 14 beats per minute. Peripheral resistance to blood flow is also reduced in icefish, which ensures that the work actually performed by the heart is kept to a minimum despite the large volume of blood being pumped. Compared to most fishes, the gill area of

© Uwe Kils

An Antarctic icefish appears pale in part due to lack of hemoglobin.

icefish is reduced and the secondary lamellae are thick. Gas exchange does occur across the gills, although up to 40% of their O_2 requirement can be obtained through the skin. An increased density of capillaries in the skin ensures adequate gas exchange. Because of these unique adaptations, Antarctic icefish can survive without the presence of Hb in their blood, but they are limited to well-oxygenated, icy cold waters.

even at rest, the cardiac output would have to be 83.3 L/min if O_2 could only be transported in dissolved form! Obviously, there must be an additional mechanism for transporting O_2 to the tissues.

In vertebrates, this mechanism takes the form of hemoglobin (Hb). Jawless fishes (lampreys and hagfish) have one to three of these polypeptides making up their hemoglobins. Other vertebrates have a tetrameric Hb (Figure 11-28a). In adult mammals, there is one type of tetramer designated $\alpha_2\beta_2$, made from two proteins, α - and β -globin. Many fish, however, have multiple variants (isomers) of α - and β -globin such that there are different tetramer combinations. Each of the four iron atoms in the tetrameric form can combine reversibly with one molecule of O_2 ; thus, each hemoglobin molecule in most vertebrates can pick up four O_2 passengers in the lungs or gills. Only 1.5% of the O_2 in the blood of mammals is free (dissolved); the remaining 98.5% is transported in combination with Hb. In fishes the amount of free O_2 is somewhat higher, at about 5% of the total O_2 content at physiological P_{O_2} levels. One notable exception is the Antarctic icefish, unique among vertebrates because it lacks Hb (see *A Closer Look at Adaptation: Life in the Cold: The Hemoglobinless Icefish*).

Recall that O_2 bound to Hb does not contribute to the P_{O_2} of the blood; thus, blood P_{O_2} is a measure not of the total O_2 content of the blood but only of the portion of O_2 that is dissolved. As we noted earlier (p. 498), bound O_2 does not factor into the diffusion equation (Fick's law, p. 494) and

by doing so, helps to maximize diffusion and thus gas exchange. Later we will show how this works in more detail.

Hemoglobin has the ability to form a loose, easily reversible combination between Fe and O_2 . When not combined with O_2 , Hb is referred to as **reduced** or **deoxyhemoglobin**; when combined with O_2 (thereby releasing protons), it is called **oxyhemoglobin** (HbO_2):

The concentration of Hb in an animal is not fixed. For example, hemoglobin increases in the plasma of mammals can occur with:

1. *Seasonal changes.* During cold, acclimatization concentrations of Hb increase (such as in the horseshoe rabbit).
2. *Locomotor activity.* This stimulates some animals to increase the release of erythrocytes from the spleen (such as horse, diving mammals, fish), and prolonged aerobic activity triggers hormonal stimulation (EPO, p. 393) of the bone marrow to produce more erythrocytes.
3. *High altitude.* This and other prolonged exposure to low ambient O_2 can also trigger the production of more erythrocytes (via EPO).
4. *Stress and disease.* For example, *anemia*—a state in which erythrocyte levels are abnormally low—can be triggered by stress hormones, immune cytokines (p. 469) and many diseases.

Myoglobin stores oxygen in aerobic muscle and may facilitate diffusion from the blood to the mitochondria

Vertebrates also have other respiratory pigments, including one called **myoglobin (Mb)**. It is a monomer (single protein unit) with one heme that serves to store O_2 in muscle, especially Type I (red aerobic) skeletal fibers (p. 362) and heart (contributing to these muscles' red color). Myoglobin's function as a reserve for O_2 is well characterized; for example, because contraction of skeletal muscle and heart reduces blood flow by squeezing actions, Mb can release O_2 to compensate. But a longstanding hypothesis predicts that Mb will provide an alternate pathway for O_2 diffusion, with Mb picking up O_2 near the membrane (where P_{O_2} is higher) and diffusing to the mitochondria where the O_2 would be released (where P_{O_2} is lower). It has proved quite difficult to test this hypothesis in the past. The technique of “knockout” genes (Chapter 2) has allowed researchers to make mice completely lacking myoglobin! The heart and muscles of these mice are pale pink rather than the normal robust red color. Amazingly, physiological studies showed no impairment in muscular or cardiovascular activity in these animals. Does this mean that myoglobin is a useless protein? No, because one study found that the hearts of these mice have a much higher density of capillaries, which delivers enough O_2 to make up for the lack of Mb storage. By unknown signals during development, low supplies of O_2 to heart fibers presumably triggered this compensatory angiogenesis. These experiments in fact show that Mb is useful and that its absence requires compensation to maintain homeostasis; but they did not clarify whether Mb's role is simply for storage or to enhance diffusion. As we noted in Chapter 2, the technique of knocking out genes does not always yield simple results and answers, because of the complex feedback processes in living systems (p. 35).

Neurons contain neuroglobin, while fibroblasts contain cytoglobin

By searching genome data for globin-type codes, researchers have found two more classes of vertebrate globin, named **neuroglobin (Nb)** and **cytoglobin (Cb)**. Neuroglobin is found in neurons including the retina, as well as some endocrine cells. This oxygen-binding protein is thought to enhance neural O_2 supply in a way similar to myoglobin. Researchers have found that Nb can protect brains of mice from stroke damage resulting from insufficient O_2 . The mice were injected with a virus that was engineered to produce high levels of Nb. Recently, Nb was also found to block a key step in apoptosis, preventing neuronal cell death following injury.

Cytoglobin has been found in fibroblasts (p. 469) and a few other cell types. Its function is uncertain, but there is evidence that it can protect the cell from free-radical damage.

The P_{O_2} is the primary factor determining the percent hemoglobin saturation

Let's return to hemoglobin. We need to answer several important questions about the role of respiratory pigments in O_2 transport. For example, what determines whether O_2 and

Hb are combined or dissociated (separated)? Why does Hb combine with O_2 in the lungs and release O_2 at the tissues? How can a variable amount of O_2 be released at the tissue level, depending on the level of tissue activity? How can we talk about O_2 transfer between blood and surrounding tissues in terms of O_2 partial pressure gradients when most of the O_2 is bound to Hb and thus does not contribute to the P_{O_2} of the blood at all?

Tetrameric hemoglobin is considered *fully saturated* when all the Hb present is carrying its maximum O_2 load of four O_2 s each. The **percent hemoglobin (% Hb) saturation**, a measure of the extent to which the Hb present is combined with O_2 , can vary from 0 to 100%. The most important factor determining the % Hb saturation is the P_{O_2} of the blood, which, in turn, is related to the concentration of O_2 physically dissolved in the blood (P_{O_2}). According to the **law of mass action**, if the concentration of one of the substances involved in a reversible reaction is increased, the reaction is driven toward the opposite side. Conversely, if the concentration of one of the substances is decreased, the reaction is driven toward that side. Applying this law to the reversible reaction involving Hb and O_2 ($Hb + O_2 \leftrightarrow HbO_2$), when the blood P_{O_2} is increased, as it is in the pulmonary capillaries, the reaction is driven toward the right side of the equation, resulting in increased formation of HbO_2 (increased % Hb saturation). When the blood P_{O_2} is decreased, as it is in the systemic capillaries, the reaction is driven toward the left side of the equation and O_2 is released from Hb as HbO_2 dissociates (decreased % Hb saturation). Thus, because of the difference in P_{O_2} at the lungs and other tissues, Hb automatically “loads up” on O_2 in the lungs, where fresh supplies of O_2 are continually being provided by ventilation, and “unloads” it in the tissues, which are constantly using up O_2 . Let us examine how this works.

Cooperativity among hemoglobin subunits allows for effective delivery of oxygen

Binding of ligands to most proteins (such as substrates to enzymes) follows a *hyperbolic* curve, not a linear relationship, as shown in Figure 11-29a (orange curve) for myoglobin (Mb) and O_2 . This type of curve results from *saturation* of the protein; that is, after a certain concentration of ligand is reached, no more bound complex can form because all the proteins are occupied by ligands. The relationship between blood P_{O_2} and % Hb saturation is not hyperbolic, however, a point that is very important physiologically. The relationship between these variables follows an S-shaped *sigmoidal* curve, known as the **O_2 -Hb dissociation (or saturation) curve** (hemoglobin curves of Figures 11-29a and b). With the exception of species that contain monomeric oxygenated Hb (such as agnathans), the curves are sigmoidal in shape because hemoglobins exhibit **cooperativity** of binding; that is, the loading or unloading of the first O_2 on Hb makes it sequentially easier for subsequent O_2 s to load or unload. Cooperativity arises from conformational changes that occur in the globins, which oscillate between one of two states: a high-affinity or “relaxed” form called the **R-state**, and a low-affinity or “tense” form called the **T-state**. The R-state is favored at high P_{O_2} levels (thus, “R” is easier to remember as the “red” form), whereas the T-state is favored at low P_{O_2} levels. To see how this works, examine Figure 11-29b.

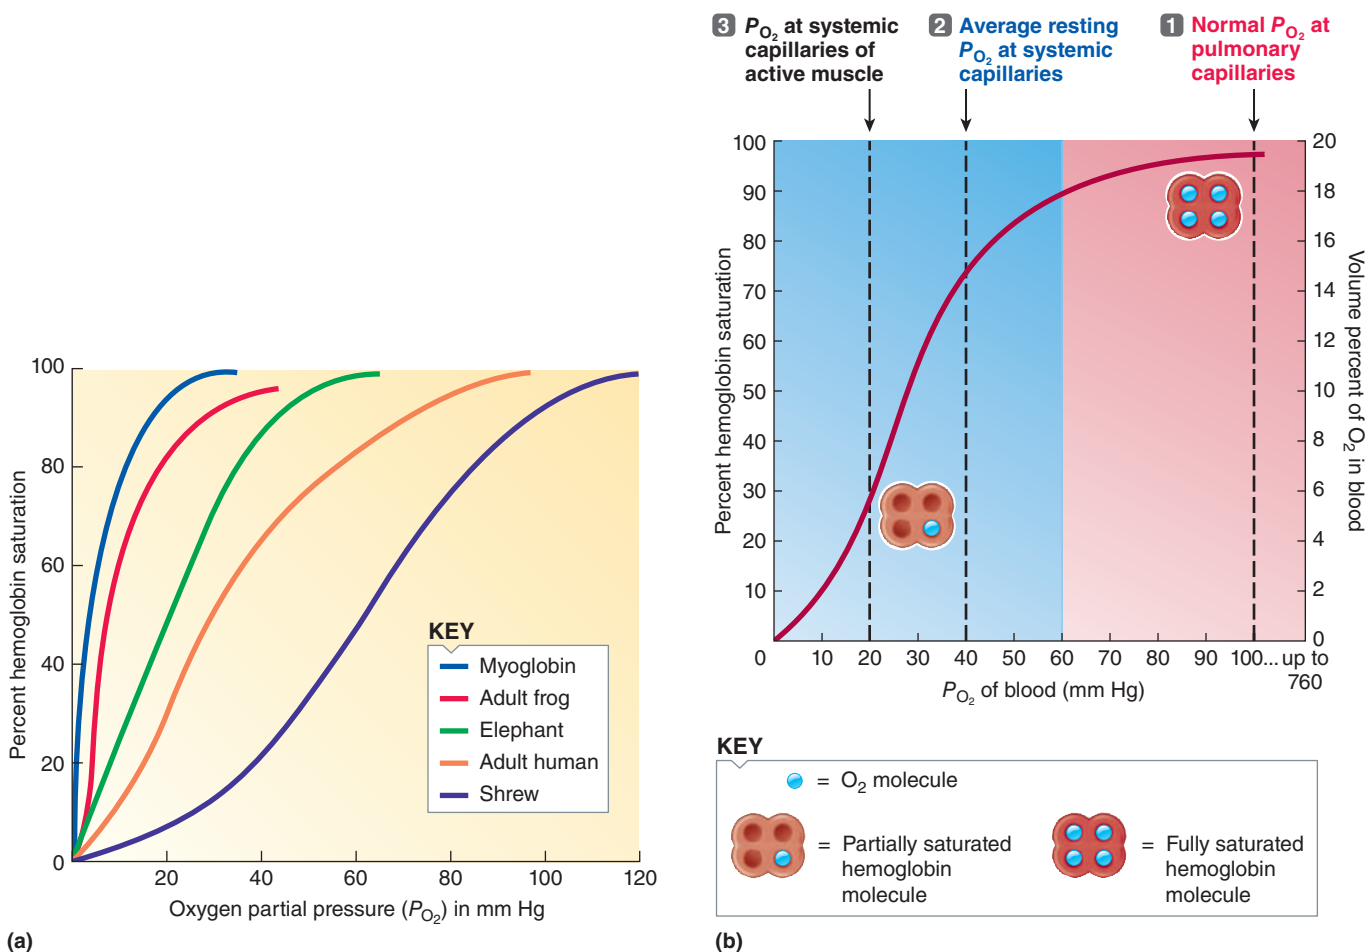

FIGURE 11-29 Oxygen-hemoglobin (O_2 -Hb) dissociation (saturation) curve. (a) The percent Hb saturation (the scale on the left side of the graph) depends on the P_{O_2} of the blood. The relationship between these two variables is depicted by a curve running from zero to high P_{O_2} , where the protein is saturated. Shown here are the curves for the myoglobin pigment, and hemoglobins from a frog, an elephant, a human, and a shrew. The myoglobin has a hyperbolic curve, while the hemoglobins have an S-shaped sigmoidal curve, with a plateau region between a blood P_{O_2} of 60 and 100 mm Hg and a steep portion between 0 and 60 mm Hg. (b) O_2 -Hb curve for a human. Points 1, 2, and 3 show the binding at the partial pressures in the lungs, average tissues, and active muscles, respectively (see text for details). Another way of expressing the effect of blood P_{O_2} on the amount of O_2 bound with Hb is the volume percent of O_2 in the blood (mL of O_2 bound with hemoglobin in each 100 mL of blood). That relationship is represented by the scale on the right side of the graph.

Unloading Oxygen At the lungs (point 1 of Figure 11-29b), the high P_{O_2} of the alveolar input favors an all R (R_4) state, so the Hb is nearly 100% saturated. Now, as the blood proceeds into systemic circulation to capillaries in a typical tissue (point 2) with an intermediate P_{O_2} level of 40 mm Hg, the T-state becomes increasingly favorable, and the Hb is in an average R_3T_1 conformation, releasing about 25% of its O_2 . Moreover, the globin that releases the first O_2 not only shifts to the T-state but will also affect its neighboring globin units, making them more likely to shift to the T-state and thus releasing their oxygens. This is co-called cooperativity makes the curve become steeper at this point.

The value of this steepness is apparent when the blood instead goes to an active muscle (point 3) with a P_{O_2} of 20 mm Hg. As the plunging curve indicates, even more O_2 's are rapidly released, with the Hb now in an average R_1T_3 state (75% unloaded). Thus, in the range of tissue P_{O_2}

(about 0–60 mm Hg), a modest drop in systemic capillary P_{O_2} can result in large amounts of O_2 immediately available to meet the O_2 needs of the more actively metabolizing tissues. As much as 85% of the Hb may give up its O_2 to actively metabolizing cells during strenuous activity. In addition to this more thorough withdrawal of O_2 from the blood, even more O_2 is made available to actively metabolizing cells, such as exercising muscles, by circulatory and respiratory adjustments that increase the flow rate of oxygenated blood through the active tissues.

Thus, for O_2 delivery, the T-state is of particular importance. Iron has an inherently high, nearly irreversible affinity for O_2 (we know the basic Fe- O_2 reaction as rust!). In the R-state, the iron does have a very high affinity. However, the protein in the T-state essentially alters the iron atom's electrons in the heme to reduce its affinity for the gas. This is why the globin is necessary; without it, the iron-heme com-

TABLE 11-2 Hemoglobin P_{50} Values for Various Mammals and Birds

Animal	Habitat; Body Size	Hemoglobin P_{50} (mm Hg)
Elephant (African)	Low altitude; 5,000 kg	20
Human	Low altitude; 70 kg	27
Deer (sika)	Low altitude; 40 kg	28
Vicuña (Andes)	3,500–5,500 m; 40 kg	21
Rodents (rat, shrew, etc.)	Low altitude; 0.005–0.8 kg	36 or higher
Long-tailed Andean chinchilla	Up to 3,000 m; 0.55 kg	27
Short-tailed Andean chinchilla	3,000–5,000 m; 0.5 kg	23
Mole (European)	Subterranean; 0.05 kg	21
Greylag goose (India)	Low altitude; 3.5 kg	39.5
Andean goose	5–6,000 m; 3 kg	34
Bar-headed goose (Himalayas)	9,000 m; 3 kg	30

© Cengage Learning, 2013

plex would readily bind O_2 at the lungs, but would then not release it unless O_2 were extremely low (as seen for myoglobin in Figure 11-29a).

Loading Oxygen The reverse sigmoidal process occurs as an unloaded hemoglobin enters an area of high P_{O_2} level (i.e., as it returns to the lungs) for rapid reloading of O_2 's. This takes place on the right side of the graph where saturation climbs steeply, then reaches a plateau. Like the steep part of the curve, the plateau also has physiological significance. Recall that mammalian systemic arterial blood leaving the lungs normally has a P_{O_2} of 100 mm Hg. Looking at the O_2 -Hb curve, note that at a blood P_{O_2} of 100 mm Hg, Hb is 97.5% saturated. Therefore, Hb in systemic arterial blood normally is almost fully saturated.

If arterial P_{O_2} falls below normal, there is little reduction in the total amount of O_2 transported by the blood until the P_{O_2} falls below 60 mm Hg (in the human example) because of the plateau. If the arterial P_{O_2} falls 40%, from 100 to 60 mm Hg, the % Hb saturation is still remarkably high at 90%. Accordingly, the total O_2 content of the blood is only slightly decreased despite the 40% reduction in P_{O_2} because Hb is still carrying an almost-full load of O_2 . However, even if the blood P_{O_2} is greatly increased, say, to 600 mm Hg by breathing pure O_2 , very little additional O_2 is added to the blood. Thus, the plateau portion of the O_2 -Hb curve provides a good margin of safety in O_2 -carrying capacity of the blood. A P_{O_2} of 60 mm Hg is about what human alveolar air would be at 2,400 m (8,000 ft) elevation; the drop in % Hb saturation to 90% is clearly noticeable to a person arriving suddenly from sea level, but the drop is generally not life-threatening in a healthy individual. However, on Mt. Everest, arterial P_{O_2} values in climbers have been measured at 28 mm Hg!

Arterial P_{O_2} may be reduced because of pulmonary or gill diseases accompanied by inadequate ventilation or defective gas exchange or by circulatory disorders that result in inadequate blood flow to the respiratory surfaces. How-

ever, unless the arterial P_{O_2} becomes markedly reduced in either pathological conditions or abnormal environmental circumstances, near-normal amounts of O_2 can still be carried to the tissues.

Evolutionary adaptation results in different hemoglobin P_{50} values

So far we've looked at the human curve in detail, but as Figure 11-29a shows, other hemoglobins can have different binding curves. Although all have a sigmoidal shape, they differ in their relative affinity of Hb for O_2 . Affinity is characterized by the P_{50} value—the partial pressure of O_2 at which 50% saturation of the blood is reached. For adult human hemoglobin (Figure 11-29b), the P_{50} is 27 mm Hg. If the affinity for O_2 is greater (that is, Hb gives up O_2 less readily), then the dissociation curve is located further to the *left* of the human one; that is, it has a *lower* P_{50} value. For example, fetal humans have a Hb made of α and γ subunits with a P_{50} value of 19 mm Hg, so it can readily take up O_2 from the mother's Hb. Consequently, the plateau region is shifted to the left, meaning the Hb can pick up O_2 at the respiratory surface at lower alveolar P_{O_2} levels than the adult human Hb. If the affinity for O_2 is lower, and so Hb gives up O_2 more easily, the curve is shifted to the *right*; that is, it has a *higher* P_{50} value. A higher P_{50} value does not indicate a lower carrying capacity for O_2 ; it simply means that O_2 is more easily unloaded at the tissues.

Let's look at the evolution of P_{50} values in terms habitats and gas gradients. Note that that there is (1) a positive correlation between Hb O_2 affinity and body size, and (2) an inverse correlation between O_2 affinity and environmental O_2 (summarized in Table 11-2).

P_{50} and Body Size In mammals, O_2 affinity increases (thus, P_{50} decreases) with body size. For example, as seen in Figure 11-29a and Table 11-2, elephant Hb has a P_{50} around 20 mm Hg, while shrews (Figure 11-29a) as well as mice and

rats have P_{50} values of 36 or higher. This is a *scaling* phenomenon, relating to the fact that metabolic rate per unit mass increases as body size decreases (see Chapter 15). For the small rodents, at the typical alveolar P_{O_2} of 100 mm Hg, Hb saturates well, but in their tissues, Hb unloads O_2 more readily than does human or elephant Hb to support their very high metabolic rates. Conversely, the elephant's relative low metabolic rate does not require as effective off-loading of O_2 , but its Hb is better able to pick up O_2 at the lungs if environmental P_{O_2} drops.

P_{50} and Environmental P_{O_2} Not surprisingly, high affinity is also common in animals adapted to high altitudes, where a low P_{50} allows Hb to saturate at the lungs even if alveolar P_{O_2} drops below 60 mm Hg. For example, compare a lowland sika deer and a high-altitude Andean vicuña (with similar body sizes) in Table 11-2. Small mammals at high altitude also show the same trend; for example, in Table 11-2 compare low-altitude rodents to the long-tailed chinchilla of the Andes, which lives on the mountain slopes up to 3,000 m, and to the congeneric short-tailed chinchilla from 3,000–5,000 m.

Animals living underground may frequently experience low ambient O_2 levels. Correspondingly, the subterranean mole *Tupa europea* has a low P_{50} (Table 11-2).

Birds show similar trends (Table 11-2). The Andean goose from 5,000–6,000 m has a Hb with a P_{50} about 6 mm Hg lower than low-altitude greylag geese. And the bar-headed goose, which has been observed flying over Mt. Everest at over 9,000 m, has a P_{50} about 10 mm Hg lower. Molecular analysis shows that only one or two amino acid differences in this bird's Hb can account for this adaptation. We will return to this remarkable bird later.

Similarly, we find low- P_{50} (high-affinity) hemoglobins in aquatic animals living in low-oxygen waters. Sluggish fish, for example, such as the plaice (a type of bottom-dwelling flatfish) and carp, rely on Hb with a low P_{50} (for example, 18 mM Hg in the European plaice) to work in an environmental P_{O_2} which may be 35 mm Hg (versus a venous P_{O_2} of 11 mm Hg; hematocrit 14%). Under these circumstances there is still a large partial pressure gradient between the water and the gill capillaries, although the gradient between the blood and the tissues is reduced. These species have thus optimized O_2 extraction from the water while maintaining a sedentary lifestyle that rarely requires strenuous activity. Recall also that many fish have multiple Hb variants. Some of these have slightly different temperature responses to aid in thermal acclimatization, but in some they have different P_{50} values. For example, the turbot (*Scophthalmus maximus*, a flatfish), has three different Hb tetramers, one of which has a higher O_2 affinity than the others.

One such hypoxia-adapted fish, the Namibian bearded goby (*Sufflogobius bibarbatus*), is being hailed as an “environmental savior”! This fish spends its days hiding in the highly anoxic seafloor, eating anaerobic bacteria. At night, it swims to the surface to reoxygenate. Overfishing off the coast of Namibia has led to a collapse in the once-dominant fish, sardines, and an explosion in jellyfish. The bearded goby, however, has begun to eat the jellyfish (the only predator to do so), preventing the ecosystem shift from getting worse.

Active aquatic species in well-oxygenated waters such as trout have a comparatively low-affinity Hb (high P_{50}),

befitting their high arterial P_{O_2} (113 mm Hg versus a venous P_{O_2} of 32 mm Hg, hematocrit 40%). Trout ($P_{50} = 24$ mM Hg) have a large diffusion gradient between the blood and the metabolizing tissues. One disadvantage of this strategy is the comparatively low efficiency of O_2 extraction from the water should the environmental P_{O_2} drop. However, active species normally inhabit well-aerated waters. Moreover, during periods of intense activity, the O_2 -carrying capacity of their blood can be rapidly increased by the release of erythrocytes from their storage site in the spleen (p. 545).

By acting as a storage depot, respiratory pigments promote the net transfer of O_2 from the respiratory surfaces to the circulatory fluid

Let's return to the role of respiratory pigments in gas exchange. Recall our earlier discussion of O_2 being driven from the alveoli to the blood by the ΔP_{O_2} between the alveoli, P_1 , and the blood, P_2 (Figure 11-28). As we have noted (p. 530), respiratory pigments play a crucial role in permitting the transfer of large quantities of O_2 before blood P_{O_2} equilibrates with the surrounding tissues (Figure 11-30). It does so by keeping P_2 low through acting as a “storage depot” for O_2 , removing the O_2 from solution by “trapping” it in a nondiffusible form as soon as it enters the blood from the alveoli. Because only diffusible (dissolved) O_2 contributes to the P_{O_2} , the O_2 bound to Hb cannot contribute to blood P_{O_2} . When systemic venous blood enters the pulmonary capillaries, its P_{O_2} is considerably lower than the alveolar P_{O_2} , so O_2 immediately diffuses into the blood, raising the blood P_{O_2} . As soon as the P_{O_2} of the blood increases, the percentage of Hb that can bind with O_2 likewise increases, as indicated by the O_2 –Hb curve. Consequently, most of the O_2 that has diffused into the blood combines with Hb. As O_2 is removed from solution by combining with Hb, blood P_{O_2} falls to about the same level it was when the blood entered the lungs, although the total quantity of O_2 in the blood actually has increased. Because the blood P_{O_2} is once again below alveolar P_{O_2} , more O_2 diffuses from the alveoli into the blood, only to be soaked up by Hb again. Essentially, this maximizes the ΔP of Fick's law by keeping P_2 low.

Net diffusion of O_2 from alveoli or water to blood occurs continuously until Hb becomes saturated with O_2 as completely as it can be at that particular environmental P_{O_2} . Not until Hb is maximally saturated for that P_{O_2} does all the O_2 transferred into the blood remain dissolved and directly contribute to the P_{O_2} . Only at this time does the blood P_{O_2} rapidly equilibrate with the alveolar P_{O_2} and halt further O_2 transfer.

The reverse situation occurs at the tissue level. Because the P_{O_2} of blood entering the systemic capillaries is considerably higher than the P_{O_2} of the surrounding tissue, the gradient favors the immediate diffusion of O_2 from the blood into the tissues, lowering the blood P_{O_2} . When blood P_{O_2} falls, Hb is forced to unload some of its stored O_2 . As the released O_2 dissolves in the blood, blood P_{O_2} increases and is once again above the P_{O_2} of the surrounding tissues. This favors further movement of O_2 out of the blood by keeping the ΔP component positive, although the total quantity of O_2 in the blood has already been reduced. Only when Hb can no longer release any more O_2 into solution can blood P_{O_2} become as

FIGURE 11-30 Hemoglobin (Hb) facilitating a large net transfer of O_2 by acting as a storage depot to keep P_{O_2} low. (a) In the hypothetical situation in which no Hb is present in the blood, the alveolar P_{O_2} and the pulmonary capillary blood P_{O_2} are at equilibrium. (b) Hemoglobin has been added to the pulmonary capillary blood. As the Hb starts to bind with O_2 , it removes O_2 from solution. Because only dissolved O_2 contributes to blood P_{O_2} , the blood P_{O_2} falls below that of the alveoli, even though the same number of O_2 molecules are present in the blood as in part (a). By “soaking up” some of the dissolved O_2 , Hb favors the net diffusion of more O_2 down its partial pressure gradient from the alveoli to the blood. (c) Hemoglobin is fully saturated with O_2 , and the alveolar and blood P_{O_2} are at equilibrium again. The blood P_{O_2} resulting from dissolved O_2 is equal to the alveolar P_{O_2} , despite the fact that the total O_2 content in the blood is much greater than in part (a) when blood P_{O_2} was equal to alveolar P_{O_2} in the absence of Hb.

© Cengage Learning, 2013

low as in the surrounding tissue. At this time, further transfer of O_2 ceases.

Hemoglobin thus permits the transfer of tremendously more O_2 from the blood into the cells than would be possible in its absence. Note that this means that measurements of blood P_{O_2} do not tell us the total O_2 being transported. If Hb levels are reduced to half of normal, as in a severely flea-bitten puppy, the O_2 -carrying capacity of the blood is reduced by 49% even though the arterial P_{O_2} is the normal 100 mm Hg with normal Hb saturation.

Increased CO_2 , acidity, temperature, and organic phosphates shift the O_2 -Hb dissociation curve to the right, favoring unloading

Even though the primary factor determining the % Hb saturation is the P_{O_2} of the blood, other factors can affect the affinity, or bond strength, between Hb and O_2 and, accordingly, can shift the O_2 -Hb curve (that is, change the % Hb saturation at a given P_{O_2}). These other factors are CO_2 , acidity, temperature, and organic phosphates, which we examine separately. The O_2 -Hb dissociation curves with which you are already familiar (Figure 11-29) are typical curves at normal arterial CO_2 and acidity levels, normal body temperatures, and normal organic phosphate concentrations.

Effect of P_{CO_2} An increase in P_{CO_2} shifts the O_2 -Hb curve to the right (Figure 11-31a). The % Hb saturation still depends on the P_{O_2} , but for any given P_{O_2} , the amount of O_2 and Hb

that can be combined is reduced. This effect is important, because the P_{CO_2} of the blood increases in the systemic capillaries as CO_2 diffuses down its gradient from the cells into the blood. This additional CO_2 in the blood in effect decreases the affinity of Hb for O_2 , so Hb unloads even more O_2 at the tissue level than it would if the reduction in P_{O_2} in the systemic capillaries were the only factor affecting % Hb saturation.

Effect of pH: The Bohr and Root Effects An increase in acidity also shifts the curve to the right (Figure 11-31a). Because CO_2 generates carbonic acid (H_2CO_3), the blood becomes more acidic at the systemic capillary level as it picks up CO_2 from the tissues. The resultant reduction in Hb affinity for O_2 in the presence of increased acidity aids in releasing even more O_2 at the tissue level for a given P_{O_2} . In actively metabolizing cells, such as exercising muscles, not only is more carbonic acid-generating CO_2 produced, but lactate also may be produced (see p. 55). The resultant local elevation of acid in the working muscles facilitates further unloading of O_2 in the very tissues that have the greatest O_2 need. The same effect occurs with arthropod hemocyanins.

The influence acid on the release of O_2 is known as the **Bohr effect**, discovered in 1904 by the Danish physiologist Christian Bohr. Both CO_2 and the hydrogen ion (H^+) component of acids can combine reversibly with Hb at sites other than the O_2 -binding sites. The result is an alteration in the molecular structure of Hb that reduces its affinity for O_2 . However, the magnitude of the Bohr effect is not the same for all animals with Hb. Generally it depends on overall

Arterial P_{CO_2} and acidity,
normal body temperature
(as at pulmonary level)

FIGURE 11-31 Key factors that alter the O_2 -Hb curve. (a) Effect of increased P_{CO_2} , H^+ , temperature, and 2,3-bisphosphoglycerate on the O_2 -Hb curve (human). Increased P_{CO_2} , acid, temperature, and 2,3-bisphosphoglycerate, as found at the tissue level, shift the O_2 -Hb curve to the right. As a result, less O_2 and Hb can be combined at a given P_{O_2} so that more O_2 is unloaded from Hb for use by the tissues. (b) Bohr and Root effects for Hb from a teleost (bony fish). The plot shows oxygen dissociation curves for teleost hemoglobins demonstrating the effects of acid. Acidosis reduces the affinity of Hb for O_2 (Bohr effect), shifting the curve to the right, and reduces the capacity of binding (Root effect), shifting the curve downward.

body size. For example, small mammals, with a higher metabolic rate and O_2 requirement, have Hb that is more sensitive to acid, which thus aids in delivery of O_2 to the tissues. Turtles, lizards, and snakes have smaller Bohr effects than mammals of comparable body size because of a reduced affinity of hemoglobin for O_2 . Alternatively, the large Bohr effect observed in crocodilians is considered an adaptation associated with the extended periods they need to remain submerged in order to drown their prey. In fish, the Bohr effect is observed after an increase in H^+ ion but not CO_2 . Recall that the concentration of CO_2 in water breathers is remarkably low and has little influence on O_2 binding.

In most species of fish and reptiles, there are multiple forms of Hb. Some forms are characterized by a low affinity for O_2 and a heightened sensitivity to pH (and to *nucleoside triphosphates*, which we describe shortly), whereas other forms are characterized by a high affinity and relative insen-

sitivity to pH and nucleoside triphosphates. The differences between the isoforms become evident under conditions where the acidity of the blood is increased. In these circumstances the maximal O_2 -binding capacity of one form is reduced. The effect of acidosis on lowering blood O_2 content is termed the **Root effect** (Figure 11-31b). Hydrogen ion binds to this isoform of Hb and drastically reduces its total capacity (not just its affinity, which is the Bohr effect) for O_2 . The Root effect is important when establishing the elevated P_{O_2} values in the gas bladder (see below) and may also play a role during periods of lactate accumulation associated with strenuous activity. The presence of an acid-insensitive isoform of Hb helps minimize disturbances in blood O_2 transport. However, in some species with multiple forms of Hb, such as the carp, each form displays a pronounced Root effect.

Effect of Temperature In a similar manner, an elevation in temperature shifts the O_2 -Hb curve to the right (Figure 11-31a), unloading more O_2 at a given P_{O_2} . This is of particular importance to ectotherms because many routinely undergo increases in body temperature and thus increases in metabolic rate. The increased O_2 demands at the higher temperature can be met by increased unloading of O_2 from Hb. In endotherms, a working muscle or other actively metabolizing cell also produces heat. The resultant local elevation in temperature enhances O_2 release from Hb for use by the more active tissues.

Recently, Kevin Campbell and colleagues were able to obtain DNA from 43,000-year-old woolly mammoth remains, and to clone the Hb gene from this extinct relative of elephants that lived in cold habitats during the last Ice Ages. Unlike other hemoglobins, the mammoth Hb's P_{50} was unaffected by temperature. Since cold temperature reduces the release of O_2 by other Hbs, the researchers propose that this insensitivity allowed mammoth Hb to release O_2 normally in the animal's extremities. Like many extant polar endotherms, the mammoth's limbs, trunk, tail and ears may have been very cold to prevent heat loss from the body core (due to countercurrent heat exchangers; see Chapter 15).

Overall, increases in CO_2 , acidity, and temperature (in most cases) at the tissue level, all of which are associated with increased cellular metabolism and increased O_2 consumption, enhance the effect of a drop in P_{O_2} in facilitating

the release of O_2 from Hb. These effects are largely reversed at the pulmonary level, where the extra acid-forming CO_2 is blown off and the local environment is cooler. Appropriately, therefore, Hb has a higher affinity for O_2 in the pulmonary capillary environment, thus enhancing the effect of the elevation in P_{O_2} in loading O_2 onto Hb.

Effect of Organic Phosphates The preceding changes take place in the *environment* of the red blood cells, but a factor *inside* the red blood cells of some species can also affect the degree of O_2 -Hb binding: **organic phosphates**. Specific types are (1) *2,3-diphosphoglycerate* (DPG) in most mammals (such as horses, humans, dogs, and rats), (2) *inositol pentaphosphate* (IPP) in birds, and (3) *nucleoside triphosphates* (NTPs) in fishes. *Adenosine triphosphate* (ATP) is the predominant NTP of salmonoids, sharks, and rays, whereas *guanosine triphosphate* (GTP) is found in eels, carp, and goldfish. These erythrocyte constituents, which are produced during red blood cell metabolism, bind reversibly with Hb and reduce its affinity for O_2 . Thus, an increased level of organic phosphate shifts the O_2 -Hb curve to the right, just as with CO_2 and H^+ (Figure 11-31), enhancing O_2 unloading as the blood flows through the tissues. However, unlike the other factors (which normally are present only in the systemic capillaries, where the right-shift is advantageous in unloading O_2), DPG is present in the red blood cells throughout the circulatory system and, accordingly, shifts the curve to the right to the same degree in both the tissues and the lungs. As a result, DPG decreases the ability to load O_2 at the pulmonary level. Accordingly, in order to favor O_2 loading in respiratory organs, the response of water-breathing vertebrates to chronic hypoxia is a *decline* in NTP to increase in O_2 affinity. Similarly, mammals like llamas that have evolved to live at high altitude have less DPG than sealevel species.

Interestingly, many artiodactyls (ruminants, giraffes, deer) and cats have inherently low-affinity hemoglobins that are relatively insensitive to the effects of DPG. In contrast, in most other sealevel mammals (including humans), have high-affinity hemoglobins with DPG sensitivity. Moreover, DPG production by red blood cells gradually *increases* whenever O_2 delivery is chronically below normal, as occurs at high altitudes or in certain types of circulatory or respiratory diseases. An increase in DPG may help maintain O_2 availability when there is a decreased arterial O_2 supply by promoting O_2 release at the tissue level (Hb right shift). However, at high altitude at least, it may also simply counteract a Hb left shift ensuing as O_2 -deprived animals hyperventilate (which offloads more CO_2 than normal and so raises blood pH).

Filling of the gas bladder is aided by the Root effect

The ability of an animal to achieve buoyancy or weightlessness in water is of obvious benefit because it greatly decreases the amount of energy required to maintain itself at any particular depth. A fish whose total body density is equal to that of the surrounding environment would thus be effectively weightless. One means of reducing density is to create a specific compartment containing low-density material. For example, all cartilaginous fishes have relatively light, nonmineralized bones. And some deep-sea sharks decrease their density by storing large amounts of lipid (squalene) in their livers. Consequently, these animals have

exceptionally large livers. But even these features do not make these animals neutrally buoyant, so they still tend to sink if they stop swimming. An alternative solution is to store gases—far more buoyant than lipid—within a particular compartment.

The **gas bladder** (or swimbladder) is a large, centrally located sac ventral to the spinal column in the abdominal cavity of teleost fish (Figure 11-32a). Whether a particular species of fish has a gas bladder is related to its physiological needs. For example, some bottom-dwelling and some deep-sea species lack gas bladders, and some deep-sea species have fat-filled rather than air-filled bladders because of the difficulty of inflating the bladder at high pressures. The extent to which the gas bladder must be filled to achieve buoyancy at any particular depth depends on whether the fish is a freshwater or marine type. Fresh water is less dense than seawater and so provides less buoyancy, necessitating a larger gas bladder (7 to 11% of body volume) than in marine fishes (4 to 6% of body volume), to prevent sinking.

The key to the success of the gas bladder is its ability to vary the total quantity of gas as a function of its depth in the water. If the gas bladder were to contain an unchanging concentration of gas, the particular fish would be weightless at only one depth. Because pressure increases with depth, the gas in the bladder is compressed, so decreasing the bladder's volume and increasing the relative density of the fish. To keep its increasingly denser body from sinking, the fish would have to expend energy to maintain its depth. Conversely, when a fish rises, the volume of the bladder increases and the fish becomes too light. In situations where a fish ascends from extreme depths to the surface, the bladder can actually burst. In some species, such as the carp, a duct connects the gas bladder to the esophagus, so gas can then be expelled through the mouth and gill cavities as it rises. In these species, gas may be added to the bladder by swallowing air at the surface. However, for most fishes, rising to the surface to gulp air prior to swimming at depths is impractical, and in these species the gas bladder is completely enclosed from the outside. The actual gases contained within the bladder are the same as those in water but are present in varying proportions. In most fish the gas bladder contains 80 to 95% O_2 , but in some species, such as the whitefish (*Coregonus albus*), it is almost pure N_2 .

The ability to adjust the quantity of gas within the bladder arises from several sources:

1. A **gas gland** within the wall of the gas bladder. The gland operates anaerobically to secrete lactate into the blood, which lowers the pH of the blood leaving the gland.
2. An unusual blood supply called the **rete mirabile** ("wonderful net"), which perfuses the gas gland. The rete mirabile is a dense bundle of capillaries arranged side by side in *countercurrent* fashion.
3. Hemoglobins exhibiting the **Root effect**.

Using these features, gas can be transferred from the blood vessels lining the gas bladder into the gas bladder. Inflating the gas bladder is an active process, because it is accomplished against a pressure gradient within the bladder, as follows (Figure 11-32b):

1. The blood arriving at the gas bladder is carrying gas at a pressure equal to that of the water passing through the gills, but with most of the O_2 in nondiffusible form as Hb- O_2 .

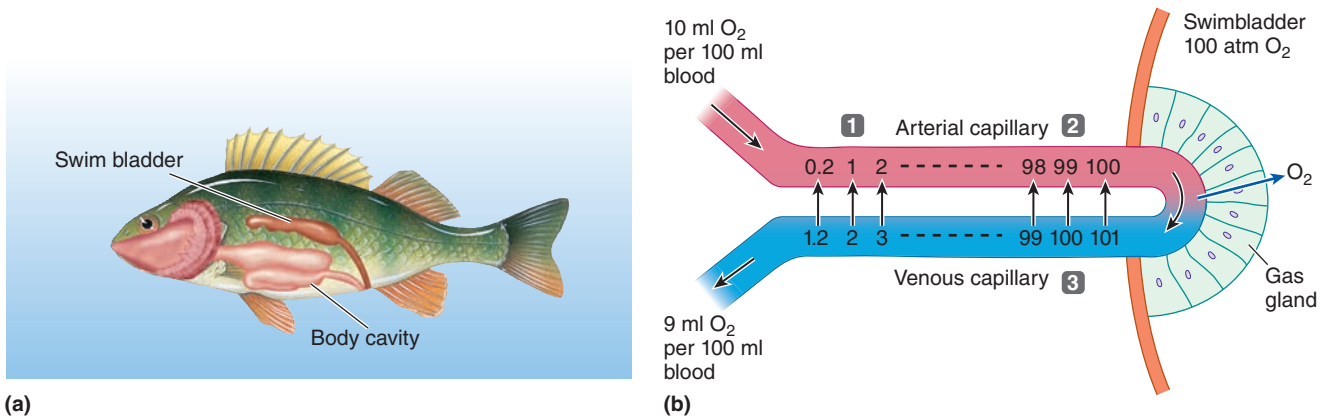

FIGURE 11-32 The gas bladder of a fish. (a) A lateral view of a teleost showing the relative location of the gas or swimbladder in the abdominal cavity. (b) Countercurrent multiplier system for filling the gas bladder. Production of lactate from the gas gland increases O_2 tension in the venous capillary (values are shown in atmospheres or atm). As a result, O_2 diffuses down its concentration gradient into the arterial capillary, thus remaining within the rete. However, the O_2 content of the venous blood exiting the rete is now lower than the incoming arterial blood with the difference deposited in the gas bladder.

2. The gas gland secretes lactate into the incoming capillaries, triggering the release of O_2 from isoforms of Hb having both the Bohr and Root effects. (Lactate also forces nitrogen out of solution.) The local partial pressure thus increases in the capillary, favoring diffusion of gas into the bladder. However, the gas exits the area by the outgoing capillary, and the partial pressure of this gas is equal to that of the gas within the gas bladder, much higher than that in the incoming capillary.
3. Because of the countercurrent blood flow between the opposing vessels, gas diffuses from the outgoing blood into the incoming blood that is supplying the gas gland. The dissolved gas increases in the vessel and so returns to the bladder. This process is repeated continuously, with higher and higher concentrations of gas collecting at the junction point of the incoming and outgoing capillaries within the gas gland.

It is the pH-dependent release of O_2 from Hb via the Root effect that ultimately accounts for the ability of fish to force O_2 into the gas bladder. Diffusion of gases stored in the bladder is restricted by the presence of multiple sheets of crystalline guanine, which line the wall of the gas bladder. The countercurrent rete prevents dissipation of the gradient.

Deflating the gas bladder as a fish decreases its depth is a passive process (favored when the gas gland is less active). Gases move down their partial pressure gradients into the surrounding capillaries, and are then transported to the gills.

Most CO_2 is transported in the blood as bicarbonate

When arterial blood flows through the tissue capillaries, CO_2 diffuses down its partial pressure gradient from the tissue cells into the blood. Carbon dioxide in vertebrates is transported in the blood in three ways (Figure 11-33):

1. *Physically dissolved.* As with dissolved O_2 , the amount of free CO_2 *physically dissolved* in the blood depends on the P_{CO_2} . Because CO_2 is more soluble than O_2 in the blood, a greater proportion of the total CO_2 in the blood is physically dissolved compared to O_2 . Even so, only about 5 to 10% of an air breather's total blood CO_2 is carried this way at the normal systemic venous P_{CO_2} level. This amount is further reduced in fish and is estimated to be less than 5% of the total CO_2 carried in the blood.
2. *Bound to hemoglobin.* Another 25 to 30% (in mammals) of the CO_2 combines with Hb to form **carbamino hemoglobin** ($HbCO_2$). Carbon dioxide binds with the globin (protein) portion of Hb, reacting with the nitrogen of the last amino acid of the protein chain:

This is in contrast to O_2 , which combines with the heme iron. However, $HbCO_2$ is unimportant in fish, because their Hb has been modified (acetylated), preventing binding.

3. *As bicarbonate.* By far, the most important means of CO_2 transport is as **bicarbonate** (HCO_3^-) ion. In fish, HCO_3^- generally constitutes approximately 90 to 95% of the total CO_2 in the blood, whereas in mammals it is about 60 to 70%. The CO_2 is converted into HCO_3^- in part by the following chemical reaction:

In the first step, CO_2 combines with H_2O to form **carbonic acid** (H_2CO_3). As is characteristic of acids, some of the carbonic acid molecules spontaneously dissociate into hydro-

ca = Carbonic anhydrase

FIGURE 11-33 Gas transport in the blood (vertebrate). *Left:* Carbon dioxide (CO_2) picked up at the tissue level is transported in the blood to the lungs in three ways: (1) physically dissolved, (2) bound to hemoglobin (Hb), and (3) as bicarbonate ion (HCO_3^-). Oxygen enters the cells primarily from Hb, which is present only in the red blood cells, as is carbonic anhydrase, the enzyme that catalyzes the production of HCO_3^- . The H^+ generated during the production of HCO_3^- also binds to Hb. Bicarbonate moves by facilitated diffusion down its concentration gradient out of the red blood cell into the plasma, and chloride (Cl^-) moves by means of the same passive carrier into the red blood cell down the electrical gradient created by the outward diffusion of HCO_3^- . *Right:* The reactions that occur at the tissue level are reversed at the pulmonary level, where CO_2 diffuses out of the blood to enter the alveoli, and O_2 enters where most of it binds to Hb.

© Cengage Learning, 2013

gen ions (H^+) and bicarbonate ions (HCO_3^-). The one carbon and two oxygen atoms of the original CO_2 molecule are thus present in the blood as an integral part of HCO_3^- . This is beneficial because HCO_3^- (1) is more soluble in the blood than CO_2 is, and (2) cannot diffuse through membranes on its own, making it more controllable than the free gas.

This reaction takes place slowly in the plasma, but it proceeds swiftly within the red blood cells because of the presence of the erythrocyte enzyme **carbonic anhydrase**, which catalyzes (speeds up) the reaction. In fact, under the influence of carbonic anhydrase, the reaction proceeds directly from CO_2 to HCO_3^- without the intervening H_2CO_3 step:

OH^- ion is derived from the ionization of water (below). As the OH^- ion is consumed by CA, the reaction is driven to the right, resulting in the generation of H^+ ion.

Carbonic anhydrase is also found in lungs and kidneys of mammals, lungs of amphibians, and in gills of fishes. Small

mammals contain higher concentrations of this enzyme because of the ability of H^+ ion to increase the rate of O_2 delivery to the tissue (Bohr effect).

Unlike hemoglobins found in most animals, crocodile Hb has evolved the unique ability to bind to HCO_3^- . Under conditions where the crocodile remains submerged for prolonged periods, the binding of HCO_3^- ions on Hb results in the progressive unloading of O_2 from its binding sites on Hb, permitting this vast reservoir of O_2 to be available to the respiring tissues.

Chloride Shift As this reaction proceeds, HCO_3^- and H^+ start to accumulate within the red blood cells in the systemic capillaries. The red-cell membrane has a $\text{HCO}_3^-/\text{Cl}^-$ *antiport carrier* (p. 85) that passively facilitates the diffusion of these ions in opposite directions across the membrane (Figure 11-33). Thus, HCO_3^- diffuses down its concentration gradient out of the erythrocytes into the plasma, where it can be transported to the gills or lungs. Because HCO_3^- is a negatively charged ion, the efflux of HCO_3^- unaccompanied by a comparable outward movement of positively charged ions creates an electrical gradient. Chloride ions (Cl^-), the dominant plasma anions, conduct into the red blood cells

down this electrical gradient to restore electric neutrality. This inward shift of Cl^- in exchange for the outflux of HCO_3^- is known as the **chloride (Cl^-) shift**.

The membrane is relatively impermeable to H^+ , where the vast majority generated by the dissociation of H_2CO_3 becomes bound to Hb (exerting the Bohr effect). Because only free dissolved H^+ contributes to the acidity of a solution, the venous blood would be considerably more acidic than the arterial blood if it were not for Hb mopping up most of the H^+ generated at the tissue level.

Haldane Effect As you have seen, the binding of both H^+ and CO_2 to oxyhemoglobin (HbO_2) favors release of O_2 (the Bohr effect). Conversely, deoxy-Hb has a greater affinity for both CO_2 and H^+ than does HbO_2 . The unloading of O_2 from Hb in the tissue capillaries therefore facilitates the picking up of CO_2 and H^+ by Hb. The ability of deoxygenated Hb to pick up CO_2 and CO_2 -generated H^+ is known as the **Haldane effect**. The Haldane effect and Bohr effect work in synchrony to facilitate gas exchange: Increased CO_2 and H^+ cause increased O_2 release from Hb by means of the Bohr effect; increased O_2 release from Hb, in turn, causes increased CO_2 and H^+ uptake by Hb through the Haldane effect. The entire process is very efficient. Deoxygenated Hb must be carried back to the lungs to reload with O_2 in any event. Meanwhile, after O_2 is released, Hb picks up new passengers— CO_2 and H^+ —that are going in the same direction to the lungs.

The reactions that occur at the tissue level as CO_2 enters the blood from the tissues are reversed due to mass action once the blood reaches the lungs or gills and CO_2 leaves the blood to enter the alveoli (Figure 11-33) or ventilatory water outside the gill epithelium.

Various respiratory states are characterized by abnormal blood gas levels

Both gases can enter in abnormal states, although some of these states occur within the normal lifestyles of some animals.

Abnormalities in Arterial P_{O_2} The term **hypoxia** refers to insufficient O_2 at the cellular level. There are four general categories of hypoxia:

1. **Hypoxic hypoxia** is characterized by a low arterial blood P_{O_2} accompanied by inadequate Hb and blood saturation. It is caused by (a) a respiratory malfunction involving inadequate gas exchange, typified by a normal alveolar (or gill chamber) P_{O_2} but a reduced arterial P_{O_2} , or (b) exposure to an environment where environmental P_{O_2} is reduced, so that alveolar (or gill chamber) and arterial P_{O_2} are likewise reduced. This occurs in low-oxygen habitats for water breathers, at high altitudes, or during diving for air breathers (see *A Closer Look at Adaptation: High Fliers and Deep Divers* on p. 544).
2. **Anemic hypoxia** refers to a reduced O_2 -carrying capacity of the blood. It can be brought about by (a) a decrease in circulating red blood cells, (b) an inadequate amount of Hb within the red blood cells, or (c) Hb poisoning (such as by *carbon monoxide*, a gas that binds more tightly to heme than does O_2). In all cases of anemic hypoxia, the arterial P_{O_2} is at a normal level, but the

O_2 content of arterial blood is lower than normal because of the reduction in available Hb.

3. **Circulatory hypoxia** arises when too little oxygenated blood is delivered to the tissues. Circulatory hypoxia can be restricted to a limited area as a result of a local vascular spasm or blockage. In contrast, widespread circulatory hypoxia can result from congestive heart failure or circulatory shock. The arterial P_{O_2} and O_2 content may be normal, but too little oxygenated blood reaches the cells.
4. In **histotoxic hypoxia**, O_2 delivery to the tissues is normal, but the cells cannot use the O_2 available to them. The classic example is *cyanide poisoning*. Cyanide blocks cellular enzymes of the mitochondrial electron-transport chain (p. 51).

Hypoxia triggers a number of genetic and cellular processes; see the box, *Molecular Biology and Genomics: HIF to the Rescue* on p. 549.

Hyperoxia, an above-normal arterial P_{O_2} , cannot occur when an animal is breathing atmospheric air at sea level. However, breathing supplemental O_2 can increase alveolar and consequently arterial P_{O_2} .

Abnormalities in Arterial P_{CO_2} The term **hypercapnia** refers to excess CO_2 in the arterial blood; it can be caused by **hypoventilation** (ventilation inadequate to meet the metabolic needs for O_2 delivery and CO_2 removal) or by exposure to high environmental CO_2 .

Hypocapnia, below-normal arterial P_{CO_2} levels, is brought about by **hyperventilation**; this occurs when an animal “overbreathes,” that is, when the rate of ventilation is in excess of the body’s metabolic needs for CO_2 removal so that CO_2 is blown off to the atmosphere more rapidly than it is produced in the tissues and arterial P_{CO_2} falls. Hyperventilation can be triggered by anxiety states and by fever. Alveolar P_{O_2} increases during hyperventilation as more fresh O_2 is delivered to the alveoli from the atmosphere than is extracted from the alveoli by the blood for tissue consumption, and arterial P_{O_2} increases correspondingly (Figure 11-34). However, because Hb is almost fully saturated at the normal arterial P_{O_2} , very little additional O_2 is added to the blood. Except for the small extra amount of dissolved O_2 , blood O_2 content remains essentially unchanged during hyperventilation.

Increased ventilation is not synonymous with hyperventilation. Increased ventilation that matches an increased metabolic demand, such as the increased need for O_2 delivery and CO_2 elimination during activity, is termed **hyperpnea**. During activity, alveolar P_{O_2} and P_{CO_2} remain constant, with the increased atmospheric exchange just keeping pace with the increased O_2 consumption and CO_2 production.

Consequences of Abnormal Blood Gas Levels The consequences of reduced O_2 availability to the tissues during hypoxia are apparent. The cells need adequate O_2 supplies to sustain their energy-generating metabolic activities. The consequences of abnormal blood CO_2 levels are less obvious. *Changes in blood CO_2 concentration primarily affect acid-base balance.* Hypercapnia results in an elevated production of carbonic acid. The subsequent generation of excess H^+ produces an acidic condition termed **respiratory acidosis**. Conversely, less-than-normal amounts of H^+ are generated

FIGURE 11-34 Effects of hyperventilation and hypoventilation on arterial P_{O_2} and P_{CO_2} .

© Cengage Learning, 2013

through carbonic acid formation in conjunction with hypocapnia. The resultant alkalotic (less acidic than normal) condition is called **respiratory alkalosis** (see Chapter 13).

Other unusual respiratory states such as apnea are not necessarily pathological

Not all unusual respiratory conditions are abnormal.

Apnea One of these is **apnea**, a temporary cessation of breathing. It is a normal characteristic of hibernating mammals and of reptiles, and of diving air breathers. In general, terrestrial reptiles have comparatively brief periods of apnea relative to their aquatic counterparts. This may be due, in part, to the energy costs associated with surfacing to breathe. Aquatic turtles and snakes exhibit periods of apnea of several minutes, whereas in crocodilians and some diving mammals, breathing may cease for periods over an hour. Periods of *sleep apnea* in elephant seals can range from 10 to 25 minutes and are followed by several minutes of regular breathing. Sleep apnea is considered similar to the diving response (see *A Closer Look at Adaptation: High Fliers and Deep Divers*) because both heart rate and metabolism decline. Sleep apnea does occur as a disorder in some humans, and is a threat to health.

Long-Term Hypoxia and Anoxia Some animals have adapted to very long periods of extreme hypoxia, or **anoxia**—the complete lack of oxygen. In 2011, researchers reported a nematode worm (*Halicephalobus mephisto*) living over 1 km beneath the Earth's surface in warm, almost anoxic waters, eating bacteria which were previously thought to be the only life this deep. Recall that certain deep-sea Loriciferans may go without O_2 their entire lives (p. 57). Other animals are thought to require O_2 for at least some periods, but some do

show a most remarkable resistance to anoxia. Goldfish (*Carassius auratus*) and their close relatives, the Crucian carp (*Carassius carassius*), are well-known examples. Indeed, this is why they became favorite pets in simple bowls in households and display fish in artificial ponds, for aeration is not required for them to survive. Unlike other pond animals such as turtles—which eventually become comatose in low O_2 —goldfish and carp remain active for one to two days with no detectable O_2 in the water. And they can survive over winter in the bottom of an oxygen-less pond sealed with ice. How can they do this?

The most critical organ in anoxia is the brain, which needs a constant high supply of ATP to maintain ion balance via its Na^+/K^+ ATPase “pumps” (p. 84). Recall that, without O_2 , only 2 ATPs are produced for each glucose molecule (compared to perhaps 30 in the presence of O_2) (p. 53). The carp and goldfish solve this low-ATP problem in part by reducing metabolism during anoxia. They also have large stores of glycogen in the liver, which is the main source of glucose for anaerobic metabolism. But in addition to energy problems, an animal in anoxia must avoid the lactate poisoning that results from normal anaerobic metabolism (Chapter 2). Remarkably, these fish (in their muscles primarily) make **ethanol**—the intoxicating ingredient of fermented beverages—as an end product, just as yeast do (p. 56). Ethanol (unlike lactate) has the advantages of being nonacidic and being able to readily diffuse out of the gills. Using this strategy, fish avoid the acid-base problems that freshwater turtles must endure (see Chapter 13). Pond-living carp employ two additional strategies to cope with the anoxic water conditions found in winter. During the fall, in response to the decline in water temperatures, these fish store large amounts of glycogen in their brain, an approximately 15-fold increase compared to that measured during the summer months. In addition, the activity of the brain's Na^+/K^+ ATPase “pumps” decreases approximately 10-fold, which dramatically lowers its energy requirements. Thus, during the winter when energy demands are low, the glycogen level that supports brain function in the carp for 16 hours would provide the same support for only eight minutes during the summer.

Equally as astounding as the goldfish's ability to withstand anoxia is the ability of the epaulette shark to survive periods of up to three hours with complete oxygen deprivation. Occasionally this reef inhabitant is left stranded in the shallows during low tide, where O_2 concentrations rapidly fall to levels that result in permanent brain damage for other fish species. How can the epaulette shark master this feat? Studies have shown that a series of biochemical events unfold as the duration of anoxia increases:

1. As P_{O_2} in the tidal pool falls, the epaulette shark reduces both its rate of respiration and heartbeat, and decreases arteriolar resistance to the brain.
2. GABA—a depressive neurotransmitter (p. 133)—is released in order to “turn off” nonessential neurological regions of the brain.
3. The animal greatly reduces its neural electrical activities, at least in the eye. Researchers found that retinas of quiescent epaulette sharks were completely unresponsive to light. They speculate that other neural circuits are also suppressed.
4. Most critically, perhaps, the anoxic shark can “turn down” the activity of its mitochondria. Normally, in most

A Closer Look at Adaptation

High Fliers and Deep Divers

As you have seen, some animals have respiratory systems that work at incredible extremes. For high altitude, the champion is probably the bar-headed goose (*Anser indicus*). It migrates biannually above 9,000 m over the Himalayas, often fighting fierce headwinds in air with O₂ less than 30% of that at sea level. Earlier, we noted that it has (1) a Hb with a higher affinity than those of other birds. However, this is not enough to explain its amazing ability. In addition, it has (2) unusually large wings to provide lift in the thin atmosphere and make use of updrafts efficiently, (3) unusually dense muscle capillary networks for enhanced O₂ delivery, (4) a much greater tidal volume than other birds (which enhances parabronchial ventilation more than increased respiratory rate would), (5) muscle mitochondria placed much closer to the fiber membranes (and thus closer to capillaries), and (6) higher aerobic capacity in terms of mitochondrial enzymes.

Now let's look at another extreme habitat, in some ways the opposite of the Himalayas: the deep sea. Perhaps most astounding are those diving mammals that are capable of taking a breath at the surface, diving to extraordinary depths in a comparatively short period of time, and then resurfacing. Let's start with the situation as a deep-sea diver descends underwater. The body is immediately exposed to greater than atmospheric pressure. Pressure increases with depth as a result of the weight of the water, increasing by about 1 atm per each 10 m deeper. High pressure has many direct effects on biological structures, including reduced membrane fluidity and perturbed pro-

tein folding. We explore adaptations to these elsewhere (pp. 145 and 625). In humans, who are not adapted to high pressure, a malady called **high-pressure neurological syndrome (HPNS)** occurs in divers at depths below 200 m, manifested as tremors and convulsions. Pressure decreases rate of action potential propagation and excitatory synaptic transmission, apparently as the result of a decrease in neurotransmitter release.

What about pressure and gases? Recall that (1) the amount of a gas in solution is directly proportional to the partial pressure of the gas and that (2) air has 79% N₂. Nitrogen is poorly soluble in body tissues, but the high pressure that occurs during deep-sea diving causes more of this gas than normal to dissolve in the body tissues. The small amount of N₂ dissolved in the tissues at sea level has no known effect, but as more N₂ dissolves at greater depths, **nitrogen narcosis**, or **raptures of the deep**, ensues in humans. Nitrogen narcosis is believed to result from a reduction in the excitability of neurons because of the highly lipid-soluble N₂ dissolving in their lipid membranes.

Another problem associated with deep-sea diving occurs during ascent. If a diver who has been submerged long enough for a significant amount of N₂ to become dissolved in the tissues suddenly ascends to the surface, the rapid reduction in pressure causes N₂ to quickly come out of solution and form bubbles of gaseous N₂ in the blood, blocking capillaries. The consequences depend on the amount and location of the bubble formation. This condition is called **decompression sickness** or **the**

bends, the latter term arising because the victim often bends over in pain. Decompression sickness can be prevented by slow ascent to the surface or by gradual decompression in a decompression tank so that the excess N₂ can slowly escape through the lungs without bubble formation.

Contrast the abilities of a human with those of a diving marine mammal. Foraging escapades can take some of these animals to depths of 1,500–2,000 m below the surface in less than 20 minutes. At these depths, pressure of 150–200 atm (over a ton per square inch) forms, and yet Weddell and elephant seals and sperm whales can stay at 1,500 m for an hour or more! The champion may be Cuvier's beaked whale, recently tracked in a dive to about 2,000 m for 85 minutes, presumably to hunt for giant squid found at these remarkable depths. These animals' ability to accomplish these feats seems to defy all known physiological limits, yet they can repeat this feat again and again over a 24-hour period. How is this possible? Several adaptations have been found over the years:

- **Dive reflex:** First, early studies of seals discovered an adaptation called the **dive reflex**:
 - (i) Elimination of blood flow to most organs (other than the heart, brain, and adrenal gland), saving O₂ by reducing metabolic demands. Interestingly, maintenance of blood flow to the adrenal gland may be important for normal release of cortisol during

species of animals, as O₂ is restored to the anoxic tissues (reperfusion), the mitochondria mysteriously generate free radicals (p. 53) from whatever O₂ becomes available. This results in brain injury and apoptosis (cell death, p. 101). Because the epaulette shark's mitochondria are functioning at a lower level, the return of O₂ to the brain cells does not result in the generation of free radicals.

As a consequence the shark becomes limp and flaccid; but should a predator or potential prey move into the vicinity, its apparently unsuppressed electroreceptors (p. 261) cause the seemingly dead animal to revert back to life!

Ischemic Preconditioning Recent studies from the laboratory of Roberto Bolli have revealed the protective mechanisms of *ischemic preconditioning* in heart tissue. In this

procedure brief periods of **ischemia** (lack of blood flow to an organ), in this case vascular occlusion for 3 to 5 minutes, results in the heart developing resistance to the potential damage resulting from later ischemia, as might occur in a heart attack. For this protection to occur three cardioprotective proteins must be induced in response to the oxidative stress:

- **iNOS** (Nitric oxide synthase) which increases nitric oxide (NO). NO reacts with the superoxide radicals generated in response to the oxidative stress to generate the harmful nitrogen radical peroxynitrite (ONOO⁻). NO may suppress mitochondrial respiration, and it also induces:
- **HO-1** (heme oxygenase) which produces carbon monoxide (CO) (along with biliverdin; p. 688). In turn, CO induces:

a dive. Evidence suggests cortisol stabilizes neurons, thus preventing the onset of HPNS.

- (ii) Suppression of shivering and reduction of body temperature by up to 3°C.
- (iii) Apnea accompanied by a decrease in heart rate to as little as 2–6 beats/min at depth. This *bradycardia* (“slow heart”) decreases the work load of the heart and thus its O₂ requirement.

Phylogenetic studies indicate that this diving reflex is ancestral in all mammals (including humans), so is not special to diving mammals except that it is more effective than in nondivers. But other adaptations are wholly unique to divers:

- **Lungs:** The effects of N₂ are mostly avoided with distinct lung features. Shallow-diving birds and turtles rely on O₂ from their lungs to sustain them during their dives. However, the lungs of the (deep-diving) seals actually collapse by approximately 40 m below the surface. Seals exhale prior to diving, which significantly lowers gas volumes within the lungs. Considering the animals’ body size, the lungs are proportionately small, further reducing their capacity for the uptake of N₂. High pressure squeezes the remaining gas out of the lungs into the bronchial air-duct system. Both the bronchi and bronchioles are supported by rings of cartilage, which resist compression at depth, with the result that these air-

ways store the remaining gases and do not introduce them into the circulation. Another advantage of exhaling before diving is to reduce the buoyancy of the animal, which aids it in the descent. However, recent studies have demonstrated that at least sperm whales suffer some complications from decompression illness. When the dissolved nitrogen reverts to a gas and forms bubbles in the bone and cartilage of these animals, the bone dies and is not repaired. In time, the injuries form deep gaps in the bone, a condition termed **osteonecrosis** in humans. Characteristically, the older the sperm whale at the time of death, the greater the amount of bone damage sustained from the bends.

- **Oxygen storage** has been greatly enhanced by adaptations involving respiratory pigments. The blood of divers has up to two times greater hemoglobin concentration than does blood of nondivers, with the hematocrit of diving mammals being 60% in the Weddell seal versus 35 to 40% in humans. Similarly, red muscle has a greater myoglobin content. Most recently, diving mammals, as well as very active shallow mammals, were found to have high neuronal levels of *neuroglobin* and *cytoglobin* (p. 533). Diving mammals can also squeeze out O₂-rich erythrocytes from their abnormally enlarged spleens (as do the spleens of horses during intense activity). Blood constitutes approxi-

mately 20% of the body weight of the elephant seal, compared to only 7% in humans.

- **Buffering:** Anaerobic acidosis is prevented during the dive by confining anaerobic metabolism to the skeletal muscles, which have extremely high buffer content in the form of histidine dipeptides (p. 641). Because blood flow to this tissue is cut off, lactate cannot be released into the blood until the animal resurfaces. Only then can the liver and kidneys metabolize this by-product.
- **Gliding:** Some diving mammals use a gliding technique to save energy during the dive. They stop all locomotory movements, and let gravity pull them down once their lungs collapse so that they are no longer buoyant. This behavioral effector saves oxygen.

- *ecSOD* (extracellular superoxide dismutase) which inactivates the superoxide radical and ONOO⁻ and induces more iNOS.

If any of these three proteins is inhibited from expression the protective effect is gone, while upregulating any one of these three proteins increases protection because each is linked to the other.

This finishes our detailed examination of circulatory bulk transport (step 3 of Figure 11-1) as a gas transport mechanism, and its effects on gas exchange. We end the chapter with a look at mechanisms for regulating ventilation and coordinating it with circulation.

11.10 Control of Respiration

Like the heartbeat and circulation, ventilation must occur frequently if not continuously to sustain life processes in many animals. Both systems (cardiac, respiratory) must also be altered coordinately during elevated activity. The underlying controls of these two systems are similar in some ways, but remarkably different in others. Both, however—in typical hierarchical control (p. 19)—are under *intrinsic* (local) and *extrinsic* (neural, hormonal) regulation. Recall that intrinsic control allows for local needs to be met with little feedback delay, while extrinsic controls can coordinate actions for bodywide needs, as well as *anticipate* actions shortly to be needed.

Spiracles that control tracheal ventilation in insects are regulated intrinsically and extrinsically for both gas exchange and evaporation control

Consider tracheal ventilation in terrestrial insects, which is often continuous during high activity, and discontinuous (intermittent) during rest. Discontinuous breathing may reduce (although the evidence is debated) a major problem of the tracheal system, that of water loss. Alternatively or in addition, it has been proposed that the purpose of discontinuous breathing is to maintain low concentrations of O₂ in the trachea. Because the tracheal system is very efficient at obtaining O₂, and too much O₂ is damaging (see p. 53), then during periods of inactivity the priority may be to limit O₂ intake. Indeed, studies conducted on the moth *Attacus atlas* over a range of ambient O₂ concentrations found that tracheal O₂ concentrations were consistently low.

Ventilation is in part controlled by valvelike spiracles (Figures 11-3e and 11-8), which in turn are regulated by both local and neural mechanisms. For example, locust spiracles will relax if exposed to CO₂, which directly reduces electrical activity at the muscle itself. This response increases ventilation rapidly as CO₂ builds up. Extrinsically, however, spiracles are tightly regulated by motor output originating in the **metathoracic ganglia**. An increase in the firing rates stimulates *closer muscles* to reduce the diameter of the elastic spiracles, which then spring open when the muscles relax. However, in some insects such as firebrats (relatives of silverfish), opening involves higher firing rates and thus contraction of the closer muscles, which cause a flap to pull back from the opening; when the muscles relax, the flap springs back to cover the opening. In either case, the resistance to gas flow as well as the total ventilation volume can respond to chemoreceptors that detect changes in CO₂ (and possibly O₂ levels) in the hemolymph. Recent studies show that in the fruit fly *Drosophila*, spiracles are opened and closed during flight such that O₂ needs are precisely met, while at the same time water loss is reduced by having the spiracles closed periodically.

Extrinsic and intrinsic controls act on the smooth muscle of mammalian airways and arterioles to maximally match ventilation to perfusion

Now let's look at ventilation in mammals, starting with the airways themselves. In Chapter 9 you learned that blood

flow is adjusted to match both local and bodywide needs during varying levels of activity. This is accomplished primarily at the *arterioles*, which have muscular valves controlled by both extrinsic and intrinsic mechanisms (pp. 432–437). For example, during elevated muscular activity, arterioles in skeletal muscles are *vasodilated* by both extrinsic epinephrine and local chemical changes (such as decreasing O₂), resulting in increased volume of blood to those muscles. This is important for matching blood supply (perfusion) to local metabolic needs. At the same time, arterioles going to the gut are *vasoconstricted* by sympathetic nerves to divert blood flow elsewhere.

Adjustments in airway size can be accomplished similarly and for comparable reasons. In particular, this is to ensure that *ventilation rates match perfusion rates* for the most effective gas exchange. If, for example, perfusion of the alveoli were to increase during activity without an increase in ventilation, the blood would not be oxygenated sufficiently to meet the increased bodywide demand. Let's see how this matching occurs.

Extrinsic Regulation The autonomic nervous system can adjust airflow to suit the animal's respiratory needs. Parasympathetic stimulation, which occurs in quiet, relaxed situations when the demand for airflow is not high, promotes **bronchoconstriction** from smooth-muscle contraction, increasing airway resistance. In contrast, sympathetic stimulation and to a greater extent epinephrine, bring about **bronchodilation** and thus decreased airway resistance by promoting bronchiolar smooth-muscle relaxation. Since sympathetic domination predominates when increased demands for O₂ uptake are anticipated or actually occurring, bronchodilation ensures that the pressure gradients in the airways can achieve maximum airflow with minimum resistance. Importantly, activation of the sympathetic system simultaneously increases blood flow (via cardiac output and vasodilation), matching perfusion with ventilation.

These processes are relevant only to the contribution of the overall resistance of all the airways collectively. However, the resistance of individual airways supplying specific alveoli can be adjusted independently in response to changes in the airways' local environment.

Intrinsic Regulation: Effect of CO₂ on Bronchiolar Smooth Muscle Like arteriolar smooth muscle, bronchiolar smooth muscle is sensitive to local changes within its immediate environment, particularly to local CO₂ levels. If an alveolus is receiving too little ventilation in comparison to its perfusion, CO₂ levels will increase in the alveolus and surrounding tissue as more CO₂ is dropped off by the blood than is being exhaled into the atmosphere. This local increase in CO₂ acts directly on the bronchiolar smooth muscle to induce the airway supplying the under-aerated alveolus to relax. The resultant decrease in airway resistance leads to an increased airflow to the involved alveolus, so its airflow now matches its blood supply (Figure 11-35). The converse is also true. A localized decrease in CO₂ associated with an alveolus that is receiving too much air for its blood supply directly increases contractile activity of the airway smooth muscle involved, causing the airway supplying this over-aerated alveolus to constrict. The result is a reduction in airflow to the overaerated alveolus.

Intrinsic Regulation: Effect of O_2 on Pulmonary Arteriolar Smooth Muscle

A similar locally induced effect on pulmonary vascular smooth muscle also takes place simultaneously to maximally match blood flow to airflow. Just as in the systemic circulation, distribution of the cardiac output to different alveolar capillary networks can be controlled by adjusting the resistance to blood flow through specific pulmonary arterioles. If the blood flow is greater than the airflow to a given alveolus, the O_2 level in the alveolus and surrounding tissues will fall below normal as more O_2 than usual is extracted from the alveolus by the overabundance of blood. The local decrease in O_2 concentration causes vasoconstriction of the pulmonary arteriole supplying this particular capillary bed; the result is a reduction in blood flow to match the smaller airflow. Conversely, an increase in alveolar O_2 concentration caused by a mismatched large airflow and small blood flow brings about pulmonary vasodilation, which increases blood flow to match the larger airflow. Note that the local effect of O_2 on pulmonary arteriolar smooth muscle is appropriately just the opposite of its effect on systemic arteriolar smooth muscle:

- Systemic arteries: vasodilate with decreased O_2 ; vasoconstrict with increased O_2
- Pulmonary arteries: vasoconstrict with decreased O_2 ; vasodilate with increased O_2

Respiratory centers in the vertebrate brain stem establish a rhythmic breathing pattern

Unlike the heartbeat in myogenic hearts, which is rhythmically triggered by an intrinsic pacemaker (p. 406), vertebrate breathing is regulated by a rhythmic neural program in the **medullary respiratory center** in the brain stem (Figure 11-36). This neural integrator has inputs from chemosensors

FIGURE 11-36 Respiratory control centers in the brain stem (human).

© Cengage Learning, 2013

that measure blood gas levels, and outputs to breathing effectors (muscles) in negative-feedback fashion. The lack of intrinsic regulation is presumably because breathing requires coordination among multiple organs. However, feedback delays are minimized by having a regulatory center that is close to the sensors and effectors and that can operate independently of higher brain centers.

We focus primarily on mammalian breathing, but note important features of other vertebrates. Neural control of respiration involves three distinct components: (1) the neu-

ral *pattern generator* program responsible for the alternating inspiration/expiration rhythm, (2) the factors that regulate the magnitude of ventilation (that is, the rate and depth of breathing) to match physiological needs, and (3) the factors that modify respiratory activity to serve other purposes. The latter modifications can be made by higher brain centers, as in the breath control required for vocalization or for nonreflex breath holding, and by reflexes, as in the respiratory maneuvers involved in a cough or sneeze.

In mammals, the primary respiratory control center consists of several aggregations of neuronal cell bodies within the medulla that provide output to the respiratory muscles. In addition, there are two other medullary respiratory centers higher in the pons—the *apneustic center* and *pneumotaxic center*. These pontine centers influence the output from the medullary respiratory center (Figure 11-36). Here is a description of how these various regions interact to establish respiratory rhythmicity.

Inspiratory and Expiratory Neurons in the Medullary Center

Mammals rhythmically breathe in and out during quiet breathing because of alternate contraction and relaxation of the inspiratory muscles supplied respectively by the phrenic nerve and intercostal nerves. The cell bodies for the neuronal fibers composing these nerves are located in the spinal cord (Figure 11-37). Impulses originating in the medullary center terminate on these motor-neuron cell bodies. When these motor neurons stimulate the inspiratory muscles, this leads to inspiration; when these neurons are not firing, the inspiratory muscles relax and expiration takes place.

The medullary respiratory center consists of two neuronal clusters (Figure 11-36).

1. The **dorsal respiratory group (DRG)** consists mostly of *inspiratory neurons* whose descending fibers terminate on the motor neurons that supply the inspiratory muscles. When the DRG inspiratory neurons fire, inspiration takes place; when they cease firing, expiration occurs. Expiration is brought to an end as the inspiratory neurons once again reach threshold and fire.
2. The **ventral respiratory group (VRG)**, connected to the DRG, is composed of *inspiratory neurons* and *expiratory neurons*, both of which remain inactive during normal quiet breathing. This region is called into play by the DRG as an

“overdrive” mechanism during periods when demands for ventilation are increased. It is especially important in active expiration. No impulses are generated in the descending pathways from the expiratory neurons during quiet breathing. Only during active expiration do the expiratory neurons stimulate the motor neurons supplying the expiratory muscles (the abdominal and internal intercostal muscles). Furthermore, the VRG inspiratory neurons, when stimulated by the DRG, rev up inspiratory activity when demands for ventilation are high.

Molecular Biology and Genomics

HIF to the Rescue

When an air breather accustomed to low altitude travels to high altitude, or a water breather accustomed to well-oxygenated waters encounters hypoxic water, internal hypoxia ensues from low oxygen availability. This is not an uncommon phenomenon in some species: consider human mountaineers or cattle migrating to high summer pastures. The body's initial reaction is an increase in ventilation and circulation, but over prolonged time at high altitude, acclimatization changes occur, including (1) an *increase in red blood cell numbers* triggered by the hormone *EPO* from the kidney (p. 393); and (2) *angiogenesis*, the growth of new capillaries triggered by the paracrine *vascular endothelial growth factor (VEGF)*. For decades, physiologists have sought the sensory mechanisms by which cells producing these hormones detect low O_2 . The key appears to be regulation of **hypoxia-inducible factor (HIF)**, a transcription factor that binds to response elements of genes (see p. 31) for proteins that are needed for hypoxia acclimatization, including genes for (1) and (2) above, for—in most cells—genes for (3) increased glucose transport and metabolism and (4) a subunit of a cytochrome in mitochondrial electron transport that enhances the efficiency of oxygen use. HIF, which is found in many different phyla, consists of two subunits, HIF α and HIF β . In *normoxia* (normal oxygen levels), HIF α is hydroxylated by **proline hydroxylase (PH)**, converting HIF α into a form that

then binds to **von Hippel-Lindau protein (pVHL)**. Together, the HIF α –pVHL complex activates **ubiquitin ligase (UL)**, an enzyme complex that adds *ubiquitin* to HIF α . As you saw in Chapter 2 (p. 46), ubiquitin is a “tag” that targets a protein for destruction by proteasomes.

Thus, in normoxia, the HIF system is relatively inactive. However, during hypoxia, PH no longer targets HIF α for destruction; therefore, HIF α combines with HIF β to form a functional transcription factor. In turn, the acclimatization genes are activated. It appears that PH requires O_2 to function, and thus it becomes less active when O_2 levels are low.

Interestingly, native Tibetan humans living permanently at high altitudes in the Himalayas have Hb and red-cell concentrations similar to humans at sea level! (In contrast, humans native to the high Andes do have elevated Hb and red-cell levels). Tibetans make up for low P_{O_2} with unusually large ventilatory volumes, no pulmonary va-

soconstriction in hypoxia (p. 547), and higher levels of nitric oxide (p. 435) to promote vasodilation and thus blood flow to tissues body-wide. Recent genomic analysis indicates that genes in their HIF system have mutated to become less sensitive to hypoxia, thus blunting the EPO response. This adaptation may be beneficial because the high red-cell count increases blood viscosity (p. 420), putting a strain on the heart, especially during pregnancy and fetal development.

Fish brainstem medullas have two centers, one active during opercular opening, and one active during closing. Primitive air breathing in vertebrates evolved as a new motor pattern, possibly arising from modified coughing and suction feeding movements. The central rhythm generator in the brain stem of higher vertebrates may have evolved through an amalgamation of these two preexisting neural generators.

Generation and Fine Tuning of Respiratory Rhythm The generation of a respiratory rhythm in mammals is now widely believed to lie, not in the DRG, but in the **pre-Botzinger complex**, a region located near the upper (head) end of the medullary respiratory center (Figure 11-36). A network of neurons in this region display pacemaker activity, undergoing self-induced action potentials similar to those of the SA node of the heart. Scientists believe the rate at which the DRG inspiratory neurons rhythmically fire is

driven by synaptic input from this complex. Thus, while both heartbeat and breathing involve pacemakers, the former's is intrinsic while the latter's is extrinsic.

Recently, researchers have found that a single gene, called *Teashirt-3* (Tshz3), may be a master regulator of the pacemaker complex's formation. In mice with this gene knocked out, fetuses failed to start breathing at birth. Autopsies showed that there was a pacemaker complex in the fetuses' brainstems, but that they had failed to develop properly.

The respiratory centers in the pons exert “fine-tuning” influences over the medullary center to help produce normal, smooth inspirations and expirations. The **pneumotaxic center** sends impulses to the DRG that help “switch off” the inspiratory neurons, limiting the duration of inspiration. Without the pneumotaxic brakes, the breathing pattern consists of deep inspiratory gasps at a low rate. In contrast, the **apneustic center** prevents the inspiratory neurons from being

FIGURE 11-38 Location of the peripheral chemoreceptors (mammal). The carotid bodies are located in the carotid sinus, and the aortic bodies are located in the aortic arch.

© Cengage Learning, 2013

switched off, thus providing an extra boost to the inspiratory drive. However, the pneumotaxic center usually dominates over the apneustic center.

The magnitude of ventilation is adjusted in response to three chemical factors: P_{O_2} , P_{CO_2} , and H^+

No matter how much O_2 is extracted from the blood or how much CO_2 is added to it at the tissue level, the P_{O_2} and P_{CO_2} of the systemic arterial blood leaving the lungs are held remarkably constant, indicating that arterial blood-gas content is precisely regulated. Arterial blood gases are maintained within the normal range by varying the magnitude of ventilation to match the animal's needs for O_2 uptake and CO_2 removal. If more O_2 is extracted from the alveoli and more CO_2 is dropped off by the blood because the tissues are metabolizing more actively, ventilation increases correspondingly to bring in more fresh O_2 and blow off more CO_2 .

The medullary respiratory center receives inputs that provide information about the body's needs for gas exchange. It responds by sending appropriate signals to the motor neurons supplying the respiratory muscles (Figure 11-37), to adjust the rate and depth of ventilation to meet those needs. The two most obvious signals to increase ventilation are a decreased arterial P_{O_2} or an increased arterial P_{CO_2} . Intuitively, you would suspect that if O_2 levels in the arterial blood declined or if CO_2 accumulated, ventilation would be stimulated to obtain more O_2 or to eliminate excess CO_2 . These two factors do indeed influence the magnitude of ventilation, but not to the same degree nor through the same pathway. Also, a third chemical factor, H^+ , notably

influences the level of respiratory activity. We next examine the role of each of these chemical factors in the control of ventilation.

Feedback monitoring of blood gases and H^+ occurs both peripherally and centrally

In mammals arterial P_{O_2} is monitored by *peripheral* chemoreceptors known as the **carotid bodies** and **aortic bodies**, which are positioned at the bifurcation of the common carotid arteries and in the arch of the aorta, respectively so that they detect hypoxia long before it reaches the central nervous system (Figure 11-38). In fishes, chemoreceptors resembling those of mammals are located on the arterial side downstream from the gills.

As you will see, peripheral receptors also react to H^+ . In addition, there are **central chemoreceptors** in mammals, located in the medulla in the vicinity of the respiratory center. These respond most strongly to H^+ , but also to O_2 (Table 11-3). These peripheral and central chemoreceptors, which respond to specific changes in the chemical content of the arterial blood that bathes them, are distinctly different from the baroreceptors located in the same vicinity as the peripheral chemoreceptors. Recall that the baroreceptors inform the brainstem's cardiovascular center about blood pressure (p. 449). However, these two sets of sensors help coordinate ventilation and perfusion through the two closely located and closely coordinated brainstem regulators.

Decreased arterial P_{O_2} increases ventilation more strongly in fish than in air breathers

In water-breathing vertebrates, P_{O_2} in the blood is the primary homeostatic variable. In fish, a reduction in blood P_{O_2} detected by the peripheral chemoreceptors leads to a marked increase in the amplitude and frequency of gill ventilation. P_{CO_2} is not a major signal, because the high solubility of CO_2 in the external water results in only small percentage changes in this gas in the blood at the gills.

Chemoreceptors of air breathers are moderately sensitive to reductions in arterial P_{O_2} . A decrease from 100 mm Hg to 80 mm Hg is sufficient to evoke afferent nerve activation in the carotid body. However, a more severe hypoxia with arterial P_{O_2} falling below 40 mm Hg triggers appropriate autonomic changes that include stimulation of breathing as well as an increase in blood pressure. Low P_{O_2} inhibits O_2 -sensitive K^+ channels, which results in depolarization of the sensory cells and the subsequent release of transmitters. Little or no adaptation of the carotid body sensors occurs during sustained hypoxia in most species, while in some such as goats, sensory activity may increase. The signal leads to reflex stimulation of respiration that serves as an important emergency mechanism in dangerously low arterial P_{O_2} states. Indeed, this reflex mechanism is a lifesaver because a low arterial P_{O_2} tends to directly depress the respiratory center via its central chemoreceptors, as it does all the rest of the brain (Figure 11-39; Table 11-3). Except for the peripheral chemoreceptors, the level of activity in all nervous tissue becomes reduced in the face of O_2 deprivation. Were it not for stimulatory intervention of the peripheral chemoreceptors when the arterial P_{O_2} falls threateningly low, a vicious cycle ending in cessation of breathing would ensue. Direct depression of the respira-

TABLE 11-3 Influence of Chemical Factors on Mammalian Respiration

Chemical Factor	Effect on the Peripheral Chemoreceptors	Effect on the Central Chemoreceptors
P_{O_2} in the Arterial Blood	Stimulates only when arterial P_{O_2} has fallen below 80 mm Hg and maximally at life-threatening levels (40–60 mm Hg); an emergency mechanism	Directly depresses the central chemoreceptors and the respiratory center itself when <60 mm Hg
P_{CO_2} in the Arterial Blood (H^+ in the Brain ECF)	Weakly stimulates	Strongly stimulates; is the dominant control of ventilation (Levels >70 –80 mm Hg directly depress the respiratory center and central chemoreceptors)
H^+ in the Arterial Blood	Stimulates; important in acid–base balance	Does not affect; cannot penetrate the blood–brain barrier

© Cengage Learning, 2013

tory center by the markedly low arterial P_{O_2} would further reduce ventilation, leading to an even greater fall in arterial P_{O_2} , which would even further depress the respiratory center until ventilation ceased and death occurred. Of particular note, the carotid body, despite its small size of a few micrograms, expresses as many types of neurotransmitters as the brain, some being excitatory while others are inhibitory! Discerning the function of this array of neurotransmitters remains an active area of study.

Because the peripheral chemoreceptors respond to the P_{O_2} of the blood, *not* the total O_2 content of the blood, O_2 content in the arterial blood can fall to dangerously low or even fatal levels without the peripheral chemoreceptors adequately responding to reflexly stimulate respiration. Remember that only physically dissolved O_2 contributes to blood P_{O_2} . The total O_2 content in the arterial blood can be reduced in anemic states, in which O_2 -carrying Hb is reduced, or in carbon monoxide (CO) poisoning, when the Hb is preferentially bound to this molecule rather than to O_2 . In both cases, arterial P_{O_2} is normal, so respiration is not stimulated, even though O_2 delivery to the tissues may be so reduced that the animal dies from cellular O_2 deprivation.

Carbon dioxide–generated H^+ in the brain is normally the main regulator of ventilation in air breathers

In contrast to arterial P_{O_2} , arterial P_{CO_2} is the most important input regulating the magnitude of ventilation under resting conditions. This role is appropriate, because changes in alveolar ventilation have an immediate and pronounced effect on arterial P_{CO_2} , whereas changes in ventilation have little effect on % Hb saturation until the arterial P_{O_2} falls by more than 40%. Even slight deviations from normal in arterial P_{CO_2} induce a significant reflex effect on ventilation:

- An increase in arterial P_{CO_2} reflexly stimulates the respiratory center, with the resultant increase in ventilation promoting elimination of the excess CO_2 to the atmosphere.
- A fall in arterial P_{CO_2} reflexly reduces the respiratory drive. The subsequent decrease in ventilation allows metabolically produced CO_2 to accumulate so that P_{CO_2} can be returned to normal.

FIGURE 11-41 Effect of increased arterial non-carbonic-acid-generated hydrogen ion ($\text{non-CO}_2\text{-H}^+$) on ventilation (mammal).

© Cengage Learning, 2013

as may occur when an animal is buried in an avalanche, directly depress the entire brain, including the respiratory center, just as very low levels of O_2 do. Up to a P_{CO_2} of 70 to 80 mm Hg, progressively higher P_{CO_2} levels induce correspondingly more vigorous respiratory efforts in an attempt to blow off the excess CO_2 . A further increase in P_{CO_2} beyond 70 to 80 mm Hg, however, does not further increase ventilation but actually depresses the respiratory neurons. For this reason, CO_2 must be chemically removed and O_2 supplied in closed environments such as closed-system anesthesia machines, submarines, or space capsules, and must not be allowed to accumulate in animal burrows. Otherwise, CO_2 could reach lethal levels, not only because of its depressant effect on respiration but also because of the resultant severe state of respiratory acidosis.

Adjustments in ventilation in response to changes in arterial H^+ are important in acid–base balance

The aortic and carotid body peripheral chemoreceptors are also highly responsive to fluctuations in arterial H^+ concentration, in contrast to their weak sensitivity to deviations in arterial P_{CO_2} and also arterial P_{O_2} until it falls 40% below normal. The result is the same as for central chemoreceptors. However, these changes in ventilation mediated peripherally are far less important than the powerful central mechanism in adjusting ventilation in response to changes in CO_2 -generated H^+ concentration.

The peripheral chemoreceptors do play a major role in adjusting ventilation in response to alterations in arterial H^+ concentration unrelated to fluctuations in P_{CO_2} . In many situations, even though P_{CO_2} is normal, arterial H^+ concentration is changed by the addition or loss of non- CO_2 -generated acid from the body. For example, arterial H^+ concentration increases from lactate during activity and also from diabetes mellitus because excess H^+ -generating keto acids (p. 316) are abnormally produced and added to the blood. Changes in ventilation by this mechanism are extremely important in regulating an animal's acid–base balance (Figure 11-41; see also Chapter 13 for acid–base details).

Activity profoundly increases ventilation, possibly due to anticipatory mechanisms

Alveolar ventilation may increase up to 25-fold during heavy locomotory activity to keep pace with the increased demand for O_2 uptake and CO_2 output. The cause of increased ventilation during activity such as exercise is still largely speculative. It would seem logical that changes in the “big three” chemical factors—decreased P_{O_2} , increased P_{CO_2} , and increased H^+ —could account for the increase in ventilation. This does not appear to be the case, however.

1. As you saw in Chapter 9 (p. 452), despite the marked increase in O_2 use during activity, arterial P_{O_2} does not decrease but remains normal or may actually increase slightly because the increase in alveolar ventilation and circulatory flow both keep pace with or even slightly exceeds the stepped-up rate of O_2 consumption.
2. Likewise, despite the marked increase in CO_2 production during activity, arterial P_{CO_2} does not increase but remains normal or decreases slightly because the extra CO_2 is removed as rapidly or even more rapidly than it is produced by the increase in ventilation.
3. During mild or moderate activity, H^+ concentration does not increase, because H^+ -generating CO_2 is held constant. During heavy activity, H^+ concentration does increase somewhat from release of H^+ -generating lactate into the blood by anaerobic metabolism in the exercising muscles. Even so, the elevation in H^+ concentration resulting from lactic acid formation is not enough to account for the large increase in ventilation accompanying activity.
4. Ventilation increases abruptly at the onset of activity (within seconds), long before changes in arterial blood gases could become important influences on the respiratory center (which requires a matter of minutes). Simple feedback from the chemosensors cannot explain this, since that has a delay (as explained on p. 452).

Researchers have suggested that a number of factors besides blood gases and acid, including the following, play a role in the ventilatory response to activity such as exercise:

1. *Reflexes originating from body movements.* Joint and muscle receptors excited during muscle contraction reflexly stimulate the respiratory center, abruptly increasing ventilation. Even passive movement of the limbs (for example, someone else alternately flexing and extending a person's knee) may increase ventilation several-fold through activation of these receptors, although no actual exercise is occurring. Thus, the mechanical events of muscular activity are believed to play an important role in coordinating respiratory activity with the increased metabolic requirements of the active muscles.
2. *Anticipatory activation by epinephrine.* Epinephrine also stimulates ventilation as well as blood circulation, as we have described (pp. 546 and 417). It can be released by the sympathetic nervous system under stress conditions in advance of physical activity.
3. *Anticipatory activation by the cerebral cortex.* Especially at the onset of activity, the motor areas of the cerebral cortex are believed to simultaneously stimulate both the medullary respiratory and cardiovascular (p. 449) centers at the same time it activates the motor neurons of the exercising muscles. In this way, the motor cortex calls forth increased ventilatory and circulatory responses to support the increased physical activity it is about to orchestrate. These anticipatory adjustments occur *before* any homeostatic factors actually change.

None of these factors or combinations of factors is fully satisfactory in explaining the abrupt and profound effect activity has on ventilation, nor can they completely account for the high degree of correlation between respiratory activity and an animal's needs for gas exchange during activity. Much remains to be learned about external respiration.

How Respiratory Systems Contribute to the Body as a Whole

Animal respiratory systems contribute to homeostasis by obtaining O_2 from and eliminating CO_2 to the external environment. Animal cells ultimately need an adequate supply of O_2 to use in oxidizing nutrients to generate ATP. Brain cells, which are especially dependent on a continual supply of O_2 , die if deprived of O_2 for more than a few minutes in most mammals. Even cells that can resort to anaerobic metabolism for energy production, such as strenuously exercising muscles, can do so only transiently by incurring an O_2 debt that ultimately must be repaid.

As a result of oxygen-using metabolism, large quantities of CO_2 are produced that must be eliminated from internal fluids. Because CO_2 and H_2O form carbonic acid, adjustments in the rate of CO_2 elimination by a respiratory system are important in the regulation of internal acid–base balance (Chapter 13). Cells can survive only within a narrow pH range.

Respiratory systems can also play a role in other physiological processes, such as fluid and solute balances, feeding, heat transfer, sound production, and immunity.

Chapter Summary

- External respiration—events in the exchange of O_2 and CO_2 between the external environment and cellular mitochondria—involves up to four major steps of bulk transport and exchange by diffusion. Step 1. Bulk transport of external media, called ventilation or breathing if it is active. Step 2. Exchange by diffusion between the environmental medium and cells or ECF at a respiratory surface or organ. Step 3. Bulk transport of ECF in a circulatory system. Step 4. Exchange by diffusion between the environment or ECF and the ICF. Not all animals have all steps.
- Gas diffusion follows Fick's law for partial pressure, not concentration, gradients. The individual pressure exerted independently by a particular gas within a mixture of gases is known as its partial pressure, designated by P_{gas} . Diffusion rate changes linearly with surface area A , coefficient D , and inversely with distance ΔX .
- External respiratory processes must meet the demands of size, metabolism, and habitat. Small, thin, and/or sluggish animals (e.g., flatworms) utilize simple integumentary exchange (steps 2 and 4 above). But larger, more active animals and those in O_2 -poor habitats (e.g., high altitude, warm waters) need enhanced bulk transport and exchange.
- Gas exchange (steps 2, 4) may be increased by (1) respiratory organs with folds (and so on) having high A , low ΔX ; bulk transport by (2) ventilation/breathing and (3) circulation, which enhance ΔP ; and (4) diffusion-enhancing proteins such as hemoglobins, which enhance ΔP by converting cases to and from nondiffusible forms, and which also boost transport capacity of circulation.
- Breathing as a form of bulk transport can be tidal (medium moving in and out of the same opening) or the more efficient flow-through, which ventilates more continuously and with little mixing of stale and fresh medium.
- Water breathers have a harder time breathing than air breathers due to water's greater viscosity, lower diffusion rates, decreased solubility with temperature, and wider habitat variation. The limitations of diffusion in water are overcome with gills (often highly branched, e.g., with pagelike lamellae) and other thin, high-surface-area structures, internal circulation, and flow-through breathing (as in fish buccal–opercular pumps). Countercurrent flow enhances gas pressure gradients in fishes because blood moving through gill lamellae continually encounters flow-through water with an O_2 content that is higher than what is present in the capillary.

- Air breathers may not need highly efficient exchange surfaces or breathing mechanisms, but their exchange surfaces need protection from drying out. Land slugs and snails use skin in moist habitats, or mantle tissue or lungs under a shell. Arachnids use internalized gill-like book lungs and/or tracheae, invaginated tubes going directly to internal organs. Insects also use tracheae, which may be actively ventilated with air sacs and body movements.
- The first air-breathing vertebrates were bimodal or trimodal, with gills and air-breathing device(s)—skin and/or lungs. All lungs except those of birds and crocodilians have tidal ventilation. Frog lungs may be simple or moderately folded and are inflated by positive pressure. Reptiles as well as birds and mammals have respiratory systems ranging from simple to elaborately folded, inflated by negative pressure.
- Mammalian airways terminate in alveoli, which are involved in both ventilation and gas exchange. Mammalian lungs are inflated and deflated tidally by cyclical changes in intra-alveolar pressure generated indirectly by respiratory muscles (ribs, diaphragm).
- Ventilation and gas exchange are separated in crocodilian and avian respiratory systems due to air sacs and parabronchi with air capillaries. Flow-through breathing due to air sacs, plus crosscurrent flow in the parabronchi, enhances gas exchange in crocodiles and birds.
- Atmospheric, intra-alveolar, and intrapleural pressures are important in respiratory mechanics of mammals, whose lungs are normally stretched to fill the thorax. Intrapleural and lung pressures decrease during inhalation and increase during exhalation, which in part depends on elasticity. Elasticity depends on connective tissue and alveolar surface tension, which is kept collapsing the alveoli by surfactant.
- Changes in certain lung volumes such as tidal volumes, measured with a spirometer, are important for analyzing disease states, aerobic activity capacities, and species differences. Pulmonary ventilation (tidal volume \times respiratory rate) scales with mammalian body mass. Alveolar ventilation is less than pulmonary ventilation because of the presence of dead space. It is important to increase tidal volume during activity since that benefits alveolar ventilation more than increased respiratory rate.
- Fish have lower dead-space problems but higher respiratory energy costs than mammals. Fish flow-through ventilation yields up to 90% O_2 extraction, while bird lungs achieve up to 40% and mammalian ones only 25%.
- Lung air has a lower partial pressure of O_2 than does atmospheric air due to humidification and dead-space mixing. Gases move to/from alveoli to blood and blood to/from body cells down partial pressure gradients maintained by breathing and circulation to be in the proper directions.
- Most O_2 in many circulatory systems is transported bound to hemoglobins (Hb), hemocyanins, and other metal-containing respiratory pigments. These trap O_2 , so they cannot contribute to P_{O_2} , thus favoring gas diffusion. Most Hbs are tetramers of globin subunits each with an iron-containing heme group.
- The P_{O_2} is the primary factor determining the percent hemoglobin saturation. O_2 binding by Hb follows a sigmoidal curve with a steep rise at intermediate P_{O_2} levels and a plateau at high levels. This arises from cooperativity, in which subunits switch between high- and low-affinity states and affect their neighbors' states. At high P_{O_2} in the lungs, Hb is nearly 100% saturated. As it enters low- P_{O_2} tissues, cooperativity ensures proper release of O_2 .
- Acid (the Bohr effect), temperature, and certain organic phosphates enhance O_2 release. O_2 affinity, measured by P_{50} values, has evolved to enhance gas delivery in different species; for example, larger mammals and those at high altitudes have higher affinities. Total saturation declines with acidity in the Root effect in fish Hbs, aiding the filling of gas bladders with acid secretion and countercurrent trapping.
- Most CO_2 is transported in vertebrates as bicarbonate due to carbonic anhydrase in erythrocytes. This reaction is also critical to acid-base balance.
- Ventilation of airways is regulated to match perfusion by pulmonary vessels by local and extrinsic mechanisms. Breathing is regulated in vertebrates by a negative-feedback system—which may be activated in anticipation of activity—of peripheral chemosensors in the arteries and brainstem medulla, multiple regulatory centers in the medulla, and effector breathing muscles. P_{O_2} is an important homeostasis signal in water breathers; P_{CO_2} and the H^+ it generates are more important in air breathers.

Review, Synthesize, and Analyze

1. Compare the respiratory mechanisms and events in a flying insect and a flying bird.
2. Compare and explain the gas exchange efficiencies of fish, birds, and mammals.
3. If an animal lives 1,600 m above sea level, where the atmospheric pressure is 630 mm Hg, what would the P_{O_2} of the inspired air be once it is humidified in the respiratory airways before it reaches the alveoli?
4. Suppose a medium-size mammal has a tidal volume of 350 mL. While breathing at 12 breaths/min, its alveolar ventilation is 80% of the pulmonary ventilation. What is its anatomic dead-space volume?
5. Compare the respiratory and blood-transport features of a bar-headed goose and an acclimatized human climber on Mt. Everest at 8,848 m altitude.
6. In mammals, fetal Hb has a lower P_{50} than adult Hb. Explain how this favors O_2 transfer across the placenta.
7. Even when partial pressure of O_2 in air is approximately the same as in water, the concentration of O_2 is much greater. Explain.
8. What mechanisms have animals come up with to survive extended periods of anoxia?
9. An increase in respiratory rate along with inappropriate voiding of your pet dog's bladder have brought you for a consultation with your veterinarian. What diagnosis do you think the practitioner will come up with and why?

Cormorants have a kidney that excretes nitrogenous waste as uric acid, a metabolically costly but nontoxic compound that requires little water to excrete and has antioxidant properties. They imbibe seawater (which is saltier than their body fluids), and have special nasal salt glands to excrete excess NaCl. The harbor seal also must excrete excess NaCl and nitrogenous waste (primarily urea). Urea is a semitoxic compound that requires some water to excrete. The seal has very efficient kidneys for concentrating salt and urea.

Paul Yancey

Excretory Systems

12.1 Evolution of Excretory Systems

One of the most crucial aspects of homeostasis is the maintenance of an internal aqueous environment that is conducive to life. This “inland sea” is regulated within narrow limits to maintain a beneficial composition of water and important solutes and a low level of wastes. Dietary intake, metabolic products, and losses or excess intake of water and ions frequently create imbalances in the internal environment. Consider a female mosquito that has just sucked blood from your skin. The animal is bloated with a relatively huge amount of water and NaCl (the major components of your blood), making it more difficult to fly and potentially disturbing internal fluid movements. The insect also digests your nutritious blood proteins (especially hemoglobin), gaining useful products but producing harmful nitrogenous wastes. Thus, she must somehow remove excess water, salt, and wastes from her body. Or consider a seal or a cormorant (see opening photograph). Because seawater is saltier than body fluids of these vertebrates, it tends to dehydrate cells by osmosis. Thus, these animals may need to excrete excess salt (as well as wastes) while conserving body water.

Selective excretion is crucial to internal fluid homeostasis and involves several systems

In these and other animals, regulation of salt and water balance and excretion of wastes depend on mechanisms of selective retention and removal of molecules. These mechanisms are generally the purpose of *excretory systems*. Note that the term “excretory” is a bit misleading, because these systems often perform selective retention as well; indeed, *retention always accompanies excretion*. In particular, the primary functions of these organs for fluid homeostasis are as follows:

1. *Maintenance of proper internal levels of inorganic solutes* (Na^+ , K^+ , Cl^- , H^+ , CO_2 , and so forth). Even minor fluctuations in concentrations of some of these electrolytes in the ECF (extracellular fluid, p. 27) can have profound influences on metabolism. For example, changes in ECF concentration of K^+ can potentially lead to fatal cardiac dysfunction.
2. *Maintenance of proper plasma water volume*, important for proper circulatory-fluid pressure and general state of tissue hydration.
3. *Removal of nonnutritive and harmful substances resulting from metabolism* (ammonia, urea, bilirubin, and so forth) or *ingestion* (such as plant alkaloids, drugs), and *removal of hormones* after they have had their desired effect. This must be done without losing useful organic molecules such as nonhormone proteins and glucose.
4. *Maintenance of osmotic balance* (which results from a combination of water and dissolved solutes) by selective retention and excretion of water and ions.

Simple aquatic animals (sponges, Cnidarians, and possibly echinoderms) do not have specialized organs for fluid-regulating processes. They rely on diffusion and membrane transporters for nonsolid wastes. (Individual cells of freshwater sponges also have *contractile vacuoles*, specialized vesicles that remove and eject excess water

out of the cell.) As aquatic animals evolved larger sizes and greater complexity, diffusion and membrane transport became inadequate for removing wastes from internal body fluids. Thus, the evolution of specialized excretory tissues was favored with **transport epithelia**: linings with specific membrane mechanisms to remove nonfecal wastes and to regulate other solutes and water. In some cases, epithelial surfaces of existing organs such as skin, gills, and hindguts evolved such mechanisms. However, in many animals these exchange surfaces became inadequate to process all body fluids or molecules for two reasons. First, as body size increased, these surfaces were too small and too distant from many body fluids. Second, evolution onto land created additional problems. Because of the lack of an aquatic environment to directly provide water for terrestrial animals and absorb their wastes, external epithelia were unable to regulate most solutes or water. To be free to move about in an often dry and ever-changing external environment, these animals had to evolve more elaborate mechanisms to maintain internal fluid homeostasis. Thus, larger and more complex aquatic animals, and all terrestrial ones, evolved specialized *tubules* lined with transport epithelia dedicated to excreting and selectively retaining key molecules of the body.

In the animal kingdom, four organ systems can be involved in excretion and retention:

1. **Respiratory systems (gills and lungs)**, which help regulate CO_2 (although we do not often think of it in these terms, the act of exhaling CO_2 is a form of waste excretion). Gills can also help remove other solutes such as ammonia and HCO_3^- . Some of these functions are covered in Chapter 11 (on respiratory physiology) and Chapter 13 (on fluid and acid–base balance).
2. **Digestive systems**, which remove not only undigested food but also some end products of internal metabolism such as biliverdin from the vertebrate liver (p. 688). Indeed, the liver in this case is acting as an excretory organ. Intestinal tract epithelia may also help regulate ions and water, and in some animals the gut receives the output of renal organs (see 4 below). Some of these functions are covered in Chapter 14 (on digestion).
3. **Integument (skin) and glands**, some of which can excrete organic wastes as secondary functions (such as sweat glands in humans), and others that evolved primarily to excrete excess inorganic ions (**salt glands** of brine shrimp and marine reptiles). The skin of many amphibians also regulates salt and water uptake.
4. **Renal organs (renalis, Latin for “kidney”)** with tubules that *filter* body fluids and regulate water, ions, and many organic substances, and then *selectively reabsorb or secrete* these molecules. We will examine several examples such as insect Malpighian tubules and vertebrate kidneys. The output of renal organs is called **urine**. These organs, together with ductwork and any **bladders** (urine-storage chambers), compose the **urinary system**.

In the next chapter, we focus on how these and other systems work in an integrated way to maintain water and solute homeostasis. In this chapter, we focus primarily on renal organs and, to a lesser extent, skin and its glands: how they process water, ions, and wastes, and how they are regulated. We begin by examining a common problem of animals: how to deal with waste produced by nitrogen metabolism.

Nitrogen metabolism creates special stresses and produces three major end products: ammonia, urea, and uric acid

Metabolism of all foodstuffs results in CO_2 as a waste product, but protein and nucleic acid metabolism produces various **nitrogenous wastes** as well. Breakdown of proteins yields amino acids (Figure 12-1, top), which may be used (1) to make new proteins for growth and maintenance, and (2) in many marine animals as *osmolytes* (see p. 617) (Figure 12-1, lobster). Excess amino acids are routinely broken down to produce ATP, yielding CO_2 , water, and **ammonia** (NH_3) (Figure 12-1, right), a potentially toxic strong base that can potentially alter acid–base balance as it binds protons and becomes **ammonium ion** (NH_4^+). The ammonium ion is also toxic; among other effects, it interferes with the Na^+/K^+ ATPase transporters of cell membranes by substituting for K^+ . This toxicity manifests in many ways but is particularly evident in neurons, which suffer morphological changes, interrupted ion conduction, and disrupted neurotransmitter metabolism. Just 0.05 mM NH_4^+ in mammals and 2 mM in fishes severely impairs neural function. Thus, NH_3 and NH_4^+ must either be highly diluted and rapidly excreted, or be converted into a less toxic form. The most common of these forms are **urea** and **uric acid** (Figures 12-1 and 12-2). The soluble form of uric acid in the blood is actually **urate**, although we will use the term “uric acid” in the text. Let’s examine these waste products in detail.

1. **Ammonia**. Most aquatic animals that breathe water—including most bony fishes, larval amphibians, and most nonvertebrates—rely on ammonia excretion, usually via gills. This feature is called **ammonotelic** (Figure 12-1, fish). Water is sufficiently available to dilute the ammonia, which readily leaves the body down a favorable diffusion gradient. Thus, it is relatively easy to keep it below its toxic level. (NH_3 , not NH_4^+ , is the primary form that leaves an aquatic animal’s body.)

Interestingly, many deep-sea squids retain high levels of NH_4Cl in some body fluids because it is very buoyant (Figure 12-1, squid). It is not certain how toxicity of NH_4^+ is avoided, but it may be due to sequestration of the ions in special fluid chambers.

2. **Urea**. Most terrestrial animals do not have the option of greatly diluting ammonia and instead must spend metabolic energy to convert ammonia into a less toxic form such as urea or uric acid, usually in the liver, and to transport the product to the excretory organs. Urea excretion is termed **ureotelic**. This concept is exemplified in amphibians, whose aquatic larval stages use ammonia excretion via their gills, whereas semiaquatic adults switch to urea production and excretion using their livers and kidneys. Urea is the primary nitrogenous waste not only of most adult amphibians but also mammals (Figure 12-1, bear) and some reptiles such as sea turtles. Urea is produced, in most vertebrates that make it, from two ammonium ions (one via aspartic acid) and a bicarbonate ion, using ATP, in the **ornithine–urea cycle**, or **OUC** (Figure 12-2a). (Some bony fishes that produce urea use the **uricolytic pathway**; Figure 12-2b.) Urea is the primary nitrogenous waste of marine chondrichthyan fishes (Figure 12-1, shark) and coelacanths (meaning “hollow spine,” referring to hollow fin rays), “living

FIGURE 12-1 General overview of nitrogen metabolism and excretion in animals. The three main nitrogen excretory products are highlighted in colored boxes. See main text for details.

fossil” lobe-finned fishes once thought to be extinct. In these fishes, urea is accumulated as their major osmolyte (see p. 621). Urea is 10 to 100 times less toxic than ammonia and thus can be accumulated to much higher concentrations, and has the added benefit of removing two nitrogens per molecule. Thus, it takes about 10 times less water to excrete a given amount of nitrogen as urea than as ammonia. Urea is, however, toxic at concentrations greater than 100 mM or so because it binds to proteins and destabilizes their structures and interferes with their ability to bind ligands. Thus, it must be kept at moderate levels, or where it is highly concentrated in chondrichthyan fishes, coelacanths, and the mammalian inner kidney, it must be *counteracted* with a protein stabilizer (p. 619; see also *Molecular Biology and Genomics: Surviving Salt and Urea*, p. 606).

In ruminants, urea has another function. After synthesis in the liver, it can enter the rumen via the salivary glands, where symbiotic microbes ferment the food; there, microbes convert urea back to ammonia, using the enzyme *urease*. The ammonia can then be used directly by these beneficial microbes for their own protein synthesis (Chapter 14).

3. **Uric acid.** In other terrestrial animals—insects, most reptiles including birds, and even a tree frog and a desert toad—uric acid is usually the primary nitrogenous waste (although some insects excrete some urea and ammonia). This is called **uricotelic** (Figure 12-1, bird). Uric acid

is the end product of amino acid and purine (nucleic acid) metabolism (Figure 12-2b) and requires even more ATP than urea (Figure 12-2a) to produce. It is less toxic because it is highly insoluble, has the added benefit of removing four nitrogens per molecule, and is excreted in a semisolid form, generally into the hindgut. (In the physiological pH range, 99% of uric acid exists as urate, the monovalent anionic form.) It takes about 50 to 100 times less water to excrete a given amount of nitrogen as uric acid than as ammonia. Compared to urea, which is essentially infinitely soluble in solution, uric acid is highly insoluble (precipitates at concentrations greater than about 0.4 mM). Uric acid also serves as a protective antioxidant (see *A Closer Look at Adaptation: Avian Longevity: Unraveling the Mystery*, p. 564).

An interesting question arises from these patterns: If uric acid is less toxic and more favorable to water conservation than urea, why do not all terrestrial animals use it as the primary nitrogenous waste? One possibility lies in the high metabolic cost of synthesizing uric acid compared to urea (12 or more ATPs versus 4 ATPs/mole, respectively), and different modes of reproduction. Birds, reptiles, and many insects lay sealed yolky eggs, often in fairly dry areas. Without a way to remove nitrogen wastes produced from metabolism of yolk proteins, such eggs may require the least toxic (but most expensive) form, which also exerts no osmotic disturbances in its crystallized state. Adult insects, because of their

small sizes and thus high surface-area-to-volume ratios (p. 10), may also need the most effective water conservation mechanisms. In contrast, amphibian adults (which usually enter water frequently) and prenatal stages of all types of mammals (whose wastes are removed by the mother's circulation) can more easily dispose of their nitrogenous wastes. Thus, using urea as a primary waste saves considerably on metabolic energy of synthesis. In any case, mammals have not evolved mechanisms to handle high concentrations of the highly insoluble uric acid, and excessive levels can lead to

arthritic **gout** and **kidney stones** because of crystals of this highly insoluble molecule forming in inappropriate places (the joints and kidney tubules, respectively). Mammals do make uric acid, but most only synthesize small amounts that are removed by the kidneys (though long-lived primates lack the degradative enzyme **uricase** and may accumulate modest amounts of uric acid). See *A Closer Look at Adaptation: Avian Longevity: Unraveling the Mystery*, p. 564.

Overall, it appears that *the use of ammonia, urea, or uric acid as the primary nitrogen waste correlates strongly with*

water availability. As we have seen, most aquatic animals use ammonia, whereas most animals with terrestrial eggs use uric acid. As another example, aquatic birds such as ducks excrete an evenly balanced mixture of uric acid and ammonia, whereas terrestrial birds excrete primarily uric acid. But there are exceptions, including the following. (1) The tilapia *Alcolapia grahami* in the highly alkaline Lake Magadi in Africa is mainly ureotelic, using the OUC (absent in most fish) (Figure 12-2a). This presumably evolved because high pH impairs ammonia excretion. (2) The Gulf toadfish *Opsanus beta* has an OUC and switches from ammonotelic to ureotelic when stressed, for example, by air exposure, crowding, or confinement, releasing urea in pulses through membrane urea transporters in the gills. (3) Some marine snails use uric acid. (4) Monotremes (egg-laying mammals—echidna [p. 423] and platypus) use primarily urea, but their embryonic development relies very little on yolk; most development occurs before the (porous) egg is laid, during which time nutrients and wastes are exchanged between the embryo and mother (p. 801). (5) The most water-stressed mammals, desert rodents such as kangaroo rats (which may never drink water in their entire lives), use urea (see p. 602). “Physiological logic” would suggest that these rodents would benefit from uric acid as their major nitrogenous waste. Perhaps evolutionary constraints (p. 2) have resulted in mammals being “locked in” to using urea because they lack the hindgut system that seems to be essential for uric acid processing. Similarly, (6) nectar-feeding birds like hummingbirds deal with an excess of liquid intake, and perhaps could benefit energetically by making urea rather than uric acid for nitrogen waste; but they do not. Perhaps birds too are “locked in.”

There are a few other forms of nitrogenous wastes. Three of these are *guanine*, the primary nitrogenous waste of arachnids; *allantoin* (Figure 12-2b), produced from uric acid in some insects; and *creatinine*, a by-product of vertebrate muscle metabolism that is constantly produced, transported, and removed by the kidneys. As discussed later, (p. 593) renal physiologists and physicians use this process to measure key renal functions.

Excretory organs have transport epithelia, which typically use Na^+/K^+ ATPases

As we noted earlier, excretory and related processes in complex animals rely on specialized transport epithelia. Recall that such transport may be *passive* and *active*. In passive types, no steps in the transport of a substance across an epithelium use direct metabolic energy, because energy is provided by electrochemical or osmotic gradients (see p. 75). In contrast, a substance is said to be actively transported if any one of the steps requires direct use of energy, even if other steps are passive. In active transport, net movement of the substance occurs against an electrochemical gradient. Though transport tissues vary in their membrane transporters, most involve two mechanisms: (1) the energetic cost of transport typically lies in an ion *ATPase* “*pump*,” which not only results in ion transport but also in an ion gradient that can be used to move other solutes in symport or antiport fashion (see Figure 3-15); and (2) *no active transporters for water molecules are known to exist*, so if water movement is involved, epithelia cells must first transport solute(s), which then build up osmotic pressure and draw water by osmosis.

Figure 12-3a and b show two common examples of active epithelial transport that use the common Na^+/K^+ ATPase

(p. 85). Note the orientation of the cells: The *basolateral* side typically faces interstitial fluid, while the *apical* side typically faces the environment or a tubular **lumen** (the cavity inside a biological tube).

Salt Transport Only Transporting salt without water involves two steps:

1. The Na^+/K^+ ATPase “pump” uses ATP to increase the Na^+ concentration outside the cell’s basolateral side, and decrease it inside the cell; some Na^+ then moves passively into the cell from the apical side through an *ENaC* channel (p. 235).
2. The build-up of positively charged Na^+ in the basolateral fluid passively draws Cl^- ions by charge attraction. Cl^- moves through either or both of the following:
 - a. A **CIC (chloride-activated chloride)** channel. CIC channels are an ancient, large family of chloride channels found in all domains and kingdoms of life. As gated channels, many CIC channels open in response to increasing Cl^- concentration, hence their name.
 - b. A **CFTR (cystic fibrosis transmembrane-conductance regulator)** chloride channel, so named because its mutated, nonworking form is responsible for the defective salt transport characteristic of *cystic fibrosis*. It is regulated by cAMP and phosphorylation. Humans with cystic fibrosis have nonfunctioning CFTRs, and cannot properly transport salt and water through membranes of several epithelia such as linings of airways, sweat glands, and intestine. In airways, for example, harmful thick, sticky mucus builds up.

Overall, then, NaCl is moved across the tissue through the cells that is, **transcellularly**. The tissue in Figure 12-3a is fairly waterproof, so little or no water moves.

Salt and Water Transport In the second tissue, Figure 12-3b, the first two steps are the same, but there are two more:

3. The osmotic pressure of transported NaCl builds up within *lateral spaces* between the cells, where it induces osmosis of H_2O from the cells. The accumulation of H_2O in those lateral spaces results in a buildup of hydrostatic pressure, flushing H_2O out of the spaces into the interstitial fluid (and, in animals with blood vessels, into nearby capillaries).
4. In some cases, some water and ions are thought to move through spaces between the cells, that is **paracellularly**, as shown here for H_2O .

We now turn to renal organs, which rely heavily on such transport epithelia.

check your understanding 12.1

What are the four major functions of excretory systems, and what are the four organ systems that can serve this role?

Discuss the usefulness and evolutionary patterns of ammonia, urea, and uric acid as nitrogenous wastes.

How do transport epithelia move NaCl alone or NaCl and water?

FIGURE 12-3 Properties of transport epithelia and tubular excretory organs. (a) Salt absorption by a waterproof epithelium. (1) Basolateral Na⁺/K⁺ ATPase pumps increase Na⁺ externally, which (2) draws Cl⁻ by electric charge through ClC and/or CFTR channels. (b) Fluid absorption by a water-permeable epithelium in a well-supported model first proposed by Peter Curran and John Macintosh in 1962. This has the same steps 1 and 2, but also (3) H₂O is drawn across osmotically through aquaporins by the NaCl buildup in lateral spaces between cells. H₂O is not drawn from the capillary because it is permeable to NaCl (recall that osmosis requires nonpermeable solutes). (4) H₂O and Cl⁻ may also move paracellularly. See main text for other details.

(c) The four basic renal processes (shown for a vertebrate): filtration, secretion, reabsorption, and osmoconcentration

FIGURE 12-3, CONT'D Properties of transport epithelia and tubular excretory organs. (c) Schematic of the principal functions of a tubular renal organ, such as the vertebrate nephron: filtration, secretion, and reabsorption. Insect, avian, and mammalian tubules may also osmoconcentrate urine.

12.2 Renal Excretory Organs: Overview

Renal organs have tubules that filter solutes and water from body fluids and subsequently modify the fluid in the tubular lumen using transport epithelia, specifically for water and solute homeostasis and waste removal. Let's look at the key processes.

Renal tubules produce urine using the processes of filtration, secretion, reabsorption, and osmoconcentration

Renal tubules operate by two or more of four basic renal processes (Figure 12-3c):

1. **Filtration**, in which solutes are selectively separated from a solution by passing through a boundary. Often this is a mostly nonselective process, in which some water with all its small solutes passes through the barrier, except that cells and large molecules such as proteins (and some water) remain behind, a process called **ultrafiltration**. Ultrafiltration is typically driven by hydrostatic pressure. Another type of filtration relies on specific transporters and is thus more selective.
2. **Secretion**, in which transport epithelia move (often actively) specific solutes into the tubule lumen for excretion.
3. **Reabsorption**, in which transport epithelia move (often actively) specific solutes (and often water) back into the body from the lumen.
4. **Osmoconcentration**, in which water is removed from the lumen fluid while leaving solutes behind, producing an excretory fluid more concentrated (*hyperosmotic*) than body fluids and thus conserving water. Some reabsorption processes are tied to this mechanism.

Methodology Numerous techniques are used to explore the functions of renal excretory systems. Here we describe two that have contributed greatly to the understanding of renal functions, which we will explore shortly:

- For studying the tubules we have just discussed, perhaps the most important method is that of the **isolated perfused tubule** (Figure 12-4). A researcher begins by carefully dissecting an intact tubule out of the animal's renal system and placing it in an appropriate bathing solution. Two holding pipettes are applied, one to each open end of the tubule. Within one pipette, a much finer pipette (the perfusion pipette) is inserted to allow injection of defined solutions into the tubule. A fine pipette within the other holding pipette is used to collect fluid exiting the tubule. By measuring solutes in this collected fluid and in the

bathing solution, researchers can determine transport and permeability features. Other devices may also be used on these tubules, such as patch clamps (p. 112) and microelectrodes for measuring potentials.

- In studying the effect of the whole kidney on retention and removal, the **plasma clearance** method has been important. To understand this method, you first need to understand certain tubule functions; we return to plasma clearance later.

The major renal organs are protonephridia, meso- and metanephridia, and Malpighian tubules

Several different kinds of renal organs have evolved, and there are several ways to classify these. One useful scheme recognizes three common types—*protonephridia*, *meso- and metanephridia*, *Malpighian tubules*—based on which body fluids are processed and how:

- **Protonephridia** (bundles of *flame cells*) use ultrafiltration driven by cilia, with secretion and reabsorption. These are the types of specialized filtration system thought to have evolved first in freshwater nonvertebrates. These are generally blind-end ducts that project into the body cavity (of which there is only one: a general interstitial

A Closer Look at Adaptation: Avian Longevity: Unraveling the Mystery

Have you ever wondered why we live for so much longer than our companion animals? If our pet dog or cat lives to be 15 or more years of age, we regard this as exceptional. What makes this even more intriguing is that birds live considerably longer than mammals of the same body size. For example, a hummingbird lives for approximately 9 years, whereas a comparably sized mouse may live for only 1.5 years. This mystery has intrigued the scientific community for as long as it has been aware of the paradox. Given certain inherently avian characteristics, prevailing theories suggest that birds should be more susceptible than mammals to the degenerative process of aging. These include the following: Birds have plasma glucose concentrations typically 2 to 6 times higher than those of mammals, metabolic rates as much as 2 to 2.5 times higher than those of similar-sized mammals, and body temperatures approximately 3°C higher. The higher metabolic rates, coupled with the extreme longevity of many avian species, result in a much greater lifetime energy expenditure per unit mass by birds than mammals. This is important because, within a class of animals, longevity is inversely correlated with metabolic rate (see scaling discussion in

Chapter 15, p. 720). With mammals, physiologists assume that lifetime energy expenditure correlates with an organism's cumulative exposure to potentially damaging free radicals (and other reactive oxygen species, or ROS) produced as normal by-products of mitochondrial metabolism (p. 53). In addition, immune cells generate ROS with which they destroy pathogens (p. 469). Normally this is beneficial, but any abnormal activation of the immune cells, as found in certain disease states, can lead to the constant generation of ROS, resulting in chronic inflammation and accelerated tissue aging. Thus, the increased avian metabolic rate should expose birds to a higher concentration of ROS and, consequently, accelerated tissue damage.

In addition, the high glucose levels (along with high body temperature) should promote accelerated tissue aging. Consider the situation in hummingbirds. They have blood sugar levels much higher than do people with Type II (noninsulin-dependent) *diabetes mellitus* (p. 323). The tissues of human and domestic dogs and cats, as a consequence of the elevated blood-sugar levels and oxidative stress, are susceptible to tissue-specific complications that manifest over time. Diabetes is the primary cause of

blindness, kidney failure, and limb amputation in America and contributes to cardiovascular disease. It has been well established that the higher the blood sugar in a diabetic, the earlier the onset of complications. Do birds suffer a similar fate to that found for diabetics?

First, how does glucose damage the body's tissues and organs? One mechanism begins with the formation of advanced **Maillard products**: Glucose covalently binds (nonenzymatically) to proteins. This *glycosylation* process may be involved in normal aging-related tissue degeneration and is accelerated in diabetes. (Interestingly, glucose is among the least reactive of the monosaccharides, which may be one reason why animals rely on this particular carbohydrate for its energy needs.) Maillard products are further modified by free radicals in an animal's body, which contribute to the formation of irreversible cross-links between adjacent proteins. This impairs protein functions; for example, elasticity of the lung and blood vessels diminishes, wrinkles appear, and the basement membranes in the kidney thickens, which reduces substrate filtration. Research has shown the diabetic population has an elevated concentration of free radi-

FIGURE 12-4 Perfusion of an isolated segment of a renal tubule. A specific perfusion fluid is injected on the right, and a sample of the outgoing fluid is taken on the left. Any modifications to the fluid made by the tubule cells can then be determined.

space, a pseudocoelom, or a coelom). They have low (fluid) hydrostatic pressure inside them relative to the body cavity, most often because of the beating of cilia in the duct, which resembles a flame (giving the cell its name), move fluid outward. This relatively negative pressure draws water and small solutes nonselectively in through a specialized cell with filtering slits or pores (ultrafiltration) from the body cavity. The duct after the filter may further modify the filtrate by reabsorbing desired molecules and secreting undesired ones. (Details of

similar mechanisms of filtration, secretion, and reabsorption are covered for the mammalian kidney later.) The action of the cilia eventually moves this modified fluid or urine out through a pore in the epidermis into the external environment. Protonephridia are generally found in more simple animals having one internal fluid compartment, such as rotifers, flatworms, larval annelids, and larval mollusks; they are also found in larval fishes and amphibians. An example is shown in Figure 12-5a.

cals and oxidative stress as a result of an immune system triggered into action by glycosylated tissue proteins.

What about the hummingbirds? With their elevated metabolism and higher body temperatures, these birds actually generate substantially more free radicals than a comparably sized mammal, yet remarkably, the concentration of glucose-derived cross-links is considerably lower than in mammals. How can this be?

Longevity appears to be a balance between free radical production and quenching of the free radicals by a combination of both endogenous (internally produced) and exogenous (dietary) *antioxidants*. Perhaps, then, birds have in their anti-aging repertoire some powerful antioxidants. A clue arises from the dual role of **uric acid**, a nitrogenous waste product (p. 559) that may also play a role in the body's antioxidant system. As you have seen, uric acid is the major nitrogenous waste in birds (and most other reptiles, some amphibians, and insects). These animals are uric acid "factories." However, uric acid is not just a waste product: It has been found to be important in combating oxidative stress and functions something like a catcher's mitt that can "pick off" any stray free radicals missed by the other antioxidant systems (see p. 53). A reduction in uric acid concentrations in chickens dramatically increases oxidative

stress and accelerates the rate of tissue aging, whereas the opposite effect is observed if uric acid levels are increased. Of interest, shorter-lived animals possess the enzyme **uricase**, which degrades uric acid into allantoin. It is an established scientific finding that long-lived species fail to express this enzyme and so enjoy an extended lifetime due in part to greater antioxidant protection.

What happens if uric acid concentrations rise too high? This results in a condition called **gout**, which can occur in humans, some other mammals, and some reptiles. Uric acid is highly insoluble and so when its concentrations increase above a certain threshold, it begins to come out of solution and crystallize in various tissues. For example, uric acid crystals forming in kidney *nephrons* can permanently impair kidney function. For unknown reasons, this increases plasma *renin* concentrations, which ultimately raises blood pressure (p. 587). Colder temperatures enhance crystallization; thus, uric acid tends to form painful urate crystals in the toes, fingers, and edge of the ears in primates. However, individuals with gout are protected against certain neurodegenerative diseases that afflict the general population. How then can birds tolerate much higher concentrations of uric acid in their tissues and blood? (In fact, both domestic and wild birds can

get gout, but not at rates higher than mammals.) One obvious answer is the much higher body temperature of birds, which increases the solubility of uric acid. The second is the unusual reaction that occurs in the nephron of the avian kidney. As soon as uric acid begins to crystallize in the avian kidney, the microvilli in the *proximal tubule* (p. 571) encapsulate the crystal with a protein coat, forming a *urate ball*, a highly soluble colloidal particle. These spheres are not physically destructive and serve to transport the uric acid crystal safely through the nephron. The colloidal suspension then passes through the ureters into the cloaca of the bird. Here the spheres are refluxed back into the ceca, pouchlike attachments off the large intestine, and microorganisms recover the protein. Most of the uric acid is also degraded in the ceca. Specific transporters located in the epithelial cells of the large intestine take up any free amino acids and sugars.

Because birds have a high concentration of blood glucose, it has been suggested that they evolved a mechanism to limit the associated damage. This mechanism includes a more efficient antioxidant system that takes the form of an apparently simple waste product: uric acid. This discovery may have important clinical applications for treating conditions associated with inflammatory stress.

- **Mesonephridia** and **metanephridia** use ultrafiltration typically driven by fluid pressure, with secretion, reabsorption, and occasionally osmoconcentration. These tubules are in animals with two or more major fluid spaces—a coelom and a circulatory fluid at a minimum. The tubules begin with a filtering capsule or funnel-like opening of some kind that ultrafilter the circulatory fluid. This is followed by tubule segments that perform selective secretion and reabsorption (and osmoconcentration in some groups) and may empty via a connecting canal or **ureter** into a hindgut or a bladder.

In vertebrates, the renal tubules are called **nephrons** (Greek *nephros*, for "kidney"), and they go through significant developmental changes in most groups. In all groups, the first renal structure is a ciliated *pronephric* one, which becomes functional only in larval fishes, amphibians, adult hagfish, and lampreys. In all other adult fishes and amphibians, the pronephric tubules degenerate except the duct, which becomes the foundation of new pressure-driven *mesonephric* tubules (the kidneys of these aquatic animals). Finally, in terrestrial vertebrates, both the pronephric and mesonephric tubules form in embryos but are replaced

by the *metanephric* tubules (more adapted for water-limited life on land). The mesonephric tubules, however, become the ducts of reproductive organs in males.

Metanephric-type tubules have evolved independently several times—in adult mollusks, in annelids (segmented worms), in some arthropods (such as crustaceans), and in vertebrates. In some cases, a single filtering tubule forms the renal organ, as in the (misnamed) *crustacean antennal gland* (Figure 12-5b). Each single tubule (one on each side of the head) begins with a capsule (end sac) that filters hemolymph; enters a *labyrinth* of epithelia and fluid spaces followed by a coiled *nephridial canal*, where selective absorption and secretion take place; and then empties into a bladder. In other animals, many meso- and metanephridial tubules are assembled together with connective tissue into large organs called **kidneys**, as in the case in "higher" vertebrates.

- **Malpighian tubules** begin filtration driven by active secretion of ions from an arthropod's hemolymph (Chapter 9), and then, in conjunction with the hindgut, use reabsorption and sometimes osmoconcentration. We begin with these.

check your understanding 12.2

Describe the four major renal processes.

How do protonephridia, mesonephridia, and metanephridia differ?

12.3 Insect Malpighian Tubules

Let's first examine in detail the excretory system of the most successful group of animals, the insects, with Malpighian tubules for excretion. These were named after their discoverer, Marcelo Malpighi, who—in Italy in the 1600s—pioneered microscopic study of anatomy (also discovering insect tracheae). Malpighian tubules are blind-end epithelial ducts, one-cell-layer thick, and are not organized into a distinct organ. The tubules project into the hemolymph from the hindgut (Figure 12-6a) in varying numbers; for example, there are four tubules in two pairs in *Drosophila melanogaster*, the common laboratory fruit fly (mosquitoes, in contrast, have five tubules; large insects like locusts may have hundreds). Some insects have small muscles that wave the tubules in the hemolymph, perhaps to create circulation. Recent genomic and proteomic studies show that the tubules have innate immune functions (p. 459) as well, at least in fruit flies.

Based on both classical microscopy studies and functional properties, the tubules can be divided into distinct regions. In fruit flies, one pair of tubules, which project anteriorly, begin with large *initial segments*, followed by *transitional segments*, *main segments*, a *lower segment*, and a junction between the two forming a common *ureter* that joins the hindgut. The other pair, which project posteriorly, have only main segments and a ureter junction. Other insects have different patterns of tubular differentiation; for example, the house cricket's tubules have three regions called *proximal*, *mid*, and *distal*.

Malpighian tubules initiate excretion by ion secretion, which causes osmosis

Malpighian tubules filter the hemolymph not by pressure, as in most other renal organs, but by secreting K^+ (and often Na^+) into tubule lumen (Figure 12-6a). This occurs in the main tubule segment in fruit flies and mid segment in crickets. Rather than using the Na^+/K^+ ATPase, this process uses a V-ATPase, one of the widespread types of proton (H^+) pumps we noted in Chapter 3 (p. 85). The V-ATPase is thought to set up a proton gradient (with H^+ higher in the lumen), which can be used to pull in K^+ and Na^+ against a gradient. This is thought to occur through CPA (*cation-proton antiport*) transporters, found in large so-called *principal cells* in fruit flies and mosquitoes (Diptera). As you

FIGURE 12-6 Malpighian tubules. (a) The arrangement of these tubules in a typical insect. First, K^+ ions are transported into the proximal end of the tubule, drawing Cl^- in by charge attraction and then water by osmosis. The tubule fluid is further modified as it travels distally in the tubule; in the rectum, large amounts of water are reabsorbed. (b) Countercurrent flow between the Malpighian tubule and hindgut in some desert insects, with osmolarities shown in mOsm. In these animals, the tubules bend posteriorly to lie against the rectum. Unlike in other insects, the side of the tubule facing the hemolymph is waterproof so that K^+ and Cl^- transported into the tubule without water following osmotically can accumulate to high levels (e.g., 4,000 mOsm). This in turn draws water osmotically from the nonwaterproof rectum, concentrating the fluid leaving the anus.

learned for sodium and glucose in Chapter 3 (Figure 3-15, p. 88), this *secondary active transport* can move substances against a gradient using the energy of another substance with a downhill gradient.

The accumulation of K^+ and Na^+ in the lumen makes the fluid more positive, which then draws in Cl^- ions via the

electrical gradient (as in Figure 12-3a, b). Cl^- is thought to move transcellularly through ClC channels (p. 561) in smaller *stellate cells* in fruit flies, and paracellularly in mosquitos. The net accumulation of KCl (and often NaCl) in turn makes the tubule fluid more concentrated, so water from the hemolymph moves in by osmosis through aquaporins in stellate cells and also by paracellular pathways (Figures 12-3b and 12-6a). The joint movement of salts and water results in a filtrate that is *isosmotic* with the hemolymph.

The tubules and hindgut modify the lumen fluid by specific secretion and reabsorption

The osmotic movement of water creates a bulk flow down the tubule, whose epithelium further modifies the lumen fluid through specific secretion and reabsorption. In particular, organic wastes such as uric acid are secreted into the tubule by transporters. Some solutes are moved by active transport, and others diffuse passively down concentration gradients through channel proteins because the lumen fluid, created by KCl , NaCl , and water initially, begins with no organic solutes, whereas the hemolymph has some. How many transporters and channels are in the tubules is not known, but the fly genome contains numerous genes with codes closely related to organic-solute transporters in mammals (see p. 592).

Moreover, the tubule cells are enriched in *detoxification* enzymes related to those in vertebrate livers, which may break down toxic molecules such as insecticides (natural or human-made).

Antidiuresis and Diuresis The tubule empties into the gut, excreting a fluid with essentially the same osmotic pressure as body fluids (that is, *isosmotic*), but with a very different solute concentration. Once in the hindgut, specialized epithelial cells of the rectum can further modify the urine. Some insects face frequent dehydrating conditions and must undergo **antidiuresis**, that is, excretion of a low-volume *hyperosmotic* (p. 78) urine, which conserves water in the body. This **osmoconcentration** process occurs by various mechanisms in different species but typically involves complex tissue anatomy that uses active transport of ions (such as KCl), followed by water osmosis. Uric acid precipitates as crystals as water is removed.

In the most efficient osmoconcentrating insects, such as mealworm beetle larvae (*Tenebrio molitor*)—which consume dry food such as flour—a *countercurrent* arrangement of the gut and Malpighian tubules is thought to be used (Figure 12-6b). Basically, the tubule runs parallel to the rectum and fluid moves in opposite directions in the two tubes.

It is thought that specialized cells called **leptophragmata**, found in waterproof domelike swellings in the initial segment, transport KCl into the upper portions of the tubule. Since water does not follow (as in Figure 12-3a), the KCl increases the lumen osmotic pressure to very high levels (e.g., 4,000 mOsm). This then draws water out of the end of the rectum through nonwaterproof membranes (Figure 12-6b), with the countercurrent arrangement enhancing the concentrating process in a manner similar to the mammalian nephron, which you will learn about later. These animal larvae appear to survive exclusively on *metabolic water* (p. 602) when consuming food with no water.

Other insects must cope with excessive loads of water. Freshwater insects are obvious examples. Another example is a nectar-feeding insect such as the butterfly, which imbibes large amounts of sugary nectar that can have a lower osmotic pressure than the insect's body fluids, thus potentially causing detrimental dilution of those fluids. These insects' tubules undergo **diuresis**—a high rate of urine production—which in this case is *hypo-osmotic*. Here, the hindgut recovers ions without concomitant water uptake.

Finally, other insects face excessive loads of both water and salt. Recall the mosquito we discussed at the beginning of the chapter, or consider the South American blood-sucking kissing bug, *Rhodnius prolixus* (see photograph)—both using piercing mouthparts to obtain huge loads of salty liquid in the form of blood from mammalian skin. The mosquito and bug rapidly bloat up from their blood meals, sometimes by a factor of 10 in mass! In both cases, the Malpighian tubules rapidly undergo diuresis, but with an approximately *isosmotic* urine: They increase their fluid excretion rates (by a factor of 1,000 in the kissing bug) to remove the excess water and salt from the body. In mosquitoes, this increase in fluid excretion occurs even before the animal has finished sucking in its meal. That means, to add insult to injury, she is urinating on you as she feeds!

unanswered Questions | Why are there virtually no marine insects?

Insects are the most successful animal group in terms of species, but curiously, they have not invaded Earth's largest habitat, the oceans. Although several hypotheses have been proposed for this, none has been well tested and found valid yet. One of these hypotheses focuses on the excretion systems, proposing that Malpighian tubules and hindguts in insects are inherently incapable of coping with seawater. How might this hypothesis be tested? <<

Insect excretion is regulated by diuretic and antidiuretic hormones

Much less is known about the regulation of excretion in insects than in vertebrates. However, it is known that insects have both **diuretic hormones**, which promote water loss, and **antidiuretic hormones**, which promote water conservation.

- **Diuretic hormones:** In the kissing bugs and mosquitoes, which must excrete considerable fluid loads, both *sero-*

A kissing bug, *Rhodnius*. The saliva of these animals contains a protein called *nitrophorin*, which binds nitric oxide (NO). After biting a human, the bug injects its saliva and the nitrophorin releases NO, which (as seen in Chapter 9, p. 392) dilates blood vessels. This action also prevents clotting. The bug subsequently takes in an enormous water and salt load (human blood), with which its excretory system must deal.

tonin and several neuropeptides stimulate excretion. One of these is *mosquito natriuretic peptide* (MNP), which selectively increases transcellular secretion of Na^+ and water after a blood meal. MNP and other diuretic hormones are structurally related to *corticotropin-releasing hormone* (CRH) in vertebrates (p. 289). These hormones are thought to be released by neurosecretory cells in the brain (*corpora cardiaca*, p. 280), abdominal ganglia, and posterior midgut after a blood meal. Serotonin appears to stimulate Ca^{2+} influx into the principal cells, whereas MNP triggers cAMP production in the same cells as a second messenger (p. 97). Ca^{2+} and cAMP, in turn, activate tubule secretion by activating the V-ATPases and subsequent fluid excretion. Other small neuropeptides called *myokinins* (e.g., *leukokinin-VII* in cockroaches) have been found in some insects that stimulate the stellate cells. The hormones act synergistically; that is, secretion is faster with them together than predicted by adding the effects of each hormone individually.

- **Antidiuretic hormones:** As antagonists, peptide hormones such as *cardioacceleratory peptide 2b* (CAP2b) in kissing bugs and *Tenmo-ADFa* in mealworm beetle larvae (*Tenebrio molitor*) trigger cGMP production in principal cells, which (in opposition to cAMP) reduces secretion and conserves water. Injection of Tenmo-ADFa into mosquitoes acts comparably. Curiously, CAP2b is a diuretic hormone in fruit flies. And in “same-key different-locks” fashion, CAP2b also has unrelated actions such as heartbeat acceleration (thus its name).

We now turn to vertebrate kidneys and their nephrons.

12.4 Vertebrate Urinary Systems and Extrarenal Organs

Vertebrate kidneys come in a variety of morphologies and functional capacities. In addition, as we noted earlier, animals may also use respiratory, digestive, and integumentary systems for nonfecal excretion and internal fluid homeostasis. Some of these *extrarenal* excretory mechanisms can be important for salt regulation in all vertebrate classes except mammals and nonmarine birds, the groups that have evolved the most effective osmoconcentrating kidneys. Here we take a look at kidneys and extrarenal organs in the major vertebrate classes. In the next chapter, you will see how each type of vertebrate integrates its mechanisms for solute and water regulation.

Vertebrate kidneys form the urine; the remainder of the urinary system is ductwork that carries the urine to the bladder or hindgut

The **urinary system** consists of the urine-forming organs—the kidneys—and the structures that carry the urine from the kidneys to the outside for elimination from the body (Figure 12-7a, b). Kidneys are paired organs that lie in the dorsal side of the abdominal cavity, one on each side of the vertebral column. Only the mammalian kidney has a “kidney-bean” shape; see Figure 12-7c for elongated mesonephric kidneys of bony fish. The kidneys of birds are divided into cranial, middle, and caudal subdivisions, with the surface of the kidney covered in rounded projections, the **renal lobules**. Each kidney is supplied by a *renal artery* and a *renal vein*. Urine drains into the two ureters (ducts walled with smooth

Overview of Functions of Parts of a Nephron

Vascular component

- **Afferent arteriole**—carries blood to the glomerulus
- **Glomerulus**—a tuft of capillaries that filters a protein-free plasma into the tubular component
- **Efferent arteriole**—carries blood from the glomerulus
- **Peritubular capillaries**—supply the renal tissue; involved in exchanges with the fluid in the tubular lumen

Tubular component

- **Bowman's capsule**—collects the glomerular filtrate
- **Proximal tubule**—uncontrolled reabsorption and secretion of selected substances occur here
- **Loop of Henle**—establishes an osmotic gradient in the renal medulla that is important in the kidney's ability to produce urine of varying concentration
- **Distal tubule and collecting duct**—variable, controlled reabsorption of Na^+ and H_2O and secretion of K^+ and H^+ occur here; fluid leaving the collecting duct is urine, which enters the renal pelvis

Combined vascular/tubular component

- **Juxtaglomerular apparatus**—produces substances involved in the control of kidney function

FIGURE 12-8 Nephrons in vertebrate kidneys. (a) A schematic representation of a nephron in a mammal, with both tubular and vascular components. (b) Schematic representations of the tubular components of nephrons from a shark (dogfish *Squalus acanthias*), a teleost or bony fish (eel *Anguilla anguilla*), and an amphibian (mudpuppy *Necturus maculosus*).

muscle), one carrying urine from each kidney to a bladder (in fish, amphibians, and mammals) or hindgut (in reptiles including birds), which temporarily stores urine (and in some animals may modify it). Periodically urine is emptied to the outside; in vertebrates with bladders, this is through

another tube, the **urethra** (which in male mammals serves both as a route for eliminating urine and as a passageway for semen from the testes; Figure 12-7a). In monotreme mammals, the urethra empties into the hindgut as in reptiles (hence their name: *mono*, “one”; *treme*, “hole”).

The nephron is the functional unit of the vertebrate kidney, using three or four of the basic renal processes

A nephron is the smallest functional unit capable of the kidney's basic functions. (Recall that a functional unit is the smallest structure within an organ capable of performing all of that organ's functions, although the mammalian renal pelvis [p. 603] may modify the urine after it leaves all the nephrons.) Nephrons are found in all vertebrate kidneys, and each kidney consists of numerous nephrons (for example, about 1.25 million in pigs, 1 million in humans, 0.5 million in dogs, 0.25 million in cats) bound together by connective tissue. Each nephron consists of the tubules and an associated *vascular* (blood vessel) component, both of which are intimately related structurally and functionally (shown for a mammal in Figure 12-8a). The arrangement of nephrons within mammalian kidneys gives rise to two distinct regions—an outer, granular-appearing region, the renal **cortex**, and an inner, striated region called the renal **medulla** (Figure 12-7b). Some mammals (generally small ones such as rodents and rabbits) have a **unipapillary** medulla, a single, striated, cone-shaped body (the papilla). Larger mammals (such as dogs and humans) have a compound medulla, containing several striated-appearing triangles, the renal **pyramids** (Figure 12-7b).

Let's first look at the associated vascular system (Figure 12-8a). On entering the kidney, the renal artery systematically subdivides to form many small vessels known as **afferent arterioles**, one of which supplies each nephron. The afferent arteriole delivers blood to the **glomerulus**, a ball-like knot of capillaries (in the cortex in mammals) through which part of the water and solutes are filtered from the blood passing through. The glomerular capillaries rejoin to form another arteriole, the **efferent arteriole**, through which blood that was not filtered into the tubular component leaves the glomerulus. This pattern is unusual (typically, arterioles break up into capillaries that rejoin to form venules) but similar to the arterioles of the hypothalamohypophyseal portal system (p. 288). At the glomerular capillaries, no O_2 or nutrients are extracted from the blood for use by the kidney tissues, nor are waste products picked up from the surrounding tissue. The efferent arteriole then subdivides into the **peritubular capillaries**, which supply the renal tissue with blood and are important in exchanges between the tubular system and blood during conversion of the filtered fluid into urine. These capillaries, as their name implies (*peri*, “around”), are intertwined around the tubular system. The capillaries rejoin to form venules that ultimately drain into the renal vein, by which blood leaves the kidney.

Returning to the glomerulus, filtered fluid leaving the capillaries passes through the tubules of the nephron. The tubules are hollow, fluid-filled tubes formed by a single layer of epithelial cells. Even though each tubule is continuous, it is specialized into various segments with different structures and functions along its length. The first three basic renal processes discussed previously—filtration, reabsorption, secretion (Figure 12-3c)—are involved in the formation of urine in all vertebrates, with the fourth (osmoconcentration) found in birds and mammals. Let's examine these functions along a mammalian nephron in Figure 12-8a:

- **Bowman's (or glomerular) capsule and filtration:** Around a glomerular capillary bed is an expanded,

double-walled cup-shaped invagination called **Bowman's (or glomerular) capsule** that collects the fluid filtered from the capillaries there. This is known as **glomerular filtration**: As blood flows through the capillaries, blood pressure forces protein-free plasma into Bowman's capsule. This ultrafiltration process is the first step in urine formation in most vertebrates and is normally continuous. In fact, in humans the kidneys filter the entire plasma volume about 65 times per day. If everything filtered were to pass out in the urine, the total plasma volume would be urinated out in less than half an hour! This does not happen, however, because the kidney tubules and peritubular capillaries are intimately related throughout their lengths (Figure 12-8a), so that materials can be transferred between the fluid inside the tubules and the blood within the peritubular capillaries. This filtration process is nondiscriminating; that is, with the exception of blood cells and most plasma proteins, all constituents within the blood— H_2O , nutrients, electrolytes, wastes, dietary toxins, small proteins, peptides such as hormones, and so on—are nonselectively filtered.

- **Proximal tubule and reabsorption/secretion:** From this capsule, the filtered fluid passes into the **proximal tubule**, which lies within the cortex and is highly convoluted throughout much of its course. Here, substances of value such as glucose, amino acids, and much of the water are returned to the peritubular capillary plasma (by mechanisms we will examine in detail later). This selective movement of substances from inside the tubule (the tubular lumen) into the blood uses energy and is called **tubular reabsorption**. Reabsorbed substances are not lost from the body in the urine but are carried instead by the peritubular capillaries to the venous system and then to the heart to be recirculated. Of the volume of plasma filtered per day, generally over 90% of the water and 100% of the glucose and amino acids are reabsorbed in mammals, with the remaining fluid eliminated as urine. In general, substances that need to be conserved are selectively reabsorbed, whereas unwanted substances that need to be eliminated remain in the urine.

The proximal tubule also performs **tubular secretion**, the selective transfer of substances from the peritubular capillary blood into the tubular lumens, a second route for substances to enter the renal tubules from the blood. Glomerular filtration (the first route) filters only about 20% of the plasma, with the remaining 80% flowing on into the peritubular capillaries. Some substances such as organic ions can be selectively transferred as well, by tubular secretion from the plasma in the peritubular capillaries into the ECF and then into the tubular lumen. Tubular secretion provides a mechanism for more rapidly eliminating selected substances from the plasma by extracting an additional quantity of a particular substance from the (unfiltered) plasma in the peritubular capillaries and adding it to the quantity of the substance already present in the tubule as a result of filtration.

Note that this multistage system starts with indiscriminate filtration followed by selective adjustment mechanisms. Because there are mechanisms for eliminating unwanted solutes by specific secretion, you might wonder why the apparently wasteful step of glomerular

filtration exists. After all, it also loses useful molecules initially, and the nephron (unlike a Malpighian tubule) has to expend energy to recover them in the reabsorption process. One possible benefit is that indiscriminant filtration helps remove *all* small harmful solutes from the body, including all those for which no specific transporters have evolved, such as novel plant toxins that an animal has not previously encountered.

- **Loop of Henle (or nephron loop) and osmoconcentration.** Next, the tubule in birds and mammals forms a sharp U-shaped or hairpin loop that dips into the renal medulla. The **descending limb** of this **loop of Henle** plunges from the cortex deep into the medulla; the **ascending limb** traverses back up into the cortex, running **countercurrent** to the descending limb. This loop is a major adaptive feature of avian and mammalian nephrons, resulting in the medulla region to become highly concentrated in NaCl (and urea in mammals); that is, the medullary ECF becomes a brine bath. As you will see later, this **osmoconcentration** process allows avian and mammalian kidneys to recover and conserve more water if necessary, further concentrating the waste products in the urine. This process is often classified as a type of tubular reabsorption, but as you will see later, it is conceptually useful to think of this as a process separate from the other three.

No loop is present in other vertebrates, which instead may have a short narrow **intermediate segment**, often ciliated and possibly involved in selective reabsorption and/or secretion. In at least one reptile, the American alligator, it makes a U-shape turn, perhaps similar to the first step that led to the evolution of the loop in birds and mammals.

- **Distal tubule and reabsorption/secretion and osmoconcentration.** The tubule once again becomes highly coiled to form the **distal tubule**, which also lies entirely within the cortex in mammals. (This tubule is absent in marine bony fishes.) It too performs selective reabsorption and/or secretion, and participates in osmoconcentration (see p. 595).
- **Collecting duct and osmoconcentration.** The distal tubule empties into a **collecting duct**, each of which in mammals drains fluid from up to eight separate nephrons. Each collecting duct releases its fluid contents (which have now been converted into urine) into ureters in most vertebrates, though in mammals, each duct empties into the renal *pelvis*, a cavity at the inner core of each kidney (Figure 12-7b). In birds and mammals, this duct is also important for osmoconcentration, as we will explain later.

This ends our survey of the main tubule; however, there is one other feature (Figure 12-8a):

- **Juxtaglomerular apparatus and regulation.** The ascending limb returns to the glomerular region of its own nephron, where it passes through the fork formed by the afferent and efferent arterioles. Here, both the tubular and vascular cells are specialized to form the **juxtaglomerular apparatus**, or JGA (*juxta*, “next to”), a structure that lies next to the glomerulus and plays an important role in sensing blood osmolarity and pressure and regulating kidney function. It or similar structures are found in most vertebrate kidneys.

Now let’s examine different vertebrates, which differ in their nephron morphologies—see Figures 12-8b and schematics of 12-9—as well as in extrarenal organs.

Elasmobranch fishes retain urea and trimethylamine oxide, and use gills, kidneys, and rectal glands for excretion and retention

Sharks and their relatives (*elasmobranchs*) are *isosmotic* or slightly *hyperosmotic* relative to seawater (recall that seawater’s osmotic pressure is about 1,000 milliosmoles/liter or mOsm; see p. 79), but not because internal NaCl is equal to that of seawater. Rather, they retain **urea** and **trimethylamine oxide (TMAO)** as major **osmolytes** (solute used to regulate osmotic balance; see p. 617 for details). Thus, they face the problem of excess NaCl entering through the gills and diet, but they do not have a problem with osmotic water loss. The gills are relatively impermeable to urea and TMAO, in part because of high cholesterol content. Also, the nephrons reabsorb most of these osmolytes from the filtrate, excreting only what is necessary for nitrogen balance. Although the nephrons have only *glomeruli*, *proximal*, and *distal tubules* (see schematic in Figure 12-9a), they are among the most complex known, apparently exhibiting multiple *countercurrent* arrangements that are probably related to this reabsorption ability (Figure 12-8b, shark). (We will examine countercurrent function in mammalian nephrons later.) Beyond this, however, extrarenal organs perform most other excretion and osmoregulatory roles. *Gills* are thought to remove some of the excess NaCl, but in particular, these fish have a specialized hindgut organ called the **rectal gland**, which has numerous blind-end tubules that excrete a hypertonic fluid high in NaCl. It actively transports salt out of the blood, but it is not considered a renal organ, because no filtration or waste excretion is involved (see p. 558).

Marine bony fishes use gills for most excretion and retention processes

In contrast to elasmobranchs, most marine bony fishes are highly *hypo-osmotic* (about 350 to 400 mOsm in most) compared to seawater (about 1,000 mOsm), so they face constant influx of excess salt through the gills and diet, and constant water loss through the gills (in Chapter 13, we will speculate on how hypo-osmotic regulation evolved). The gills of these fishes are responsible for most of the functions we typically associate with kidneys. To reverse the water loss, these fish must drink seawater, a process known to be stimulated by *angiotensin II* (which we will examine later in mammals, p. 588). Initially, this also creates an excess of salt in the blood. The gills compensate for this excess, using specialized epithelial *chloride cells*, which actively transport NaCl outward faster than water leaks out (see Chapter 13, p. 625).

The kidneys play a minor role in correcting salt imbalances: The vast majority of marine fishes studied cannot produce a sufficiently hyperosmotic urine that would remove NaCl and conserve water. Kidneys in most species have small *glomeruli* and *proximal tubules* but no distal tubules (which would unnecessarily create a hypo-osmotic urine) (Figures 12-8b and 12-9b); they function primarily to

FIGURE 12-9 Schematic representations of nephrons from the major classes of vertebrates showing the major tubule segments. See main text for details.

Source: W. H. Dantzler. (1989). *Comparative Physiology of the Vertebrate Kidney*. Berlin: Springer.

remove excess divalent ions (such as Mg^{2+}) in a low-volume, isosmotic urine.

Kidneys also have little role in nitrogenous waste removal. Instead, the gills excrete NH_3 and NH_4^+ , the primary nitrogenous wastes, probably by mechanisms better understood in freshwater fish (which we will discuss shortly). Thus, the gills serve as extrarenal osmoregulatory and excretory organs (see Chapter 13).

A few **aglomerular** species (Figure 12-9c), including many Antarctic fish, lack glomeruli and so do not use ultrafiltration. These species, such as toadfish (*Opsanus tau*), may have lost their glomeruli through evolution because they (and all marine bony fishes) produce very little urine. What urine they do produce begins initially by salt and water secretion into the proximal tubule lumen, much like Malpighian tubules (p. 566). Furthermore, the lack of glomeruli in some Antarctic fish may help them retain the small *antifreeze glycoproteins* they have in their blood (Chapter 15).

Freshwater bony fishes excrete water with their kidneys, and their gills excrete wastes and take up salts

Freshwater bony fishes must maintain an internal osmotic pressure far above that of the environment—that is, they are *hyperosmotic*—and are faced with constant influx of water through the gills and mouth (from eating, because they rarely drink). Accordingly, their kidneys have evolved to excrete a

voluminous, highly dilute (hypo-osmotic) urine. Kidneys have large *glomeruli* with nephrons having *proximal tubules*, sometimes ciliated *intermediate tubules*, *distal tubules*, and *collecting ducts* (Figure 12-9d). Most of these segments reabsorb nutrients and minerals; the *distal tubule* helps create the hypo-osmotic urine by removing ions from the lumen (a process you will learn about for the mammalian loop later).

Dietary intake and active transport by the gills brings in NaCl and other ions to replace those lost in the urine. As in marine fish, the gills are primarily responsible for excreting NH_3 and NH_4^+ . The charged form NH_4^+ , which does not pass through lipid bilayers, is thought to be transported by Na^+/K^+ symporters and ATPases, which can transport NH_4^+ in place of K^+ . Although the gas form NH_3 can diffuse passively through membrane bilayers, its permeability is now thought to be greatly increased by **Rh (rhesus) channels** in gill-cell membranes. The Rh family of proteins was first discovered on erythrocyte membranes in humans and rhesus monkeys as critical factors in blood transfusions (because erythrocytes of people having a certain form of Rh protein trigger immune rejection in other people without that form). But only recently have scientists discovered one of their functions, namely as NH_3 channels. In models developed by Patricia Wright, Chris Wood, and others, gills of freshwater fish have Rh channels that not only allow NH_3 to diffuse rapidly out to the environment but also transport H^+ out at the same time. The H^+ ions react with the external NH_3 to convert it to NH_4^+ , which cannot diffuse back into the cell through the Rh channel.

Terrestrial vertebrates evolved new renal and extrarenal mechanisms to maintain an “internal sea”

As lungs replaced gills in the evolution of vertebrates onto land, renal organs evolved new functions (with the loss of mesonephric and gain of metanephric tubules), in part because lungs, unlike gills, can neither excrete $\text{NH}_3/\text{NH}_4^+$ nor regulate NaCl . To a large extent, vertebrates that live on dry land independent of the sea succeed because of their kidneys, which, in concert with hormonal and neural extrinsic control, have become crucial regulators of ECF volume and composition. In effect, they maintain a consistent “internal sea” in the ECF for the benefit of cells. In mammals, kidneys are the most important organs for such maintenance. By adjusting the quantity of water and various plasma constituents that are either conserved for the body or eliminated in the urine, the kidneys can maintain water and electrolyte balance within the very narrow range compatible with mammalian cells, despite wide variations in intake and losses of these constituents through other avenues.

When there is a surplus of water or a particular electrolyte such as NaCl in the ECF, mammalian kidneys can eliminate the excess in the urine. If there is a deficit in the body, kidneys cannot actually provide additional quantities of the depleted constituent, but in birds and mammals, they can limit (though not completely halt) the urinary losses of the material in short supply and thus conserve it until more of the depleted substance can be ingested. Accordingly, kidneys can compensate more efficiently for excesses than for deficits.

Terrestrial kidneys are also the primary route for eliminating potentially toxic metabolic wastes and foreign compounds from the body. Most wastes usually cannot be eliminated in solid form; they must be excreted in solution (especially in mammals). Because the H_2O eliminated in the urine is derived from the plasma, animals unable to obtain H_2O eventually urinate themselves to death by depleting the plasma volume to a fatal level. However, except under such extreme circumstances, the kidneys can maintain stability in the internal fluid environment despite the usual variations in intake of fluids and electrolytes.

Not only can kidneys adjust for wide variations in ingestion of H_2O , salt, and other electrolytes, but they also compensate for abnormal losses from thermoregulatory evaporation (sweating, panting), vomiting, diarrhea, or hemorrhage. Thus, urine composition varies widely as the kidneys adjust for differences in intake as well as losses of various substances in an attempt to maintain the ECF within the narrow limits required by most terrestrial vertebrates' cells.

Amphibians use kidneys and bladders for excretion and retention

Amphibians demonstrate the transition to a life on land. Metanephric nephrons in adult amphibians are similar to the mesonephric ones of freshwater fish (Figures 12-8b and 12-9e), with similar functions (to excrete water and reabsorb ions and nutrients) but with the added function of urea excretion. Also unlike fish, terrestrial frogs can shut down glomerular filtration to almost zero when faced with dehydration (a similar shutdown occurs in mammals under acute stress and severe dehydration).

Moreover, the urinary bladder in terrestrial amphibians has a secondary role, that of a temporary water reservoir. After the salty urine reaches the bladder, active transporters move the salt back to the blood, leaving highly purified water behind (much like the functioning of the thick ascending loop of Henle in mammals; see p. 595). Certain frogs such as the Australian water-holding frog (*Cyclorana platycephala*) that burrow and estivate (dry-weather equivalent of hibernation) store this nearly pure water to be returned to the blood when needed. The native human inhabitants of Australia have long made use of this as a source of safe drinking water in the desert, released by squeezing the animal! When these and other terrestrial amphibians suffer dehydration stress, the hypothalamic hormone *arginine vasotocin* (AVT) triggers water uptake into the main body from the wall of the bladder via *aquaporins* (p. 81). (The closely related hormone *arginine vasopressin* AVP in mammals works similarly, as you will see later; p. 598.) Uptake of water through the skin may also occur, driven by sodium uptake by the mechanism of Figure 12-3b.

Nonavian reptiles use amphibian-like kidneys, hindguts, and (in marine and desert species) salt glands for excretion and retention

Nonavian reptiles have nephrons similar to aquatic vertebrates in having *capsules*, *proximal tubules*, ciliated *intermediate tubules*, *distal tubules*, and *collecting ducts* (Figure 12-9f). The ureters carry urine in a liquid or semisolid form into the **cloaca**, the final chamber of the hindgut (Figure 12-10). In order to remove excess water from the body, freshwater reptiles have larger glomeruli compared to terrestrial species. For the latter, without a loop of Henle, the nephrons cannot produce a significantly hyperosmotic urine to conserve body water. However, they can conserve water in three ways. (1) Uric acid as the primary nitrogenous waste conserves water, as we have seen. (2) The **cloaca** or *lower intestine* can reabsorb some water by first transporting salt (as in Figure 12-3b). This precipitates the uric acid left behind even further, creating a more solid urine, although it usually does not make a hyperosmotic urine. (3) Marine and some desert reptiles (nonavian) have an extrarenal organ, the *nasal salt gland* (see Figure 12-11 for the avian equivalent) that is dedicated to excreting a highly salty fluid by the same mechanisms found in birds (see the next section). For marine species, NaCl is the primary salt, but glands of herbivorous lizards also excrete KCl to compensate for the high potassium content of ingested plant food.

Birds have kidneys with reptile- and mammal-like nephrons, hindguts, and (in marine species) salt glands for excretion and retention

Since birds are now classified as reptiles, it is not surprising that their urinary system also involves a liquid or semisolid urine, and a cloaca and lower intestine (Figure 12-10) that can recover some water. Bird kidneys are also usually dominated by so-called *reptilian type* nephrons (Figure 12-9g), which have the same segments as (nonavian) reptile nephrons. However birds also have some so-called *mammalian type* nephrons with loops of Henle that can form a concen-

FIGURE 12-10 Avian urinary systems. (a) The kidney, showing its organization into lobes with short “reptilian”-type and long “mammalian”-type nephrons. (b) The hindgut, showing retrograde flow of urine from the ureter into the coprodaeum and colon.

trated urine (Figure 12-9h). In turn, there are two mammalian types called *cortical* and *juxtamedullary*, which we will explore in detail for mammals in the next section. For now, note that the juxtamedullary nephrons are responsible for making a concentrated urine, important for water

conservation. As an example, G. Casotti and K. C. Richardson found that arid-zone white-fronted honeyeaters (*Phylidonyris albifrons*) in Australia have a higher percentage of juxtamedullary nephrons in their kidneys than do wet-zone New Holland honeyeaters (*Phylidonyris novaehollandiae*) of similar size.

Most birds form only modestly hyperosmotic urines, but (as we noted earlier) much of their primary nitrogenous waste is uric acid. (Uric acid is transported into the renal tubules by the organic ion mechanism, p. 592.) Most of this uric acid precipitates as crystals (as uric acid is inherently insoluble), which exert no osmotic pressure but can potentially damage the nephron because of their “spiky” structure. For this reason the precipitated uric crystals are then covered by a protein coat (albumin) to form **urate balls**. These are sufficiently small enough to be filtered through the pores into the capsule. (Protein concentration in mammalian urine is normally less than 0.1 mg/mL, while in a chicken’s urine it may be 3–5 mg/mL.) Because of this consolidation of uric acid we should not expect very high osmotic pressures in the urines of birds. Nevertheless some species of songbirds, which have no salt glands, produce urine osmolalities up to 2,000 mOsm if they live in arid or high-salt habitats. For example, the Chilean Seaside Cinclodes (*Cinclodes nigrofummosus*), which eats marine nonvertebrates, needs to produce a urine over 1,000 mOsm, because its prey have extracellular fluid concentrations of NaCl equal to seawater (see Chapter 13, p. 617). In contrast, the White-Winged Cinclodes (*C. atacamensis*) of river and grassland habitats produces urines of 765 mOsm or less.

Salt Glands Most marine birds, which must drink seawater, also have a **nasal salt gland** located near the eyes, with ducts leading to the nasal passages (Figure 12-11). These glands contain blind-end tubules lined with active salt-secreting cells that apparently transport NaCl out of the blood without concomitant osmotic water movement (as in Figure 12-3a). Unlike kidneys but like shark rectal glands, these extrarenal cells perform no filtration or waste excretion; moreover, they are not constantly active but rather work only when the bird is dehydrated or overloaded with salt.

The NaCl concentration excreted by the salt gland depends on what a particular species eats. A cormorant (see opening figure of this chapter) eats bony fish, which (as we noted earlier) are very hypo-osmotic compared to seawater (p. 572).

Cormorant salt glands accordingly excrete a fluid with about 500 mM NaCl (930 mOsm), osmotically more concentrated than its body fluids, but not quite equal to seawater. In contrast, a petrel that eats marine nonvertebrates secretes a fluid that is 1,100 mM NaCl (over 2,000 mOsm).

**FIGURE 12-11** The salt glands of a gull.

regions of the kidney and, more importantly, for understanding detailed renal function. In addition, the medulla is divided into *outer* and *inner* regions. As we just noted for birds, there are two types of nephrons distinguished by the location and length of some of their structures (Figure 12-12). All nephrons originate in the cortex, but the glomeruli of **cortical nephrons** lie in the outer layer of the cortex, whereas the glomeruli of **juxtamedullary nephrons** lie in the inner layer of the cortex, adjacent to the medulla. The presence of all glomeruli and their Bowman's capsules in the cortex give this region a granular appearance. These two nephron types differ most markedly in the structure of their loops of Henle. The hairpin loop of a cortical nephron dips only slightly into the outer medulla, whereas the loop of a juxtamedullary nephron plunges through into the inner medulla. This relatively simple dichotomy is more complex in animals with relatively large renal medullas, such as desert rodents (see p. 601), in which the loops of juxtamedullary nephrons vary considerably: some barely penetrate the inner medulla, some reach midway, while others descend to the innermost tip.

The peritubular capillaries of juxtamedullary nephrons form hairpin vascular loops known as **vasa recta** ("straight vessels"), which run in close association with the loops (Figures 12-8a and 12-12). As they course through the medulla, the collecting ducts of both cortical and juxtamedullary nephrons run parallel to the ascending and descending limbs of the juxtamedullary nephrons' loops of Henle and vasa recta. This parallel arrangement of tubules and vessels creates the medullary tissue's striated appearance in the papilla or pyramids (see Figure 12-7b). More importantly, as you will see, this arrangement plays a key role in the kidneys' ability to produce urine of varying concentrations, and in the evolution of mammals to different habitats.

All plasma constituents that gain access to the tubules—that is, are filtered or secreted—but are not reabsorbed, remain in the tubules and pass into the renal pelvis to be excreted as urine and eliminated from the body. (Do not confuse *excretion* with *secretion*.) Conversely, anything filtered and subsequently reabsorbed or not filtered at all enters the venous blood and thus is conserved for the body, despite passage through the kidneys. The kidneys act only on the plasma. However, because of the free exchange between plasma and interstitial fluid across the capillary walls (with the exception of plasma proteins), interstitial fluid composition reflects the composition of plasma. Thus, by performing their regulatory and excretory roles on the plasma, the kidneys maintain the proper interstitial fluid environment for optimal cell function. Now we will discuss how the renal processes are accomplished and regulated to help maintain homeostasis. (The processes described are thought to be the same in all mammals, but the particular concentrations and rates given are mainly from humans and laboratory mammals.)

Recall that the process begins with *glomerular filtration*. Let's now examine how these remarkable cleansing systems work.

12.5 Mammalian Urinary System: Overview and Glomerular Filtration

Mammalian kidneys, as well as those of many of the other vertebrates we just surveyed, are effectors for the four major functions noted at the beginning of the chapter (p. 557): regulating (1) major inorganic solutes (including ions involved in acid-base balance), (2) plasma volume, (3) harmful or unneeded organic molecules, and (4) osmotic balance. In mammals, kidneys have the following additional functions (the first two of which are not effector but rather integrator functions):

5. *Secretion of erythropoietin*, a hormone that stimulates red blood cell production (p. 393).
6. *Secretion of renin*, a hormone important for salt conservation (as you will see later).
7. *Conversion of vitamin D into its active form* (p. 329).
8. *Excretion of pheromones* for sexual signaling, marking territories, and so forth.

Mammalian (and avian) kidneys have cortical and juxtamedullary nephrons

Let's begin with an in-depth examination of nephron function. Knowing the structural arrangement of an individual nephron that we described earlier (Figure 12-8a) is essential for understanding the distinction between the *cortical* and *medullary*

FIGURE 12-12 Comparison of juxtamedullary and cortical nephrons (mammalian kidney). The glomeruli of cortical nephrons lie in the outer cortex, whereas the glomeruli of juxtamedullary nephrons lie in the inner part of the cortex next to the medulla. The loops of Henle of cortical nephrons dip only slightly into the medulla, but the juxtamedullary nephrons have long loops of Henle that plunge deep into the medulla. The juxtamedullary nephrons' peritubular capillaries form hairpin loops known as *vasa recta*.

For better visualization, the nephrons are grossly exaggerated in size, and the peritubular capillaries have been omitted, except for the *vasa recta*.

The glomerular membrane has three layers forming a fine molecular sieve

Fluid filtered from a glomerulus into Bowman's capsule must pass through the three layers that make up the glomerular membrane. Collectively, these layers function as a fine molecular sieve that retains the blood cells and most

FIGURE 12-14 Layers of the glomerular membrane (mammalian kidney).

plasma proteins but permits H_2O and solutes of small molecular size to filter through (Figures 12-13 and 12-14):

1. The *glomerular capillary wall* consists of a single layer of flattened endothelial cells. It is perforated by many pores (*fenestrations*) that make it more than 100 times more permeable to H_2O and solutes than capillaries elsewhere in the body. The pores, though large, are too small for most plasma proteins to fit through.
2. The *basement membrane* is not a phospholipid bilayer but rather a noncellular gelatinous layer composed of collagen and glycoproteins that is sandwiched between the glomerulus and Bowman's capsule. The collagen provides structural strength, and the glycoproteins discourage the filtration of small plasma proteins. The wall pores are just barely large enough to permit passage of albumin, the smallest of plasma proteins. However, because the glycoproteins are negatively charged, they repel albumin and other plasma proteins, which are also negatively charged. Therefore, less than 1% of the albumin molecules escape into the capsule. In mammals, unlike in reptiles (including birds), the small proteins

that do slip into the filtrate are picked up by the proximal tubule by endocytosis, then degraded into constituent amino acids that are returned to the blood. Thus, urine is considered protein free. This process of protein exclusion from filtrate can be disrupted during certain disease conditions, such as diabetes.

3. The final layer is the *inner layer of Bowman's capsule*. It consists of **podocytes** (*pedo*, "foot"), octopus-like cells that encircle the glomerular tuft. Each podocyte bears many elongated foot processes (meaning projections) that interdigitate with foot processes of adjacent podocytes, much as you interlace your fingers between each other when you cup your hands around a ball (Figure 12-13). The narrow slits between adjacent foot processes, known as **filtration slits**, provide a pathway through which fluid leaving the glomerular capillaries can enter the lumen of Bowman's capsule.

Thus, the route that filtered substances take across the glomerular membrane is completely extracellular—first through capillary pores, then through the acellular basement membrane, and finally through capsular filtration slits (Figure 12-14).

The glomerular capillary blood pressure is the major force that causes glomerular ultrafiltration

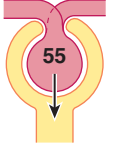

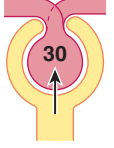

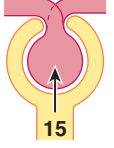

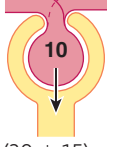

To accomplish glomerular filtration, a force—pressure—is required to drive a portion of the plasma out of the glomerular capillaries and into Bowman’s capsule. (There is no active transport as in Malpighian tubules.) Because the glomerulus is a tuft of capillaries, the same principles of fluid dynamics that are responsible for ultrafiltration across other capillaries apply (see p. 443), except for two important differences: (1) The glomerular capillaries are much more permeable than capillaries elsewhere, so more fluid is filtered for a given filtration pressure, and (2) the balance of forces across the glomerular membrane is such that filtration occurs throughout the entire length of the capillaries, in contrast to the reabsorption that occurs toward the ends of other capillaries (see p. 444).

Three physical forces are involved in glomerular filtration (Table 12-1); the first favors filtration while the second two oppose it:

1. The *glomerular capillary blood pressure* is the fluid pressure exerted by the blood within the glomerular capillaries. It ultimately depends on contraction of the heart to create blood pressure and the resistance to blood flow offered by the afferent and efferent arterioles. The glomerular capillary blood pressure, at an estimated average value of 55 mm Hg in humans, is higher than capillary blood pressure elsewhere, because the diameter of the afferent arteriole is larger than that of the efferent arteriole. Because blood can more readily enter the glomerulus through the wide afferent arteriole than it can leave through the narrower efferent arteriole, glomerular capillary blood pressure is elevated by blood “damming up” in the glomerular capillaries. This high glomerular blood pressure tends to push fluid out of the glomerulus into Bowman’s capsule along the glomerular capillaries’ entire length, and it is the major force responsible for producing glomerular filtration.
2. *Plasma-colloid osmotic pressure* is caused by the unequal distribution of plasma proteins across the glomerular membrane. Recall that plasma proteins are in the glomerular capillaries but not in Bowman’s capsule. Thus, the concentration of H_2O is higher in the capsule than in the glomerular capillaries, so H_2O is drawn osmotically back into the glomerulus. This movement opposes glomerular filtration, with an osmotic force averaging 30 mm Hg.
3. *Bowman’s capsule hydrostatic pressure*, the pressure exerted by the fluid in this initial part of the tubule, is estimated to be about 15 mm Hg. This pressure opposes the movement filtration of fluid out of the glomerular capillaries.

Glomerular Filtration Rate As can be seen in Table 12-1, the forces acting across the glomerular membrane are not in balance. The glomerular capillary blood pressure at 55 mm Hg is opposed by the total of the other two pressures at about 45 mm Hg. The difference (10 mm Hg) is called the **net filtration pressure**. This modest pressure forces large volumes of fluid from the blood through the highly permeable glomerular membrane. The actual rate of filtration, the **glomerular filtration rate (GFR)**, depends not only on the net filtration pressure but also on how much glomerular surface area is avail-

TABLE 12-1 Forces Involved in Glomerular Filtration

Force	Effect	Magnitude (mm Hg)
Glomerular Capillary Blood Pressure	Favors filtration	
Plasma-Colloid Osmotic Pressure	Opposes filtration	
Bowman’s Capsule Hydrostatic Pressure	Opposes filtration	
Net Filtration Pressure (Difference between Force Favoring Filtration and Forces Opposing Filtration)	Favors filtration	 $55 - (30 + 15) = 10$

able for penetration and how permeable the glomerular membrane is (that is, how “holey” it is). These properties of the glomerular membrane are collectively referred to as the **filtration coefficient (K_f)**. Accordingly,

$$GFR = K_f \times \text{net filtration pressure}$$

Normally, in humans about 20% of the plasma that enters the glomerulus is filtered at the net filtration pressure of 10 mm Hg. This produces 180 liters of glomerular filtrate each day for an average GFR of 125 mL/min in male humans (versus an average GFR of 115 mL/min in female humans). GFR is lower in the kidneys of most newborn animals compared to mature animals (correlating with low arterial pressures in newborns), pony foals being an exception where GFR remains relatively constant throughout the postnatal period. To compare species, GFR is expressed in terms of body weight, revealing that GFR *scales* (p. 10) with body weight such that GFR per unit mass decreases with body size, just as does metabolic rate (see Chapter 15, p. 270). For example, in a 70-kg male human the GFR is about 1.8 mL/min/kg, whereas in dogs, it is approximately 4 mL/min/kg.

Changes in the GFR result primarily from changes in glomerular capillary blood pressure

Because the net filtration pressure is simply the result of an imbalance of opposing physical forces between the glomerular capillary and capsule fluids, alterations in any of these physical forces can affect the GFR. Let’s examine important alterations.

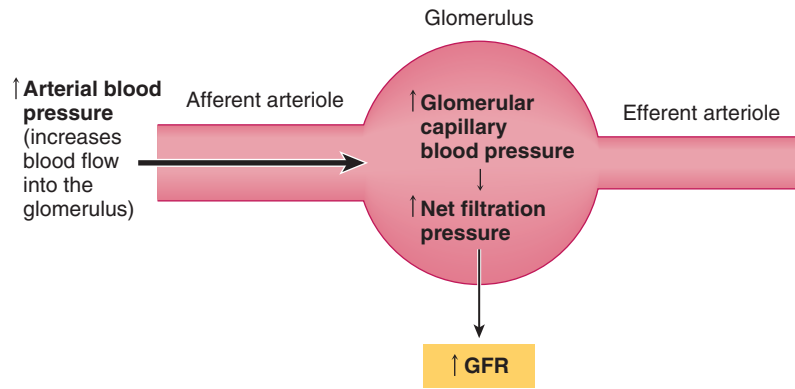

Unregulated Influences on the GFR Plasma-colloid osmotic pressure and the capsule hydrostatic pressure are not subject to regulation and normally do not vary much. However,

they can change pathologically and thus inadvertently affect GFR. Because plasma-colloid osmotic pressure opposes filtration, a decrease in plasma protein concentration leads to an increase in the GFR. Such a reduction might occur, for example, in severely burned victims who lose a large quantity of protein-rich, plasma-derived fluid through the exposed burned surface of their skin. Conversely, in situations in which the plasma protein concentration is elevated, such as in cases of dehydrating diarrhea, the GFR is reduced.

Bowman's capsule hydrostatic pressure can become uncontrollably elevated, and filtration can subsequently decrease. This is a common occurrence, if a urinary tract obstruction, such as a kidney stone (a problem in humans and certain cat and dog breeds) or enlarged prostate in males, is present. The damming up of tubular fluid behind the obstruction elevates capsular hydrostatic pressure.

Controlled Adjustments in the GFR Unlike plasma-colloid osmotic and capsule hydrostatic pressures, glomerular capillary blood pressure can be controlled to adjust the GFR to suit the body's needs. Assuming that all other factors stay constant, as the glomerular capillary blood pressure goes up, the net filtration pressure (and therefore GFR) increases. The magnitude of the glomerular capillary blood pressure depends on the rate of blood flow within each glomerulus. The amount of blood flowing into a glomerulus per minute is determined largely by the magnitude of the mean systemic arterial blood pressure and the resistance offered by the afferent arterioles. If *resistance increases* in the *afferent* arteriole, *less blood* flows into the glomerulus, decreasing the GFR. Conversely, if afferent arteriolar *resistance is reduced*, *more blood* flows into the glomerulus and the GFR increases. Two major control mechanisms regulate glomerular blood flow by regulating the radius and thus the resistance of the afferent arteriole: (1) *autoregulation*, intrinsic mechanisms aimed at preventing spontaneous changes in GFR; and (2) *extrinsic sympathetic* control, which is aimed at long-term regulation of arterial blood pressure.

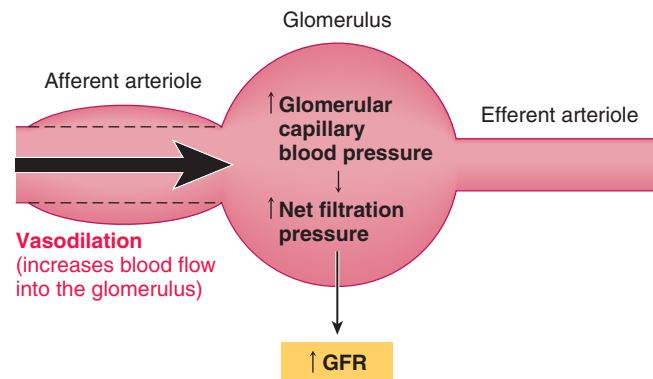

Autoregulation of GFR Because arterial blood pressure drives blood into the glomerulus, the glomerular capillary blood pressure and, accordingly, the GFR would increase in direct proportion to an increase in arterial pressure if everything else remained constant (Figure 12-15a). Similarly, a fall in arterial blood pressure would be accompanied by a decline in GFR. Such spontaneous, inadvertent changes in GFR are largely prevented by regulatory mechanisms initiated by the kidneys themselves, an example of intrinsic regulation called **autoregulation** (see p. 435). The kidneys can, within limits, maintain a constant blood flow into the glomerular capillaries (and thus a stable GFR) despite changes in the driving arterial pressure. They do so primarily by altering af-

(a) Direct effect of arterial blood pressure on the glomerular filtration rate (GFR).

(b) Arteriolar vasoconstriction decreases the GFR

(c) Arteriolar vasodilation increases the GFR

FIGURE 12-15 Alteration mechanisms for glomerular filtration rate (GFR; mammalian kidney). (a) Direct effect of arterial blood pressure on the GFR. (b) Arteriolar adjustment to reduce the GFR. (c) Arteriolar adjustment to increase the GFR.

ferent arteriolar caliber, thereby adjusting resistance to flow through these vessels. For example, if the GFR increases as a result of a rise in arterial pressure, the net filtration pressure and GFR can be reduced to normal by constriction of the afferent arteriole to decrease the flow of blood into the glomerulus (Figure 12-15b). This local adjustment lowers the GFR to normal. The opposite effects occur if there is a decline in arterial pressure (Figure 12-15c), which leads to vasodilation. The resulting increase in glomerular blood volume increases local blood pressure and thus GFR.

FIGURE 12-16 The juxtaglomerular apparatus (mammalian kidney). The juxtaglomerular apparatus consists of specialized vascular cells (the granular cells) and specialized tubular cells (the macula densa) at a point where the distal tubule passes through the fork formed by the afferent and efferent arterioles of the same nephron.

© Cengage Learning, 2013

Two intrarenal mechanisms contribute to autoregulation:

1. The **myogenic** (“muscle produced”) mechanism is a common property of arteriolar vascular smooth muscle, which contracts inherently in response to the stretch accompanying increased pressure within the vessel (see p. 435). Accordingly, the afferent arteriole automatically does this when it is stretched because of an increased arterial driving pressure, limiting blood flow into the glomerulus despite the elevated arterial pressure. Conversely, inherent relaxation of an unstretched afferent arteriole when pressure within the vessel is reduced increases blood flow into the glomerulus despite the fall in arterial pressure.
2. The **tubuloglomerular feedback (TGF)** mechanism involves the **juxtaglomerular apparatus (JGA)**, the specialized structure near the glomerulus (Figures 12-8a and 12-16). Unlike the rest of the kidney, which is an effector organ, the JGA is an integrator in a negative-feedback sense (p. 14). The smooth muscle cells within the wall of the afferent arteriole in the JGA are specialized to form glandlike **granular cells**, so called because they contain many secretory granules. Specialized tubular cells in the JGA are collectively known as the **macula densa**, which detect changes in the salt level of the fluid flowing past them through the tubule.

If the GFR is increased due to an elevation in arterial pressure, more fluid than normal is filtered and

flows through the distal tubule. In response to the resultant rise in salt delivery to the distal tubule, the macula densa cells release ATP and *adenosine*. These are paracrine (p. 91), which act on the adjacent afferent arteriole, causing it to constrict and thus reducing glomerular blood flow and returning GFR to normal. In the opposite situation, when less salt is delivered to the distal tubule because of a spontaneous decline in GFR accompanying a fall in arterial pressure, the macula densa releases less paracrine. The resultant afferent arteriolar vasodilation increases the glomerular flow rate, restoring the GFR to normal. To exert even more exquisite control over TGF, the macula densa cells also secrete the vasodilator *nitric oxide* (p. 435), which puts the brakes on the action of ATP and adenosine at the afferent arteriole. By means of the TGF mechanism, the tubule of a nephron is able to monitor the salt level in the fluid flowing through it and adjust its own GFR accordingly to maintain fluid and salt delivery in the distal tubule.

The myogenic and TGF mechanisms work in unison to autoregulate the GFR during the transient changes in blood pressure that accompany daily activities unrelated to the need for the kidneys to regulate H₂O and salt excretion, such as the normal elevation in blood pressure accompanying exercise (p. 452). Autoregulation is important because unintentional shifts in GFR could lead to dangerous imbalances of fluid, electrolytes, and wastes. Since a given portion of the filtered fluid is always excreted, the amount of fluid

excreted in the urine is automatically increased as the GFR increases. If autoregulation did not occur, the GFR could increase and H_2O and solutes would be lost needlessly whenever arterial pressure rises during intense activity. If the GFR were too low, the kidneys could not adequately eliminate unneeded materials.

When changes in mean arterial pressure fall outside the range over which autoregulation works, 80 to 180 mm Hg in humans, these mechanisms cannot compensate. Therefore, dramatic changes in mean arterial pressure (<80 mm Hg or >180 mm Hg) directly cause the glomerular capillary pressure and, accordingly, the GFR to decrease or increase in proportion to the change in arterial pressure.

Extrinsic Sympathetic Control of the GFR In addition to the intrinsic autoregulatory mechanisms, the GFR can be controlled by extrinsic control mechanisms that override the autoregulatory responses. This control, mediated by sympathetic nervous system, is aimed at regulating overall body arterial blood pressure.

If plasma volume is decreased—for example, by hemorrhage—the resulting fall in arterial blood pressure is detected by the arterial carotid sinus and aortic arch baroreceptors, which initiate the neural *baroreceptor reflex* to raise blood pressure toward normal (Figure 12-17). Recall from Chapter 9 (p. 449) that this reflex response is coordinated by the cardiovascular control center in the brainstem and is mediated primarily through increased sympathetic activity to the heart and blood vessels. Although the resulting increase in both cardiac output and total peripheral resistance helps raise blood pressure toward normal, plasma volume is still reduced by the disturbance and must be restored to normal. One compensation for a depleted plasma volume is reduced urinary output to conserve fluid, which is partially accomplished by reducing the GFR.

Recall that during the baroreceptor reflex, vasoconstriction occurs in most arterioles throughout the body as a compensatory mechanism to increase total peripheral resistance. The glomerular afferent arterioles have α_1 adrenergic receptors (see p. 163) and are heavily innervated with sympathetic vasoconstrictor fibers compared to the efferent arterioles. When the glomerular afferent arterioles constrict from increased sympathetic activity, less blood flows into the glomeruli and GFR is reduced (Figure 12-15b). Thus, less urine forms and some of the H_2O and salt that would otherwise have been lost are saved for the body, helping to restore plasma volume to normal. Other mechanisms, such as increased tubular reabsorption of H_2O and salt as well as increased thirst (described more thoroughly elsewhere), also contribute to long-term maintenance of blood pressure by helping to restore plasma volume.

Conversely, if blood pressure is elevated (for example, because of an expansion of plasma volume following ingestion of excessive fluid), the opposite responses occur. When

FIGURE 12-17 Baroreceptor reflex influence on the GFR in long-term regulation of arterial blood pressure (mammal).

© Cengage Learning, 2013

the baroreceptors detect a rise in blood pressure, sympathetic vasoconstrictor activity to the arterioles is reflexly reduced, allowing afferent arteriolar vasodilation to occur. As more blood enters the glomeruli, glomerular capillary blood pressure rises, and increases the GFR (Figure 12-15c) and urinary output. A hormonally adjusted reduction in the tubular reabsorption of H_2O and salt also contributes to the increase in urine volume. These two renal mechanisms are key in removing excess fluid from the body.

The GFR can be influenced by changes in the filtration coefficient

Thus far, we have discussed changes in the GFR as a result of changes in net filtration pressure. The rate of glomerular filtration, however, also depends on the filtration coefficient

FIGURE 12-18 Change in the number of open filtration slits caused by podocyte relaxation and contraction (mammalian kidney).

(a) Podocyte relaxation narrows the bases of the foot processes, increasing the number of fully open intervening filtration slits spanning a given area. (b) Podocyte contraction flattens the foot processes and thus decreases the number of intervening filtration slits.

(K_f). For years K_f was considered a constant, except in disease situations in which the glomerular membrane becomes leakier than usual. However, research indicates that K_f is subject to physiological control. Both factors on which K_f depends—the surface area and the permeability of the glomerular membrane—can be modified by contractile activity within the membrane.

The surface area available for filtration within the glomerulus is represented by the extent of the capillary surface that faces the fluid in Bowman's capsule. Each tuft of glomerular capillaries is held together by **mesangial cells**, which form rings around the capillaries (Figure 12-16). These cells contain actinlike contractile elements. Like vascular sphincters, contraction of these mesangial cells reduces the radius of the filtering capillaries, which reduces the surface area available for filtration within the glomerular tuft. When the net filtration pressure remains unchanged, this reduction in K_f decreases GFR. Sympathetic stimulation causes the mesangial cells to contract, thus providing a second mechanism (besides afferent arteriolar vasoconstriction) by which sympathetic activity can decrease the GFR.

Podocytes also possess actinlike contractile filaments, whose contraction or relaxation can, respectively, decrease or increase the number of filtration slits open in the inner membrane of Bowman's capsule by changing the shapes and proximities of the foot processes (Figure 12-18). The more open slits, the greater the permeability. Contractile activity of the podocytes, which in turn affects permeability and the K_f , is under physiologic control by mechanisms incompletely understood.

Describe the pressure forces in glomerular filtration and how both autoregulation and extrinsic sympathetic regulation come into play.

12.6 Mammalian Kidneys: Tubular Reabsorption

As we noted earlier, filtration through the glomerular capillaries is largely indiscriminant. Filtered constituents include not only wastes but also nutrients, electrolytes, and other substances the body cannot afford to lose in urine. Indeed, through ongoing glomerular filtration greater quantities of these materials are filtered per day than are even present in the entire mammalian body. It is important that these essential materials be returned to the blood by the process of *tubular reabsorption* (p. 571). As we noted earlier, reabsorption of most substances occurs in the proximal tubule.

Tubular reabsorption involves passive and active transepithelial transport and is tremendous, highly selective, and variable

Tubular reabsorption is a highly selective process. All constituents except plasma proteins (and protein-bound solutes such as iron) are at the same concentration in the glomerular filtrate as in the plasma. In most cases, the quantity of each material reabsorbed is the amount required to maintain the proper composition and volume of the internal fluid environment. In general, the tubules have a high reabsorptive capacity for substances needed by the body and little or no reabsorptive capacity for substances of no value (Table 12-2). Accordingly, only a small percentage, if any, of filtered plasma constituents that are useful to the body are present in the urine. Only excess amounts of essential materials such as electrolytes are excreted in the urine. As H_2O and valuable solutes are reabsorbed, the waste products remaining in the tubular fluid become highly concentrated. Considering the magnitude of glomerular filtration, the extent of tubular reabsorption is tremendous: Mammalian tubules typically reabsorb 99% of the filtered H_2O and salt and 100% of the filtered glucose and amino acids (Table 12-2).

FIGURE 12-19 Steps of transepithelial transport (mammalian kidney).

© Cengage Learning, 2013

Recall that, throughout its entire length, the tubule is in close proximity to a surrounding peritubular capillary (Figure 12-8a) and it is also only one-cell thick (Figure 12-19). Adjacent tubular cells touch each other only where they are joined by tight junctions at their lateral edges near their apical membranes, which face the tubular lumen. Interstitial fluid lies in the gaps between adjacent cells—the **lateral spaces**—as well as between the tubules and capillaries. The basolateral membrane faces the interstitial fluid at the base and lateral edges of the cell. The tight junctions largely prevent substances except H₂O from moving between the cells, so materials must move transcellularly to leave the tubular lumen and gain entry to the blood. To be reabsorbed, a substance must traverse five distinct barriers (Figure 12-19). It must (1) leave the tubular fluid by crossing the apical membrane of the tubular cell, (2) pass through the cytosol from one side of the tubular cell to the other, (3) traverse the basolateral membrane of the tubular cell to enter the interstitial fluid, (4) diffuse through the interstitial fluid, and (5) penetrate the capillary wall to enter the blood plasma. This entire sequence is known as **transepithelial transport** and relies on transport epithelia that we discussed in general terms earlier (e.g., Figure 12-3).

Recall that there can be both *passive* and *active* transport (p. 84). Substances that are actively reabsorbed against a gradient and are of particular importance to the body include organic nutrients such as glucose and amino acids, and electrolytes such as Na⁺ and PO₄³⁻. Rather than specifically describing the reabsorptive process for each of the many filtered substances that are returned to the plasma, we provide illustrative examples of the general mechanisms involved after first highlighting the unique and important case of Na⁺ reabsorption.

TABLE 12-2 Fate of Various Substances Filtered by Mammalian Kidneys

Substance	AVERAGE PERCENTAGE OF FILTERED SUBSTANCE	
	Reabsorbed	Excreted
Water	99*	1
Sodium	99.5	0.5
Glucose	100	0
Urea (a waste product)	50	50
Phenol (a waste product)	0	100
Amino acids	100	0

*Value for average humans; may be less in some situations and species

Sodium reabsorption is essential for the reabsorption of nutrients, Cl⁻, and H₂O, and for the regulation of ECF osmolality and volume

Sodium reabsorption is unique and complex—passive in some sections of the tubule but active in most sections. In fact, about 80% of the total energy requirement of the kidneys is estimated to be used for Na⁺ transport, indicating the importance of this process. Of the Na⁺ filtered in a laboratory rodent, 99% is normally reabsorbed, of which on average 67% is reabsorbed in the proximal tubule, 25% in the

loop of Henle, and 8% in the distal tubules and collecting ducts. Sodium reabsorption plays different important roles in each of these segments, as will become apparent as our discussion continues.

- Na^+ reabsorption in the proximal tubule plays a pivotal role in the reabsorption of glucose, amino acids, Cl^- , and urea, as well as H_2O for the regulation of ECF volume.
- Na^+ reabsorption in the loop of Henle, along with Cl^- reabsorption, plays a critical role in the kidneys' ability to adjust ECF osmolality by producing urine of varying concentrations and volumes, depending on the need to conserve or eliminate salt and/or H_2O .
- Na^+ reabsorption in the distal portion of the nephron is important in the regulation of ECF volume and in secretion of K^+ and H^+ .

Sodium is reabsorbed throughout the tubule with the exception of the descending limb of the loop of Henle. You will learn about the significance of this exception later. Throughout all Na^+ -reabsorbing segments of the tubule, the active step in Na^+ reabsorption involves the energy-dependent Na^+/K^+ ATPase pump located in the tubular cell's basolateral membrane (Figure 12-3a, b). The apical Na^+ channels and/or transport carriers that permit movement of Na^+ from the lumen into the cell vary for different parts of the tubule, but in each case, movement of Na^+ across the apical membrane is always a passive step. For example, in the proximal tubule, Na^+ crosses the apical border by means of a cotransport carrier that simultaneously moves Na^+ and an organic nutrient such as glucose from the lumen into the cell (see p. 87). By contrast, in the collecting duct, Na^+ crosses the apical border through an Na^+ leak channel. Na^+ continues to move down its electrochemical gradient from its high concentration in the lateral space into the surrounding interstitial fluid and finally into the peritubular capillary blood. Thus, net transport of most of the Na^+ from the tubular lumen into the blood occurs at the expense of energy. This obviously helps conserve NaCl , but the movement of Na^+ can also help transport other molecules, as we show next.

Water Reabsorption Water is passively reabsorbed by osmosis in several regions of the tubule. Of the H_2O filtered, 45 to 65% is reabsorbed in the proximal tubules and about 15% in the descending loops of Henle (discussed later), osmotically following solute reabsorption (Figure 12-3b). This amount is not regulated extensively. The remaining 20 to 25% is reabsorbed in the distal tubules and collecting ducts, and is subject to hormonal control, depending on the body's state of hydration (see the section on osmoconcentration later).

During reabsorption, H_2O passes primarily through water channels or *aquaporins* (AQPs; p. 81). Different AQPs are selectively expressed in the various parts of the nephron. For example, the water channels in the proximal tubule, AQP-1, are always open, accounting for the high H_2O permeability of this region. However, the AQP-2 channels in the distal tubule and collecting duct are regulated by the hormone *vasopressin*, which accounts for the variable H_2O reabsorption in this region.

This return of filtered H_2O to the plasma is enhanced by the fact that the plasma-colloid osmotic pressure is greater in the peritubular capillaries than elsewhere because of their

elevated concentration of plasma proteins (p. 579). The resulting plasma-colloid osmotic pressure tends to “pull” H_2O into the peritubular capillaries, simultaneous with the “push” of the hydrostatic pressure in the lateral spaces that drives H_2O toward the capillaries. Note that ATP is not directly utilized for this tremendous reabsorption of H_2O .

Chloride Reabsorption The negatively charged chloride ions are passively reabsorbed down the electrical gradient created by the active reabsorption of the positively charged sodium ions. CFTR Cl^- channels are found here (Figure 12-3a). The amount of Cl^- reabsorbed is determined by the rate of active Na^+ reabsorption instead of being directly controlled by the kidneys.

Glucose and amino acids are reabsorbed by Na^+ -dependent secondary active transport

Large quantities of nutritionally important organic molecules such as glucose and amino acids are filtered each day, but normally none of these materials is excreted in the urine. This rapid and thorough reabsorption occurs early, in the proximal tubules, where glucose and amino acids are actively moved uphill against their concentration gradients from the tubular lumen into the blood. Again, no ATP is directly used to operate the glucose or amino acid carriers. These nutrients are transferred by means of secondary active transport utilizing a specialized symporter that simultaneously transfers both Na^+ (down its gradient) and the specific organic molecule (up its gradient) from the lumen into the cell (such as the sodium-glucose cotransporter *SGLT* in Figure 3-15, p. 88), just as the actively generated H^+ gradient moves K^+ or Na^+ in the Malpighian tubule. Again, the lumen-to-cell Na^+ electrochemical gradient maintained by the energy-consuming basolateral Na^+/K^+ ATPase pump drives this cotransport system. Because the overall process of glucose and amino acid reabsorption depends on the use of ATP, these organic molecules are considered actively reabsorbed, even though ATP is not used directly to transport them across the membrane.

Once transported into the tubular cells, glucose and amino acids passively diffuse down their concentration gradients across the basolateral membrane into the plasma, facilitated by a non-energy-dependent carrier (such as the glucose transporter *GLUT* in Figure 3-15).

With the exception of Na^+ , actively reabsorbed substances exhibit a tubular maximum

All actively reabsorbed substances bind with plasma membrane carriers that transfer them across the membrane against a concentration gradient. Each carrier is specific for the types of substances it can transport. As you learned in Chapter 3 (Figure 3-12, p. 83), because a limited number of each carrier type are present in the cells lining the tubules, there is an upper limit on the quantity of a particular substance that can be actively transported from the tubular fluid in a given period of time. The maximum reabsorption rate is reached when all the carriers specific for a particular substance are fully “occupied” or saturated. This transport maximum, designated as the **tubular (or transport) maximum**, or T_m , in the kidney tubules is the maximum amount of a substance that the tubular cells can actively transport

within a given time period. With the exception of Na^+ , all actively reabsorbed substances display a T_m . (Sodium does not display a T_m , because *aldosterone*, which we discuss later, promotes the synthesis of more active Na^+/K^+ ATPase carriers as needed.) Any quantity of a substance filtered beyond its T_m fails to be reabsorbed, and escapes instead into the urine.

The plasma concentrations of some but not all substances that display carrier-limited reabsorption are regulated by the kidneys. To illustrate, we compare glucose, a substance that has a T_m but is not regulated by the kidneys, with phosphate, a T_m -limited substance that is regulated by the kidneys.

Glucose reabsorption is not regulated by the kidneys and has a T_m that is exceeded in diabetes

Because glucose is freely filterable at the glomerulus, it passes into Bowman's capsule at the same concentration it has in the plasma, which is about 100 mg/100 mL in humans and many other mammals. Ordinarily, no glucose appears in the urine because all the filtered glucose is reabsorbed. Not until the filtered load of glucose exceeds the T_m does glucose start spilling into the urine. The plasma concentration at which the T_m of a particular substance is reached and the substance first starts appearing in the urine is known as the **renal threshold**. This value is about 180 mg/100 mL in humans and dogs, and 240–290 mg/100 mL in domestic cats, well above the filtered value of 100. As glucose concentration in the filtrate increases above the threshold, reabsorption begins to taper off and urine levels begin to climb, until about 300 mg/100 mL, where the T_m is reached. Above that, reabsorption remains constant at its maximum rate (Figure 12-20), with the excess filtered glucose remaining in the filtrate to be excreted. As you saw in Chapter 7 (p. 322), the plasma glucose concentration can become extremely high in diabetes mellitus. Glucose in the urine was used as the original diagnosis of diabetes mellitus (*mellitus* is Latin for “honey-sweet”), which the Chinese called *sweet urine disease*.

With the T_m for glucose well above the normal filtered load, the kidneys normally transport all the luminal glucose, thereby protecting against the loss of this important nutrient. However, the kidneys do not regulate glucose per se, because they do not maintain glucose at some specific plasma concentration; instead, this concentration is normally regulated by endocrine and liver mechanisms, with the kidneys merely maintaining whatever plasma glucose concentration is set by these other mechanisms (except at excessively high levels). The same general principle holds true for other organic plasma nutrients, such as amino acids and water-soluble vitamins.

PO_4^{3-} (phosphate) reabsorption is regulated by the kidneys

The kidneys do directly contribute to the regulation of many electrolytes, such as phosphate (PO_4^{3-}) and calcium (Ca^{2+}), because the renal thresholds of these inorganic ions equal their normal plasma concentrations. The transport carriers for these electrolytes are located in the proximal tubule. We use PO_4^{3-} as an example. Some animal diets are rich in PO_4^{3-} , but because the tubules can reabsorb up to the nor-

FIGURE 12-20 Renal handling of glucose as a function of plasma glucose concentration. At a constant GFR, the quantity of glucose filtered per minute is directly proportional to the plasma concentration of glucose. All the filtered glucose can be reabsorbed up to the renal threshold, the plasma concentration at which glucose first starts appearing in the urine. If the amount of glucose filtered per minute exceeds the tubular maximum T_m , no more glucose is reabsorbed and the rest stays in the filtrate to be excreted in urine.

© Cengage Learning, 2013

mal plasma concentration's worth of PO_4^{3-} and no more, the excess ingested PO_4^{3-} is quickly spilled into the urine, restoring the plasma concentration to normal.

However, unlike the reabsorption of organic nutrients, the reabsorption of PO_4^{3-} and Ca^{2+} is also subject to hormonal control. *Parathyroid hormone* can alter the renal thresholds for these ions, thus adjusting the quantity of these electrolytes conserved, depending on the body's momentary needs (p. 324).

In general, unwanted waste products, except urea, are not reabsorbed

Because of extensive reabsorption of H_2O in the proximal tubule, the original volume of filtrate is progressively reduced. Substances that have been filtered but not reabsorbed become progressively more concentrated in the tubular fluid as H_2O is reabsorbed. Waste products from metabolism and ingested toxins become concentrated for later excretion and are not subject to physiological control. When renal function is normal, these uncontrolled excretory processes proceed at a satisfactory rate.

Urea molecules are an important exception because they are the only wastes to be passively reabsorbed as a result of this concentrating effect. Urea's initial concentration at the glomerulus is identical to its concentration in the plasma entering the peritubular capillaries. However, like other wastes, it is concentrated several-fold at the end of the proximal tubule. A concentration gradient for urea is thus created, which results in urea's passive diffusion from the tubular lumen into the peritubular capillary plasma (thought to leak through paracellular pathways due to its small mo-

lecular size). Even so, the walls of the proximal tubules are only moderately permeable to urea, so only about 40% of the filtered urea is passively reabsorbed by this means. (As you will see later, urea permeability depends on urea transporters in other nephron segments.) Even though only 60% of the filtered urea is eliminated from the plasma with each pass through the nephrons, this rate is adequate.

The renin–angiotensin–aldosterone system stimulates Na^+ reabsorption in distal tubules and collecting ducts, elevates blood pressure, and stimulates thirst and salt hunger

Reabsorption of filtered Na^+ is subject to hormonal control in the nephron. This occurs primarily in the distal tubule and collecting ducts, and to a lesser extent in the proximal tubule as well. The extent of this controlled reabsorption is inversely related to the magnitude of the Na^+ load in the body. If there is too much Na^+ , little Na^+ reabsorption occurs and is instead lost in the urine. In contrast, if Na^+ is depleted, most or all Na^+ is reabsorbed and conserved for the body.

The Na^+ load in the body is reflected by the ECF volume. Sodium and chloride account for more than 90% of the ECF's osmotic pressure (p. 103). When the Na^+ load is above normal, making the ECF hyperosmotic, osmosis of H_2O out of cells expands the ECF volume. Conversely, when the Na^+ load is below normal, thereby making the ECF hypo-osmotic, less H_2O than normal stays in the ECF, so its volume shrinks. Because plasma is a component of the ECF, the most important consequence of a change in ECF volume is the corresponding change in blood pressure accompanying expansion (increased blood pressure) or reduction (decreased blood pressure) of the plasma volume (see Figure 9-67, p. 454). Thus, long-term control of arterial blood pressure ultimately depends on Na-regulating mechanisms. We now turn our attention to these mechanisms.

Cardiotonic Steroids A new class of hormones called *cardiotonic steroids* (CTS) has been found that are related to exogenous compounds like *ouabain* (p. 87) that affect the Na^+/K^+ ATPase. Moreover, that pump has been found to be a receptor in complexes residing in *caveolae* (p. 89), tethering and regulating tyrosine kinases. Recent studies show that high- Na^+ or low- K^+ diets increase CTS levels (from the adrenal gland, probably stimulated by the hypothalamus). CTSs in turn bind the ATPase-receptor complexes in the proximal tubule. The resulting kinase signal cascade causes down-regulation of the ATPases, so less Na^+ is reabsorbed, enhancing **natriuresis** (urinary sodium excretion).

Activation of the Renin–Angiotensin–Aldosterone System

The most important and best-known hormonal system involved in regulating Na^+ is the **renin–angiotensin–aldosterone system (RAAS)**. It begins with integrating granular cells of the JGA (Figure 12-16) secreting a hormone, **renin**, into the blood in response to a fall in NaCl /ECF volume/blood pressure. This function is in addition to the role the JGA plays in autoregulation. Specifically, the following three inputs to the granular cells increase renin secretion:

1. The granular cells themselves function as *intrarenal baroreceptors*. They are sensitive to pressure changes

within the afferent arteriole. When the granular cells detect a fall in blood pressure, they secrete more renin.

2. The macula densa cells in the tubular portion of the juxtaglomerular apparatus are sensitive to the NaCl moving past them through the tubular lumen. In response to a fall in NaCl , the macula densa cells trigger the granular cells to secrete more renin.
3. The granular cells are innervated by the sympathetic nervous system. When blood pressure falls below normal, the baroreceptor reflex increases sympathetic activity, which stimulates the granular cells to secrete more renin.

These interrelated signals for increased renin secretion function together to increase salt in the ECF and to expand the plasma volume to increase the arterial pressure to normal on a long-term basis. Through the complex RAAS, increased renin secretion brings about these changes in several ways, as we will examine next (Figure 12-21).

Effects of the RAAS Once secreted into the blood, renin functions as an enzyme to convert **angiotensinogen** into **angiotensin I**. Angiotensinogen is a plasma protein synthesized by the liver and always present in the plasma in high concentration. On passing through the lungs via the pulmonary circulation, angiotensin I is converted into **angiotensin II** by **angiotensin-converting enzyme (ACE)**, which is abundant in the pulmonary capillaries. Angiotensin II is the primary stimulus for the secretion of the hormone **aldosterone** from the adrenal cortex (p. 304). These do the following:

1. **Na^+ reabsorption:** Among its actions, aldosterone increases Na^+ reabsorption by the distal tubules and collecting ducts. Specifically, it works on *principal* cells, one of two major cell types making up these tubules (the other type, *intercalated* cells, are involved in acid–base balance which is covered in Chapter 13.) Aldosterone is a steroid hormone, which exerts its effects by binding to an internal receptor and regulating gene transcription (Chapters 2 and 7). For aldosterone, gene regulation leads to the insertion of additional ENaC Na^+ channels into the apical membranes and Na^+/K^+ ATPase pumps into the basolateral membranes (Figure 12-3a) of the distal-tubule and collecting-duct cells. (Angiotensin II itself also stimulates Na^+ reabsorption in the proximal and distal tubules and the collecting ducts.) The net result is a greater passive inward flux of Na^+ into the tubular cells from the lumen and increased active pumping of Na^+ out of the cells into the plasma, with Cl^- following passively and H_2O following by osmosis. The RAAS thus promotes salt retention resulting in H_2O retention and elevation of arterial blood pressure.
2. **Water retention:** Angiotensin II stimulates hypothalamic release of **vasopressin**, a hormone that increases H_2O retention by the kidneys (p. 597), elevating blood pressure.
3. **Vasoconstriction:** Angiotensin II is so named (*angeion*, Greek for blood vessel, plus “tense”) because it is also a potent constrictor of the systemic arterioles, thereby directly and rapidly increasing blood pressure by increasing total peripheral resistance (see Figure 9-48, p. 438). Furthermore, stimulation of vasopressin (*vas*, Latin for blood vessel, plus “pressure”) adds to this effect since it is also a vasoconstrictor.

FIGURE 12-21 Renin–angiotensin–aldosterone system (RAAS) in a mammal. The kidneys secrete the enzymatic hormone renin in response to reduced NaCl, ECF volume, and arterial blood pressure. Renin activates angiotensinogen, a plasma protein produced by the liver, into angiotensin I. Angiotensin I is converted into angiotensin II by angiotensin-converting enzyme (ACE) produced in the lungs. Angiotensin II stimulates the adrenal cortex to secrete the hormone aldosterone, which stimulates Na^+ reabsorption by the kidneys. The resulting retention of Na^+ exerts an osmotic effect that holds more H_2O in the ECF. Together, the conserved Na^+ and H_2O help correct the original stimuli that activated this hormonal system. Angiotensin II also exerts other effects that help rectify the original stimuli, such as by promoting arteriolar vasoconstriction.

© Cengage Learning, 2013

4. **Thirst and salt hunger:** Angiotensin II stimulates *thirst*. It also stimulates **salt hunger** in the brain, that is, it triggers a craving for dietary salt intake. Aldosterone appears to do this as well, but angiotensin is the most important stimulant. Salt hunger and thirst trigger corrective behaviors that fall into the category of *behavioral effector processes* (p. 16). Thirst results in increased water consumption, while salt hunger favors the consumption of salty foods or licking salt deposits. Both actions help correct the imbalances.

Thus, acting in negative-feedback fashion, activation of the RAAS alleviates the factors that triggered the initial release of renin—namely, salt depletion, plasma volume reduction, and decreased arterial blood pressure (Figure 12-21).

Suppression of the RAAS The opposite situation exists when the Na^+ load, ECF and plasma volume, and arterial blood pressure are above normal. Under these circumstances, renin secretion is inhibited, which prevents the angiotensin II–induced release of aldosterone (and vasopressin). Without aldosterone, the modest aldosterone-dependent (regulated) portion of Na^+ reabsorption in the proximal and distal tubules does not occur. Instead, this unreabsorbed Na^+ , and the Cl^- and water that would have come with it, are lost in urine. This ongoing loss can rapidly remove excess NaCl (and water) from the body.

In the complete absence of aldosterone, a human may excrete 20 g of salt per day. With maximum aldosterone secretion, almost all the filtered Na^+ (and Cl^-) is reabsorbed,

so salt excretion in the urine is very low (although probably never zero). The amount of aldosterone secreted, and consequently the relative amount of salt conserved versus salt excreted varies according to intake. Herbivores, for example, have a high-potassium, low-sodium diet because of the ion composition of plants, while carnivores may have a substantial sodium intake. With the renin mechanism, the kidneys maintain the salt load and ECF volume/arterial blood pressure at a relatively constant level despite wide variations in salt consumption and abnormal losses of salt-laden fluid (hemorrhage).

This system is responsible in part for the fluid retention and edema accompanying congestive heart failure, a condition suffered by many aging mammals. When a fall in blood pressure occurs due to a failing heart, the salt- and fluid-retaining reflexes triggered by the low blood pressure are inappropriate. Excess sodium in the ECF and the resulting volume expansion exacerbates the problem because the weakened heart cannot pump the additional plasma volume. As you saw in Chapter 1, this is an example of a *positive-feedback process* that is not beneficial (p. 18). Treatment normally involves the blockage of aldosterone function in afflicted animals, usually by administering an **inhibitor of ACE** (angiotensin converting enzyme in the lung) to block the conversion of angiotensin I into angiotensin II.

Atrial and brain natriuretic peptides antagonize the RAAS, inhibiting Na⁺ reabsorption and reducing blood pressure

Whereas RAAS exerts the most powerful influence on the renal handling of Na⁺, this Na⁺-retaining, blood pressure-raising system is opposed by an Na⁺-losing, blood pressure-lowering system that involves the hormones **atrial natriuretic peptide** (ANP) and **brain natriuretic peptide** (BNP) (*natriuretic* means “inducing excretion of sodium in the urine”). The heart, in addition to its pump action, has endocrine cells that release ANP and BNP. As its name implies, ANP is produced in the atrial cardiac muscle cells. BNP was first discovered in the brain but is produced primarily in the ventricular cardiac muscle cells. ANP and BNP are stored in granules and released when the heart muscle cells are mechanically stretched by an expansion of the circulating plasma volume when the ECF volume is increased. This expansion, which occurs as a result of Na⁺ and H₂O retention, increases arterial blood pressure. In turn, both ANP and BNP promote natriuresis and accompanying *diuresis*, decreasing the plasma volume, and also directly lower the blood pressure, as follows (Figure 12-22):

1. **Natriuresis and diuresis:** The main function of ANP and BNP is to directly inhibit Na⁺ reabsorption in the distal parts of the nephron, thus increasing Na⁺ and accompanying osmotic H₂O excretion in the urine. They further increase Na⁺ excretion in the urine by inhibiting two steps of the Na⁺-conserving RAAS. The NPs inhibit renin secretion by the kidneys and act on the adrenal cortex to inhibit aldosterone secretion. In addition, they inhibit the secretion and actions of vasopressin, the H₂O-conserving hormone. ANP and BNP dilate the afferent arterioles and constrict the efferent arterioles, thus raising glomerular capillary blood pressure and

increasing the GFR. They further increase the GFR by relaxing the glomerular mesangial cells, leading to an increase in K_f . As more salt and water are filtered, more salt and water are excreted in the urine.

2. **Reduced blood pressure:** Besides indirectly lowering blood pressure by reducing the Na⁺ load and hence the fluid load in the body, ANP and BNP directly lower blood pressure by decreasing the cardiac output and reducing peripheral vascular resistance by inhibiting sympathetic nervous activity to the heart and blood vessels.

The relative contributions of ANP and BNP in maintaining salt and H₂O balance and blood pressure regulation are being intensively investigated.

Describe how the RAAS works and is opposed by the ANP/BNP system.

12.7 Mammalian Kidneys: Tubular Secretion

Next we turn to the counterpart of reabsorption, which also involves transepithelial transport, but now the steps are reversed. By providing a second route of entry into the tubules for selected substances, **tubular secretion**—the discrete transfer of substances from the peritubular capillaries into the tubular lumen—is a supplemental mechanism that hastens elimination of selected compounds from the body. The most important substances secreted by the tubules are *hydrogen ion* (H⁺), *potassium* (K⁺), and *organic anions and cations*, many of which are foreign to the body.

Hydrogen ion secretion is important in acid–base balance

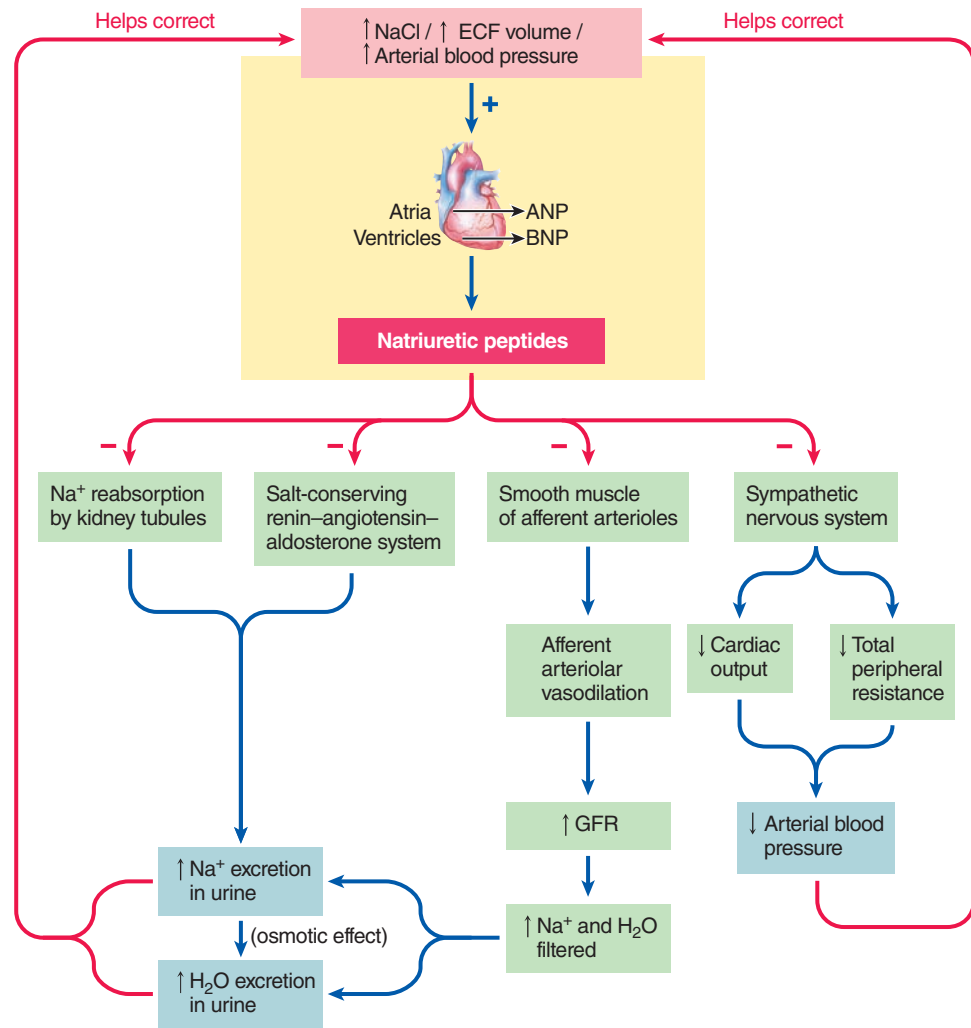

Renal H⁺ secretion is extremely important in the regulation of the acid–base balance in the body. Hydrogen ion can be added to the filtered fluid by being secreted by the proximal, distal, and collecting segments, using proton-pumping *V-ATPases* (see p. 85 and Malpighian tubules, p. 566). The extent of H⁺ secretion depends on the acidity of the body fluids. When the body fluids are too acidic, H⁺ secretion increases. Conversely, H⁺ secretion is reduced when the H⁺ concentration in the body fluids is too low. (See Chapter 13 for further details.)

Potassium secretion is controlled by aldosterone

Potassium is one of the most abundant cations in the body, but about 98% of the K⁺ is in the ICF because the Na⁺/K⁺ pump actively transports K⁺ into the cells. Because only a relatively small amount of K⁺ is in the ECF, even slight changes in the ECF K⁺ load can have a pronounced effect on the plasma K⁺ concentration. Changes in the plasma K⁺ concentration can be dangerous, as we will describe.

FIGURE 12-22 Atrial and brain natriuretic peptides (mammal). The cardiac atria secrete the hormone atrial natriuretic peptide (ANP) and the cardiac ventricles secrete brain natriuretic peptide (BNP) in response to being stretched by Na^+ retention, expansion of the ECF volume, and increase in arterial blood pressure. ANP and BNP, in turn, promote natriuretic, diuretic, and hypotensive effects to help correct the original stimuli that resulted in their release.

Therefore, plasma K^+ concentrations are tightly controlled, primarily by the kidneys.

Potassium ion is selectively moved in opposite directions in different parts of the tubule. It is actively reabsorbed in the proximal tubule, but it can also actively secreted by principal cells in the distal and collecting tubules, where, moreover, one type of intercalated cell actively secretes K^+ and another type actively reabsorbs K^+ in conjunction with H^+ transport (see Chapter 13). Early in the tubule K^+ reabsorption is unregulated, whereas K^+ secretion by the principal cells in the distal tubule is variable and subject to regulation. Because the filtered K^+ is almost completely reabsorbed in the proximal tubule, most K^+ in the urine is derived from controlled K^+ secretion in the distal parts of the nephron.

During periods of K^+ depletion, K^+ secretion in the distal portions of the nephron is reduced to a minimum, so only the small percentage of filtered K^+ that escapes reabsorption in the proximal tubule is excreted in the urine. In this way, K^+ that normally would have been lost in the urine is conserved for the body. In contrast, when plasma K^+ levels are elevated, K^+ secretion is adjusted so that just enough K^+ is added to the filtrate for elimination to reduce the plasma K^+ concentration to normal. Thus, K^+ secretion, not the filtration or reabsorption of K^+ , is varied in a controlled fashion

to regulate the rate of K^+ excretion and maintain the desired plasma K^+ concentration.

Mechanism and Control of K^+ Secretion Potassium ion secretion in the distal tubules and collecting ducts is coupled to Na^+ reabsorption by means of the basolateral Na^+/K^+ pump (Figure 12-23). This pump not only moves Na^+ into the lateral space but also transports K^+ into the tubular cells. The resulting high intracellular K^+ concentration favors the net diffusion of K^+ from the cells into the tubular lumen. Movement across the apical membrane occurs passively through the large number of K^+ leak channels present in this barrier. By keeping the interstitial fluid concentration of K^+ low as it transports K^+ into the tubular cells from the surrounding interstitial fluid, the basolateral pump encourages the passive diffusion of K^+ out of the peritubular capillary plasma into the interstitial fluid. Potassium exiting the plasma in this manner is subsequently pumped into the cells, from which it diffuses into the lumen. In this way, the basolateral pump actively induces the net secretion of K^+ from the peritubular capillary plasma into the tubular lumen.

Note that the different pathways for K^+ movement are dependent on the location of the passive K^+ channels. In the distal tubules and collecting ducts, these channels are found mainly in the apical membrane, providing a route for K^+

FIGURE 12-23 Potassium secretion (mammalian kidney). The basolateral pump simultaneously transports Na^+ into the lateral space and K^+ into the tubular cell. In the parts of the tubule that secrete K^+ , this ion leaves the cell through channels located in the apical border, thus being secreted. (In the parts of the tubule that do not secrete K^+ , the K^+ pumped into the cell during the process of Na^+ reabsorption leaves the cell through channels located in the basolateral border, thus being retained in the body.)

© Cengage Learning, 2013

FIGURE 12-24 Dual control of aldosterone secretion of K^+ and Na^+ (mammal).

© Cengage Learning, 2013

pumped into the cell to exit into the lumen. In the other tubular segments, the K^+ channels lie primarily in the basolateral membrane. As a result, K^+ pumped into the cell from the lateral space by the Na^+/K^+ pump simply diffuses back out into the lateral space through these channels. This K^+ recy-

cling permits the ongoing operation of the Na^+/K^+ pump to accomplish Na^+ reabsorption with no local net effect on K^+ .

Several factors can alter the rate of K^+ secretion, the most important being *aldosterone*, which stimulates K^+ secretion by the tubular cells late in the nephron simultaneous to enhancing these cells' reabsorption of Na^+ . An elevation in plasma K^+ concentration directly (independently of the RAAS) stimulates the adrenal cortex to increase output of aldosterone, which in turn promotes urinary excretion and elimination of the excess K^+ . Conversely, a decline in plasma K^+ concentration reduces aldosterone secretion, which correspondingly reduces aldosterone-stimulated renal K^+ secretion.

Note that a rise in plasma K^+ directly stimulates aldosterone secretion, whereas a fall in plasma Na^+ concentration stimulates aldosterone secretion via the RAAS (Figure 12-24). Thus, aldosterone secretion can be stimulated by two separate pathways. No matter what the stimulus, however, increased aldosterone secretion always promotes simultaneous Na^+ reabsorption and K^+ secretion. For this reason, K^+ secretion can be inadvertently stimulated as a result of increased aldosterone activity brought about by Na^+ depletion, ECF volume reduction, or a fall in arterial blood pressure. The resulting inappropriate loss of K^+ can lead to K^+ deficiency.

Because this process has the net effect of swapping K^+ for Na^+ in the urine, and because it can be regulated, the amount of KCl and NaCl excreted in the final urine can vary widely among animals and among diets. Herbivores, for example, eat food often with a high potassium and low sodium content (most plants) and therefore excrete more KCl than NaCl . Indeed, such mammals exhibit salt hunger (stimulated by angiotensin II and aldosterone, p. 589), including a strong behavioral attraction to salt licks (natural or human-made deposits of NaCl and other minerals).

Normally the kidneys exert a fine degree of control over plasma K^+ concentration. This is extremely important because even minor fluctuations in plasma K^+ concentration can

have life-threatening consequences. Potassium ion plays a key role in the membrane potential and electrical activity of excitable tissues (Chapters 3 and 4). Either increases or decreases in the plasma (ECF) K^+ concentration can alter the intracellular-to-extracellular K^+ concentration gradient. A rise leads to a reduction in resting potential (bringing the cell closer to threshold potential) and a subsequent increase in excitability, especially in cardiac and neural tissue. This cardiac overexcitability can lead to a rapid heart rate and even fatal cardiac arrhythmias, although pharmacological solutions of K^+ are used to slow the heart during surgical procedures. Conversely, a fall in ECF K^+ concentration results in hyperpolarization of nerve and muscle cell membranes, which reduces their excitability. The manifestations of ECF K^+ depletion are skeletal muscle weakness, diarrhea and abdominal distention caused by smooth muscle dysfunction, and abnormalities in cardiac rhythm and impulse conduction.

As we noted earlier, inadvertent loss of K^+ because of Na^+ depletion can occur. This has important implications for domestic herbivores such as cattle because they are sometimes fed herbage with extremely low NaCl and high KCl content. In one early study, cattle were fed such a diet and monitored carefully. After two months, they began licking walls and dirt, chewing the bark of trees, eating manure, and drinking the urine of other cows, driven by an intense salt hunger. The ion content of their urines was dominated by KCl with virtually no NaCl. After 10 months, the animals began to lose weight, while some developed muscle tremors and eventually died. Autopsies revealed hypertrophied (excessively enlarged) adrenal cortexes, probably because of a high rate of aldosterone production.

Another factor that can inadvertently alter the magnitude of K^+ secretion is the acid–base status of the body. An antiport transporter in the distal tubules' intercalated cells can secrete either K^+ or H^+ in exchange for reabsorbed Na^+ . An increased rate of secretion of either K^+ or H^+ is accompanied by a decreased rate of secretion of the other ion. Normally the kidneys secrete a preponderance of K^+ , but when the body fluids are too acidic and H^+ secretion is increased as a compensatory measure, K^+ secretion is correspondingly reduced. This reduced secretion leads to inadvertent K^+ retention in the body fluids.

Organic anion and cation secretion helps eliminate foreign compounds from the body

The proximal tubule contains two distinct types of secretory carriers, one for organic anions and another for organic cations. These carriers serve several important functions:

- By adding more of a particular type of organic ion to the quantity that has already gained entry to the tubular fluid by means of glomerular filtration, these organic secretory pathways facilitate excretion of these substances. Included among these organic ions are certain blood-borne chemical messengers such as prostaglandins, histamine, and norepinephrine that, having served their purpose, must be rapidly removed from the blood so that their biological activity is not unduly prolonged.
- In some important instances, organic ions are poorly soluble in water. To be transported in blood, they are extensively but not irreversibly bound to plasma proteins. Because they are attached to plasma proteins,

these substances cannot be filtered through the glomeruli. Tubular secretion facilitates elimination of these nonfilterable organic ions in urine. Even though a given organic ion is largely bound to plasma proteins, a small percentage of the ion always exists in free or unbound form in the plasma. Removal of this free organic ion by secretion permits “unloading” of some of the bound ion, which can then be secreted.

- Most important is the ability of the organic ion secretory systems to eliminate many foreign compounds from the body. The organic ion systems can secrete a large number of different organic ions, both those produced endogenously (within the body) and those foreign organic ions that have gained access to the body fluids. This nonselectivity permits these organic ion secretory systems to hasten removal of many (but by no means all) foreign organic chemicals, including food additives, environmental pollutants (such as pesticides), drugs, and other nonnutritive organic substances that have entered the body.

Even though these mechanisms help rid the body of unwanted compounds, they do not appear subject to physiologic adjustments. The carriers cannot pick up their secretory pace when confronting an elevated load of these organic ions.

The vertebrate liver plays an important role in this process. Many foreign organic compounds are not ionic in their original form, so they cannot be secreted by the organic ion systems. The liver converts these foreign substances into an anionic form that facilitates their secretion by the organic anion system, which thus accelerates their removal.

This completes our discussion of the reabsorptive and secretory processes that occur across the proximal and distal portions of the nephron. To generalize:

- The *proximal tubule* does most of the reabsorbing. This “mass reabsorber” transfers much of the filtered water and needed solutes back into the blood in unregulated fashion. The proximal tubule is also the major site of secretion (with the exception of K^+).
- The *distal tubules and collecting ducts* then determine the final amounts of H_2O , Na^+ , K^+ , and H^+ that are excreted in urine. They do so by “fine-tuning” the amount of Na and H_2O reabsorbed and the amount of K^+ and H^+ secreted.
- Many of these processes are subject to control, especially in the distal part of the nephron, depending on the body's momentary needs. The unwanted filtered waste products are left behind to be eliminated in urine, along with excess amounts of filtered or secreted nonwaste products that fail to be reabsorbed.

Before turning to the last function of the mammalian nephron—osmoconcentration—let's see how researchers measure the combined actions of filtration, reabsorption, and secretion for individual substances by a parameter called **plasma clearance**.

Plasma clearance is the volume of plasma cleared of a particular substance per minute

Compared to the plasma entering the kidneys through the renal arteries, the plasma leaving the kidneys through the renal veins lacks the materials that were left behind to be elimi-

nated in the urine. By excreting substances in the urine, the kidneys clean or “clear” the plasma flowing through them of these substances. For any substance, its **plasma clearance** is defined as the volume of plasma that is completely cleared of that substance by the kidneys per minute. Plasma clearance is actually a more useful measure than urine excretion; it is more important to know what effect urine excretion has on removing materials from body fluids than to know the volume and composition of the urine. Plasma clearance expresses the kidneys’ effectiveness in removing various substances from the internal fluid environment.

Plasma clearance can be calculated for any plasma constituent as follows:

$$\text{Clearance rate of a substance (mL/min)} = \frac{\text{urine concentration of the substance (quantity/mL urine)} \times \text{urine flow rate (mL/min)}}{\text{plasma concentration of the substance}}$$

The plasma clearance rate varies for different substances, depending on how the kidneys handle each substance, as follows.

1. *Plasma clearance rate equals the GFR if a substance is freely filtered but not reabsorbed or secreted.* Assume that a plasma constituent, substance X, has these properties. If, for example, 125 mL/min of plasma are filtered and none of X is subsequently reabsorbed or secreted, all of substance X originally contained within the 125 mL is left behind in the tubules to be excreted. Thus, 125 mL of plasma are cleared of substance X each minute.

There is no endogenous chemical with these characteristics: All substances normally present in the plasma are reabsorbed or secreted to some extent. However, **inulin** (do not confuse with insulin), a harmless carbohydrate produced by Jerusalem artichokes (which are not artichokes, but the tubers of a sunflower species), is freely filtered and not reabsorbed or secreted—an ideal substance X. Inulin can be injected and its plasma clearance determined as a clinical means of ascertaining the GFR. Because all glomerular filtrate formed is cleared of inulin, the volume of plasma cleared of inulin per minute equals the volume of plasma filtered per minute—the GFR.

Although the determination of inulin plasma clearance is accurate, it is not very convenient because inulin must be infused continuously during the analysis. Therefore, the plasma clearance of **creatinine**—an end product of muscle metabolism (p. 561)—is often used instead to give a rough estimate of the GFR. Creatinine is produced at a relatively constant rate, is freely filtered and not reabsorbed but is only slightly secreted. Accordingly, creatinine clearance is not a completely accurate reflection of the GFR, but it does provide a close approximation and can be more readily determined than inulin clearance.

2. *If a substance is filtered and reabsorbed but not secreted, its plasma clearance rate is always less than the GFR.* Because less than the filtered volume of plasma will have been cleared of the substance, the plasma clearance rate of a reabsorbable substance is always less than the GFR. For example, the plasma clearance for glucose is normally zero since the filtered glucose is reabsorbed.

For a substance that is partially reabsorbed, such as urea, only part of the filtered plasma is cleared of that substance. With about 40% of the filtered urea being passively reabsorbed, only half of the filtered plasma, or 62.5 mL, is cleared of urea each minute.

3. *If a substance is filtered and secreted but not reabsorbed, its plasma clearance rate is always greater than the GFR.* Tubular secretion allows the kidneys to clear certain materials from the plasma more efficiently. Only 20% of the plasma entering the kidneys is filtered. The remaining 80% passes unfiltered into the peritubular capillaries. The only means by which this unfiltered plasma can be cleared of any substance during this trip through the kidneys before being returned to the general circulation is by the process of secretion. An example is H^+ . Not only will the plasma that is filtered be cleared of nonreabsorbable H^+ , but the plasma from which H^+ is secreted will also be cleared of H^+ . For example, at the normal GFR of 125 mL/min, if the quantity of H^+ that is secreted is equivalent to the quantity of H^+ present in 25 mL of plasma, the clearance rate for H^+ will be 150 mL/min (125 mL through the process of filtration and failure of reabsorption, and 25 more mL through the process of secretion).

Describe mechanisms of K^+ secretion, and its regulation and importance.

Describe the three different types of plasma clearance in relation to GFR.

12.8 Mammalian Kidneys: Osmoconcentration

Having considered how the glomerulus and proximal and distal tubules operate, we now focus on renal handling of NaCl and H_2O in the loop of Henle (in concert with the distal tubule and collecting duct) in a process we call *osmoconcentration*. Although these segments are engaged in reabsorption of NaCl and water, we consider this process of osmoconcentration a distinct renal function because it occurs only in birds and mammals (among vertebrates) and because NaCl reabsorption from the tubules does not necessarily return NaCl to the body.

The ability to excrete urine of varying concentrations varies among species and depends on hydration state

The ECF osmolarity (solute concentration) depends on the relative amount of H_2O compared to solute, which is primarily NaCl. At normal fluid balance and solute concentration, body fluids are said to be *isotonic* or *isosmotic* at an osmolarity of about 300 milliosmoles/liter (mOsm) in most terrestrial vertebrates (Chapter 3, p. 79, and Chapter 13, p. 625). Recall that, if there is too much H_2O relative to the solute load, body fluids are *hypotonic* or *hypo-osmotic*.

(osmolarity <300 mOsm). In contrast, if an H_2O deficit exists relative to the solute load, body fluids are too concentrated, that is, are *hypertonic* or *hyperosmotic* (osmolarity >300 mOsm).

Generally speaking, the osmolarity of the ECF is uniform throughout the body (except, as you will see, in the renal medulla, and also intestinal villi exposed to swallowed water). Knowing that the driving force for H_2O reabsorption throughout the entire length of the tubules is an osmotic gradient between the tubular lumen and surrounding interstitial fluid, you might expect, based on osmotic considerations, that the kidneys could not excrete urine of different osmolarity than the body fluids. Indeed, this would be the case if the interstitial fluid surrounding the tubules in the kidneys were identical in osmolarity to the remaining body fluids. Water reabsorption would proceed only until the tubular fluid equilibrated osmotically with the interstitial fluid, and there would be no way to eliminate excess H_2O when the body fluids were hypotonic or to conserve H_2O in the presence of hypertonicity.

However, a large *vertical osmotic gradient* is uniquely generated in the interstitial fluid of the medulla of avian and mammalian kidneys. The concentration of the interstitial fluid progressively increases from the cortical boundary down through the depth of the renal medulla until it reaches a maximum, which is at the junction with the renal pelvis in mammals (Figure 12-25). This vertical osmotic gradient remains there (although it may change in magnitude) regardless of the fluid balance of the body.

The presence of this gradient enables the kidneys to produce urine that ranges in concentration from less than 100 mOsm to highly hypertonic, depending on the species and a body's state of hydration. Examples of maximal concentrating ability will be discussed later, but in brief, these run from a modest 520 mOsm in the beaver (a freshwater animal with plentiful water supply) to a reported 9,400 mOsm in one desert rodent! As a benchmark value, recall that seawater is about 1,000 mOsm, mostly NaCl. As shown in Figure 12-25, humans can osmoconcentrate up to 1,200–1,400 mOsm, but some of this is due to urea. Human kidneys cannot concentrate NaCl to 1,000 mOsm, so humans cannot safely drink seawater, because it causes a net accumulation of salt in the body. Desert rodents, marine mammals, and some marine birds, in contrast, have no trouble drinking highly saline water (and eating salty food) and excreting excess salt, with a net gain of water to the body.

Antidiuresis and Diuresis When a mammal is in ideal fluid balance, isotonic urine is produced at a moderate rate (1 mL/min in humans). This can be altered between two extremes of antidiuresis and diuresis. When the body is dehydrated, the kidneys can put out a small volume of concentrated urine (hypertonic; down to 0.3 mL/min in humans), thus conserving H_2O (antidiuresis). Conversely, when the body is overhydrated (too much H_2O), the kidneys can produce a large volume of dilute urine (hypotonic at 100 mOsm or less; up to 25 mL/min in humans), thus eliminating the excess H_2O in the urine (diuresis).

Unique anatomic arrangements and complex functional interactions between the various nephron components in the renal medulla are responsible for the establishment and use of the vertical osmotic gradient. Recall that the hairpin loop of Henle in the *juxtamedullary nephrons* plunges through

FIGURE 12-25 Vertical osmotic gradient in the human renal medulla. Schematic representation of the kidney rotated 90° from its normal position in an upright human for better visualization of the vertical osmotic gradient in the renal medulla. All values are in mOsm. The osmolarity of the interstitial fluid throughout the renal cortex is isotonic at 300 mOsm, but the osmolarity of the interstitial fluid in the renal medulla increases progressively from 300 mOsm at the boundary with the cortex to a maximum of 1,200 mOsm at the junction with the renal pelvis.

© Cengage Learning, 2013

the entire depth of the medulla so that the tip of the loop lies near the renal pelvis (Figure 12-12). Also, the vasa recta of the juxtamedullary nephrons have a similar deep hairpin loop. Flow in the loops of Henle and the vasa recta is considered **countercurrent**, because the flow in the two closely adjacent limbs of the loop and blood vessel is in opposite directions. Also running through the medulla, in the descending direction only, are the collecting ducts that serve both types of nephrons on their way to the renal pelvis. This arrangement, coupled with the permeability and transport characteristics of these tubular segments, plays a key role in the kidneys' ability to provide for water conservation or elimination. Briefly, the juxtamedullary nephrons' long loops of Henle establish the vertical osmotic gradient; their vasa recta prevent the dissolution of this gradient while providing blood to the renal medulla, and the collecting ducts use the gradient, in conjunction with the hormone vasopressin, to produce urine ranging from diuretic to antidiuretic. Collectively, this entire functional organization is known as the **medullary countercurrent-multiplier system**. We examine each of its facets in greater detail.

The medullary vertical osmotic gradient is established by countercurrent multiplication

We will follow the filtrate through a juxtamedullary nephron that lies primarily in the outer medulla to see how this structure establishes a vertical osmotic gradient. Immediately after the filtrate is formed, uncontrolled osmotic reabsorption of filtered H_2O occurs in the proximal tubule secondary to active Na^+ reabsorption. As a result, by the end

of the proximal tubule, 45 to 65% of the filtrate has been reabsorbed, but the 35 to 55% remaining in the tubular lumen still has the same osmolarity (300 mOsm) as the body fluids. That is, it is still isotonic. An additional 15% of the filtered H_2O is obligatorily reabsorbed from the loop of Henle during the establishment and maintenance of the vertical osmotic gradient, with the osmolarity of the tubular fluid being altered greatly in the process.

Properties of the Limbs of a Long Henle's Loop The following functional distinctions among the *descending limb* of a long Henle's loop (which carries fluid from the proximal tubule down into the depths of the medulla), the *hairpin turn*, and the *ascending limb* (which carries fluid up and out of the medulla into the distal tubule) are crucial for establishing the incremental osmotic gradient in the medullary interstitial fluid. The ascending limb is further subdivided into a *thin segment* in the inner medulla (for longer nephrons) and a *thick segment* in the outer medulla (see Figure 12-8a and Figure 12-26, initial scene).

The *descending limb* (primarily the upper part):

1. is highly permeable to H_2O (via abundant, always-open AQP-1 water channels).
2. does not actively transport Na^+ .

The *hairpin turn* region, including the lower descending and the *thin ascending limb* in the inner medulla:

1. has low water permeability (due to lack of aquaporins).
2. has no active salt transport, but in the loop and thin ascending segments is permeable to NaCl due to leak channels.

The *thick ascending limb*:

1. actively transports NaCl out of the tubular lumen into the surrounding interstitial fluid.
2. is always impermeable to H_2O , so salt leaves the tubular fluid without H_2O osmotically following along.

Mechanism of Countercurrent Multiplication The close proximity and countercurrent flow of the two limbs allow important interactions between them. Even though the flow of fluids is continuous through the loop of Henle, we will visualize what happens step by step in Figure 12-26 for the outer medulla, much like an animated film run so slowly that each frame can be viewed:

- **Initial scene:** if no vertical osmotic gradient is established, the medullary interstitial and tubular fluid concentrations would be uniformly 300 mOsm, isosmotic with other body fluids.
- **Step 1.** The active salt pump in the waterproof *thick ascending limb* transports Na^+ followed by Cl^- (via ClC channels; see Figure 12-3a) out of the lumen until the surrounding interstitial fluid is 200 mOsm more concentrated than (hyperosmotic to) the tubular fluid in this limb. Water cannot follow osmotically from the ascending limb, but it does osmose from the *upper descending limb* through AQP-1 into the (hypertonic) interstitial fluid. This passive movement of H_2O out of the descending limb continues until the osmolarities of the fluid in the descending limb and interstitial fluid become equi-

brated. Thus, the isosmotic tubular fluid entering the loop of Henle immediately starts to become more concentrated as it loses H_2O . At equilibrium, the osmolarity of the ascending limb fluid is 200 mOsm and the osmolarities of the interstitial fluid and descending limb fluid are equal at 400 mOsm in this hypothetical situation.

- **Step 2.** If we now advance the entire column of fluid in the loop of Henle several frames, a mass of 200 mOsm fluid exits from the top of the ascending limb into the distal tubule, and a new mass of isotonic fluid at 300 mOsm enters the top of the descending limb from the proximal tubule. At the bottom of the loop, a comparable mass of 400 mOsm fluid from the descending limb moves forward around the tip into the ascending limb, placing it opposite a 400 mOsm region in the descending limb. In the *hairpin turn* and *thin ascending limb*, some NaCl escapes through leak channels (including ClC types) into the medulla, raising its osmolarity (not shown). Note that the 200 mOsm concentration difference has been lost at both the top and the bottom of the loop.
- **Step 3.** The thick ascending limb pump again transports NaCl out, while H_2O passively leaves the descending limb until a 200 mOsm difference is reestablished between the ascending limb and both the interstitial fluid and descending limb at each horizontal level. Note, however, that the concentration of tubular fluid is progressively increasing in the descending limb and progressively decreasing in the ascending limb.
- **Steps 4 and 5.** As the tubular fluid is advanced still further, the 200 mOsm concentration gradient is disrupted once again at all horizontal levels. Again, active extrusion of NaCl from the ascending limb, coupled with the net diffusion of H_2O out of the descending limb, reestablishes the 200 mOsm gradient at each horizontal level.
- **Step 6 and so on.** As the fluid flows slightly forward again and this stepwise process continues, the fluid in the descending limb becomes progressively more hypertonic until it reaches a maximum concentration of 1,200 mOsm (in humans) at the bottom of the loop, four times the normal concentration of body fluids. Because the interstitial fluid always achieves equilibrium with the descending limb, an incremental vertical concentration gradient ranging from 300 to 1,200 mOsm is likewise established in the medullary interstitial fluid. In contrast, the concentration of the tubular fluid progressively decreases in the ascending limb as salt is pumped out, but H_2O is unable to follow. In fact, the tubular fluid even becomes hypotonic before leaving the ascending limb to enter the distal tubule at a concentration of 100 mOsm or less, one-third the normal concentration of body fluids.

Note that although a gradient of only 200 mOsm exists between the ascending limb and the surrounding fluids at each medullary horizontal level, a much larger vertical gradient exists from the top to the bottom of the medulla. Even though the ascending limb pump can generate a gradient of only 200 mOsm, this effect is multiplied into a large vertical gradient because of the countercurrent flow within the loop. This is the concentrating mechanism accomplished by the loop of Henle known as **countercurrent multiplication**. This is also termed a **single-effect** process since Na^+ pumping drives all the major events.

FIGURE 12-26 Countercurrent multiplication by the "single effect" in the mammalian renal medulla. All values are in mOsm.

© Cengage Learning, 2013

We have artificially described single-effect countercurrent multiplication in a stop-and-flow, stepwise fashion to facilitate understanding of this process. It is important to realize that once the incremental medullary gradient is established, it stays relatively constant because of the continuous flow of fluid coupled with the ongoing ascending limb active transport and accompanying descending limb passive fluxes.

Benefits of Countercurrent Multiplication If you consider only what happens to the tubular fluid as it flows through the loop of Henle, the whole process seems an exercise in futility. The isotonic fluid that enters the loop becomes progressively more concentrated as it flows down the descend-

ing limb, achieving a maximum concentration of about 1,200 mOsm in humans, only to become progressively more dilute as it flows up the ascending limb, finally leaving the loop at a minimum concentration of 100 mOsm. What is the point of concentrating the fluid fourfold and then turning around and diluting it until it leaves at one-third the concentration at which it entered? Such a mechanism offers two benefits:

1. It establishes the vertical osmotic gradient in the medullary interstitial fluid; this gradient, in turn, is used by the collecting ducts to concentrate the tubular fluid so that a low-volume urine *more concentrated* than normal body fluids can be excreted (antidiuresis).

KEY

→ = Passive diffusion of H₂O (osmosis)
 ←○ = Active transport of NaCl

1 The active salt pump in the ascending limb establishes a 200 mOsm gradient at each horizontal level.

2 As the fluid flows forward several “frames,” a mass of 200 mOsm fluid exits into the distal tubule and a new mass of 300 mOsm fluid enters from the proximal tubule.

5 The 200 mOsm gradient at each horizontal level is established once again.

6 The final vertical osmotic gradient is established and maintained by the ongoing countercurrent multiplication of the long loops of Henle.

- Conversely, the fact that the fluid is hypotonic as it enters the distal parts of the tubule enables the kidneys to excrete a voluminous urine *more dilute* than normal body fluids (diuresis). Let's see how.

Vasopressin-controlled, variable H₂O reabsorption occurs in the final tubular segments

After obligatory H₂O reabsorption from the proximal tubule and loop of Henle, the remaining filtered H₂O remains in the lumen to enter the distal and collecting tubules for variable reabsorption that is under hormonal control. The

fluid leaving the loop of Henle enters the distal tubule at 100 mOsm, so it is hypotonic to the surrounding isotonic (300 mOsm) interstitial fluid of the renal cortex through which the distal tubule passes. The distal tubule then empties into the collecting duct, which is bathed by progressively increasing concentrations of surrounding interstitial fluid as it descends through the medulla.

Role of Vasopressin For H₂O absorption to occur across a segment of the tubule, two criteria must be met: (1) an osmotic gradient must exist across the tubule, and (2) the tubular segment must be permeable to H₂O. The distal and collecting tubules are *impermeable* to H₂O except in the

presence of **vasopressin**, or **antidiuretic hormone** (ADH), which increases their permeability to H_2O . In most mammals including humans, it is a version called **arginine vasopressin** (AVP) to distinguish it from other forms such as *lysine vasopressin* in pigs. Vasopressin is produced by several specific neuronal cell bodies in the *hypothalamus*, then stored in the *posterior pituitary gland* (p. 284), where its release into the blood is regulated by the hypothalamus. Osmoreceptors in the hypothalamus are sensitive to changes in osmotic pressure so that, in negative-feedback fashion, vasopressin secretion is triggered by an H_2O deficit when the ECF is too concentrated (that is, hypertonic) and H_2O must be conserved for the body. Conversely, vasopressin secretion is inhibited by an excess of H_2O in the ECF (that is, hypotonic) and surplus H_2O must be eliminated in urine. Low blood pressure can also stimulate its release.

Vasopressin reaches the basolateral membrane of the principal cells lining the distal and collecting tubules through the circulatory system. Here it binds with specific G-protein-coupled receptors (Figure 12-27), which activate the cyclic AMP (cAMP) second-messenger system within the tubular cells (p. 97). This leads to increased permeability of the opposite apical membrane to H_2O by promoting exocytotic docking and fusion of vesicles laden with aquaporins (specifically, *AQP-2*) on this membrane. Without AQPs, the apical membrane is impermeable to H_2O . Once H_2O enters the tubular cells from the filtrate through these vasopressin-regulated apical water channels, it passively leaves the cells down the osmotic gradient across the cells' basolateral membrane to enter the interstitial fluid. The aquaporins in the basolateral membrane of the distal and collecting tubule (*AQP-3* and *AQP-4*) are always present and open, so this membrane is always permeable to H_2O . Overall, then, there is increased H_2O reabsorption from the filtrate into the interstitial fluid.

The increase in apical membrane water channels is not permanent, however. The channels are retrieved by endocytosis in response to a decline in vasopressin and thus cAMP concentrations. These H_2O channels are stored in the internalized vesicles ready for reinsertion the next time vasopressin secretion increases. This shuttling of *AQP-2* into and out of the apical membrane provides a means of rapidly controlling H_2O permeability of the distal and collecting tubules, responding in turn to the degree of hydration in the body.

Vasopressin influences H_2O permeability only in the distal part of the nephron, especially the collecting ducts. Recall that the ascending limb of Henle's loop is always impermeable to H_2O , even in the presence of vasopressin.

This system is crucial to two important situations:

1. *H_2O deficit (dehydration)*: When vasopressin secretion increases, the permeability of the distal and collecting tubules to H_2O accordingly increases. As the hypotonic tubular fluid (about 100 mOsm) enters the distal part of the nephron, progressively more H_2O enters the interstitial fluid due to the osmotic pressure generated by the increasing osmolarity of the medullary interstitial fluid (Figure 12-28a). Consequently, the tubular fluid loses progressively more H_2O by osmosis and becomes increasingly concentrated, reaching about the maximum found in the interstitium (e.g., about 1,200 mOsm in humans).

The result of the vasopressin-induced reabsorption of H_2O in the late segments of the tubule is antidiuresis (a small volume of concentrated urine excreted). The reabsorbed H_2O entering the medullary interstitial fluid is picked up by the peritubular capillaries and returned to the general circulation, thus being conserved for the body.

Although vasopressin promotes H_2O conservation by the body, it cannot completely halt urine production, because a minimum volume of H_2O must be excreted with the solute wastes. Collectively, the waste products and other constituents eliminated in human urine average 600 milliosmoles each day. Because the maximum urine concentration is 1,200 mOsm, the minimum volume of urine required to excrete these wastes is 500 mL/day (600 milliosmoles of wastes/day \div 1,200 milliosmoles/liter of urine = 0.5 liter, or 500 mL/day, or 0.3 mL/min). Thus, under maximal vasopressin influence, 99.7% of the 180 liters of human plasma H_2O filtered per day is returned to the blood, with an obligatory H_2O loss of 0.5 liter.

The kidneys' response to dehydration by tremendously concentrating urine to minimize H_2O loss when necessary is possible only because of the presence of the vertical osmotic gradient in the medulla. If this gradient did not exist, the kidneys could not produce a urine more concentrated than the body fluids no matter how much vasopressin was secreted, because the only driving force for H_2O reabsorption is a concentration differential between the tubular fluid and the interstitial fluid.

2. *H_2O excess (overhydration)*: Conversely, when a mammal consumes large quantities of H_2O , the excess H_2O must be removed from the body without simultaneously losing solutes that are critical for maintaining homeostasis. Under these circumstances, no vasopressin is secreted, so the distal and collecting tubules remain impermeable to H_2O . The tubular fluid entering the distal tubule is hypotonic (100 mOsm), having lost salt without an accompanying loss of H_2O in the ascending limb of Henle's loop. As this hypotonic fluid passes through the distal and collecting tubules (Figure 12-28b), the medullary osmotic gradient cannot exert any influence because of the late tubular segments' impermeability to H_2O . Thus, no water in the filtered fluid that reaches the distal tubule is reabsorbed. Meanwhile, excretion of wastes and other urinary solutes remains constant. The net result is diuresis: a large volume of dilute urine, which helps rid the body of excess H_2O . Urine osmolarity may be as low as 100 mOsm, the same as in the fluid entering the distal tubule. Human urine flow may be increased up to 25 mL/min in the absence of vasopressin, compared to the normal urine production of 1 mL/min.

The ability to produce urine less concentrated than the body fluids depends on the fact that the tubular fluid is hypotonic as it enters the distal part of the nephron, due to the ascending limb's active NaCl transport in the absence of H_2O movement. Therefore, the loop of Henle, by simultaneously establishing the medullary osmotic gradient and diluting the tubular fluid before it enters the distal segments, plays a key role in allowing the kidneys to excrete urine over a wide range of volumes and osmolarities.

- 1 Bloodborne vasopressin binds with its receptor sites on the basolateral membrane of a principal cell in the distal or collecting tubule.
- 2 This binding activates the cyclic AMP (cAMP) second-messenger system within the cell.
- 3 Cyclic AMP increases the opposite luminal membrane's permeability to H_2O by promoting the insertion of AQP-2 water channels into the membrane. This membrane is impermeable to water in the absence of vasopressin.
- 4 Water enters the tubular cell from the tubular lumen through the inserted water channels.
- 5 Water exits the cell through a different water channel (either AQP-3 or AQP-4) permanently positioned at the basolateral border, and then enters the blood, in this way being reabsorbed.

FIGURE 12-27 Mechanism of action of vasopressin in a mammal.

Countercurrent exchange within the vasa recta conserves the medullary vertical osmotic gradient

The renal medulla must be supplied with blood to nourish the tissues in this area as well as to transport water that is reabsorbed by the loops of Henle and collecting ducts back to the general circulation. In doing so, however, it is important that circulation of blood through the medulla does not disturb the vertical gradient of hypertonicity established by the loops of Henle. Consider the situation if blood were to flow straight through from the cortex to the inner medulla and then directly into the renal vein (Figure 12-29a). Because capillaries are freely permeable to $NaCl$ and H_2O , the blood would progressively pick up salt and lose H_2O through passive fluxes down concentration and osmotic gradients as it flowed through the depths of the medulla. Isotonic blood entering the medulla, upon equilibrating with each medullary level, would leave the medulla as a very hypertonic solution. It would be impossible to establish and maintain the medullary hypertonic gradient because the $NaCl$ pumped into the medullary interstitial fluid would continuously be carried away by the circulation.

This dilemma is avoided by the hairpin construction of the vasa recta, which, by looping back through the concentration gradient in reverse, allows the blood to leave the medulla and enter the renal vein essentially isotonic to in-

coming arterial blood (Figure 12-29b). As blood passes down the descending limb of the vasa recta, equilibrating with the progressively increasing concentration of the surrounding interstitial fluid, it picks up salt and loses H_2O until it is very hypertonic by the bottom of the loop. Then, as blood flows up the ascending limb, salt diffuses back out into the interstitium, and H_2O reenters the vasa recta as progressively decreasing osmolarities are encountered in the surrounding interstitial fluid. This passive exchange of solutes and H_2O between the two limbs of the vasa recta and the interstitial fluid is known as **countercurrent exchange**. Unlike countercurrent multiplication, it does not *establish* the concentration gradient. Rather, it *preserves* (prevents the dissolution of) the gradient. Because blood enters and leaves the medulla at the same osmolarity as a result of countercurrent exchange, the medullary tissue is nourished with blood, yet the gradient of hypertonicity in the medulla is preserved.

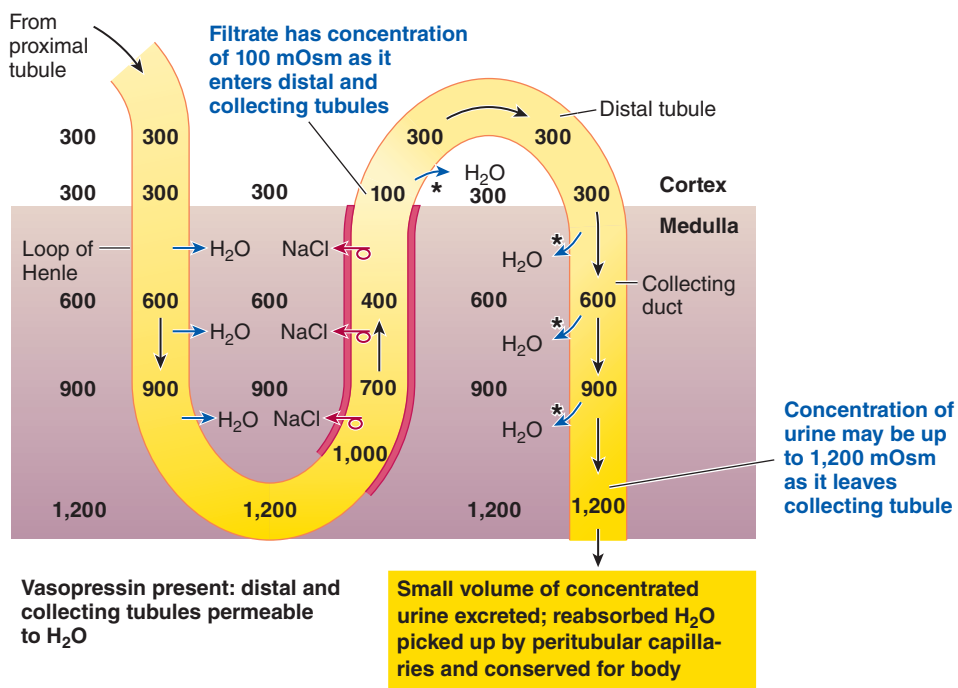

Passive urea recycling in the renal medulla contributes to medullary hypertonicity

In addition to $NaCl$, accumulation of *urea* in the medullary interstitial fluid also adds to its hypertonicity, especially in the inner medulla (as we will explain).

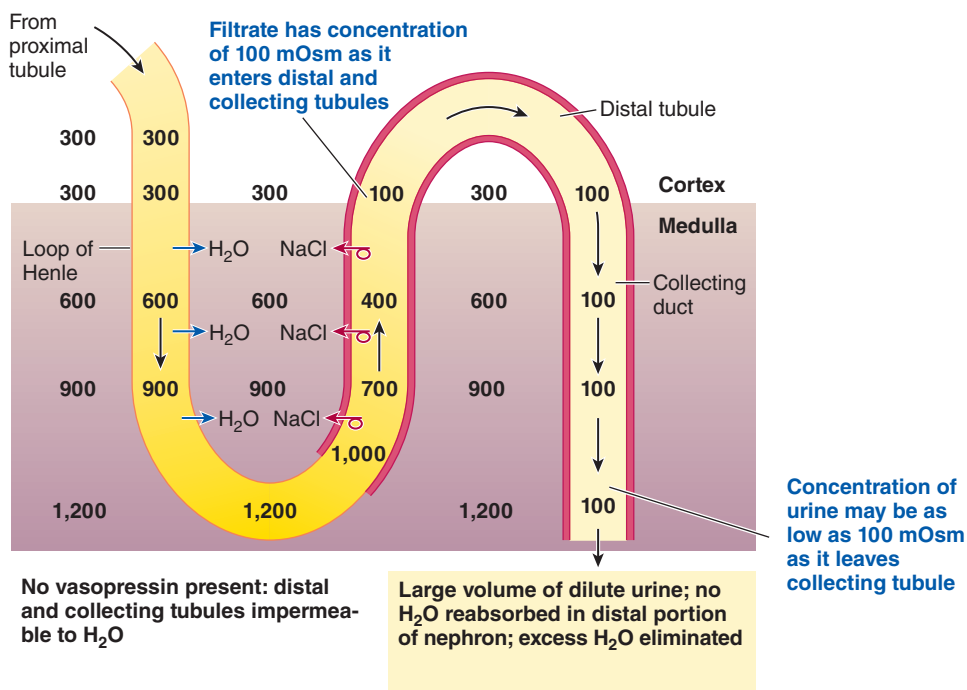

For example, the fluid in the inner medulla of a laboratory rat on normal water and protein intake is 800 mOsm from salts and 900 mOsm from urea. The latter can rise dramatically on high protein diets and drop to very low levels on low-protein diets (Table 12-3). However, unlike $NaCl$, urea accumulation appears to be entirely passive and due to a process called *urea recycling*.

Like the thick ascending limb of the loop, the top and middle portion of the collecting duct is impermeable to urea (because of lack of urea transporters; Figure 12-30). Consequently, urea becomes progressively more concentrated inside this segment as H_2O is reabsorbed in the presence of vasopressin. By the time the fluid reaches the innermost portion of the collecting duct, its urea concentration is greater than in the surrounding interstitial fluid. This last section of the duct contains many urea transporters called *UT-A*s in its membranes (which are upregulated by vasopressin). These transporters are closely related to the ones in toadfish that we noted on p. 561. The concentration difference favors the diffusion of urea out of the duct into the interstitial fluid, creating a high urea concentration in the inner medullary interstitial fluid. Moreover, some urea enters the bottom of the long loops of Henle (via *UT-A* transporters) and gets carried back up to the distal tubule, to undergo the same process again. This is the recycling aspect (Figure 12-30).

Urea movement out of the collecting duct has at least one major function: prevention of urea-induced water loss

FIGURE 12-29 Countercurrent exchange in the mammalian renal medulla. All values are in mOsm. (a) If the blood supply to the renal medulla flowed straight through from the cortex to the inner medulla, the blood would be isotonic on entering but very hypertonic on leaving, having picked up salt and lost H₂O as it equilibrated with the surrounding interstitial fluid at each incremental horizontal level. It would be impossible to maintain the vertical osmotic gradient, because the salt pumped out by the ascending limb of Henle's loop would be continuously flushed away by blood flowing through the medulla. (b) Blood equilibrates with the interstitial fluid at each incremental horizontal level in both the descending limb and the ascending limb of the vasa recta, so blood is isotonic as it enters and leaves the medulla. This countercurrent exchange prevents dissolution of the medullary osmotic gradient while providing blood to the renal medulla.

associated with antidiuresis. As urea becomes progressively concentrated as it moves down the collecting ducts, its osmotic pressure could begin to oppose the reabsorption of water from those ducts. Allowing it to leave the innermost duct region prevents this from happening. However, urea recycling may have another role: enhancing the process of osmoconcentration, which is not fully understood for the inner medulla (Figure 12-26 is primarily for the outer medulla). See *Challenges and Controversies: The Inner Mystery* (p. 603).

Different osmoconcentrating abilities among species depend on nephron anatomy and metabolic rates

For osmoconcentration, we have been using mainly human values, with a 1,200–1,400 mOsm maximum. However, ability to osmoconcentrate the urine varies enormously among mammals, as shown in Table 12-3. Note in particular the desert rodents. How do they manage such high levels? Two features are thought to explain this:

1. **Relative loop length and medullary area.** Weak osmoconcentrators such as the beaver have primarily cortical nephrons; in contrast, the best osmoconcentrators (such as desert rodents) usually have all juxtamedullary nephrons with very long loops within an elongated medulla.

This anatomy provides a relatively long length over which the countercurrent effect can operate. Indeed, it was observations of these differences that first led physiologists to suspect that the loop was responsible for osmoconcentration. Related to this, concentrating ability correlates with *relative medullary area* (Figure 12-31), that is, with the proportion of the kidney devoted to the medulla.

2. **Metabolic rate.** The correlation between concentrating ability and both absolute medullary length and relative area cannot fully explain the amazing osmoconcentrating ability of some desert rodents (Table 12-3). Whereas these animals do have much longer loops relative to rodents from moist habitats, the loops are much shorter on an absolute scale than those of a large mammal that is a poor or modest osmoconcentrator (such as a pig). Another factor is necessary, and may be the metabolic rate of the animal, which could enhance the multiplier aspect of the countercurrent. As you will see in Chapter 15, smaller animals have higher metabolic rates per unit mass than larger animals (a *scaling* phenomenon; see p. 10). In the thick ascending limb, the cells have a higher density of mitochondria and active transport proteins and thus can move NaCl out much faster than the limbs of a larger mammal. Thus, the multiplier effect of the loop that depends on active metabolism can be much higher in a small mammal.

FIGURE 12-30 Urea recycling in the mammalian renal medulla. Urea becomes more concentrated in the fluid in the early portion of the collecting tubules as H_2O is osmotically reabsorbed in the presence of vasopressin; the urea cannot move out down its concentration gradient because this segment is impermeable to urea. Urea does diffuse out via UT-A transporters of the late portion of the collecting tubule down its concentration gradient into the surrounding interstitial fluid and into the urea-permeable bottoms of the long Henle's loop. Inside the loop fluid, urea is carried back up through urea-impermeable segments to start the process all over again; thus, the process is called *urea recycling*. The buildup of urea in interstitial fluid contributes to hypertonicity in the inner medulla, preventing urea from drawing water into the collecting duct and possibly enhancing NaCl buildup (see main text).

Desert rodents are particularly remarkable in their urine-concentrating abilities. Some species live on relatively dry plant materials in a hot, dehydrating environment without drinking any free water for their entire lives. Kangaroo rats of western North American deserts have been closely studied (by the Schmidt-Nielsen, using the Krogh principle, p. 3; see also Chapter 13, p. 630) to determine how they accomplish this amazing feat. First, like any animal, kangaroo rats have an internal source of water called **metabolic water**. Recall that basic aerobic metabolism (p. 53) produces water as an end product ($C_6H_{12}O_6 + 6 O_2 \rightarrow 6 CO_2 + 6 H_2O$ for glucose). Kangaroo rats get about 90% of their water needs from metabolic water and 10% from water in its food. (Humans can use metabolic water, of course, but only about 12% of water needs can be met with this.) Beyond use of metabolic water, adaptation in the kangaroo rat involves both behavior and internal physiology. *Avoidance* (p. 13), in the form of nocturnal foraging above ground and daytime

residence in an insulating burrow, reduces both heat exposure and water loss (behavior effectors). Physiological adaptations include a nasal passage that traps moisture (pp. 515 and 745), and reduced excretory loss. The lower intestine removes almost all the fecal water, so that feces consist of nearly dry pellets. And, perhaps most importantly, their kidneys can produce a urine at up to 5,500 mOsm (Table 12-3). This saves water, while aldosterone regulation also saves sodium, which is low in this animal's seed-based diet: The urine osmolality is primarily K-salts and urea rather than Na-salts.

Another issue involving osmoconcentration is the extreme osmotic stress faced by renal cells, particularly in the medulla. This is an area of active research; see *Molecular Biology and Genomics: Surviving Salt and Urea: Organic Osmolytes and Gene Regulation* (p. 606).

We have now finished our examination of the mammalian kidney's mechanisms. In summary, mammalian kidney

Challenges and Controversies

The Inner Mystery

Thus far, you might conclude that the NaCl and H₂O exchanges between the two limbs of the long loops of Henle and the interstitial fluid, driven by the thick ascending limb's "single-effect" NaCl pumping, are solely responsible for the vertical osmotic gradient in the medullary interstitial fluid. Indeed, countercurrent processes are thought to be the major factors contributing to medullary hypertonicity and the resulting ability of the kidneys to concentrate urine. However, while the model of Figure 12-26 works well for the outer medulla, it does not fully account for the inner medulla where concentrations are highest, especially in the best osmoconcentrators like desert rodents, which can generate urine of up to 9,400 mOsm (Table 12-3). Mathematical modeling of the countercurrent process suggests that the basic countercurrent model does not fully explain this ability, particularly since no active NaCl transport occurs in the inner medulla. Let's look at some hypotheses.

- **Urea recycling or "solute-separation/solute-mixing":** One major hypothesis is that NaCl passively leaves the *thin* ascending limb driven by a concentration gradient created by urea recycling. Recall that the thin ascending limbs, which lie in the inner medulla, can passively "leak" NaCl but do not actively extrude NaCl; only the thick ascending limb does this. In this hypothesis, high osmotic pressure of urea in the inner medulla pulls H₂O out of the *descending* limbs of the long loops as they plunge through the inner medulla. Osmotic removal of H₂O from the descending limbs increases the NaCl concentration inside them. As this NaCl-rich fluid enters into the NaCl-permeable, H₂O-impermeable loop and thin ascending limbs, NaCl would passively diffuse down its concentration gradient into the interstitial fluid. Anita Layton and colleagues have termed this the "solute-separation/solute-mixing" mechanism, in which NaCl and urea are *separated* in the thick ascending limb of the outer medulla, then *mixed* in the inner medullary interstitium.

This model for the enhancing effect of urea on NaCl concentration, though widely accepted, has several problems. First, mathematical models using known urea and NaCl permeabilities of key nephron segments do not completely match the model. Second, the desert sand rat (*Psammomys obesus*), which eats salty dry seeds, can concentrate urine NaCl more effectively than most rodents but is relatively poor at concentrating urea. Similarly, laboratory rats fed a high-salt, low-protein diet excrete very salty urines with very low urea in either the urine or medulla. Third, mice with UT-A genes knocked out had lower urea but the same NaCl concentrations compared to controls in their inner medullas (although whether there was still a salt gradient within that region was not determined). Finally, many birds can concentrate NaCl quite effectively with no urea at all; for example, the salt-marsh savannah sparrow (*Passerculus sandwichensis beldingi*) can produce a urine of about 2,000 mOsm (primarily due to salt) in the laboratory, an ability reflecting its diet of salty marine organisms.

- **Pelvic pumping:** Bodil Schmidt-Nielsen (p. 4), Mark Knepper, and co-workers have proposed that the renal pelvis uses *hydrostatic* pressure created by muscles to increase *osmotic* pressure. The pelvis has been observed to contract and relax rhythmically, moving the urine into and out of the papilla. This process may set up pressure gradients that help draw water out of the collecting ducts, enhancing the concentration process begun in the countercurrent loop. In support of this, osmotic pressure of the inner medulla decreases in the absence of pelvic pumping.
- **External osmolytes:** Some researchers have proposed that the generation of organic osmolytes in the inner medulla could enhance the osmoconcentration process if they were transported into the interstitial fluid. However, this hypothesis has not yet been tested.
- **Three countercurrent systems:** Several researchers have noted that the three-

dimensional configurations of the loops, collecting ducts, and vasa recta may be crucial and, moreover, are different in the upper and lower parts of the inner medulla. In this model, tubules are arranged around tightly packed vascular bundles, with the descending limbs positioned closer to the bundles. As a consequence, interactions between the tubules and vasa recta are enhanced, leading to a more efficient countercurrent exchange, urea recycling, and inner medullary urea accumulation. Anita and Harold Layton, William Dantzler, and Thomas Pannabecker have proposed that three countercurrent systems (two in the upper inner medulla and one in the lower inner medulla) are required for the complete concentrating process. In the lower inner medulla, loops having wide lateral bends wrapped around collecting ducts greatly increase the surface area for NaCl release in close proximity to the ducts.

nephrons use four processes—glomerular filtration, tubular reabsorption, tubular secretion, and osmoconcentration—to produce a urine of selective composition. Table 12-4 summarizes the key movements of sodium and water in these processes. Hormones—primarily aldosterone, angiotensin II, ANP, and vasopressin—regulate some of these processes, so that the final composition that is excreted helps maintain homeostasis of internal body fluids. Then there are two final stages: storage of urine in the bladder, and removal from the body.

12.9 Mammalian Urinary System: Bladder Storage and Micturition

In mammals, amphibians, and fishes, urine formed in the kidneys is carried through the ureters to the urinary bladder.

Urine is temporarily stored in the bladder, which is emptied by micturition

The mammalian bladder wall consists of smooth muscle lined by transitional epithelium with special cells called *umbrella cell*. Umbrella cells are joined by tight junctions (p. 66) that form an impermeable barrier. Physiologists once assumed the bladder was an inert sac. However, both its epithelium and smooth muscle actively participate in its ability to accommodate large fluctuations in urine volume. The umbrella cells can increase and decrease their surface area by the orderly process of membrane recycling as the bladder alternately fills and empties. Membrane-enclosed cytoplasmic vesicles are inserted into the plasma membrane by means of exocytosis into the surface area during bladder filling; then the vesicles are withdrawn by endocytosis to shrink the surface area after emptying. As is characteristic of smooth muscle, bladder muscle can stretch tremendously without a buildup in bladder wall tension. In addition, the highly folded bladder wall flattens out during filling, to increase bladder storage capacity.

The bladder smooth muscle is richly supplied by parasympathetic fibers, stimulation of which causes bladder contraction. If the passageway through the urethra to the outside is open, bladder contraction empties urine from the bladder. The exit from the bladder, however, is guarded by two sphincters, the *internal urethral sphincter* and the *external urethral sphincter* (Figure 12-32). The **internal urethral sphincter**—which consists of smooth muscle and is not un-

FIGURE 12-32 Comparison of the urethra in human females and males. (a) In females, the urethra is straight and short. (b) In males, the urethra, which is much longer, passes through the prostate gland and penis.

© Cengage Learning, 2013

der cortical control—is not really a separate muscle but instead consists of the last portion of the bladder. Although not a true sphincter, it performs the same function. When the bladder is relaxed, the arrangement of the internal urethral sphincter region closes the outlet of the bladder. The **external sphincter** is skeletal muscle and is under cortical control via a motor neuron, which is normally active to keep the sphincter closed.

Molecular Biology and Genomics

Surviving Salt and Urea: Organic Osmolytes and Gene Regulation

As we discussed in Chapter 3, osmosis and cell volume regulation are among the most crucial processes facing cells in general. Consider the external osmotic environment of a nephron cell in the mammalian renal medulla. The countercurrent mechanism, in a dehydrated animal, produces very high levels of NaCl and urea, threatening the cells with both osmotic shrinkage from the salt and protein damage from urea. How do the cells cope with this? It was not until after the publication of research on *osmolytes* in marine organisms that this medically important question was answered; moreover, it led to a possible treatment for cystic fibrosis.

As you will see in detail in Chapter 13, cells of most organisms subjected to high osmotic stress—such as seawater—accumulate organic solutes called **organic osmolytes** to maintain cell volume. NaCl cannot be used at high levels inside cells because it disrupts proteins and damages DNA. Medical researchers who read about organic osmolytes in marine organisms discovered that the mammalian kidney is no exception—to prevent osmotic water loss from the high NaCl in the medulla, renal cells exclude excess NaCl and instead accumulate high levels of the sugar alcohols *sorbitol* and *myo-inositol*, the sulfur amino acid *taurine*, and the methylamines *glycerophosphorylcholine* (*GPC*) and *glycine betaine* (*GB*). These are the same chemical types of osmolytes used by marine algae and animals to balance the high osmotic pressure of seawater (see p. 617). These osmolytes have been identified in the renal medullas of all mammalian species examined (humans, dogs, rats, rabbits, and desert rodents). In all cases, the total concentrations of these osmolytes correlates with osmotic pressure of medulla fluids; that is, animals with a low water intake have increased NaCl levels in the ECF and organic osmolytes in the ICF (compared to well-hydrated animals). Notably, GPC is the only osmolyte that increases in response to an increase in medullary levels of both salt and urea; the others rise primarily in response to increased salt concentration.

Why are sugar alcohols, taurine, and methylamines used as osmolytes? Again, as you will see in Chapter 13 in detail, organic osmolytes are generally *compatible* with cellular macromolecules, that is—unlike salt ions—they do not perturb protein functions and are therefore safe to accumulate in cells over a wide concentration range. The methylamine osmolytes such as GPC provide another benefit: They strongly *stabilize* proteins, by maintaining the protein in its folded state. Urea is a noncompatible protein denaturant that unfolds proteins, and it penetrates most medullary cells. Rats on a high-protein diet, whose kidneys must concentrate very high levels of urea (Table 12-3), have a correspondingly high level of GPC in their medullary cells. Why might this be? The first clue came from the discovery that the methylated amine *TMAO* in sharks and their relatives (pp. 572 and 622) has protein-stabilizing properties that *counteract* the deleterious effects of urea (their main osmolyte) on proteins (p. 559). GPC has since been shown to act similarly.

Interestingly, kidneys do not malfunction in cystic fibrosis patients despite the presence of CFTR-type chloride channels (p. 561) in nephrons. Some researchers have speculated that organic osmolytes enable the mutant CFTR proteins to fold properly. Indeed, Marybeth Howard, William Welch, and colleagues showed that addition of renal osmolytes to CFTR cells in culture restores normal chloride transport.

How do renal cells exposed to high osmotic stress regulate the accumulation of osmolytes? Salt stress leads to the activation of genes for key enzymes and transporters:

- Sorbitol increases by conversion from glucose due to the enzyme *aldose reductase* (*AR*).
- GPC increases due to an enzyme that synthesizes it and by simultaneous inhibition (by both NaCl and urea) of an enzyme that breaks it down.
- GB, myo-inositol, and taurine are accumulated from external fluids via *betaine/GABA transporters* (*BGT1*), *sodium/myo-inositol transporters* (*SMIT*), and *taurine transporters* (*TauT*), respectively.

Physiologists now know these genes share a highly similar regulatory promoter (Chapter 2) called the **osmotic response element (ORE)** or **tonicity enhancer (TonE)**. Moreover, the genes for aquaporin *AQP-2*, urea transporter *UT-A*, and *vasopressin* have TonE sequences.

Here are some actual enhancer codes “upstream” from the protein-coding genes:

Rabbit AR ORE	CGGAAAATCAC . . . [coding gene for AR]
Canine BGT1 TonE	TGGAAAAGTCC . . . [coding gene for BGT1]
Human SMIT TonE	TGGAAAAC TAC . . . [coding gene for SMIT]
Rat UT-A TonE	TGGAAAAC TCC . . . [coding gene for UT-A]
Mouse AQP-2 TonE	TGGAAATTTCTT . . . [coding gene for AQP-2]

Studies have revealed an **ORE-binding** or **TonE-binding protein** (OREBP or **ToneBP**), which functions as a *transcription factor* (Chapter 2). These regulatory proteins bind to the OREs/TonEs in a renal cell's DNA and, in antidiuretic states, activate transcription of all the osmolyte (and *AQP-2* and *UT-A*) genes simultaneously (and presumably the *vasopressin* gene in the hypothalamus). Knockout of ToneBP/OREBP leads to embryonic death in mice, and the few survivors have severe atrophy of the inner medulla and cannot regulate osmolyte genes in antidiuresis. How is osmotic stress sensed and transduced into signal(s) that activate ToneBP? So far, researchers have found that high NaCl in renal cells (1) stabilizes ToneBP mRNA, leading to more protein synthesis; (2) triggers dimerization (two proteins joined) and phosphorylation of ToneBPs, making them active; and (3) activates proteins that rapidly import ToneBPs into the nucleus from the cytoplasm (where they reside at low osmotic stress). The exact processes by which NaCl does all this are actively being studied.

Micturition, or urination, the process of bladder emptying, is governed by two mechanisms: the micturition spinal reflex and cortical control. The micturition reflex is initiated when stretch receptors within the bladder wall are stimulated (Figure 12-33). The greater the distension beyond a certain minimum—250 to 400 mL in a human—the greater the extent of receptor activation. Afferent fibers from the stretch receptors carry impulses into the spinal cord and eventually, via interneurons, stimulate the parasympathetic supply to the bladder and inhibit the motor neuron supply to the external sphincter. Parasympathetic stimulation of the bladder causes it to contract. No special mechanism is required to open the internal sphincter; changes in the shape of the bladder during contraction mechanically pull the internal sphincter open. Simultaneously, the external sphincter relaxes as its motor neuron supply is inhibited. Now both sphincters are open, and urine is expelled through the urethra by the force of bladder contraction.

In addition to triggering the micturition reflex, bladder filling also sends signals to the brain cortex, giving rise to the urge to urinate. Control of micturition by the brain can override the micturition reflex so that bladder emptying can take place at the animal's convenience rather than at the time bladder filling first reaches the point of activating the stretch receptors. See p. 138 for the mechanism involved. Micturition is also an animal's normal response to an extremely stressful situation, because emptying the bladder reduces body weight.

Urination cannot be delayed indefinitely. As the bladder continues to fill, reflex input from the stretch receptors increases with time. Finally, reflex inhibitory input to the external-sphincter motor neuron becomes so powerful that it can no longer be overridden by cortical excitatory input, so the sphincter relaxes and the bladder uncontrollably empties.

check your understanding 12.9

Describe how the urine fills and then empties, including external regulatory features.

12.10 Renal Diseases

Urine excretion and the resulting clearance of wastes and excess electrolytes from the plasma are crucial for maintaining homeostasis. Thus, kidney pathologies are dangerous and are unfortunately relatively common ailments of aging humans and domestic cats and small dogs.

Renal diseases are numerous and have wide-ranging consequences

Renal problems have a variety of causes, some of which begin elsewhere in the body and affect renal function secondarily. Among the causes are (1) *cellular damage* resulting

FIGURE 12-33 Reflex and higher-cortical control of micturition (mammal).

© Cengage Learning, 2013

from excessive glucose in diabetes, or infectious organisms, either bloodborne or gaining entrance to the urinary tract through the urethra; (2) *toxic agents*, such as lead, arsenic, pesticides, or even long-term exposure to high doses of aspirin or ibuprofen in humans; (3) *inappropriate immune responses*, such as glomerulonephritis, which occasionally follows certain infections as antigen-antibody complexes are deposited in the glomeruli; (4) *obstruction* of urine flow because of the presence of infectious agents, kidney stones, tumors, cysts, or enlargement of the prostate gland, with the back pressure reducing GFR as well as damaging renal tissue; and (5) an *insufficient renal blood supply* that leads to inadequate filtration pressure. The latter can occur secondarily to diabetes or circulatory disorders such as heart failure, hemorrhage, shock, or narrowing of the renal arteries as a result of atherosclerosis.

In aging domestic cats, for example, renal disease can be due, among other things, to diabetes, parasites, bacteria, feline leukemia virus—which can trigger glomerular nephritis and tumor formation—and ingested toxins such as antifreeze from car radiators. Most antifreezes contain ethylene glycol, which is converted in the liver and kidney to a toxic product that changes the pH of the bloodstream and destroys the kidneys by depositing calcium oxalate crystals in the renal tubules. In some cat breeds, *polycystic kidney disease (PKD)* is also a common genetic problem, in which damaging cysts slowly form in the kidney with age.

TABLE 12-5 Potential Ramifications of Various Types of Renal Failure in a Mammal

Uremic toxicity caused by retention of waste products
Nausea, vomiting, diarrhea, and ulcers caused by a toxic effect on the digestive system
Bleeding tendency arising from a toxic effect on platelet function
Mental changes—e.g., reduced alertness, insomnia, shortened attention span, progressing to convulsions and coma—caused by toxic effects on the central nervous system
Abnormal sensory and motor activity caused by a toxic effect on the peripheral nerves
Metabolic acidosis* caused by the inability of the kidneys to adequately secrete H ⁺ that is continually being added to body fluids as a result of metabolic activity
Altered enzyme activity caused by the action of too much acid on enzymes
Depression of the central nervous system due to acid interfering with neuronal excitability
Potassium retention* resulting from inadequate tubular secretion of K ⁺
Altered cardiac and neural excitability due to changes in resting membrane potential
Sodium imbalances caused by the inability of the kidneys to adjust Na ⁺ excretion to balance the changes in Na ⁺ consumption
Elevated blood pressure, generalized edema, and congestive heart failure
Hypotension and, if severe enough, circulatory shock if too little Na ⁺ is consumed
Phosphate and calcium imbalances arising from impaired reabsorption of these electrolytes
Disturbances in skeletal structures caused by abnormalities in deposition of calcium phosphate crystals, which harden bone
Loss of plasma proteins as a result of increased “leakiness” of the glomerular membrane
Edema caused by a reduction of plasma-colloid osmotic pressure
Inability to vary urine concentration as a result of impairment of the countercurrent system
Hypotonicity of body fluids if too much H ₂ O is ingested
Hypertonicity of body fluids if too little H ₂ O is ingested
Hypertension arising from the combined effects of salt and fluid retention and vasoconstrictor action of excess angiotensin II
Anemia caused by inadequate erythropoietin production
Depression of the immune system most likely caused by toxic levels of wastes and acids
Increased susceptibility to infections

*Among the most life-threatening consequences of renal failure.

Domestic male cats are also very prone to **feline urologic syndrome (FUS)**: reduced or blocked urination because of infections, magnesium ammonium phosphate crystals, and other damage to the bladder or urethra. Crystal blockage illustrates the importance of understanding evolutionary adaptation: Cats are essentially desert animals that normally obtain most or all of their water from moist prey meat and have kidneys capable of producing urine about 10 times more hypertonic than plasma (Table 12-3). Highly concentrated urine can lead to mineral crystallization, causing FUS. However, wild cats, which as pure carnivores eat a high-meat diet, have an acidic urine that prevents crystallization. Problems occur in domestic cats that are fed foodstuffs not formulated to match natural diets (those containing an unnaturally high content of fat, nonmuscle protein, and/or carbohydrate), leading to a high-pH urine that enhances crystallization. Similar problems are present in laboratory

rats, where minute fluctuations in dietary mineral, protein, and lipid content can initiate the development of renal disease.

When the functions of both kidneys are disrupted to the point that they cannot perform their regulatory and excretory functions sufficiently to maintain homeostasis, **renal failure** is said to exist. An animal may die from acute renal failure, or the condition may be reversible and lead to full recovery. Chronic renal failure, in contrast, is not reversible. Gradual, permanent destruction of renal tissue eventually proves fatal.

We will not sort out the different stages and symptoms associated with various renal disorders, but Table 12-5, which summarizes the potential consequences of renal failure, can give you an idea of the broad effects that kidney impairment can have. The extent of these effects should not be surprising, considering the central role the kidneys play

in maintaining homeostasis. By the time end-stage renal failure occurs, literally every body system has become impaired to some extent.

check your understanding 12.10

Describe four general causes of renal problems, with one specific example of each.

making connections

How Excretory Systems Contribute to the Body as a Whole

Excretory organs in more complex animals contribute to internal fluid homeostasis more extensively than most other single organs. Major examples are gills in fishes and kidneys in mammals. Both help maintain the plasma constituents they regulate within the narrow range compatible with life, despite wide variations in intake and losses of these substances through other avenues. Excretory organs can sometimes serve as sensors and integrators that contribute to regulating the excretory processes by negative feedback.

Here are the specific ways in which mammalian kidneys contribute to homeostasis:

1. *Effector functions* include:
 - Regulating the quantity and concentration of most ECF electrolytes, important in osmotic balance and membrane potentials.
 - Maintaining proper plasma volume, which is important in the long-term regulation of arterial blood pressure, by controlling the salt and water balance.
 - Maintaining water balance for maintaining proper ECF osmolarity (concentration of solutes), to prevent cells from swelling or shrinking by osmosis.
 - Excreting the often-toxic end products of metabolism (such as ammonia, urea, uric acid), as well as many foreign compounds that gain entrance to the body.
 - Conserving useful substances, such as glucose, and water in animals subject to dehydration.
 - Contributing to maintenance of proper pH (Chapter 13).
2. *Integrator/hormonal functions* include:
 - Secretion of erythropoietin (EPO) to stimulate red blood cell production (p. 393).
 - Secretion of renin to initiate the renin–angiotensin–aldosterone pathway for controlling renal tubular Na^+ reabsorption.
3. *Metabolic functions*:
 - The kidneys help convert vitamin D into its active form. Vitamin D is essential for Ca^{2+} absorption from the digestive tract.

Chapter Summary

- Selective excretion is crucial to internal fluid homeostasis and involves respiratory, digestive, integumentary, and renal systems.
- Nitrogen metabolism creates special stresses and produces three major end products: ammonia (metabolically “cheap” but toxic; mainly in aquatic organisms), urea (moderately costly and toxic; in elasmobranchs, adult amphibians, and mammals), and uric acid (nontoxic but costly; in insects, reptiles including birds, and mammals).
- Excretory organs have transport epithelia, which typically use Na^+/K^+ ATPases to set up cation gradients, which can be used to move other substances secondarily.
- Renal tubules produce urine using the processes of filtration, secretion, reabsorption, and osmoconcentration. The major renal organs are protonephridia, meso- and metanephridia, and Malpighian tubules.
- Malpighian tubules in insects initiate excretion by ion secretion, which causes osmosis. The tubules and hindgut modify the lumen fluid by specific secretion and reabsorption. Insect excretion is regulated by diuretic and antidiuretic hormones.
- Vertebrate kidneys form the urine; the remainder of the urinary system is ductwork that carries the urine to the bladder or hindgut. The nephron is the functional unit of the vertebrate kidney, using the basic renal processes. The glomerulus and Bowman’s capsule perform ultrafiltration; the proximal and distal tubules perform specific reabsorption and secretion; and the loop of Henle and collecting duct perform osmoconcentration (only in birds and mammals).
- Elasmobranch fishes retain urea and trimethylamine oxide (TMAO) as osmolytes, and use gills, kidneys, and rectal glands for excretion and retention. Marine bony fishes use gills for most excretion and retention processes. Freshwater bony fishes excrete water with their kidneys, and their gills excrete wastes and take up salts.
- Terrestrial vertebrates evolved new renal and extrarenal mechanisms to maintain an “internal ocean.” Amphibians use kidneys and bladders for excretion and retention. Nonavian reptiles use amphibian-like kidneys, hindguts, and (in marine and desert species) salt glands for excretion and retention. Birds have kidneys with reptile- and mammal-like nephrons, hindguts, and (in marine species) salt glands for excretion and retention. Mammalian (and avian) kidneys have cortical and juxtamedullary nephrons.
- For glomerular filtration, the glomerular membrane has three layers forming a fine molecular sieve. The glomerular capillary blood pressure is the major force that causes glomerular ultrafiltration. Changes in the glomerular filtration rate or GFR result primarily from changes in glomerular capillary blood pressure.
- Tubular reabsorption involves passive and active transepithelial transport and is tremendous, highly selective, and variable. Sodium reabsorption is essential for the reabsorption of nutrients, Cl^- , and H_2O , and for the regulation of ECF osmolality and volume. Glucose and amino acids are reabsorbed by Na^+ -dependent secondary active transport. Most actively reabsorbed substances exhibit a tubular maximum. Glucose reabsorption is not regulated by the kidneys and has a maximum important in diabetes. PO_4^{3-} (phosphate) reabsorption, in contrast, is regulated. In general, unwanted waste products, except some urea, are not reabsorbed.

- The renin–angiotensin–aldosterone system (RAAS) stimulates Na^+ reabsorption in distal tubules and collecting ducts, elevates blood pressure, and stimulates thirst and salt hunger. Atrial and brain natriuretic peptides (ANP, BNP) antagonize the RAAS, inhibiting Na^+ reabsorption and reducing blood pressure.
- In tubular secretion, H^+ secretion is important in acid–base balance. K^+ secretion is controlled by aldosterone. Organic anion and cation secretion helps eliminate foreign compounds from the body. Plasma clearance, the volume of plasma cleared of a particular substance per minute, is used to characterize secretion.
- In osmoconcentration, the ability to excrete urine of varying concentrations varies among species and depends on hydration state. A medullary vertical osmotic gradient is established by countercurrent multiplication with the thick ascending limb of the loop pumping out NaCl without water following. The interstitial NaCl buildup draws water out of the descending limb. In dehydration, vasopressin from the hypothalamus–pituitary triggers insertion of aquaporins in the collecting duct. Water is then drawn out by the medullary gradient to conserve water (antidiuresis). In overhydration, no vasopressin is released, so the collecting duct retains its water, excreting excess from the body (diuresis).
- Countercurrent exchange within the vasa recta conserves the medullary vertical osmotic gradient. Passive urea recycling in the renal medulla contributes to medullary hypertonicity and prevents urea diuresis. Different osmoconcentrating abilities among species depend on nephron anatomy and metabolic rates, with animals having long loops and high metabolic rates capable of the highest levels of osmoconcentration.
- Urine is temporarily stored in the bladder, which is emptied by micturition.
- Renal diseases such as feline urologic syndrome are numerous and have wide-ranging consequences.

Review, Synthesize, and Analyze

1. Distinguish between *secretion* and *excretion*.
2. Compare and contrast insect Malpighian tubules and mammalian nephrons. In doing so, describe all tubular transport processes that are linked to the basolateral Na^+/K^+ ATPase in nephrons and the V-ATPase in Malpighian tubules.
3. The Gulf toadfish *Opsanus beta* (p. 561) switches from ammonotelic to ureotelic when crowded or confined, releasing urea in pulses. Hypothesize why it might do this.
4. Explain *tubular maximum* (T_m) and *renal threshold*. Compare two substances that display a T_m : one substance that *is* and one that *is not* regulated by the kidneys.
5. Calculate an animal's rate of urine production, given an inulin clearance of 75 mL/min and urine and plasma concentrations of inulin of 300 mg/liter and 3 mg/liter, respectively.
6. If the urine concentration of a substance is 7.5 mg/mL of urine, its plasma concentration is 0.2 mg/mL of plasma, and the urine flow rate is 2 mL/min, what is the clearance rate of the substance? Is the substance being reabsorbed or secreted by the kidneys?
7. If the plasma concentration of substance X is 200 mg/100 mL and the GFR is 125 mL/min, what is the filtered load of this substance? If the T_m for substance X is 200 mg/min, how much of the substance will be reabsorbed at a plasma concentration of 200 mg/100 mL and a GFR of 125 mL/min? How much of substance X will be excreted?
8. *Conn's syndrome* is an endocrine disorder in some older domestic cats brought about by excessive growth of the adrenal cortex (sometimes due to a tumor). The result is secretion of unregulated excessive aldosterone. Given what you know about the functions of aldosterone, describe what the most prominent features of this condition would be.
9. Because of a mutation, an animal was born with an ascending limb of Henle that was water permeable. What would be the minimum/maximum urine osmolarities (in units of mOsm) the animal could produce?
10. A dog suffers permanent damage of the lower spinal cord in an accident and is paralyzed from the waist down. Describe what governs bladder emptying in this animal.

Paul Varney

Intertidal anemones and snails. Both animals and their relatives (marine Cnidarians and mollusks, respectively) are osmoconformers; that is, the osmotic pressure of their body fluids is equal to that of the environment. The snails have CaCO_3 shells that form well at the naturally basic pH of seawater, but their shells may now be weakening from increasing acidity resulting from anthropogenic CO_2 .

Fluid and Acid–Base Balance

13.1 Introduction

The concept of homeostasis as first delineated by Claude Bernard and Walter Cannon (p. 11) focused on the *milieu intérieur*, that is, the *extracellular fluid (ECF)* that bathes all cells of an animal. The idea was that individual cells could be spared the cost of struggling against disturbances to their *intracellular fluids (ICF)* if the ECF is regulated on their behalf. The composition of the ICF and ECF results from a variety of key molecular components: the solvent water and its solutes—salts, nutrients such as glucose, proteins, and other organic molecules, ions such as calcium for shells and skeletons, and hydrogen ions. In accordance with the original homeostasis concept, many animals can regulate these constituents at the level of the ECF. The *total concentration* of all solutes, which determines osmotic pressure; the *concentration of individual solutes*; and the *total fluid volume* are the key components that need to be regulated.

As you have seen in Chapter 12, excretory organs play a key role in such regulation. However, single excretory organs such as kidneys do not regulate every aspect of the ECF. Other organs contribute (CO_2 , for example, is mainly regulated by respiratory

systems), and the ECF may vary in composition in some types of animals, such that individual cells must cope on their own. Overall, though, critical features of cellular homeostasis are still achieved, as you will see. Therefore, the regulation of the ECF and ICF composition is not attributable to one single physiological system. Rather, it is an inherently integrative process involving individual cells and more than one organ system. In Chapter 12, we focused primarily on the excretion and retention of specific solutes (salts, wastes) and water. In this chapter, we look at fluid-related regulation at a more integrative level by focusing on three aspects of the ECF and ICF that are crucial to the whole animal and to its individual cells: (1) the *osmotic balance*, determined primarily by the total concentration of major solutes; (2) the *total fluid volume* of the body, which directly affects circulatory pressure; and (3) the *acid–base balance*. Hydrogen ions alter the acid–base status (measured as pH) of body fluids, a factor crucial to the functioning of proteins.

Before we examine these, however, let's look at how the composition of the ECF can change in basic terms.

If balance is to be maintained, input must equal output

The quantity of any particular substance in the ECF is considered a readily available internal pool. The amount of the substance in the pool may be increased either by transferring more in from the external environment (such as via the gut or the integument) or by metabolically producing it within the body (Figure 13-1). Substances may be removed from the body by loss to the outside (through excretion, sweating, and so forth) or by being used up in a metabolic reaction. If the quantity of a substance is to remain stable within the body, its input must be balanced by an equal output by means of excretion or metabolic consumption. This relationship, known as the **balance concept**, is extremely important in maintaining homeostasis. Not all input and output pathways are applicable for every body fluid constituent. For example, salt is not synthesized or altered metabolically by organisms, so the stability of salt concentration in

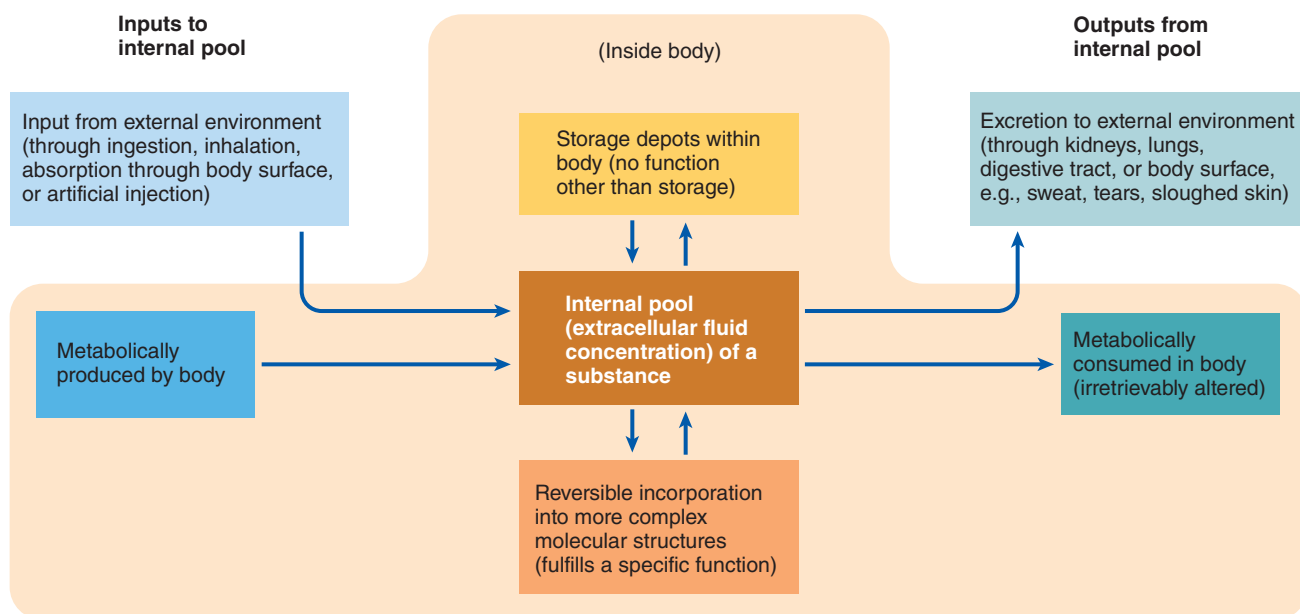

FIGURE 13-1 Inputs to, and outputs from, the internal pool of a body constituent.

© Cengage Learning, 2013

body fluids depends entirely on a balance between salt intake and salt excretion.

The ECF pool can further be altered by transferring a particular ECF constituent into storage within cells or certain extracellular features (such as shells, bladder fluid). If a body as a whole has a surplus or deficit of a particular stored substance, the storage site can be expanded or partially depleted to maintain the ECF concentration of the substance within homeostatically prescribed limits. For example, some amphibians use their bladders for temporary water storage (see p. 574). Some storage involves chemical conversions; for instance, after a mammal has absorbed a meal, when more glucose is entering the plasma than is being consumed by the cells, the excess glucose can be temporarily stored in liver cells in the form of glycogen. This storage depot can then be tapped between meals as necessary to maintain the plasma glucose level when no new nutrients are being added to the blood by eating. It is important to recognize, however, that internal storage capacity is limited. Although an internal exchange between the ECF and a storage depot can temporarily restore the plasma concentration of a particular substance to normal, in the long run any excess or deficit of that constituent must be compensated for by appropriate adjustments in total body input or output.

Some exchanges between the pool and the remainder of the body involve structures with functions beyond mere storage. Consider calcium: It is an essential component of an animal's skeleton or shell for support and protection, but it is also necessary as a cellular messenger and trigger of muscle contraction. If plasma and cell calcium fall too low, calcium may be taken out of the shell or skeleton. This process differs from simple storage, which serves no additional purpose.

Some body constituents may be poorly controlled. For example, the plasma volume and composition of many *osmoconformers* (animals whose internal osmotic pressure is equal to that of the environment; see p. 616) passively changes with the external environment, forcing individual cells to adjust at least in part on their own. Some constitu-

ents undergo frequent and/or large disturbances. Salt and H_2O can be lost to the terrestrial environments to varying degrees through the digestive tract (vomiting, diarrhea), skin (sweating), lungs (panting), and elsewhere without regard for salt or H_2O balance in the body. Hydrogen ions are uncontrollably generated internally (especially during muscle activity) and added to body fluids. If possible, compensatory adjustments must be made for these uncontrolled changes.

Body water is distributed between the intracellular and extracellular fluid compartments

Water is by far the most abundant component of most animals, though the proportion varies considerably. For example, water is about 60% of mammalian body weight on average, and it can be more than 90% in some soft aquatic animals. Yet water content may drop well below 10% in certain **anhydrobiotic** animals, such as encysted tardigrades, rotifers, and brine shrimp embryos that have entered a dormant state. However, anhydrobiotic states exhibit no detectable metabolism, illustrating that normal metabolic functions are associated with high water content. (Note that some anhydrobiotic stages of organisms can remain viable under harsh conditions for years, even many millennia in the case of some prokaryotes. It is not fully understood how they accomplish this. See *A Closer Look at Adaptation: The Sweet Solution to Desiccation*.)

Among the major body components, plasma, as you might suspect, is the most watery, typically more than 90% H_2O . But even soft tissues such as skin, muscles, and internal organs consist of 70 to 80% H_2O . Drier structural materials such as shells and skeletons may be only about 20% H_2O . Fat and external coverings such as hair are the driest tissues of all, having only 10% H_2O content or less. These drier examples include many metabolically inactive components; in contrast, the active cytosols and organelles of the cells within shells, skeletons, and fat tissue have high water

A Closer Look at Adaptation The Sweet Solution to Desiccation

Biologists routinely talk about life being incompatible with the absence of water. Although this is basically correct (at least for life on Earth), a remarkable group of unrelated organisms can enter a dormant state with almost no water, and for years and even decades can survive in the sense of being able to restore normal functions upon exposure to free water. These **anhydrobiotic** (“no-water life”) organisms range from bacteria and yeast (in cyst or spore stages) to nematodes to certain arthropods. If you have ever baked bread or brewed beer, you may be familiar with anhydrobiotic yeasts, which are sold in dry form in the store and which “come back to life” on being mixed in the moist dough or beer mash. Less familiar, perhaps, are the brine shrimp *Artemia*, sold as a novelty item often called “sea monkeys.” As adults, these inhabit highly saline lakes such as the Great Salt Lake in Utah. However, they and their eggs can dry out if washed ashore or if a desert pond they inhabit dries out. This kills the adults, but an early embryonic stage can encyst and survive for years with less than 2% water internally. The Arctic springtail (*Megaphorura arctica*) also survives winter by drying up to prevent freezing. More remarkably, **tardigrades** (see photograph), small, segmented, exoskeletal animals found in ponds and forest litter, can encyst as adults with less than 1% water and survive for years and under harsh treatments such as immer-

sion in alcohol and freezing in liquid nitrogen! Moreover, tardigrades not only survived but reproduced normally after they were exposed to the vacuum of space on a European Space Agency spacecraft.

How can these organisms do this? Typically, they have an impermeable outer cover of dense proteins or wax to reduce exchanges with the environment. But more importantly, these resistant stages accumulate large amounts of disaccharide sugars, most commonly **trehalose** (diglucose). Although the mechanism is still being studied, trehalose appears to use its hydroxyl groups (–OH) to hydrogen bond to macromolecules and membranes in the place of water molecules. This keeps these structures from irreversible damage (although they are non-functional until water returns). The sugar not

only stabilizes proteins and membranes, but also turns into a glasslike material that holds the cytoplasm and all its constituents in a smooth, undamaged condition (see Chapter 15). Recently, many anhydrobiotic organisms, including brine shrimp, have been found to produce *LEA* proteins (late embryogenesis abundant), named after their occurrence in late stages of plant seed development. LEA proteins are thought to facilitate glass formation by trehalose and to help stabilize other proteins in the dry state.

Regardless of how trehalose works, its remarkable preservation abilities have been put to use: Human red blood cells can be dried and preserved with this sugar, carried around in a lightweight form (such as by a soldier), and then rehydrated into usable form when needed for transfusions.

contents, but those cell spaces are a minor component of those tissues.

Major Fluid Compartments Body H_2O is distributed between two major fluid compartments: the ICF and the ECF (Figure 13-2). Table 13-1 shows values for a mammal (human). The ICF compartment comprises about two thirds of total body H_2O in insects and vertebrates, but only about one third to one half in marine mollusks and crustaceans. Even though each contains its own unique mixture of constituents, these numerous minute fluid compartments are similar enough to be considered collectively as one large fluid compartment.

FIGURE 13-2 A model of the major body compartments in an animal and exchange routes (arrows) between them. ECF, extracellular fluid; ICF, intracellular fluid.

The remaining body H₂O—in the ECF compartment—is primarily the hemolymph in animals with open circulatory systems (Chapter 9). In animals with closed circulation, such as cephalopods and vertebrates, the ECF is subdivided primarily into plasma and interstitial fluid. Vertebrate plasma, which makes up about 15% (in bony fishes) to 40% (in birds) of the ECF volume, is the fluid portion of the blood. The interstitial fluid, which represents most of the remaining ECF compartment, constitutes the true internal environment that bathes the tissue cells.

Minor ECF Compartments Some animals have two other relatively minor ECF fluids. *Lymph*, found in most vertebrates, is fluid being returned from the interstitial fluid to the plasma via the lymphatic system (Chapter 9). **Transcellular** fluids consist of a number of small specialized fluid volumes that are secreted by specific cells into a particular body cavity to perform some specialized function. In vertebrates, these include *cerebrospinal fluid* (p. 169); *intraocular fluid* (maintaining the shape of and nourishing the eye); *synovial fluid* (lubricating the joints); and *pericardial*, *intrapleural*, and *peritoneal* fluids (lubricating movements of the heart, lungs, and intestines, respectively). Although important functionally, these fluids usually represent an insignificant fraction of the total body H₂O (Table 13-1). Furthermore, many transcellular fluids do not reflect changes in the body's fluid balance. For example, the mammalian cerebrospinal fluid does not decrease in volume when the body as a whole is experiencing a negative H₂O balance. Therefore, the transcellular compartment can usually be ignored when analyzing fluid balance.

Finally, a fluid compartment found in all animals is that which is produced by the digestive tract. Technically this is part of the external environment because the digestive tract connects to the outside world. However, this fluid contains components from the body (such as digestive enzymes, and

sometimes water) and can be particularly dynamic in ruminant and postgastric fermenters (see Chapter 14). It is usually a small percentage of the ECF but cannot always be ignored, because it potentially can be major source of gains and losses of water and solutes.

In vertebrates, the plasma and interstitial fluid are similar in composition, but the ECF and ICF are markedly different in all animals

Several barriers separate vertebrate body fluid compartments, limiting the movement of H₂O and solutes between the various compartments to differing degrees. The two components of the ECF—plasma and interstitial fluid—are separated by the walls of the blood vessels. However, H₂O and all plasma constituents with the exception of plasma proteins are continuously and freely exchanged between the plasma and the interstitial fluid by passive means across capillary walls (p. 440). Accordingly, the two fluids are nearly identical in composition, except that interstitial fluid lacks plasma proteins. Any change in one of these ECF compartments is quickly reflected in the other compartment.

In contrast to the close similarity between plasma and interstitial fluid, the composition of the ECF as a whole differs considerably from that of the ICF (Figure 13-3) in all animals. Each cell is surrounded by a highly selective plasma membrane that permits passage of certain materials while excluding others. Movement through the membrane barrier occurs by both passive and active means and may be highly discriminating. Among the major differences between the ECF and ICF are:

1. *Cellular proteins* that cannot permeate the plasma membranes to leave the cells.
2. *Cellular organic osmolytes* (see p. 617; typically higher in the ICF than in the ECF).
3. *Na⁺ and K⁺* and their attendant anions: In most organisms, Na⁺ is the primary ECF cation, and K⁺ is the primarily ICF cation. This is due in part to action of the membrane-bound Na⁺/K⁺ ATPase pump that is present in all cells (although this is not the only factor; see p. 103). The unequal distribution of Na⁺ and K⁺, coupled with differences in membrane permeability to these ions, is responsible for the electrical properties of cells, including the action potentials in excitable tissues (see Chapters 3 and 4).

Except for the extremely small electrical imbalance in the intracellular and extracellular ions involved in membrane potential, the majority of the ECF and ICF ions are electrically balanced. In the ECF, Na⁺ is accompanied primarily by the anion Cl⁻ and to a lesser extent by HCO₃⁻ (bicarbonate). In the ICF, K⁺ is accompanied primarily by the anion PO₄³⁻ (phosphate) and by the negatively charged proteins trapped within the cell.

Although all cells' plasma membranes display selective permeability, cells are typically permeable to H₂O. The movement of H₂O between the plasma and the interstitial fluid across capillary walls is governed by relative imbalances between capillary blood pressure (a fluid, or hydrostatic, pressure) and colloid osmotic pressure (see p. 443). In contrast, the net transfer of H₂O between the interstitial fluid and the ICF across plasma membranes occurs as a

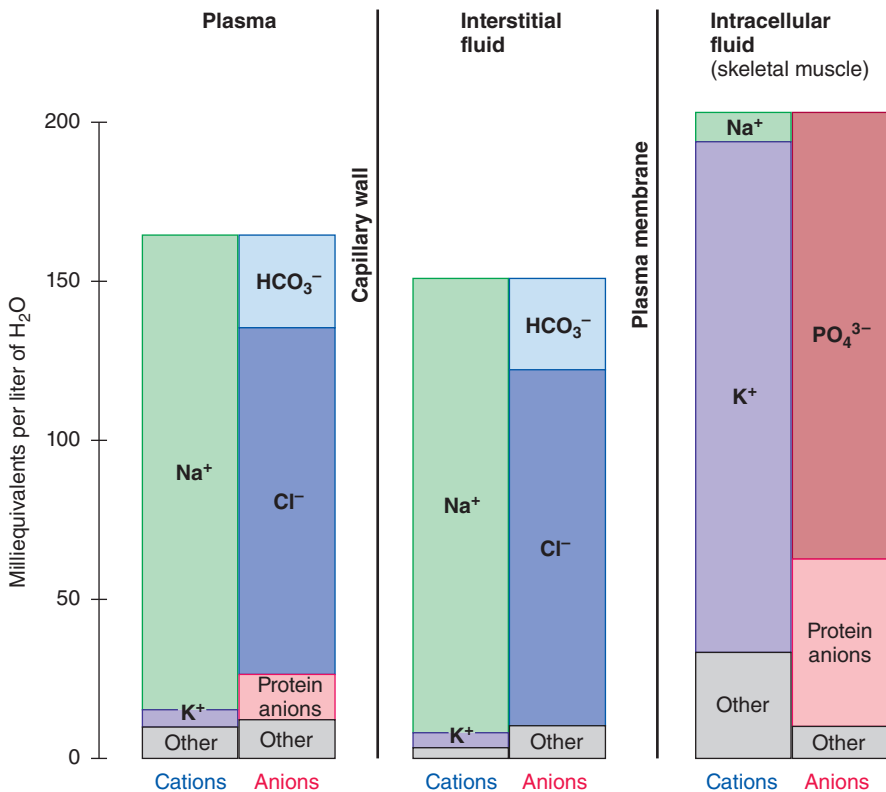

FIGURE 13-3 Ionic composition of the major body fluid compartments in a mammal.

result of osmotic effects alone because these fluids have very low hydrostatic pressures.

check your understanding 13.1

Explain the balance concept.

Outline the distribution of animal body H₂O in the various fluid compartments.

Compare the ionic composition of plasma, interstitial fluid, and intracellular fluid.

13.2 Osmotic and Volume Balance: Overview and Osmoconformers

As you saw in Chapter 3, osmotic forces are among the crucial factors with which cells must cope. Lacking true cell walls as found in bacteria, plants, algae, and fungi, most cells of animals become osmotically equalized with the ECF that bathes them. Thus, the osmotic composition of the ECF directly affects cell volume homeostasis. Recall that water molecules alone apparently cannot be moved directly by ATPase pumps (p. 561), but rather must passively follow the movement of solutes. Inorganic ions, especially NaCl, are dominant in this process (see Figure 12-3).

Osmotic problems that threaten cells and animals include salinity, evaporation, ingestion and excretion, freezing, and certain pathologies

One problem that all animal cells face is a potential swelling arising from the unequal Na⁺ distribution in the ECF and ICF. Because ECF Na⁺ has both an inward electrical and a chemical gradient (Chapter 4), Na⁺ leaking into cells raises the solute concentration and thus can elevate osmotic pressure, which in turn would cause water to enter the cell by osmosis. The primary, and nearly universal, mechanism to correct this situation is the Na⁺/K⁺ ATPase “pump.” By exporting more Na⁺ than the K⁺ it imports (3 Na⁺ out for each 2 K⁺ in), the pump not only maintains ion gradients but also reduces total cellular osmotic pressure.

Beyond this basic problem of cells, internal osmotic balance can be disturbed in several major ways. The ECF can become too concentrated or too dilute because of the following:

1. **Salinity** of the environment, probably the first osmotic stress faced by the earliest life. Marine organisms must prevent dehydration and limit excess salt influx in high salinity, while freshwater organisms have the opposite problems. Organisms in estuaries and aquatic migrators such as salmon (which move between freshwater and the ocean) face both situations.
2. **Evaporation** of body water into air: The evolution of terrestrial organisms created this problem, sometimes accompanied by salt loss, through processes such as breathing, sweating, panting, transpiration, and general loss through outer layers.
3. **Ingestion and excretion**: Intake of water and solutes through the digestive tract may not be of the correct amounts and types for an animal body, while excretion of waste products often requires water, a problem more critical for terrestrial than for aquatic organisms.
4. **Freezing**, which locks up water in ice crystals and concentrates ions in the residual unfrozen water.
5. **Pathologies** such as diabetes in which ECF osmolarity increases because of excessive glucose levels, cystic fibrosis in which salt transport is impaired, and *hyponatremia* (low blood sodium) due to excessive water drinking.

Changes in the ECF osmolarity in turn can cause cells to swell or shrink. Let's use environmental salinity to illustrate how disturbances can occur. The universal dissolved constituents of cells—macromolecules, metabolites, K⁺, and so forth—typically yield an osmotic concentration of roughly 300–400 milliosmolar (mOsm) in most organisms (this does not include nonuniversal *organic osmolytes*, which we discuss shortly). Recall that open ocean contains about 3.5%

salt, yielding about 1,000 mOsm (see p. 79). *Brackish* waters have less than 3.0% but greater than 0.5%. The lowest salinities are considered freshwater, approximating as low as 0 mOsm; in contrast, some brine lakes such as the Dead Sea in Israel can reach over 20% salt at 6,000 mOsm! In any environment greater than 300–400 mOsm, organisms must have adaptations to maintain cell volume in the face of this potentially dehydrating force. In contrast, lower osmolarities threaten to overhydrate organisms.

Animals have evolved two strategies to cope with osmotic challenges: osmoconforming and osmoregulating

How do animals maintain a proper balance of ICF and ECF volumes and compositions in the face of different environments? Adaptations include a cell membrane (or the extracellular layer next to it) that is impermeable to water, an option that turns out to be extremely limiting because it reduces the ability of a cell to exchange vital solutes. This solution has evolved in some epithelial layers exposed to osmotically challenging environments and is usually achieved with extracellular waterproofing layers on one side of a cell layer. For example, epidermal cells of insects secrete a non-cellular cuticle of waterproof *waxes*, whereas the epidermis of terrestrial vertebrates produces a *keratinized* layer with low permeability (p. 466). Another solution is found in some freshwater sponges, which have special water-pumping organelles called *contractile vacuoles* (p. 557). However, most animal cells, lacking cell walls, impermeable membranes, and contractile vacuoles, typically must have the total concentration of molecules in their ICF equal to that of the ECF. Thus, in the long run there are no osmotic gradients between most animal cells' ICF and the nearby ECF.

What solutions have animals evolved to limit swelling or shrinking of their cells, given that the external environment may have quite a different osmotic concentration and that perturbing changes in the environment may alter the osmotic state of the ECF (and thus alter the ICF)? There are two very different strategies of maintaining osmotic balance (Figure 13-4a):

- **Osmoconformers:** Body fluids and cells are generally equal in osmotic pressure to the environment (most commonly salty waters), with adjustments to both ECF and ICF made using small molecules called *osmolytes*.
- **Osmoregulators:** The osmotic pressure of body fluids is homeostatically regulated and typically very different from that of the external environment.

As shown in Figure 13-4b and c, there are varying degrees of osmoconforming and osmoregulating. Let's look at osmoconformers first.

Osmoconformers use compatible and counteracting organic osmolytes in their cells

Osmoconformers have little tendency to gain or lose water, except when the environment changes. The main examples of osmoconformers are found in the oceans, where osmolarity averages 1,000 mOsm. Most marine organisms—especially soft-bodied ones, which have no impermeable coverings to reduce osmotic forces—are also about 1,000 mOsm inter-

nally. In these animals, the ECF is very similar to seawater. Na^+ and Cl^- are critical to maintaining osmotic balance and are considered **inorganic osmolytes** as well as electrolytes. What about the ICF? Following small, short-term disturbances to the ECF, cells often do alter their internal K^+ and other ion levels to prevent swelling or shrinking. But for larger and long-term osmotic challenges, the story is quite different. Instead, ICF osmotic pressures are raised predominantly with certain organic solutes called *compatible* and *counteracting organic osmolytes*. Thus, a marine osmoconformer has:

- An ECF at the same osmotic pressure as seawater (e.g., 1,000 mOsm), dominated by NaCl .
- An ICF with the same osmotic pressure, but due to roughly 400 mOsm of universal solutes (K^+ , macromolecules, and so forth) and about 600 mOsm of organic osmolytes.

Structures of common organic osmolytes are shown in Figure 13-5, and distributions in the animal kingdom are listed in Table 13-2. Note that organic osmolytes fall into a few broad categories of chemical types:

- **Carbohydrates** such as polyols and sugars (e.g., myo-inositol in mammalian kidneys).
- **Free amino acids** such as glycine and taurine (an unusual, sulfur-based amino acid found in many marine animals and also mammalian kidney and brain).
- **Methylamine** solutes. A common example in marine animals is TMAO (**trimethylamine oxide**). Whether you know it or not, you are probably quite familiar with this compound: Its breakdown is the primary cause of “fishy” smell in many marine animals. On the animal's death, bacteria convert TMAO into a volatile gas, *TMA (trimethylamine)*, which has a strong odor of rotten fish; and minor amounts of TMA are present in live animals. Indeed, the marine food industry monitors TMA in fish flesh as an indicator of spoilage.
- **Urea (and other nitrogenous wastes)**. As we noted in Chapter 12, urea is the major organic osmolytes of Chondrichthyes (p. 572). Mammalian kidneys also concentrate it for excretion and may use it as an osmolyte to help the concentrating mechanism (p. 603).
- **Methylsulfonium** solutes. The main example is DMSP (dimethylsulfoniopropionate), a major osmolyte in many marine algae and also found in some marine animals such as corals (Cnidaria) with symbiotic unicellular algae. DMSP is also familiar to most people who have been to an ocean beach: Its breakdown product is a gas DMS (dimethyl sulfide), which is the sweet sulfurous odor of decaying seaweed often called “the smell of the sea.” DMS and DMSP are also major components of the Gaia hypothesis for a homeostatic planet Earth (see *Challenges and Controversies: Can a Planet Have Physiology?* p. 14, Chapter 1).

Why do osmoconformers use these particular organic solutes as osmolytes, which cost metabolic energy, rather than the readily available inorganic ions? At first glance, it might seem that simply moving the high external NaCl of the ECF into the cell would easily eliminate osmotic imbalances. However, this does not appear feasible, for two reasons.

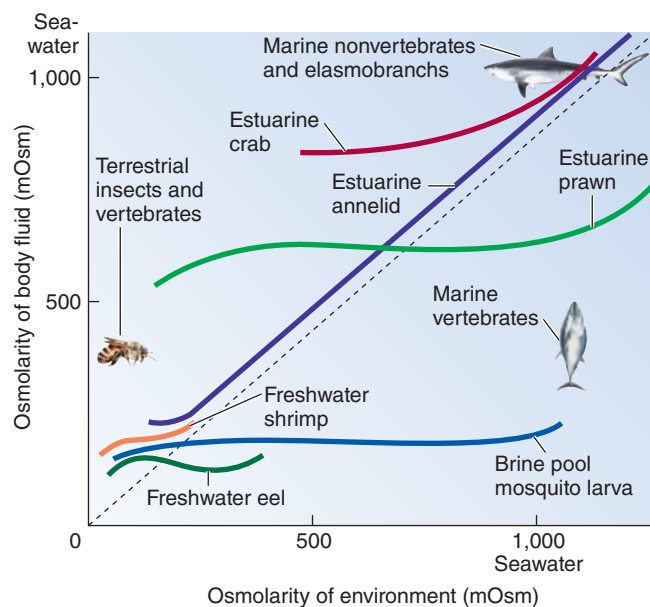

FIGURE 13-4 Osmotic adaptations of marine animals. (a) Generalized osmotic contents of three different types of adaptation in marine animals. TMAO is trimethylamine oxide. Osmoconformers use primarily free amino acids as organic osmolytes in their cells, while osmoconforming hypo-ionic regulators use primarily urea and TMAO. In contrast, hypo-osmotic hypo-ionic regulators have very low levels of organic osmolytes. (b) General categories of responses of animal body fluids to variations in external concentrations, with (c) examples.

(b) Principles

(c) Examples

- Many cells use Na^+ gradients for useful, basic functions such as coupled transport and signal conduction, whereas movement of Cl^- ions into the cell is unfavorable because of the cell's negative charge (p. 108).
- More universally, inorganic ions (especially Na^+ and Cl^-) at high concentrations can disrupt the structure and function of macromolecules, in part because of charge interactions (Figure 13-6). Were NaCl to accumulate in cells to the level of the ECF and seawater, the conformation of many proteins would become abnormal. Moreover, exposure of a variety of eukaryotic cells to elevated NaCl leads to double-strand breaks in DNA.

Of the common inorganic ions, K^+ disrupts macromolecules least, perhaps explaining why it is the universal cellular cation; but it too is disruptive at high concentrations (Figure 13-6).

Organic osmolytes differ from inorganic ions in two important ways:

- Compatibility:** Most organic osmolytes do not disturb macromolecules even at high concentrations, and so are termed **compatible solutes** (Figure 13-6). (A major exception is urea, which we discuss later.) In general, compatible solutes can be safely up-regulated or down-

regulated to keep an osmoconforming cell's osmotic pressure equal to that of the ECF. Cell volume changes are therefore small. Importantly, some compatible solutes protect cells through chemical reactions, for example, by acting as antioxidants.

- **Counteraction:** Some organic osmolytes are not simply compatible, but rather have the ability to stabilize macromolecules against denaturing forces, such as high temperature and perturbing solutes such as NaCl and urea. When stabilizing solutes are used in cells for both osmotic balance and to offset destabilizing forces, they are termed **counteracting solutes**. As you will see, the methylamine osmolytes such as TMAO (Figure 13-4) have been found to be the strongest stabilizers in many situations (Figure 13-7). Unlike compatible solutes that undergo protective reactions, counteracting solutes do not change, but rather are thought to affect the hydrogen-bonded network of water in ways that favor protein folding.

TABLE 13-2 Major Classes of Organic Osmolytes and Their Distribution among Animals

Elevated concentrations of osmolyte-type solutes for cryoprotection (freezing avoidance) are included.

Animal and Water Stress	Organic Solute
1. Polyhydric Alcohols (Polyols) and Sugars	
Insects—freezing	Glycerol, sorbitol, erythritol, sucrose
Insects—salinity	Trehalose
Bony fish (Arctic)—freezing	Glycerol
Amphibia—freezing	Glucose, glycerol
Mammals—kidney salinity	Sorbitol, myo-inositol
Mammals—brain salinity	Myo-inositol
2. Amino Acids and Amino Acid Derivatives	
Nonvertebrates—salinity	Glycine, alanine, proline, serine, taurine, etc.
Insects, aquatic—salinity	Proline, serine
Cyclostomes—salinity	Glycine, alanine, proline
Chondrichthyes—salinity	Taurine, glycine, β -alanine
Osteichthyes—salinity	Taurine, myo-inositol
Amphibians—salinity	Various α -amino acids
Mammal kidney, brain—salinity	Taurine, glutamine
Bird erythrocytes—salinity	Taurine
3. Methylamine Compounds	
Nonvertebrates—salinity	Glycine betaine, TMAO, proline betaine
Cyclostomes—salinity	TMAO
Chondrichthyes—salinity	TMAO, glycine betaine, sarcosine
Coelacanth—salinity	TMAO, glycine betaine
Amphibia, marine—salinity	Glycerophosphorylcholine (GPC)
Mammal kidney, brain—salinity	GPC, glycine betaine
4. Methylsulfonium Compound	
Cnidaria—salinity	Dimethylsulfoniopropionate (DMSP)
5. Urea (and Other Nitrogenous Wastes)	
Gastropods, terrestrial—estivation	Urea, uric acid, guanine
Chondrichthyes—salinity	Urea with methylamines
Coelacanth—salinity	Urea with methylamines
Lungfish—estivation	Urea only?
Amphibians, marine—salinity	Urea with methylamines and amino acids
Amphibians, terrestrial—estivation; hibernation	Urea with methylamines and amino acids
Mammal kidney—salinity	Urea with methylamines

Organic osmotic effectors in cartilaginous fishes. In R. Gilles & M. Gilles-Ballien, eds., *Transport Processes, Iono- and Osmoregulation*. Berlin: Springer.

The use of organic osmolytes is widespread in nature and not just in marine organisms. Organisms subjected to freezing, for example, often use them for both cell volume maintenance and lowering freezing points (see Chapter 15). Mammalian kidney cells use them to osmoconform to the

high osmotic pressure in the kidney medulla and to counteract the harmful effects of urea, a major waste product (see Chapter 12, *Molecular Biology and Genomics: Surviving Salt and Urea*, p. 606).

All marine osmoconformers use organic osmolytes but are not alike in terms of their use of these solutes. Rather, they fall into two broad subcategories: strict osmoconformers and hypo-ionic osmoconformers (Figure 13-4a).

Strict osmoconformers include most marine nonvertebrates and hagfish

As we have noted, most osmoconformers have ECF compositions that closely resemble seawater (Figure 13-4a, ECF), except for lower concentrations of certain solutes such as magnesium (which inhibits transmission at the neuromuscular junction) and ions adjusted for buoyancy (see *A Closer Look at Adaptation: Life at the Top*, p. 622). However, their cells are often dominated by organic osmolytes (Figure 13-4a, ICF). Most marine nonvertebrates fall into this category. Typically, their cells accumulate free amino acids such as glycine and taurine and methylamines such as glycine betaine (trimethylglycine) (Table 13-2). While most vertebrates are either hypo-ionic osmoconformers or osmoregulators (as you will see), hagfish (jawless fishes) are the exception. As osmoconformers, hagfish rely primarily on NaCl to maintain ECF osmotic pressure, with amino acids and methylamines as osmolytes in the ICF.

What happens if an osmoconformer faces a change in the osmotic pressure of the outside medium? Two distinct responses are seen: *stenohalinity* and *euryhalinity*.

Stenohalinity Some pure osmoconformers have a limited tolerance to changes in salinity and are termed **stenohaline**. Stenohaline animals typically die if exposed to significant changes in external salinity. Their cells swell or shrink from osmosis as the ECF osmotic state changes because they cannot regulate their osmolytes to compensate. To survive, their primary strategy is *avoidance* (p. 13). Most marine Cnidarians (such as jellies, corals, and sea anemones) and all echinoderms (such as seastars, sea urchins, and sea cucumbers) are examples of animals restricted to life within a narrow range of salinity, and they avoid disturbances by remaining in the ocean (however, if their larvae are swept by currents into a low-salinity environment, they will likely die). Indeed, to our knowledge no echinoderm has managed to adapt to freshwater, whereas some Cnidarians (such as hydra) have. Hagfish are also stenohaline; because they live primarily in deep water, they probably never face changing salinities.

Euryhalinity In contrast, some osmoconformers are relatively tolerant of changes in the salinity of the surrounding medium and can survive substantial dilution or concentration of their ECFs; these animals are termed **euryhaline**. While many aquatic habitats from freshwater to brine are relatively stable in salinity, some habitats can change significantly. Animals living in the intertidal zone live a particularly precarious existence. During parts of the day they are covered by seawater. However, when the tide is out they may face increased salinities be-

cause of evaporation of water from a tide pool, or evaporation directly from their bodies if the animals are on a rock face. Or they may face a marked decline in salinity because of heavy rainfall. Consider also animals in brackish estuaries, where freshwater streams and rivers mix with ocean water. In both intertidal and estuary environments, salinity and hence the osmotic pressure change with the tides, and do so unpredictably, because of variations in river flow, precipitation, and tidal height. Other organisms are euryhaline over their life cycle when migration between freshwater and marine environments is involved (as is the situation for some species of eels and salmon).

Euryhaline osmoconformers can successfully adapt to variable salinities by regulating the organic osmolytes in their cells, thereby keeping the ICF in balance with the ECF. For an example, let us consider the Eastern oyster (*Crassostrea virginica*). Some populations are resident of the estuaries bordering the east coast of North America. Oysters are not mobile: They attach themselves to river bottoms and form vast oyster beds. During high tides saltwater is forced inland such that during a 24-hour period animals anchored in this environment are alternately exposed to both freshwater and saltwater. Cell volume in these bivalves is ultimately regulated by changing the concentration of intracellular compatible amino acids in response to changes in extracellular osmotic pressure. During the transition to saline water, cellular mitochondria produce amino acids, which are then transported to the cytosol. The process is thought to be triggered by the increasing levels of cellular Na^+ . Conversely, while in brackish water these organic osmolytes are reduced to low concentrations by being transported out of the cells (Figure 13-8). Osmotic neutrality is thus maintained under both conditions, and the cells undergo limited volume changes as a result. (What occurs in freshwater exposure is discussed later.) Studies have shown that the acute response to osmotic stress involves an increase in the amino acid *alanine*, whereas chronic (several days) exposure to saltwater results in the successive replacement of alanine with *glycine* and *proline*. Physiologists do not know why the amino acids change in this way.

These estuarine oysters cannot adapt to long-term exposure to full-strength seawater. In contrast, populations of the same species on the open Atlantic coast live well in seawater. Interestingly, their tissues use methylamine *glycine betaine* and the nonprotein sulfonic amino acid *taurine* (Figure 13-5) as osmolytes. The latter can make up as much as 70% of the cytosolic amino acid pool. Whether these particular osmolytes are better suited for adaptation to full seawater than are typical amino acids remains unknown. The reasons for taurine (a derivative of the amino acid cysteine) are particularly unclear. In mammals, it serves not only an osmolyte (p. 606), but for unknown reasons, it is also essential for brain development and may be an antioxidant and modulator of Ca^{2+} . However, these roles in mammals are not fully understood (for example, taurine is a major ingredient in many sports drinks for no clear reasons), and similar roles (if any) have not been well studied in nonvertebrates.

In fact, the composition of osmolytes used by marine nonvertebrates varies, with some relying primarily on protein-building amino acids such as glycine (in sponges, for example), whereas others (such as many mollusks) use a mixture of taurine, glycine betaine, and glycine. Researchers are not certain why this might be. However, they have re-

FIGURE 13-8 Adjustments to changes in Na^+ levels in a brackish-water nonvertebrate. A reduction in external Na^+ and osmotic concentration (OC) causes a reduction in the blood (step 1), leading to osmosis of water into cells (step 2). This in turn triggers a reduction in cellular amino acid osmolytes (step 3), which enter the blood (step 4) to be broken down.

cently discovered one pattern related to the environment. Cells of shallow-water marine shrimp use mainly glycine, with small amounts of the methylamines glycine betaine and TMAO. However, in deep-sea shrimp (examined at 2,000 and 3,000 m), TMAO levels increase (and glycine levels decrease) with depth. Why might this be? We will return to this pattern later when we discuss deep-sea fish (p. 625).

Because ECF and ICF osmotic pressures vary considerably in euryhaline osmoconformers, they do not exhibit homeostasis of body fluids in the classic sense (of Bernard and Cannon) first applied to mammals. But they do exhibit the crucial homeostasis of cell volume regulation by regulating osmolytes. This form of homeostasis is called *enantiostasis* (Chapter 1).

Although evidence shows that rising cellular Na^+ levels triggers osmolyte accumulation, in most cases the "sensors" and genes involved in adapting to higher osmolarity are poorly characterized. See *Molecular Biology and Genomics: A Worm in Saltwater*, p. 624.

Hypo-ionic osmoconformers include marine chondrichthyans and coelacanth and some arthropods

The other subcategory of osmoconformation, which also involves cellular osmolytes, is termed *osmoconforming hypo-ionic regulation* (Figure 13-4a). These animals, exemplified by the chondrichthyan fishes (sharks, skates, rays, chimaeras), also have ECF and ICF osmolarities equal to or slightly higher than the environment. Thus, again they show

A Closer Look at Adaptation

Life at the Top

An important adaptation closely related to water and solute regulation is that of buoyancy. Pelagic aquatic animals—those that swim or drift above the bottom—often benefit from mechanisms that help them float. This is a problem because some biological materials—proteins, shells, and skeletons—are heavier (denser) than water. A major example of an adaptation is the gas bladder of bony fish (see Chapter 11, p. 539). Another example is found in a variety of zooplankton (animal drifters). Jellies (scyphozoan Cnidarians), for example, float with the currents and catch prey using an array of stinging tentacles extending below the main body, or bell. Jellies can stay up in the water by pulsing their bells, but many must halt this pulsing when they extend their tentacles in a cylindrical or complex trap, something like a spider's web. While “fishing” this way, it is important for the jelly to remain neutrally buoyant because any change in the configuration of the ex-

tended web reduces both the effectiveness of the web and the volume of water that it controls. Furthermore, any active swimming movements made to maintain its position in the water might alert potential prey of its presence. How then can the jelly maintain buoyancy? Measurement of concentrations of solutes found in the body fluids of the jelly provided a clue. Jellies are osmoconformers. However, examination of the ion profile in the jelly revealed some intriguing differences. In the jelly *Aurelia*, the concentration of sulfate ion (SO_4^{2-}) in the body fluids is maintained at around 16 mM, whereas in the surrounding seawater, it is approximately 29 mM. Chloride ion in seawater is 560 mM, whereas in the body fluids of *Aurelia*, the concentration is maintained at approximately 580 mM. Why then might the jelly benefit from excluding SO_4^{2-} and replacing it with Cl^- ? Consider that the molecular weight of SO_4^{2-} is a comparatively hefty 98, while Cl^- is a mere

A marine jelly, which removes SO_4^{2-} ions from its body fluids to increase buoyancy.

35. Exclusion of SO_4^{2-} coupled with replacement with Cl^- is a solution numerous marine nonvertebrates use to achieve buoyancy. Squid and larval tunicates use a similar solution as an aid to buoyancy but instead accumulate NH_4^+ at the expense of heavier cations such as Ca^{2+} , Mg^{2+} , and Na^+ . Some vertebrates may use similar strategies: The osmolytes urea and TMAO of chondrichthyan fishes are more buoyant than seawater, and unusual buoyant gelatinous layers with low ion contents have been found in some deep-sea fishes.

no tendency to lose water and may even benefit from a modest gain. However, in contrast to pure osmoconformers, they also actively regulate their extracellular fluids to have considerably lower salt concentrations than the environment. They achieve osmotic parity with seawater by producing the organic solutes *urea* and *TMAO*, found throughout their bodies in both ECF and ICF. In both fluid compartments, urea is at 300–400 mOsm, whereas TMAO is typically 40–70 mOsm in the ECF and 150–200 mOsm in the ICF. These animals are called **ureosmotic** conformers because urea is typically the dominant osmolyte. Some species are stenohaline, unable to regulate their osmolytes in the face of environmental changes. In euryhaline species such as the Nicaraguan shark that migrates from the ocean to freshwater lakes, urea and TMAO are down-regulated (to a greater extent than inorganic ions) for osmotic adjustments.

In contrast to most organic osmolytes, which are compatible with cellular macromolecules, urea at the concentrations in the fluids of these animals would be inhibitory or even fatal to most animals because of the destabilizing effects it has on protein structure and function. As you saw in Chapter 12, urea is the major nitrogenous waste of mammals, which must not be allowed to build up in the blood (think about that the next time you eat shark meat). The reasons why chondrichthyan fishes can thrive with elevated urea concentrations in their fluids is threefold:

1. **Urea resistance:** Some proteins (such as in the eye lens) in these animals have evolved structures resistant to the denaturing effects of urea.

2. **Urea requirement:** Some proteins (such as the enzyme lactate dehydrogenase, p. 55) have evolved overly stable features and require urea to “loosen” them up for proper function.
3. **Counteraction:** TMAO, when present at concentrations about half that of urea, counteracts the destabilizing effects of urea. An example is shown in Figure 13-7. Keeping a 2:1 ratio of urea to TMAO is thought to be the most common adaptation in these fishes.

A summary of body water and solutes in marine chondrichthyan fishes is shown in Figure 13-9a. Regulation of urea, TMAO, and water involves the gills, digestive tract, kidneys, and the *rectal gland*. See Chapter 12 (p. 572) for more information.

The coelacanth fish (p. 558) also uses urea and TMAO as its major organic osmolytes. Another vertebrate using this strategy of osmotic adaptation is the crab-eating frog (*Rana cancrivora*) of Southeast Asia. When this frog moves from land to brackish estuarine water, it accumulates urea in all body fluids (along with amino acids in its cells), rather than salt, to osmoconform to the environment.

Finally, a few arthropods are hypo-ionic osmoconformers. In particular, larvae of some species of *Culex* mosquitoes develop in salt ponds that have a salinity about 70% that of seawater. They regulate their hemolymph ions to stay relatively constant and, like chondrichthyan fishes, build up additional osmotic pressure with organic osmolytes in their hemolymph and cells. These osmolytes include *proline* and *trehalose*.

Molecular Biology and Genomics

A Worm in Saltwater

In the last couple of decades, a soil-dwelling nematode worm, *Caenorhabditis elegans*, has emerged as an important model animal in the study of development and genetics. Like other nematodes, every individual of this remarkable species has an exact number of cells after it reaches maturity—959 cells in this species, of which 81 cells are muscles, 302 are neurons, and so on. Thus, it is a model organism for studying how a single fertilized egg divides and differentiates into a multicellular organism. Its genome has been sequenced, and the patterns of gene regulation involved in its development are being investigated.

Physiologists are using *C. elegans* as a model animal as well. For example, Todd Lamitina, Keith Chloe, Kevin Strange, and colleagues examined this worm's ability to

adapt to salty conditions in conjunction with gene expression. They found that the worms could acclimate to 400 mM NaCl, equivalent to about 75% seawater. In doing so, they accumulate large amounts of the compatible osmolyte *glycerol*. The researchers also analyzed the worm's genetic responses to high osmolarity using RNA interference (RNAi, p. 33) to inhibit expression of 19,000 genes individually. They found 49 genes that were crucial to survival in high salt, many of which are involved in removal of damaged proteins by lysosomes and proteasomes (p. 44). This is probably important because hypertonicity leads to damaged and aggregated proteins in the cell. Inhibition of these genes, and others that regulate protein translation and folding, also leads to constant glycerol production. Their

Courtesy of Ian Chin-Sang

***C. elegans*, a nematode worm that is used as a model animal for many biological studies.**

experiments suggest that hypertonic exposure initially causes protein damage in the cell, which in some way acts as a signal to activate genes for glycerol production. As some damaged proteins are cleared out, and as glycerol replaces inorganic ions, the remaining cell proteins resume normal function. This model worm is one of the first to provide understanding of genetic mechanisms for osmotic adaptation.

check your understanding 13.2

Describe the types of osmotic challenges faced by animals.

Compare osmoconformers and osmoregulators in general terms.

What are the major types of organic osmolytes, and how are they used in marine nonvertebrates and chondrichthyan fishes?

Compare stenohaline and euryhaline animals.

13.3 Osmotic and Volume Balance: Osmoregulators

Osmoregulators have a very different approach to cell volume homeostasis. Much as a thermoregulator maintains a steady body temperature in the face of a variable environment, osmoregulators maintain a relatively steady ECF osmotic pressure regardless of osmotic changes in the external environment. Most cells are thus not exposed to volume changes and so do not need to regulate organic osmolytes.

There are two types of osmoregulators. Marine osmoregulators are usually *hypo-osmotic* (having internal osmolalities less than the environment's; see p. 78). In contrast, all freshwater organisms are *hyperosmotic* osmoregulators (having internal osmolalities greater than the environment's) by necessity because to osmoconform would mean to have virtually *no* cellular solutes, a condition clearly incompatible with life. Let's examine each of these.

Hypo-osmotic regulators include most marine vertebrates and some arthropods

Some crustaceans in salty habitats, some mosquito larvae in saline ponds and lakes, and most marine vertebrates (lampreys, bony fish, amphibians, reptiles including birds, and mammals) are hypo-osmotic osmoregulators. These vertebrates, for example, have internal ECF and cellular osmotic concentrations of 250–400 mOsm whether the environment is brackish (estuary) or higher than seawater (such as an evaporating tide pool). As a consequence of being hypo-osmotic to seawater, these animals tend to lose water and gain excess salt. Cells in these marine animals usually use only low concentrations of organic osmolyte (Figure 13-4a); for example, most bony fishes have only low TMAO concentrations.

Hypo-osmotic osmoregulators use special transport epithelia to remove excess salt

To achieve osmotic regulation, special transport epithelia (p. 561), plus an impermeable skin, are generally needed. In Chapter 12, we discussed the contributions of excretory organs. Let's look at how their functions integrate with other systems in marine fish (Figure 13-9b). To replace lost water, they must drink seawater. The digestive tract epithelium can restrict the influx of some ions, but NaCl must be imported for water to follow (see Figure 12-3b; recall that no ATPase pumps actively move water molecules alone). Interestingly, Cl^- is imported by a $\text{Cl}^-/\text{HCO}_3^-$ antiporter, which also has the role of stopping uptake of excess Ca^{2+} : The HCO_3^- transported into the gut reacts with Ca^{2+} imbibed in seawater to form CaCO_3 precipitates, which are then excreted. Scientists now think that this process is so prolific that it is responsible for 15% or more of the marine carbon cycle!

The gut's import process creates an excess of salt in the blood. The gills then use specialized epithelial **chloride cells** (Figure 13-10) to actively transport NaCl outward with little simultaneous water movement. Unlike the basic salt-transport model of Figure 12-3a (p. 562), fish (as well as crab) gills use *NKCC* symporters that move 1 Na⁺, 1 K⁺, and 2 Cl⁻ ions (Figure 13-10); but the principles are the same as in Figure 12-3.

Removal of excess salt from the blood requires other organs in marine air breathers. Marine birds and reptiles use special *salt glands* (Figure 12-11, p. 576). Marine mammals have efficient *kidneys* with long nephron loops for the same purpose. Water and solute movements in these marine vertebrates are summarized in Figure 13-9c and d.

Hypo-osmotic regulation occurs in some arthropods in briny habitats. For example, the brine shrimp *Artemia* (see *A Closer Look at Adaptation: The Sweet Solution to Desiccation*, p. 614) can live in desert brine lakes in the Great Basin of the United States. In broad terms, their adaptations are similar to fishes, although some details are different: These crustaceans must drink the briny water (as much as 8% of their body weight per day) to gain needed water and unwanted ions, retain water with a highly impermeable exoskeleton, and then excrete the excess ions with special salt glands on their gills. Larvae of some *Aedes* mosquito species are also strong hypo-osmotic regulators, developing in brine ponds up to three times more saline than the ocean, while maintaining a lower and constant internal ion level. These larvae have evolved an extra segment on their rectums, which actively transport ions out of the body (see the mechanisms of insect excretion in Chapter 12, p. 566).

Some osmoregulating vertebrates have high levels of organic osmolytes

Some exceptions to the basic osmotic pattern of osmoregulating vertebrates have been found.

Polar and Deep-Sea Fishes Some marine fishes in the Arctic accumulate the compatible osmolyte *glycerol* to the point that they become isosmotic with seawater at 1,000 mOsm! Glycerol functions as an antifreeze (see Chapter 15, p. 739). Some polar marine fishes and in the deep sea have high TMAO content in their cells and high NaCl in their blood, with osmotic concentrations at 600 mOsm or more. These fish are still hypo-osmotic to seawater, but with higher concentrations than typical bony fish. TMAO accumulation in polar fishes is not consistent: One species may have high levels, whereas a related species may not. However, the pattern is clearer for the deep sea: *TMAO content in deep-sea fish increases with depth* in the ocean. This is the same pattern seen in osmoconforming deep-sea shrimp (p. 621). Why do osmoregulating fish need to retain such large amounts of TMAO? Possibly reducing the water gradient between the internal and environmental fluids lowers the energetic costs of hypo-osmoregulation in these environments, where cold temperatures and (in the deep sea) low food supply may make energy more limiting. Alternatively, recall that TMAO is a *counteracting* osmolyte that can stabilize proteins against urea in Chondrichthyes (p. 622). Experiments in the

FIGURE 13-10 Model for ion transport mechanisms in seawater teleost chloride cell. The process starts with active transport of Na⁺ and K⁺ ("pump" indicated by "ATP"). The resulting Na⁺ electrochemical gradient is used by an *NKCC* cotransporter (shown as the small blue membrane protein) to move one Na⁺, one K⁺, and two Cl⁻ ions into the cell. The resulting high electrochemical gradient for Cl⁻ (primarily due to the cell's negative charge) allows those ions to exit into seawater via a CFTR channel. This creates a negative charge that helps draw Na⁺ across the tight junctions between cells (paracellular pathway, top green arrow) as well as some K⁺ from the cell.

laboratory have shown that TMAO can also counteract the effects of hydrostatic pressure, which tends to inhibit folding and activity of proteins by trapping a dense layer of water molecules around them. Moreover, in Chondrichthyes, not only does the stabilizer TMAO increase with depth, but the destabilizer urea decreases with depth.

Estivating Animals Some transitional vertebrates (living in water and on land), although they are ion regulators, use organic osmolytes in dormancy. Lungfish are found in Africa, South America, and Australia; the former two enter a state of **estivation** (summer hibernation) when their habitats become dry. They burrow and seal themselves in a mucus cocoon and become largely dormant. During estivation, they build up large amounts of urea (reportedly up to 400 mM), presumably as a less toxic alternative to ammonia for nitrogen waste storage during estivation (Table 13-2). By elevating osmotic pressure, the urea also helps retain water and may draw in water from the soil by osmosis. Similarly, some amphibians (such as the American spadefoot toad and wood frog) and Australian desert frogs estivate during dry periods and accumulate urea. (Some terrestrial snails also do the same.) These estivators accumulate only small amounts of counteracting osmolytes, perhaps because the counteraction is unnecessary: The inhibitory effects of urea may actually be useful in this situation where suppression of metabolism is important for survival. For example, Timothy Muir, Jon Costanzo, and Richard Lee found that addition of urea to organs isolated from three species of urea-using estivators markedly inhibited metabolism.

unanswered Questions | Why are most marine vertebrates hypo-osmotic?

If you think about it, the osmoconforming strategy makes good physiological sense, but hypo-osmotic regulation does not. Why should a marine bony fish, for example, have to spend a large percentage of its metabolic energy to replace osmotically lost water and remove excess salt from its body, when it might simply accumulate NaCl in its ECF and compatible osmolytes in its ICF? We do not know, though several hypotheses have been put forth. A recent one by Hans Ditrich is based on osmoregulatory features of developing vertebrate kidneys (see p. 565). Ditrich (see Suggested Readings) concludes that early vertebrates were osmoconformers in estuaries at about 300–350 mOsm, the osmotic pressure retained in modern osmoregulating vertebrates. From there, two different paths into the ocean were taken. Hagfish and chondrichthyans stayed as osmoconformers at higher salinity by evolving mechanisms to regulate osmolytes, while the ancestors of lampreys and bony fishes evolved homeostatic osmoregulation to maintain 300–400 mOsm internally even in full seawater. Unless definitive fossil evidence is found, we may never know if this hypothesis is correct. <<

Hyperosmotic regulation is found in all freshwater animals

Across the planet, fewer species of life reside in freshwater than in the oceans. This may indicate that life did not evolve first in freshwater, and it also indicates that this habitat is not easily adapted to. The primary reason is osmotic stress. In effect, organisms in freshwater are constantly taking in unwanted water that they must somehow “bale” out. In addition, valuable solutes are constantly lost through gills, feces, and urine. Gills are particularly problematic because of their comparatively large surface areas and the necessity of minimizing protective coverings to maximize gas exchange (see p. 499). What mechanisms have evolved to enable an animal to survive in a low salinity or freshwater environment? A summary of water and solute movements in freshwater fish is shown in Figure 13-11; details for these and some nonvertebrates are as follows:

- **Active uptake of ions:** To combat the loss of salts from its body fluids, freshwater animals must expend energy (ATP) in transport epithelia to move ions from the environment into the body. Crustacea may have feathery accessory gills in the form of modified *epipodites* (outer branch of some crustacean legs) that do this. Fish gills have *chloride cells* (different from those of marine fishes) that take up Cl^- and Ca^{2+} and *pavement cells* that take up Na^+ via an electrical potential generated by H^+ V-ATPases (p. 85). Extrusion of H^+ makes the cell more negative, which increases the electrical gradient for Na^+ to enter the cell via sodium channels.

For freshwater frogs and worms, the skin is an important site of ion uptake. Frog skin, for example, also uses H^+ V-ATPases in the same way that fish gills do. Indeed, it was August Krogh (p. 3) over 70 years ago who

first showed that frogs can take up salt from water with NaCl as low as 0.01 millimolar!

- **Hypotonic fluid excretion:** To combat excess water gained from osmosis and eating, most freshwater animals remove it by excreting a voluminous fluid that is hypo-osmotic to body fluids. This requires (1) transport epithelia that secrete ions followed by water into an excretory space, (2) other epithelia to recover the ions while leaving the water behind, and (3) excretion of the subsequent hypo-osmotic fluid. In freshwater hydra (Cnidarians), cells lining the coelenteron (primitive gut) are thought to do this, beginning with secretion into special intercellular vacuoles. In more complex animals, kidneys provide these functions. To produce diuresis, freshwater fish tend to have more *glomeruli* (p. 571), the filtering structures of renal nephrons, than do marine fish. Conversely, freshwater Prussian carp acclimated to 40% seawater lost most of their glomeruli.
- **Lower internal osmolarities:** To help reduce water influx, solute concentrations in freshwater animals are maintained at lower levels in comparison to their marine relatives. For example, freshwater teleost fish have internal osmolalities in the range of 250–300 mOsm, slightly lower than the 300–400 mOsm of most marine species. With this strategy the animal expends less energy to maintain homeostasis. Similarly, most freshwater crustaceans have osmolalities of 300–500 mOsm, in contrast to about 1,000 mOsm in their marine counterparts. The difference in freshwater animals lies primarily in less NaCl in the ECF and little or no amino acid osmolytes in the ICF.
- **Low permeability of integument:** To reduce efflux of solutes and influx of water in freshwater, many animals have reduced permeability of the outer body surface. For example, freshwater decapod crustaceans (crabs, crayfish) are approximately 10-fold less permeable to Na^+ and Cl^- than their marine counterparts. Problems arise in those species (such as mussels that open their shells to feed) that expose sizable portions of their unprotected body surfaces to freshwater. Uncontrolled water entry and loss of valuable ions are the price these animals must pay. Amazingly, solute concentrations in the freshwater mussel *Anodonta* are reported to be only about 66 mOsm, probably the lowest osmotic concentration recorded in a living organism and deserving of further study.

Some animals such as salmon alternate between modes of osmotic adaptation

Osmoconforming is the most common adaptation in the oceans, but it has a limit: It cannot be used to adapt fully to freshwater (although some osmoconformers such as estuarine bivalves may avoid damage by “clamming up,” that is, avoiding the problem temporarily). Thus, euryhaline animals that adapt to both habitats must have at least some osmoregulatory capacity. Some of the best animals at doing so are killifish in tide pools. Killifish were noted in Chapter 1 (p. 16) to illustrate the use of both physiological and behavioral processes to cope with salinity changes. Fishes that spawn in either fresh or seawater and migrate to the other habitat to grow are also highly adaptable. Here we look at salmon. These fish are particularly interesting because, as

FIGURE 13-11 Diagram of major osmotic gains, losses, regulation, and body fluid concentration in a freshwater bony fish.

Source: From C. E. Bond, (1996). *Biology of Fishes*, 2nd ed. Belmont, CA: Brooks/Cole Thomson Learning, p. 405, Figure 24-4.

excellent osmoregulators, they are hypo-osmotic in the oceans but hyperosmotic in rivers. The changes these fish make are classic examples of *acclimatization* regulation (Chapter 1) coupled with an *anticipation* mechanism that reduces delays in adaptation. When they hatch in freshwater and begin migrating to the sea, *growth hormone*, which is controlling their general maturation, and the stress hormone *cortisol* (see Chapter 7) begin to alter the gill epithelial cells even before seawater exposure (an anticipation mechanism). As they enter estuaries, increased internal Na^+ triggers more cortisol production. Together, the hormones trigger the growth of the seawater-type chloride cells, reversing the direction of ion transport, as well as increasing Na^+/K^+ ATPase activity for removing excess salt from the blood.

After maturing for a few years at sea, the fish are ready to return to their home streams to spawn, so the gills must be altered yet again with freshwater chloride cells. The hormone *prolactin* (p. 288) has been found to induce this change in salmon. In freshwater fishes in general, prolactin maintains proper ion and water permeabilities in the epithelial cells of osmoregulatory organs, including the gill, intestine, kidney, and bladder. Hypophysectomy (removal of the pituitary gland) of freshwater fish results in a loss of ions and eventually death unless prolactin is administered to the surgically manipulated animals.

Some animals switch between osmoconforming and osmoregulating (e.g., crab in Figure 13-4c). An example is the green shore crab (*Carcinus maenas*); it is native to the Atlantic coast of Western Europe, but due to in part to its euryhaline adaptations, it has invaded bays and estuaries worldwide (probably by its larvae being carried in ballast water of ships) and is having disruptive effects on ecosystems. This animal and other euryhaline crabs are osmoconformers at high salinities but osmoregulate at low salinities. To do so, they up-regulate transcription of Na^+/K^+ ATPase in their gills to increase salt uptake from the environment. Using DNA microarrays (p. 35), David Towle and colleagues found that reduced salinity alters transcription of a variety of other genes, including an increase in mitochondrial genes involved in ATP production. This may be necessary to power the increasing activity of Na^+/K^+ ATPases as environmental NaCl declines.

Many terrestrial animals osmoregulate in the face of both low water and salt availability

The problems of osmotic balance are different on land compared to water. For animals in the ocean, salt is in excess, whereas water is limiting; in freshwater, the problems are

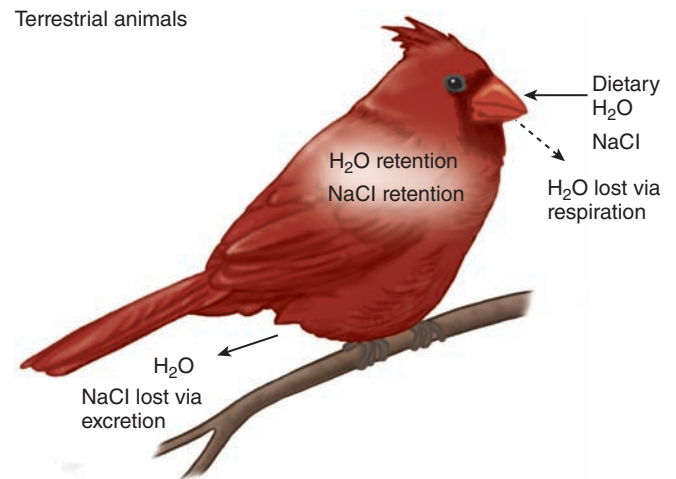

FIGURE 13-12 Diagram of major osmotic gains, losses, regulation, and body fluid concentration in a terrestrial vertebrate.

Source: Modified from Y. Takei, (2000). Comparative physiology of body fluid regulation in vertebrates with special reference to thirst regulation, *Japanese Journal of Physiology* 50:171–186.

reversed. But on land, both water and salt may limiting factors. Losses of water and ions occur via evaporation and through the excretory and digestive systems, and in most cases, water and solutes must be obtained via dietary intake (Figure 13-12). Terrestrial animals are by necessity osmoregulators to some extent because the environment (air) has no solutes (exceptions are animals such as earthworms in the soil, but because they live only in moist conditions they are effectively aquatic). Excretory and digestive systems are also the most common sites of regulation (as you saw in Chapter 12), but other mechanisms come into play. In addition to physiological mechanisms, behaviors as effectors are also important. For example, most amphibians venturing onto land seek moist, cool habitats.

The most successful fully terrestrial animals are arthropods and vertebrates. Reflecting their ancestry, terrestrial vertebrates typically have osmotic concentrations at about 280–350 mOsm, with the ECF dominated by NaCl. Insect fluids can have even higher osmotic concentrations in some species, in part because of high concentrations of amino acids in the hemolymph; and whereas the dominant ECF cation is usually Na^+ , some herbivorous insects (such as some Coleoptera) have higher K^+ than Na^+ , although

individual neurons are loosely wrapped in a neural sheath that maintains elevated Na^+ concentrations (pp. 126–127).

Although water is typically restored by oral intake, interesting exceptions are found in certain insects and arachnids, which can extract water out of humid air! The house dust mite *Dermatophagoides*, for example, uses its salivary glands to secrete a fluid droplet that is so concentrated with inorganic and organic osmolytes that it can draw water vapor into it. A beetle (*Onymacris*) in the coastal desert of Namibia has a bumpy cuticle, with hydrophobic troughs and hydrophilic peaks that can attract water molecules from fog that forms from the ocean. Other arthropods use the excretory systems; for example, the rat flea *Xenopsylla* draws moist air into its rectum and shows a net water gain. How it accomplishes this is uncertain.

As for most physiological processes, research on mammals has provided the most details of volume, solute, and water regulation, including hormonal control. As you will see, osmotic regulation is also closely tied to volume regulation. Therefore, we now turn to these animals to illustrate fluid homeostasis in detail.

check your understanding 13.3

Compare the osmoregulatory problems and adaptations of a hypo-osmotic shallow marine fish, a hyperosmotic freshwater fish, a deep-sea fish, a salmon, and a terrestrial vertebrate.

13.4 Osmotic and Volume Balance in Mammals

Recall that cells in osmoregulators usually do not experience any net gain (swelling) or loss (shrinking) of volume, because the concentration of nonpenetrating solutes in the ECF is carefully regulated. In mammals, this is done primarily by the kidneys, which work to maintain the same osmolarity (about 300 mOsm) as found within most body cells.

Fluid balance is maintained by regulating ECF volume and osmolarity

Plasma is the only fluid that can be directly acted on to control its volume and composition. However, as we noted earlier, changes in the volume and composition of the plasma also directly change the interstitial fluid bathing the cells. Thus, any control mechanism that operates on the plasma in effect regulates almost the entire ECF. The ICF in turn is influenced by changes in the ECF to the extent permitted by the permeability of membranes surrounding the cells.

Two factors are regulated to maintain **fluid balance** in the mammalian body: ECF volume and ECF osmolarity. Although regulation of these two factors is closely interrelated, both being dependent on the relative NaCl and H_2O load in the body, the reasons they are closely controlled differ significantly:

- **ECF osmolarity** must be closely regulated to prevent swelling or shrinking of the cells, as discussed. Maintenance of both water and salt balance are important for this process.

- **ECF volume** must be closely regulated to help maintain **blood pressure**. Maintenance of both water and salt balance is important for this regulation, with salt balance being more important in the long term.

Let's examine each of these factors in more detail.

Control of ECF osmolarity prevents changes in ICF volume from hyper- or hypotonicity

As you have seen, normally the osmolarities of the ECF and ICF are the same because the total concentration of K^+ and other effectively nonpenetrating solutes inside the cells is equal to the total concentration of Na^+ and other effectively nonpenetrating solutes in the ECF. It is the number (not the nature) of the particles per volume that determines the fluid's osmolarity.

However, any circumstance that results in a loss or gain of free H_2O that is not accompanied by comparable solute deficit or excess leads to changes in ECF osmolarity. If there is a deficit of free H_2O in the ECF, the solutes become too concentrated, making the osmolarity abnormally high (that is, *hypertonic*; p. 80). If there is excess free H_2O in the ECF, the solutes become too dilute, so the osmolarity becomes abnormally low (that is, *hypotonic*). When the ECF osmolarity changes with respect to the ICF osmolarity, osmosis takes place, with H_2O either leaving or entering the cells. The osmolarity of the ECF must therefore be regulated to prevent these undesirable shifts of H_2O into or out of the cells.

First we examine the causes of hypertonic or hypotonic ECF. Then we consider how water balance and subsequently ECF osmolarity are normally maintained to minimize detrimental changes in cell volume. Although this section focuses on mammals, we note a few examples of other animals for comparison.

ECF Hypertonicity Hypertonicity of the ECF is usually associated with dehydration, or a negative free H_2O balance. Dehydration with accompanying hypertonicity can be brought about in several ways:

1. *Insufficient H_2O intake*, such as might occur during a drought or in a desert habitat.
2. *Excessive H_2O loss*, such as might occur in a mammal from heavy sweating or panting, vomiting, diarrhea, or diabetes (even though both H_2O and solutes can be lost during these conditions, relatively more H_2O is usually lost, so the remaining solutes become more concentrated). Also, an air-breathing animal exercising heavily in cold, dry air can suffer excessive water loss, as we discuss later. Finally, a stenohaline freshwater animal exposed to saltwater would also lose too much water and gain too much salt.
3. *Drinking hypertonic saline water*, as occurs in marine mammals, reptiles, and birds. Here, although water is entering the body, the salts are excessively high and may dehydrate cells.
4. *Alcohol* inhibits vasopressin secretion and can lead to ECF hypertonicity by promoting excessive free H_2O excretion.

On rare occasions, the ECF becomes hypertonic in the absence of dehydration because of the abnormal accumulation

of osmotically active solutes that do not normally contribute significantly to ECF osmotic activity. This occurs, for example, with the high blood glucose in diabetes and with the high blood urea levels in uremia (from kidney failure; see p. 607).

Whenever the ECF compartment becomes hypertonic, H_2O moves out of the cells by osmosis, and so the cells shrink. Of particular concern is the fact that considerable shrinking of neurons causes disturbances in brain function, which can bring about convulsions or coma in more severe hypertonic conditions.

Although shrinkage does occur in such situations, many cells exhibit a process called **regulatory volume increase (RVI)** to compensate. In osmoregulators such as mammals, RVI occurs by transport of ions (Na^+ , K^+ , Cl^- serving as inorganic osmolytes) into the cell to draw water in osmotically, but there are limits to this strategy because those ions cannot be allowed to build up to levels that inhibit proteins and disrupt membrane potential. Thus, either shrinkage cannot be stopped beyond a certain point, or cells must act like euryhaline osmoconformers and import or synthesize cellular organic osmolytes. These compatible solutes can be accumulated to levels that prevent shrinkage altogether.

Interestingly, a few types of mammalian cells can use organic osmolytes for RVI. In Chapter 12 we described how cells of the inner kidney accumulate organic osmolytes to prevent shrinkage (see *Molecular Biology and Genomics: Surviving Salt and Urea*, p. 606). To some extent neurons, glial cells, and cardiac cells act similarly, accumulating compatible organic osmolytes such as *taurine* to stop shrinkage in severe dehydration. But these cells can adapt to only modest changes in osmolarity. (It is important that attempts to reduce the osmolarity of severely dehydrated animals including humans be done *slowly*. If it is done rapidly, the neurons do not have time to excrete their organic osmolytes and can suffer damage from cell swelling.)

Some mammals can tolerate whole-body dehydration and hypertonicity to an extraordinary degree. One is the camel (such as the dromedary), which can survive up to two weeks without drinking and tolerate about 30% loss of body water (compared to most mammals, which do not survive more than about 15% loss). To survive severe dehydration, the camel slows its metabolism, maintains plasma volume at the expense of other fluid compartments (which shrink), and extracts most of the water from feces in the colon and much of the water from the filtrate in the kidneys. On finding water after prolonged dehydration, the camel can also restore water balance via rapid drinking in a few minutes, a process that would also be lethal to other mammals because of the osmotic shock to cells. Camels survive because water is very slowly absorbed from their gut and because their red blood cells are more tolerant of swelling than are those of other mammals. These cells are oval rather than disc shaped as in most mammals (p. 391), have a hemoglobin that holds onto more water molecules than do other mammalian hemoglobins, and have membranes that have densely packed proteins that seem to form a “skeleton” to prevent rupture.

ECF Hypotonicity Hypotonicity of the ECF is usually associated with overhydration; that is, excess free H_2O is present, making the ECF is more dilute than normal. Because it is generally $NaCl$ that is too low, this condition may be

called **hyponatremia** (“low sodium”). Usually, any surplus free H_2O is promptly excreted in the urine, so hypotonicity/hyponatremia is rare. However, hypotonicity can arise in two ways:

1. *Intake of relatively more H_2O than solutes* more rapidly than the kidneys can compensate. This would occur if, for example, a stenohaline marine fish were exposed to freshwater (and possibly if a euryhaline fish is exposed too quickly). Also, many human athletes have suffered (and some have died) from drinking too much water without sufficient salt intake after heavy sweating.
2. *Retention of excess H_2O without solute* as a result of inappropriate secretion of vasopressin. Vasopressin in mammals (discussed in Chapter 12, p. 598, and below) is normally secreted in response to an H_2O deficit, which is relieved by increasing H_2O reabsorption in the kidney. However, vasopressin secretion can be increased in response to pain, acute infections, trauma, and other stressful situations, even when there is no H_2O deficit. The resultant H_2O retention may be appropriate in anticipation of potential blood loss in the stressful situation: The extra retained H_2O could minimize the effect a loss of blood volume would have on blood pressure. However, if there is no such injury, excess retention can occur.

Whichever way it is brought about, a hypotonic ECF causes cells to swell as H_2O moves into them osmotically. Like shrinking, pronounced swelling of brain cells also leads to brain dysfunction. Symptoms include irritability, lethargy, vomiting, drowsiness, and in severe cases, convulsions, coma, and death. Nonneural symptoms of overhydration include weakness caused by the swelling of muscle cells and circulatory disturbances, including hypertension and edema, caused by expansion of the plasma volume.

As with shrinkage, swelling in many cells triggers a compensating process called **regulatory volume decrease (RVD)**. In osmoregulators, RVD occurs through the transport of osmolytes (KCl for most cells and organic osmolytes for those cells that use them) out of the cell, followed by water. However, once again there are limits to this strategy because the cell must have a certain level of ions for macro-molecular functions and membrane potential.

Isotonic Fluid Gain or Loss Let's contrast the situations of hypertonicity and hypotonicity with what happens as a result of isotonic fluid gain or loss. The major problem created by such changes is a *blood volume* disturbance, which we consider shortly. Isotonic gains are a rare occurrence in the animal world. Examples include drinking of brackish water at about 300 mOsm, or the therapeutic intravenous administration of an isotonic solution. When the isotonic fluid is injected into the ECF compartment, the ECF volume increases, but the concentration of ECF solutes remains unchanged (isotonic). The ECF compartment has increased in volume without causing a shift of H_2O into the cells.

Isotonic loss is more common because it occurs in hemorrhage. The loss is confined to the ECF with no corresponding loss of fluid from the ICF because there is no osmotic gradient to draw H_2O out of the cells. Of course, many other mechanisms come into play to counteract the loss of blood, but the ICF compartment is not directly affected by the loss.

Control of ECF volume is important in the long-term regulation of blood pressure

Now let’s turn to the second major component of body fluid homeostasis—the ECF volume. A reduction in ECF volume lowers arterial blood pressure by decreasing plasma volume. Conversely, a rise in ECF volume increases the arterial blood pressure by expanding the plasma volume. It is not volume itself is but rather its effect on blood pressure that is sensed by regulatory mechanisms. Two compensatory measures come into play to transiently adjust blood pressure until the ECF volume can be restored to normal:

1. *Baroreceptor reflex* mechanisms alter both cardiac output and total peripheral resistance through autonomic nervous system effects on the heart and blood vessels (see p. 449). These rapid cardiovascular responses minimize the effect that any deviation in circulating volume has on blood pressure.
2. *Fluid shifts* occur temporarily and automatically between the plasma and interstitial fluid. A reduction in plasma volume is partially compensated for by a shift of fluid out of the interstitial compartment into the blood vessels, expanding the circulating plasma volume at the expense of the interstitial compartment. Conversely, when plasma volume is too large, much of the excess fluid is shifted into the interstitial compartment. These shifts occur immediately and automatically as a result of changes in the balance of hydrostatic and osmotic forces acting across the capillary walls that arise when plasma volume deviates from normal (see p. 443).

These two measures provide temporary relief to help keep blood pressure fairly constant, but they are not long-term solutions. Furthermore, these short-term compensatory measures have a limited ability to minimize a change in blood pressure. If the plasma volume is too low, blood pressure also remains too low no matter how vigorous the pump action of the heart, how constricted the resistance vessels, or what proportion of interstitial fluid shifts into the blood vessels. Conversely, if the plasma volume is greatly over-expanded, blood pressure cannot be restored to normal even with maximum dilation of the resistance vessels and other short-term measures.

Thus, for disturbances to both ECF osmolarity and volume, long-term regulatory mechanisms are important. These involve regulation of both water and solutes, mainly NaCl. Let’s now look at those mechanisms, starting with water.

Water balance depends on input from food, drink, and metabolism, and output via urine, feces, and insensible and sensible cutaneous and respiratory losses

Control of H₂O balance is crucial for maintaining ECF osmolarity and also affects ECF volume. To maintain a stable H₂O balance, H₂O input must equal H₂O output (the balance concept). Table 13-3 shows data for a human and a kangaroo rat as examples. Let’s first examine input, which has several routes:

1. *Food consumption*: Perhaps surprisingly, a significant amount of water is obtained in most animals just from

TABLE 13-3 Typical Daily Water Balance in Two Mammals

1. Human			
WATER INPUT		WATER OUTPUT	
Avenue	Quantity (mL/day)	Avenue	Quantity (mL/day)
Fluid intake	1,250	Insensible loss (from lungs and non-sweating skin)	900
H ₂ O in food intake	1,000		
Metabolically produced H ₂ O	350	Sweat	100
		Feces	100
		Urine	1,500
Total input	2,600	Total output	2,600

2. Kangaroo Rat (in Laboratory Fed on Dry Barley; 25°C, 33% Relative Humidity)*			
Avenue	Quantity (g H ₂ O/100 g barley)	Avenue	Quantity (mL/day)
Fluid intake	0	Insensible loss	43.9
H ₂ O in food intake	6	Feces	2.6
Metabolically produced H ₂ O	54	Urine	13.5
Total input	60	Total output	60

*Source: B. Schmidt-Nielsen & K. Schmidt-Nielsen. (1951). A complete account of the water metabolism in kangaroo rats and an experimental verification. *Journal of Cellular and Comparative Physiology* 38:165–181.

eating solid food. Recall that muscles consist of about 75% H₂O; meat is therefore 75% H₂O because it is animal muscle. Likewise, fruits and vegetables consist of 60 to 90% H₂O. Eaters of dry food like seeds (such as some birds and rodents), in contrast, receive much less water this way.

2. *Drinking* external water: This is triggered by thirst sensations in the hypothalamus.
3. *Metabolically produced H₂O*: Recall that aerobic metabolism converts food and O₂ into energy stores, producing CO₂ and H₂O in the process. Amazingly, some desert mammals can survive primarily on this water source (see Chapter 12, p. 602, and Table 13-3).

As you saw earlier, water vapor in humid air may be taken up by some insects and arachnids. But there is no evidence that mammals can do this.

On the output side of the H₂O balance tally, there are several pathways of loss:

1. *Urine excretion*. This is the most important output mechanism in most mammals.

2. **Insensible cutaneous and respiratory loss.** During the process of respiration, inspired air becomes saturated with H_2O within the airways. This H_2O is lost when the moistened air is subsequently expired. This **insensible** (that is, unregulated) loss can be recognized on cold days, when the H_2O vapor condenses (because cold air cannot hold as much vapor as warm body air) and exhaled air is “visible.” Cold dry air is particularly dehydrating. (Birds and mammals have folds in their nasal passages to reduce water and heat loss; see Chapter 15, p. 745.) The other insensible loss is the continual loss of H_2O from ordinary skin even in the absence of sweating. Water molecules can move through the cells of ordinary skin and evaporate. Mammalian and avian skin is fairly waterproof because of its keratinized exterior layer, which protects against a great loss of H_2O by this avenue (although some species use cutaneous evaporation in thermoregulation; see p. 747). And some mammals, such as marine mammals with their blubber layers, have skins that are effectively fully waterproof. Reptile skin is also quite waterproof.
3. **Sensible cutaneous and respiratory loss.** H_2O may be lost through sweating and panting, primarily for the purpose of thermoregulation. Regulated loss of water this way (called **sensible** loss) can vary substantially, of course, depending on the environmental temperature and humidity and the degree of physical activity and stress levels.
4. **Feces loss.** This is normally a minor pathway. During the process of fecal formation in the large intestine, most of the H_2O is absorbed out of the tract lumen into the blood (p. 703). Additional losses of H_2O can occur from the tract through vomiting or diarrhea.

Water balance is regulated primarily by the kidneys and thirst

Of the many sources of H_2O input and output, only two are regulated significantly to maintain H_2O balance:

1. On the intake side, *thirst* influences the amount of fluid ingested.
2. On the output side, the *kidneys* can adjust the amount of urine formed. This is the more important mechanism in mammals.

Some of the other factors are regulated but not for maintaining H_2O balance. Food intake is regulated to maintain energy balance, whereas control of sweating and panting is important in maintaining body temperature. Metabolic H_2O production and insensible losses are generally unregulated (although there are exceptions; see p. 747).

Control of Water Output in the Urine by Vasopressin In mammals, fluctuations in ECF osmolarity caused by imbalances between H_2O input and output are quickly compensated for by adjusting the urinary excretion of H_2O without changing the usual excretion of salt; that is, H_2O reabsorption and excretion are partially dissociated from solute reabsorption and excretion, so the amount of free H_2O retained or eliminated can be varied to quickly restore ECF osmolarity to normal. Free H_2O reabsorption and excretion are regulated through changes in *vasopressin* secretion (as discussed in Chapter 12, p. 598).

Control of Water Input by Thirst and Drinking Thirst is the internal craving that drives an animal to ingest H_2O (although only humans can report the subjective perception of thirst). A *thirst center* in the hypothalamus lies in close proximity to the vasopressin-secreting cells. Drinking increases H_2O input as a behavioral effector.

Simultaneous Regulation of Vasopressin and Thirst The hypothalamic control centers that regulate vasopressin secretion (and thus urinary output) and thirst (and thus drinking input) act in concert. Vasopressin secretion and thirst are both stimulated by a free- H_2O deficit (hypertonic blood) and suppressed by a free- H_2O excess (hypotonic blood). Thus, appropriately, the same circumstances that call for reduced urinary output to conserve body H_2O also give rise to the sensation of thirst to replenish body H_2O . As we noted in Chapter 12 (p. 598), the predominant excitatory input for both vasopressin secretion and thirst comes from hypothalamic *osmoreceptors* located near the vasopressin-secreting cells and thirst center. These osmoreceptors monitor the osmolarity of the fluid surrounding them, which in turn reflects the osmolarity of the entire ECF. They are thought to use TRP receptor proteins closely related to those found in many sensor cells (p. 217). As the osmolarity increases, vasopressin secretion and thirst are both stimulated (Figure 13-13).

In addition to an increase in ECF osmolarity, the vasopressin-secreting cells and thirst center are both influenced to a moderate extent by changes in ECF volume mediated by input from the *left atrial volume receptors*. Located in the left atrium, these volume receptors monitor blood pressure, which reflects the ECF volume. In response to a major reduction in ECF volume and arterial pressure, as during hemorrhage, the left atrial volume receptors reflexly stimulate both thirst and vasopressin secretion. Vasopressin in the circulation exerts a potent vasoconstrictor effect on arterioles (hence its name), in addition to affecting the kidney tubules. By increasing total peripheral resistance, vasopressin helps relieve the low blood pressure that elicited vasopressin secretion (Figure 13-13).

Conversely, vasopressin and thirst are both inhibited when ECF/plasma volume and arterial blood pressure are raised. The resultant suppression of H_2O intake, coupled with elimination of excess ECF/plasma volume in urine, helps restore blood pressure to normal.

As we noted in Chapters 7 and 12, vasopressins are mammalian hormones, the most common being *arginine vasopressin* (AVP), but closely related hypothalamic peptide hormones are found in all vertebrates. Reptiles, including birds, fishes, and some amphibians, have *arginine vasotocin* (AVT), which differs from AVP by one amino acid in its peptide chain. It too promotes water conservation. For example, AVT enhances water uptake by the skin in toads (p. 547).

One other hormone, *angiotensin II*, also leads to increases in ECF volume by altering water balance, as you saw in Chapter 12 (see p. 587). In addition, thirst has its own regulatory process: There is evidence of some kind of “oral H_2O metering” that constitutes an example of *anticipation* control of basic homeostasis (p. 16). At least in some mammals, a thirsty animal will rapidly drink only enough H_2O to satisfy its H_2O deficit. It stops drinking before the ingested H_2O has had time to be absorbed from the digestive tract and actually return the ECF compartment to normal.

FIGURE 13-13 Control of increased vasopressin secretion and thirst during an H₂O deficit (shown for a human).

© Cengage Learning, 2013

Exactly what factors are involved in signaling that enough H₂O has been consumed is still uncertain. It may be a learned anticipatory response based on past experience.

Now let's turn to the other major regulated component, salt.

Salt balance is regulated primarily by the kidneys and salt hunger

Because sodium and its attendant anions account for more than 90% of the ECF solutes in a mammal, it is the main contributor to ECF osmolarity. Moreover, the total Na⁺ load (the total quantity of NaCl, not its concentration) in the ECF determines the total amount of H₂O that is osmotically retained in the ECF. The total mass of Na⁺ salts in the

ECF therefore determines the ECF volume, and, appropriately, long-term regulation of ECF volume depends on controlling salt balance even more than on water balance.

To achieve balance, salt input must equal salt output. The only avenue for salt input is ingestion, which can exceed some mammals' need to replace obligatory salt losses. Carnivores (meat eaters), which naturally get sufficient NaCl in fresh meat (because meat contains an abundance of salt-rich ECF) and marine mammals (as well as other marine vertebrates), normally do not show a physiological appetite to seek additional salt. In contrast, terrestrial vertebrate herbivores, which have low NaCl in their plant diets, develop *salt hunger* due to angiotensin II. As a result, mammalian herbivores will travel miles to a salt lick (as we noted in Chapter 12, p. 591).

The excess salt ingested by carnivores, omnivores, and marine mammals must be excreted to maintain salt balance. The three avenues for salt output are obligatory loss of salt in sweat and feces and controlled excretion of salt in the urine (see Table 13-4 for human data as an example). Fecal and excretory losses are most common because few mammals sweat. The total amount of sweat produced is unrelated to salt balance, being determined instead by factors that control body temperature. However, *aldosterone* (p. 591) can reduce the sweat's salt content, thus helping conserve salt in a hot environment. The small salt loss in the feces is thought not to be regulated, and it can be exacerbated by diseases. In mammals, the most important regulation is again accomplished by the kidneys, which precisely excrete excess salt in urine to maintain salt balance. By regulating the rate of urinary salt excretion, kidneys normally keep the

total Na⁺ mass in the ECF constant despite any notable changes in dietary intake of salt or unusual losses through sweating, diarrhea, or other means. By keeping the total Na⁺ mass in the ECF constant, ECF volume in turn is maintained within the narrowly prescribed limits essential for normal circulatory function. (Recall that other osmoregulating marine vertebrates have other excretory organs for salt, such as salt glands in marine reptiles including birds, and gills in bony fishes; see pp. 572–576.)

In contrast, mammalian herbivores typically face an excess of potassium rather than sodium from eating plants. Their kidneys compensate for this by swapping Na⁺ for K⁺ in the nephron's distal tubule (regulated by aldosterone; p. 591). For example, the omnivorous laboratory rat has about equal concentrations of Na⁺ and K⁺ in its urine, but a

TABLE 13-4 Daily Salt Balance in a Human

SALT INPUT		SALT OUTPUT	
Avenue	Amount (g/day)	Avenue	Amount (g/day)
Ingestion	10.5	Obligatory loss in sweat and feces	0.5
		Controlled excretion in urine	10.0
Total input	10.5	Total output	10.5

desert pocket mouse (which eats primarily seeds containing high levels of K^+) has about twice as much K^+ as Na^+ in its urine.

Deviations in ECF volume accompanying changes in salt load are responsible for triggering renal compensatory responses that quickly bring the Na^+ load and ECF volume back into line. Sodium is freely filtered at the glomerulus and actively reabsorbed, but it is not secreted by the tubules, so the amount of Na^+ excreted in urine represents the amount of Na^+ that is filtered but is not subsequently reabsorbed:

$$Na^+ \text{ excreted} = Na^+ \text{ filtered} - Na^+ \text{ reabsorbed}$$

The kidneys accordingly adjust the amount of salt excreted by controlling two processes: (1) glomerular filtration rate (GFR) and (2) more importantly, tubular reabsorption of Na^+ .

Control of the Amount of Na^+ Filtered through Regulation of the GFR The GFR is deliberately changed to alter the amount of salt and fluid filtered as part of the general baroreceptor reflex response to a change in blood pressure (see Chapter 12, p. 582). Because changes in plasma Na^+ can alter blood pressure via its effects on ECF volume, it is fitting that baroreceptors monitoring fluctuations in blood pressure are responsible for adjusting the amounts of Na^+ filtered and eventually excreted. (Interestingly, recent studies suggest that total body sodium is itself a regulated state, but how this might be sensed is unknown.)

Control of the Amount of Na^+ Reabsorbed through the Renin–Angiotensin–Aldosterone and ANP Systems The amount of Na^+ reabsorbed also depends on regulatory systems that play an important role in controlling blood pressure. As you saw in Chapter 12 (p. 587), the main factor controlling the extent of Na^+ reabsorption in the mammalian nephron is the powerful *renin–angiotensin–aldosterone system* (RAAS), which promotes Na^+ reabsorption and thereby Na^+ retention. Sodium retention in turn promotes os-

motonic retention of H_2O and the subsequent expansion of plasma volume and elevation of arterial blood pressure. Appropriately, this Na^+ -conserving system is activated by a reduction in ECF $NaCl$ and volume and arterial blood pressure.

Clearly, control of GFR and Na^+ reabsorption are highly interrelated and intimately tied in with long-term regulation of ECF volume as reflected by blood pressure. Specifically, a fall in arterial blood pressure brings about a twofold response in the renal handling of Na^+ (Figure 13-14): (1) a reflex reduction in the GFR to decrease the amount of Na^+ filtered and (2) an RAA-adjusted increase in the amount of Na^+ reabsorbed. Together, these effects reduce the amount of Na^+ excreted, thereby conserving the Na^+ and accompanying H_2O necessary to compensate for the fall in arterial pressure.

Conversely, a rise in arterial blood pressure brings about (1) increases in the amount of Na^+ filtered and (2) a reduction in RAA activity, which decreases salt (and fluid) reabsorption. This is partly controlled by the *ANP* (*atrial natriuretic peptide*) hormone system from the right atrium, which as you saw in Chapter 12 is a feedback antagonist to the RAAS (p. 589). Together, these actions increase salt (and fluid) excretion, eliminating the extra fluid that was expanding plasma volume and raising arterial pressure.

The RAAS is the most important factor in regulating mammalian ECF volume and blood pressure, with the vasopressin and thirst mechanism playing only a supportive role. In addition, as we noted in Chapter 12 (p. 587), angiotensin II acts directly on the brain to stimulate both thirst and va-

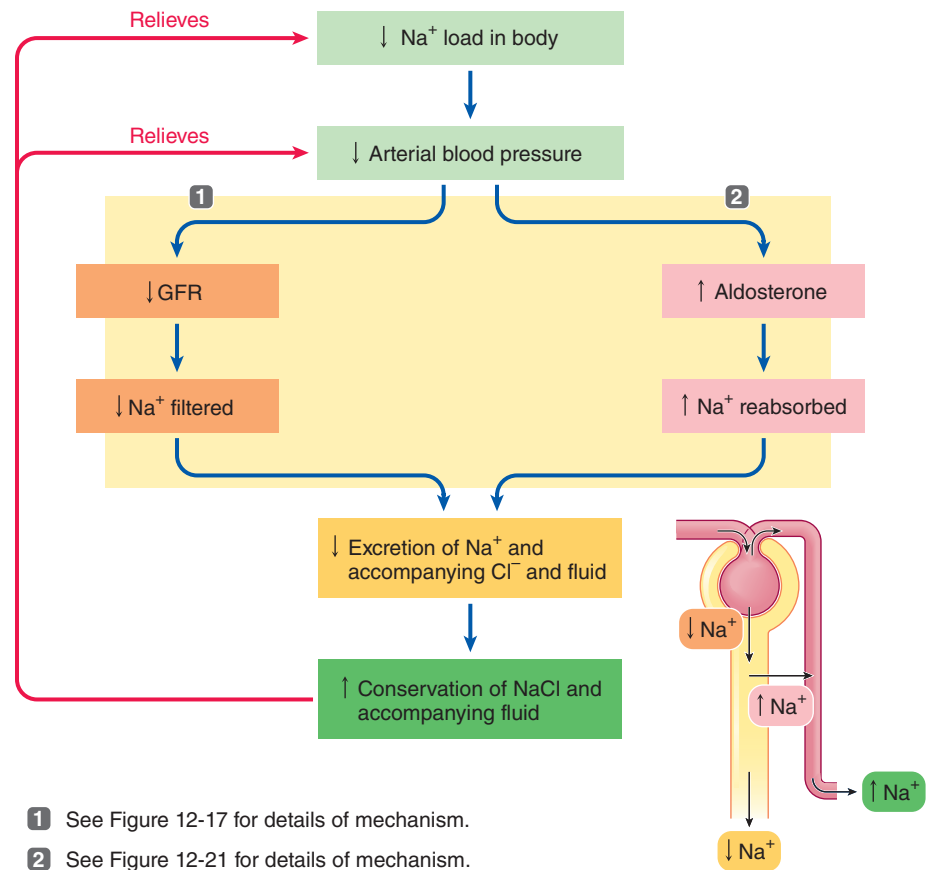

FIGURE 13-14 Dual effect of a fall in arterial blood pressure on renal handling of Na^+ . See main text for details.

TABLE 13-5 Summary of the Regulation of ECF Volume and Osmolarity

Regulated Variable	Need to Regulate the Variable	Outcomes if the Variable Is Not Normal	Mechanism for Regulating the Variable
ECF Volume	Important in the long-term control of arterial blood pressure	↓ ECF volume → ↓ arterial blood pressure ↓ ECF volume → ↓ arterial blood pressure	Maintenance of salt balance; salt osmotically “holds” H ₂ O, so the Na ⁺ load determines the ECF volume. Accomplished primarily by aldosterone-controlled adjustments in urinary Na ⁺ excretion
ECF Osmolarity	Important to prevent detrimental osmotic movement of H ₂ O between the ECF and ICF	↓ ECF osmolarity (hypotonicity) → H ₂ O enters the cells → cells swell ↑ ECF osmolarity (hypertonicity) → H ₂ O leaves the cells → cells shrink	Maintenance of free H ₂ O balance. Accomplished primarily by vasopressin-controlled adjustments in excretion of H ₂ O in the urine

© Cengage Learning, 2013

sopressin release to enhance renal H₂O reabsorption. The resultant increased H₂O intake and decreased urinary output help correct the reduction in ECF volume that triggered the renin–angiotensin–aldosterone system. (Angiotensin II is an ancient vertebrate hormone; for example, it stimulates drinking in fishes. The hormone induces drinking in most birds but not desert birds, which drink whenever possible, nor in carnivorous and succulent-plant-eating birds, which obtain water from each meal.)

During hemorrhagic shock, circulatory functions and fluid balance are coordinately regulated

We conclude this section of the chapter by examining the consequences of and compensations for hemorrhage (Figure 13-15). This figure may look intimidating, but we will work through it step by step. This important illustration pulls together many of the mechanisms discussed in this chapter, in Chapter 9 on circulation, and in Chapter 12 on excretion, showing how various systems in the mammalian body work together in an integrated way. The numbers in the text correspond to the numbers in the figure and indicate the portion of the figure being discussed.

- After severe loss of blood, reduction in circulating blood volume leads to a decrease in venous return [1] and a subsequent fall in cardiac output and arterial blood pressure. (Note the blue boxes, which indicate consequences of hemorrhage.) (Chapter 9, p. 447) Compensatory measures immediately attempt to maintain adequate blood flow to the brain. (Note the pink boxes, which indicate compensations for hemorrhage.)
- The baroreceptor reflex response to the fall in blood pressure brings about increased sympathetic and decreased parasympathetic activity to the heart [2]. The result is an increase in heart rate [3] to offset the reduced stroke volume [4] brought about by the loss of blood volume. With severe fluid loss, the pulse is weak because of the reduced stroke volume but rapid because of the increased heart rate. (Chapter 9, p. 451)
- As a result of increased sympathetic activity to the veins, generalized venous vasoconstriction occurs [5], increasing venous return by means of the Frank-Starling mechanism [6]. (Chapter 9, p. 417)

- Simultaneously, sympathetic stimulation of the heart increases the heart’s contractility [7] so that it beats more forcefully and ejects a greater volume of blood, also increasing the stroke volume. (Chapter 9, p. 417)
- The increase in heart rate and increase in stroke volume collectively lead to an increase in cardiac output [8].
- Sympathetically induced generalized arteriolar vasoconstriction [9] leads to an increase in total peripheral resistance [10]. (Chapter 9, p. 435)
- Together, the increase in cardiac output and total peripheral resistance bring about a compensatory increase in arterial pressure [11]. (Chapter 9, p. 436)
- The original fall in arterial pressure is also accompanied by a fall in capillary blood pressure [12], which results in fluid shifts from the interstitial fluid into the capillaries to expand the plasma volume [13]. This response is sometimes referred to as *autotransfusion*. (Chapter 9, p. 444)
- This ECF fluid shift is enhanced by plasma protein synthesis by the liver during the next few days after hemorrhage [14]. The plasma proteins exert a colloid osmotic pressure that helps retain extra fluid in the plasma.
- Urinary output is reduced, thereby conserving water that normally would have been lost from the body [15]. This additional fluid retention helps restore plasma volume [16]. Expansion of plasma volume further augments the increase in cardiac output brought about by the baroreceptor reflex [17]. Reduction in urinary output results from decreased renal blood flow caused by compensatory renal arteriolar vasoconstriction [18] (Chapter 12, p. 582). The reduced plasma volume also triggers increased secretion of vasopressin and activation of the salt- and water-conserving RAAS, which further reduces urinary output [19] (pp. 587 and 633).
- Increased thirst is also stimulated by a fall in plasma volume [20]. The resultant increased fluid intake helps restore plasma volume.
- Over a longer course of time (a week or more), lost red blood cells are replaced through increased red blood cell production triggered by reduced O₂ delivery to the kidneys [21]. (Chapter 9, p. 393)

This completes our examination of fluid balance. Table 13-5 summarizes mammalian regulation of ECF volume and osmolarity.

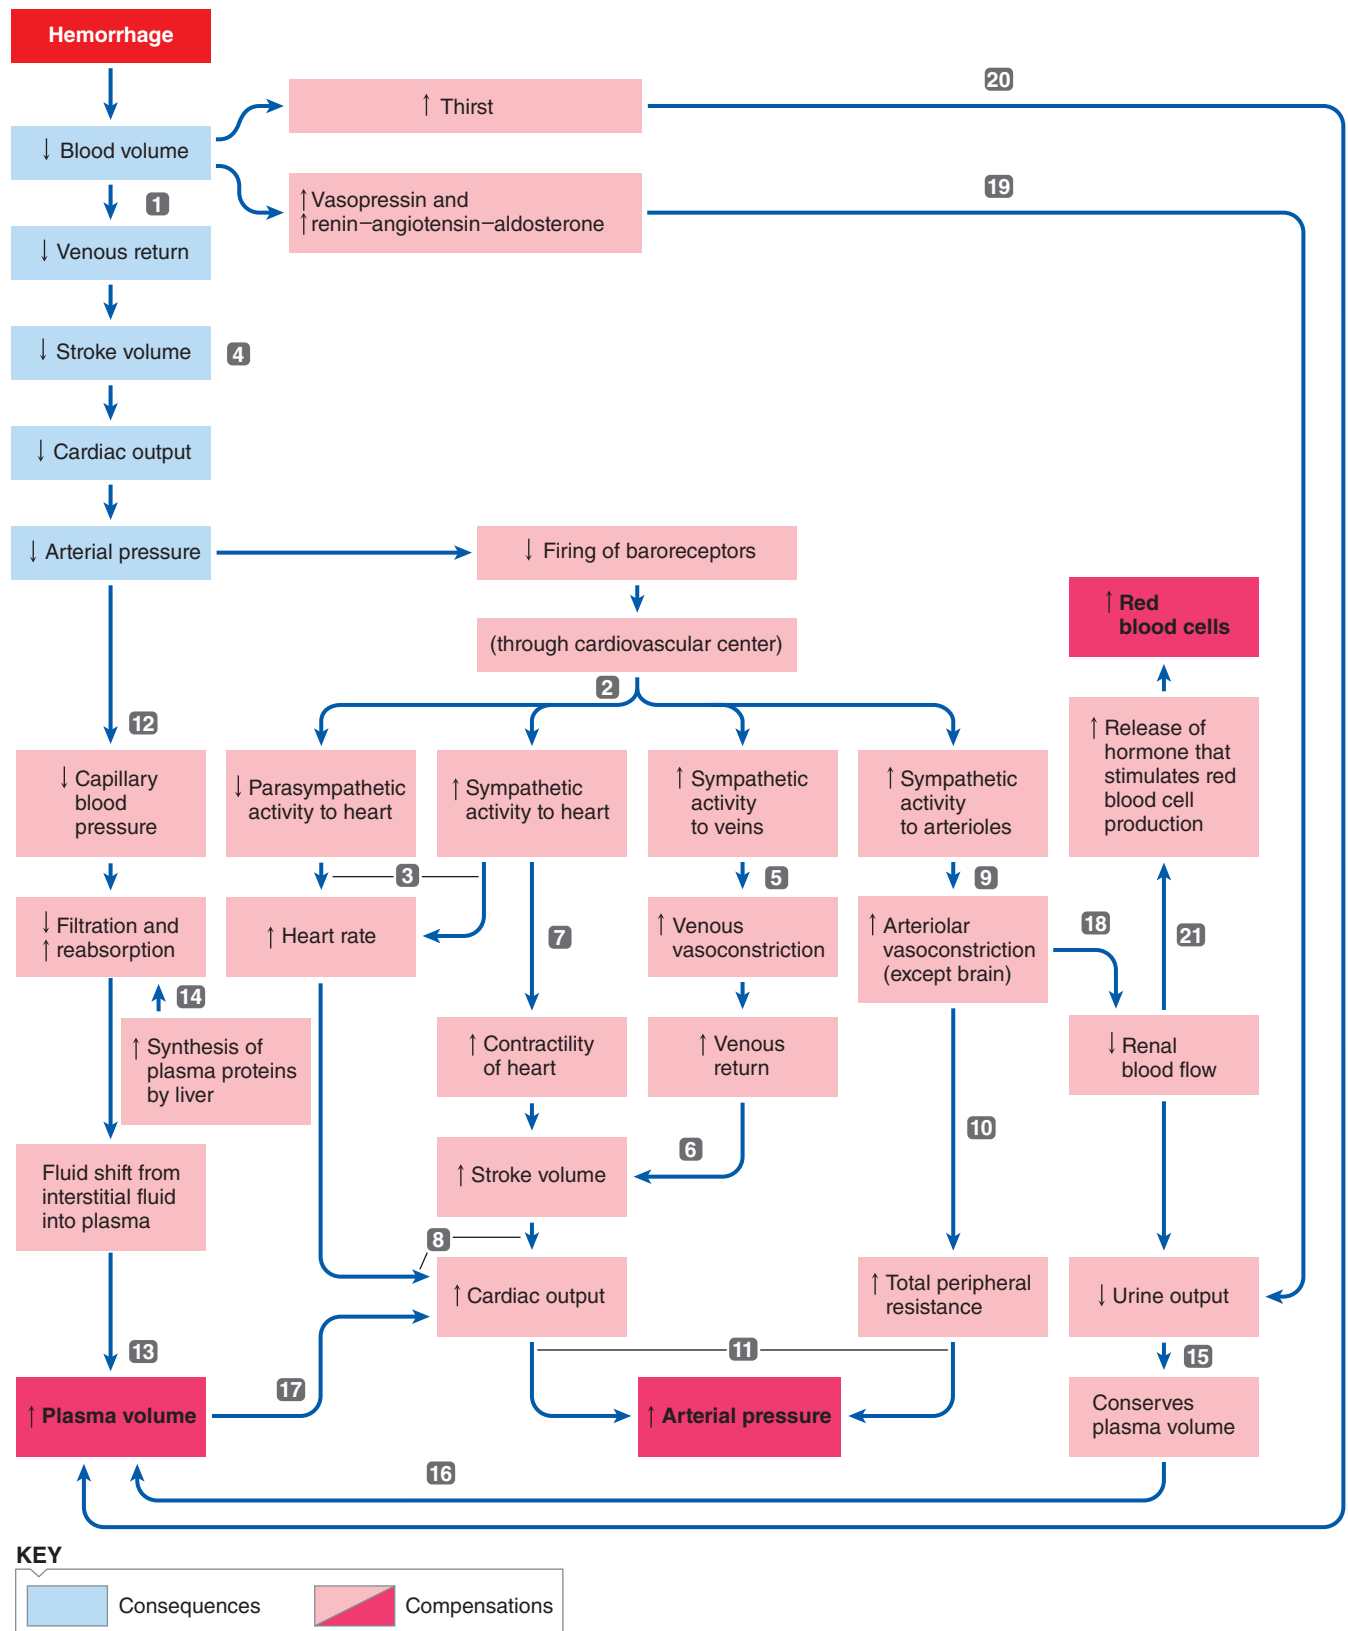

FIGURE 13-15 Consequences and compensations of hemorrhage in a mammal. The reduction of blood volume resulting from hemorrhage leads to a fall in arterial pressure. (Note the *blue* boxes, representing consequences of hemorrhage.) A series of compensations ensue (*light pink* boxes) that ultimately restore plasma volume, arterial pressure, and the number of red blood cells toward normal (*dark pink* boxes). Refer to the text (on the previous page) for an explanation of the circled numbers and a detailed discussion of the compensations.

13.5 Acid–Base Balance: General Concepts

The final aspect of internal fluid and solute regulation that we consider is that of **acid–base balance**—the precise regulation of free hydrogen ions (H⁺) in body fluids. This is crucial to the entire organism because protein structure and function is typically highly dependent on the concentration of H⁺ ions around them.

Acids liberate free hydrogen ions, whereas bases accept them

Water itself normally exists in an equilibrium between its uncharged form and two charged products: *hydronium* and *hydroxide* ions:

In pure water, which is 55.6 M, this equilibrium is far to the left, with 10^{−7} M of the ions at 25°C (a pH of 7.0, as we explain shortly). Technically, acid–base balance correlates with hydronium ions, but because acids and bases react with hydrogen ions, from which hydronium ions are formed, hydronium ions are treated as hydrogen ions by convention.

Acids are a special group of hydrogen-containing substances that dissociate, or separate, when in solution to liberate free H⁺ and anions (negatively charged ions). Many other substances (for example, carbohydrates) also contain hydrogen, but they are not classified as acids, because the hydrogen is tightly bound within their molecular structure and is never liberated as free H⁺.

A strong acid has a greater tendency to dissociate in solution than does a weak acid; that is, a greater percentage of a strong acid's molecules separate into free H⁺ and anions. Hydrochloric acid (HCl) is an example of a strong acid; virtually every HCl molecule dissociates into free H⁺ and Cl[−] (chloride) when dissolved in H₂O. With a weaker acid such as *carbonic acid* (H₂CO₃), only a portion of the molecules dissociate in solution into H⁺ and HCO₃[−] (*bicarbonate* anions). The remaining H₂CO₃ molecules remain intact. Only the free hydrogen ions contribute to the acidity of a solution, so H₂CO₃ is a weaker acid than HCl because H₂CO₃ does not yield as many free hydrogen ions

FIGURE 13-16 Comparison of a strong and a weak acid. (a) Five molecules of a strong acid. A strong acid such as HCl (hydrochloric acid) completely dissociates into free H⁺ and anions in solution. (b) Five molecules of a weak acid. A weak acid such as H₂CO₃ (carbonic acid) only partially dissociates into free H⁺ and anions in solution.

© Cengage Learning, 2013

per number of acid molecules present in solution (Figure 13-16).

The extent of dissociation for a given acid is always constant at a constant temperature and ionic composition; that is, when in solution, the same proportion of a particular acid's molecules always separate to liberate free H⁺, with the other portion always remaining intact. The constant degree of dissociation for a particular acid "A" is expressed by its *dissociation constant*, K_a , as follows:

$$[\text{H}^+][\text{A}^-]/[\text{HA}] = K_a$$

To indicate the concentration of a chemical, its symbol is enclosed in brackets; thus, [H⁺] designates H⁺ concentration. Thus, [H⁺][HA[−]] represents the concentration of ions resulting from acid dissociation, whereas [HA] represents the concentration of intact (undissociated) acid. Note that dissociation constants vary among different acids, with stronger acids having lower values.

Conversely, a **base** is a substance that can combine with a free H⁺ and thus remove it from solution. A strong base can bind H⁺ more readily than a weak base can. A base "B" is characterized by an *association constant*, K_b , as follows:

$$[\text{HB}^+][\text{OH}^-]/[\text{B}] = K_b$$

FIGURE 13-17 pH considerations in chemistry and physiology.

© Cengage Learning, 2013

The pH designation is used to express hydrogen ion concentration

The $[H^+]$ in a typical mammalian ECF is about 4.3×10^{-8} or 0.00000004 equivalents per liter. The concept of pH has been developed to express $[H^+]$ more conveniently. Specifically, pH equals the logarithm (log) to the base 10 of the reciprocal of the hydrogen ion concentration:

$$pH = \log 1/[H^+]$$

Thus, the pH of typical mammalian ECF is 7.4. Three important points should be noted about this formula:

1. Because $[H^+]$ is in the denominator, a *high* $[H^+]$ corresponds to a *low* pH, and a *low* $[H^+]$ corresponds to a *high* pH.
2. Every unit change in pH actually represents a 10-fold change in $[H^+]$ because of the logarithmic relationship. For example, the log of 10 = 1, whereas the log of 100 = 2. A solution with a pH of 7 has a $[H^+]$ 10 times less than that of a solution with a pH of 6 (1 pH-unit difference) and 100 times less than that of a solution with a pH of 5 (2 pH-unit difference).

The pH of pure H_2O is 7.0 at 25°C, and 6.81 at 37°C (typical mammalian body temperature); either value is con-

sidered chemically neutral. Because OH^- can bind with H^+ to once again form an H_2O molecule, it is considered basic. Because an equal number of acidic hydrogen ions (actually hydronium) and basic hydroxyl ions are formed, H_2O is neutral, being neither acidic nor basic. Solutions having a pH less than 7.0 contain a higher $[H^+]$ than pure H_2O and are considered acidic. Conversely, solutions having a pH value greater than 7.0 have a lower $[H^+]$ and are considered basic or alkaline (Figure 13-17a). Figure 13-18 compares the pH values of common solutions.

Animal Blood pH The pH of arterial blood of a typical mammal is normally 7.45 and the pH of venous blood is 7.35, for an average blood pH “set point” of 7.4. The pH of venous blood is slightly lower (more acidic) than that of arterial blood because of H^+ generated by the formation of H_2CO_3 from CO_2 picked up at the tissue capillaries. **Acidosis** exists whenever the blood pH falls below 7.35, whereas **alkalosis** occurs when the blood pH is above 7.45 (Figure 13-17b). Note that the reference point for determining the body’s acid–base status is not neutral pH (6.81 at 37°C), but the normal plasma pH of 7.4. Thus, a plasma pH of 7.2 is considered acidotic even though in chemistry a pH of 7.2 is considered basic. Death can occur if arterial pH falls outside the range of 6.8 to 8.0 for more than a few seconds because

FIGURE 13-18 Comparison of pH values of common solutions.

© Cengage Learning, 2013

an arterial pH of less than 6.8 or greater than 8.0 is not compatible with many cellular functions. Obviously, therefore, [H^+] in body fluids must be carefully regulated.

These particular pH values do not necessarily apply to other animals. The reason is that pH set points in animals vary, and also change with temperature. A *poikilotherm* (animal whose body temperature varies with that of the environment; p. 733) from a warm habitat similar to that of mammalian body temperatures may also have a blood pH of about 7.4. But a poikilotherm in a cold habitat (such as a polar fish) typically has a higher internal pH (such as 8.0), though may reduce its pH if it is warmed up. The reasons for this are uncertain, although it has been suggested to be a mechanism for stabilizing proteins with temperature changes

(as discussed in Chapter 15, p. 738). Regardless of the pH that is regulated, the acidotic and alkalotic effects do apply to these animals if major pH deviations occur.

Fluctuations in [H^+] alter nerve, enzyme, and K^+ activity

Only a narrow pH range is compatible with most life functions. Even slight deviations in [H^+] alter the shape and activity of protein molecules, usually detrimentally; for example, respiratory pigments do not deliver oxygen properly. The power of pH has been demonstrated clearly in fertilized sea urchin eggs, where an increase of only 0.13 pH units is enough to activate metabolism from a nearly dormant state to a level that supports the new embryo's development. This represents a useful pH change, but in normal, nondormant multicellular animals, changes are not desirable (except with internal temperature changes; see p. 738). The main consequences of fluctuations in [H^+] are as follows:

- **Alteration of enzyme activity.** Because enzymes are proteins, a shift in the body's acid–base balance disturbs the normal pattern of cellular activity catalyzed by these enzymes. Some cellular chemical reactions are accelerated; others are depressed.
- **Disturbances to K^+ levels.** Because of the intimate relationship between secretion of H^+ and K^+ by the kidneys, an increased rate of secretion of one of these ions is accompanied by a decreased rate of secretion of the other. For example, if more H^+ than normal is eliminated by the kidneys, as occurs when the body fluids become acidotic, less K^+ than usual can be excreted (see p. 592). The resultant K^+ retention can affect cardiac, neural, and muscular functions, in addition to having other detrimental consequences.
- **Changes in excitability of nerve and muscle cells.** The major effect of increased [H^+] (acidosis) at the whole-body level, presumably because of effects on proteins and K^+ , is depression of the central nervous system. Acidotic vertebrates, for example, become disoriented and, in more severe cases, eventually die in a coma. In contrast, the major effect of decreased [H^+] (alkalosis) is overexcitability of the nervous system, first the peripheral and later the central nervous system. Peripheral nerves become so excitable that they fire even in the absence of normal stimuli, bringing about muscle twitches and, in more pronounced cases, severe muscle spasms. In extreme alkalosis death may occur because spasm of the respiratory muscles seriously impairs breathing. In addition, severely alkalotic animals may die of convulsions resulting from overexcitability of the central nervous system. In less serious situations, CNS overexcitability is manifested as extreme nervousness in mammals.

Changes in body fluid pH can arise from both internal and external disturbances, as we examine next.

Hydrogen ions are continually being added to body fluids from metabolic activities

As with any other constituent, to maintain a constant [H^+] in body fluids, input of hydrogen ions must be balanced by an equal output. On the input side, only a small amount of acid capable of dissociating to release H^+ is taken in with

food, such as the weak citric acid found in oranges. Most H^+ in the body fluids is generated internally from metabolic activities.

Internal Sources of H^+ Normally, H^+ is continually being added to body fluids from the following three sources:

1. *Carbonic acid produced in metabolism.* The major source of H^+ is through H_2CO_3 formation from metabolically produced CO_2 . Recall that cellular oxidation of nutrients yields CO_2 and H_2O as end products (p. 53). CO_2 and H_2O spontaneously react to form H_2CO_3 , although rather slowly. Once formed, H_2CO_3 mostly dissociates to liberate free H^+ and HCO_3^- (bicarbonate):

Recall that in some cell types such as erythrocytes, the reaction is rapidly catalyzed by the enzyme *carbonic anhydrase* (CA, p. 392), although in an indirect way:

The reduction in OH^- in turn causes a change in H^+ formation from water:

These reactions are readily reversible, proceeding in either direction depending on the concentrations of the substances involved as dictated by the law of mass action, as we described in Chapter 11 (p. 541). In brief, while CO_2 production by respiring cells increases acidity, exhalation of CO_2 at the lungs reduces it. When the respiratory system can keep pace with the rate of metabolism, there is no net gain or loss of H^+ in the body fluids from metabolically produced CO_2 . This is a major regulatory process we will discuss later (p. 642). If the rate of CO_2 removal by the lungs does not match the rate of CO_2 production at the tissue level, however, the resultant accumulation or deficit of CO_2 in the body leads to an excess or shortage, respectively, of free H^+ in the body fluids.

2. *Inorganic acids produced during catabolism.* Dietary proteins and other ingested nutrient molecules that are found abundantly in meat contain a large quantity of sulfur and phosphorus. When these molecules are broken down, sulfuric acid and phosphoric acid are produced as by-products. Being moderately strong acids, these two inorganic acids dissociate to a large extent, liberating free H^+ into the body fluids. In contrast, catabolism of plants produces bases that, to some extent, neutralize the acids derived from protein metabolism. Generally, however, more acids than bases are produced during the breakdown of ingested food, leading to an excess of these acids.
3. *Organic acids resulting from metabolism.* Numerous organic acids are produced during normal metabolism (see pp. 55 and 316). For example, fatty acids are produced during fat metabolism, and vertebrate muscles produce lactate during strenuous activity. These acids partially dissociate to yield free H^+ .

Hydrogen ion generation therefore normally goes on continuously as a result of ongoing metabolic activities. Furthermore, in certain disease states additional acids may be produced that further contribute to the total body pool

of H^+ . One of these, diabetes mellitus, will be discussed later (p. 649).

External Sources of H^+ Finally, inputs from outside the body may also add to the total load of H^+ that must be handled by the body. Examples include types of acid-producing medications and carbonic acid arising from excess atmospheric CO_2 from human activities such as fossil-fuel burning. As you have seen, CO_2 acidifies water when it dissolves. We will examine this issue in more depth later (p. 650).

Three Lines of Defense against $[H^+]$ Changes Generation of H^+ is unceasing, highly variable, and essentially unregulated in an animal. The key to H^+ balance is maintaining the normal alkalinity of the ECF (such as pH 7.4 in most mammals) despite this constant onslaught of acid. The generated free H^+ must be largely removed from solution while in the body, and ultimately must be eliminated so that the pH of body fluids can remain within the normal range. Mechanisms must also exist to compensate rapidly for the occasional situation in which the ECF becomes too alkaline.

Three lines of defense against changes in $[H^+]$ operate to maintain the $[H^+]$ of body fluids at a nearly constant level despite unregulated input: (1) chemical buffer systems, (2) respiratory mechanisms of pH control, and (3) excretory mechanisms of pH control. We look at each of these methods, primarily in vertebrates.

check your understanding 13.5

Distinguish acids from bases, and define pH.

Why is pH important to animals, and what are the sources of excess H^+ ?

13.6 pH Regulation: Buffers

When pH begins to change, the first corrective response to act is that of *buffering*.

Chemical buffer systems act as the first line of defense against changes in $[H^+]$ by binding with or releasing free H^+

A **chemical buffer system** is a mixture in a solution of two (or perhaps three) chemical compounds that minimize pH changes when either an acid or a base is added to or removed from the solution. A buffer system consists of a pair of substances involved in a reversible reaction—one substance that can yield free H^+ as the $[H^+]$ starts to fall and another that can bind with free H^+ (thus removing it from solution) when $[H^+]$ starts to rise. An important example of such a buffer system is the carbon dioxide-bicarbonate buffer system, which is involved in the following reversible reaction that we noted earlier:

When a strong acid such as HCl is added to an unbuffered solution, all the dissociated H^+ remains free in the solution (Figure 13-19a). In contrast, when HCl is added to a

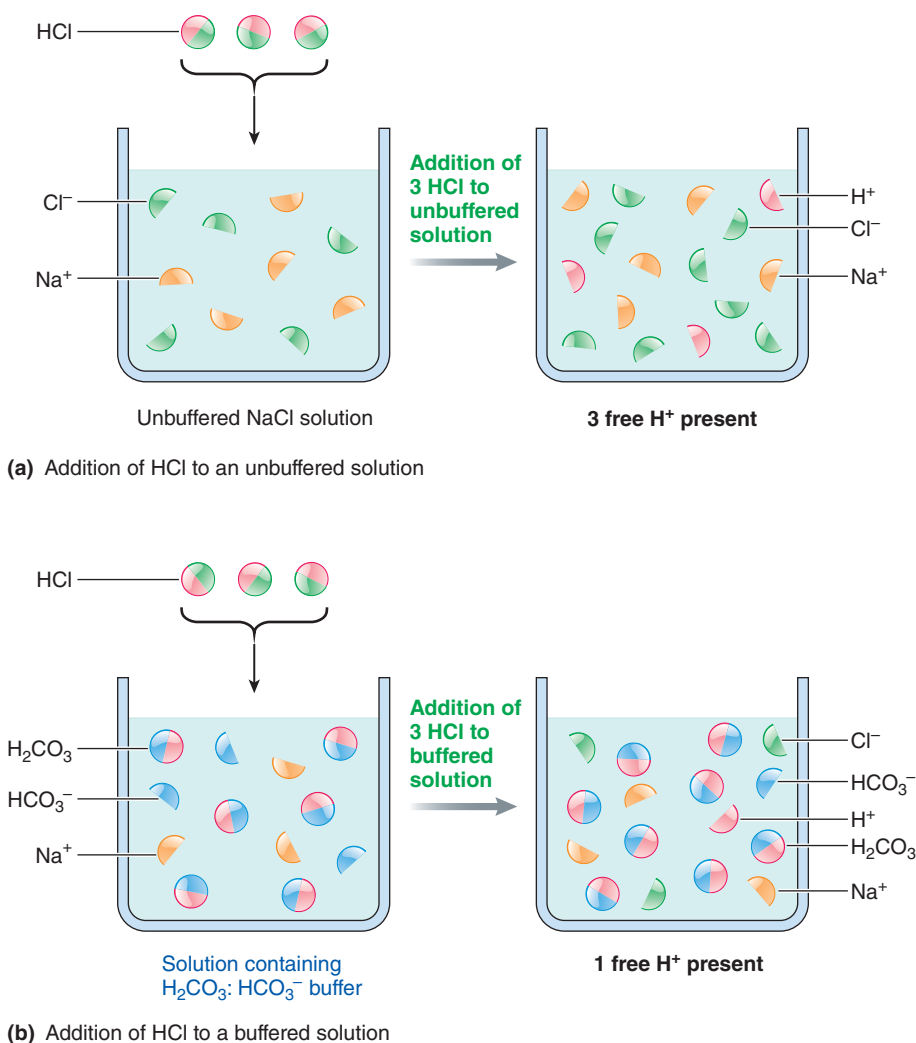

FIGURE 13-19 Action of chemical buffers. (a) Addition of HCl to an unbuffered solution. All the added hydrogen ions (H⁺) remain free and contribute to the acidity of the solution. (b) Addition of HCl to a buffered solution. Bicarbonate ions (HCO₃⁻), the basic member of the buffer pair, bind with some of the added H⁺ and remove them from solution so that they do not contribute to its acidity.

© Cengage Learning, 2013

solution containing the CO₂-HCO₃⁻ buffer system (Figure 13-19b), the HCO₃⁻ immediately binds with the free H⁺ to form H₂CO₃ and thus H₂O + CO₂. In contrast, when the pH of the solution starts to rise because of the addition of base or loss of acid, the H⁺-yielding member of the buffer system, H₂CO₃, releases H⁺ to minimize the rise in pH (reducing H₂O + CO₂).

All chemical buffer systems act immediately, within fractions of a second, to minimize changes in pH. When [H⁺] is altered, the buffer systems' reversible chemical reactions shift at once in favor of compensating for the change in [H⁺]. Accordingly, the buffer systems are the first line of defense against changes in [H⁺] because they are the first mechanism to respond. There are four buffer systems in vertebrates:

1. **CO₂-HCO₃⁻ buffer system:** primary ECF buffer for noncarbonic acids.
2. **Peptide and protein buffer system:** primary ICF buffer.

3. **Hemoglobin buffer system:** primary erythrocyte buffer for carbonic acid changes.
4. **Phosphate buffer system:** secondary ICF and primary urinary buffer.

Each serves a different important role, as we will now discuss.

The CO₂-HCO₃⁻ buffer system is the primary ECF buffer for noncarbonic acids

The CO₂-HCO₃⁻ buffer system dominates in the ECF, where it is very effective for two reasons:

1. HCO₃⁻ is abundant in the ECF, so this system is readily available to absorb excess protons, and conversely there is sufficient CO₂ and H₂CO₃ to produce protons when they decrease below normal concentration. If, for example, proton concentrations increase through lactate released into the ECF from exercising muscles, the buffer reaction is driven toward the right side of the equation, so the rise in [H⁺] is abated. In the converse situation, when the plasma [H⁺] occasionally falls below normal for some reason other than a change in CO₂ (such as the loss of plasma-derived HCl in the gastric juices during vomiting), the reaction is driven toward the left side of the equation.
2. More importantly, key components of this buffer pair are closely regulated. The kidneys regulate H⁺ and HCO₃⁻, and the respiratory system regulates CO₂, which generates H₂CO₃.

This buffer system cannot buffer changes in pH induced by fluctuations in H₂CO₃. A buffer system cannot buffer itself. Consider, for example, the situation in which the plasma [H⁺] is elevated because of CO₂ retention associated with a respiratory problem. The rise in CO₂ drives the reaction to the left according to the law of mass action, resulting in an elevation in [H⁺]. The increase in [H⁺] occurs because of an increase in CO₂, so the elevated [H⁺] cannot drive the reaction to the right to buffer the increase in [H⁺]. Only if the increase in [H⁺] is brought about by some mechanism other than CO₂ accumulation can this buffer system be shifted to the CO₂ side of the equation and be effective in reducing the [H⁺]. Likewise, in the opposite situation, the CO₂-HCO₃⁻ buffer system cannot compensate for a reduction in [H⁺] caused by a deficit of CO₂ by generating more H⁺-yielding H₂CO₃ when the problem in the first place is a shortage of H₂CO₃-forming CO₂. Other mechanisms, described shortly, are available for resisting fluctuations in pH caused by changes in CO₂ levels.

Henderson-Hasselbalch Equation The relationship between $[H^+]$ and the members of a buffer pair can be expressed according to the **Henderson-Hasselbalch equation**, which, for the CO_2 - HCO_3^- buffer system, is as follows:

$$pH = pK_a + \log [HCO_3^-]/[CO_2]$$

Although you do not need to know the mathematical manipulations involved, it is helpful to understand how this formula is derived. Recall the dissociation constant K_a formula for acids (p. 636); for H_2CO_3 , it is

$$[H^+] [HCO_3^-]/[H_2CO_3] = K_a$$

Practically speaking, $[H_2CO_3]$ is a direct reflection of the concentration of dissolved CO_2 , henceforth referred to as $[CO_2]$, because most of the CO_2 in the plasma is converted into H_2CO_3 . Thus, we substitute H_2CO_3 with CO_2 and then solve the formula for $[H^+]$ (that is, $[H^+] = K_a \times [CO_2]/[HCO_3^-]$). Finally, by converting this to the logarithmic form, we come up with the Henderson-Hasselbalch equation (recall that pH is the logarithm of $1/[H^+]$; similarly, pK_a is the logarithm of $1/K_a$).

For H_2CO_3 derived from CO_2 , the pK_a is 6.1 under mammalian conditions. Because the pK_a is, like K_a , a constant at a given temperature and ionic strength, changes in pH are associated with changes in the ratio between $[HCO_3^-]$ and $[CO_2]$. Normally, the ratio between $[HCO_3^-]$ and $[CO_2]$ in the ECF is 20 to 1; that is, there is 20 times more HCO_3^- than CO_2 . Plugging this ratio into our formula:

$$\begin{aligned} pH &= pK_a + \log [HCO_3^-]/[CO_2] \\ &= 6.1 + \log 20:1 \end{aligned}$$

The log of 20 is 1.3. Therefore $pH = 6.1 + 1.3 = 7.4$, which is the normal pH of mammalian plasma.

When the ratio of $[HCO_3^-]$ to $[CO_2]$ increases above 20:1, pH increases. Accordingly, either a rise in $[HCO_3^-]$ or a fall in $[CO_2]$, both of which increase the $[HCO_3^-]/[CO_2]$ ratio if the other component remains constant, shifts the acid-base balance toward the alkaline side. In contrast, when the $[HCO_3^-]/[CO_2]$ ratio decreases below 20:1, pH decreases toward the acid side. This can occur either if the $[HCO_3^-]$ decreases or if the $[CO_2]$ increases while the other component remains constant. Because $[CO_2]$ is regulated by the lungs and gills, and both $[H^+]$ and $[HCO_3^-]$ are regulated by the kidneys and gills, the pH of the plasma can be shifted up and down by renal and respiratory contributions. Also because of the Henderson-Hasselbalch relationship, renal or respiratory dysfunction can induce acid-base imbalances by altering the $[HCO_3^-]/[CO_2]$ ratio.

Before we leave the topic of CO_2 - HCO_3^- buffer systems, note that other forms of carbonate can participate in buffering in some animals, such as those that must cope with much greater acid loads than others. One example is the painted turtle *Chrysemys picta*, found in ponds in the northern United States and southern Canada. In the winter, it can survive in iced-over waters with no oxygen for months. In part, it survives by having large energy stores (glycogen in the liver, muscle, and heart) for anaerobic metabolism, coupled with a greatly reduced metabolic rate in the cold (p. 751). Nevertheless, months of metabolism without O_2 produces large quantities of lactate, as it would in most vertebrates. The turtles do have extremely high bicarbonate levels to help absorb protons released by lactate. But this is not nearly enough. How can they cope? The extraordinary

Paul Yancey

A red-eared slider turtle (*Trachemys scripta*), which (like the painted turtle) uses its shell as an aid in acid-base regulation.

answer lies in their massive shells, which make up about a third of their body weight and are the major repository of the animals' minerals. The shell helps deal with acid load in two ways. First, acid buildup begins to demineralize the shell and appears primarily to cause the release of calcium and magnesium carbonate (CO_3^{2-}). The latter anion is thought to buffer the protons (binding them). Second, lactate along with its acidic proton accumulate in the shell itself, perhaps bound to calcium and carbonate, respectively. This effectively removes as much as half of the acid threat from the blood. Weeks later, the turtle emerges into the spring sunshine to begin breathing and metabolizing normally again, and the lactate can be safely released and metabolized. In this way, the shell itself serves as a buffer!

The peptide and protein buffer system, including hemoglobin in erythrocytes, is primarily important intracellularly

The most plentiful buffers of the ICF are the cell proteins. A more limited number of plasma proteins reinforce the CO_2 - HCO_3^- system in ECF buffering. Proteins are excellent buffers because they contain both acidic and basic groups that can bind or release H^+ . Quantitatively, the protein system is most important in buffering changes in $[H^+]$ in the ICF because of the sheer abundance of the intracellular proteins. The most important buffering amino acid is *histidine* because it is the only one with a pK_a close to 7. In addition, muscles of some fishes, birds, and mammals have large concentrations of **dipeptides** (chains of two amino acids) containing histidine. These serve as a reserve buffer system in muscles that produce a substantial load of acid during activity. For example, the highest known concentration of histidine dipeptides has been found in diving mammals, whose muscles must work using anaerobic metabolism for considerable periods (p. 545).

Hemoglobin (Hb) in vertebrate erythrocytes is a key example of a protein buffer. It buffers the H^+ generated from metabolically produced CO_2 in transit between the tissues

and the lungs or gills. At the systemic capillary level, CO_2 continuously diffuses into the blood from the tissue cells where it is being produced. Recall that most of this CO_2 forms H^+ and HCO_3^- . Simultaneously, some of the oxyhemoglobin (HbO_4) releases O_2 , which diffuses into the tissues (Figure 11-33, p. 541). Reduced (unoxxygenated) Hb has a greater affinity for H^+ than HbO_2 does. Therefore, most of the H^+ generated from CO_2 at the tissue level becomes bound to histidines of reduced Hb and no longer contributes to the acidity of the body fluids:

At the respiratory organ the reactions are reversed. As Hb picks up O_2 diffusing from the lungs or gills into the red blood cells, the affinity of Hb for H^+ is decreased, so H^+ is released from histidines. This liberated H^+ combines with HCO_3^- to yield H_2CO_3 , which in turn produces CO_2 , which is removed from the body. Meanwhile, the hydrogen ion has been reincorporated into neutral H_2O molecules. Were it not for Hb, the blood would become much too acidic after picking up CO_2 at the tissues. Because of the tremendous buffering capacity of the Hb system, venous blood is only slightly more acidic than arterial blood despite the large volume of H^+ -generating CO_2 carried in the venous blood.

The phosphate buffer system is important in the ICF and urine

The phosphate buffer system consists of an acid phosphate salt (NaH_2PO_4) that can donate a free H^+ when the $[\text{H}^+]$ falls and a basic phosphate salt (Na_2HPO_4) that can accept a free H^+ when the $[\text{H}^+]$ rises. Basically, this buffer pair can alternately switch an H^+ for an Na^+ as demanded by the $[\text{H}^+]$:

The phosphate pair in the ECF is rather low, so it is not very important as an ECF buffer. Because phosphates are more abundant within the cells, this system contributes significantly to intracellular buffering, being rivaled only by the more plentiful intracellular proteins. Even more importantly, the phosphate system serves as an excellent urinary buffer. When an animal consumes more phosphate than is needed, the excess phosphate filtered through the kidneys is not reabsorbed but remains in the tubular fluid to be excreted (because the renal threshold for phosphate is exceeded; see p. 586). This excreted phosphate buffers the urine as it is being formed by removing from solution the H^+ secreted into the tubular fluid. None of the other body fluid buffer systems are present in the tubular fluid to play a role in buffering urine during its formation. Most or all of the filtered HCO_3^- and CO_2 are reabsorbed, whereas Hb and most plasma proteins are not even filtered.

Buffers are a temporary mechanism because they do not eliminate excess $[\text{H}^+]$

Through the mechanism of buffering, most hydrogen ions seem to “disappear” from the body fluids between the time of their generation and their elimination. It must be emphasized, however, that none of the chemical buffer systems actually eliminates H^+ from the body by themselves. Protons are merely removed from solution by being incorporated

within one of the members of the buffer pair, thus preventing the hydrogen ions from contributing to the body fluids’ acidity. Because each buffer system has a limited capacity to “soak up” H^+ , the H^+ that is unceasingly produced must ultimately be removed from the body. If H^+ were not eventually eliminated, soon all the body fluid buffers would already be bound with H^+ and there would be no further buffering ability.

As we have mentioned, actual removal of excess H^+ occurs in excretory and respiratory systems (for example, excretion of NaH_2PO_4 in urine, and exhaling of CO_2 by lungs). However, these systems respond more slowly than the chemical buffer systems. We now turn our attention to these other defenses against changes in acid–base balance.

Discuss the primary buffers of the ECF and the ICF (including hemoglobin).

13.7 pH Regulation: Respiration and Excretion

If a deviation in $[\text{H}^+]$ is not swiftly and completely corrected by the buffer systems, respiratory systems come into action a few minutes later.

Respiratory systems as a second line of defense regulate $[\text{H}^+]$ through adjustments in ventilation

Respiratory systems play an important role in acid–base balance through their ability to alter ventilation to control exchange H^+ -generating CO_2 in gills and lungs, or to alter transport of H^+ and HCO_3^- in gills. These responses are slower than buffering because of the time it takes to transport all the affected blood past the respiratory surfaces, plus the time it takes to alter ventilation rates. Thus, they can be considered as the second line of defense against changes in $[\text{H}^+]$. (An exception to this delay occurs in exercise and stress, in which breathing is activated in *anticipation* of both the oxygen needs and pH regulation necessary during heavy muscle use; see p. 554.) Let’s compare lungs and gills.

Air Breathers Every day, lungs remove from the body fluids manyfold more H^+ derived from carbonic acid than the kidneys can eliminate from noncarbonic-acid sources. Furthermore, the respiratory system, through its ability to regulate arterial $[\text{CO}_2]$, can adjust the amount of H^+ added to body fluids from this source as needed to restore pH toward normal when fluctuations in $[\text{H}^+]$ from noncarbonic-acid sources occur. (Noncarbonic acids include keto acids; p. 316.) Because of this ability, it is not surprising that the level of respiratory activity is governed at least in part by the arterial $[\text{H}^+]$, as you saw in Chapter 11. Let’s review this in terms of pH regulation:

- When arterial $[\text{H}^+]$ increases (pH decreases), the respiratory center in the terrestrial-vertebrate brain stem is re-

flexibly stimulated (see p. 552) to increase ventilation (the rate at which gas is exchanged between the respiratory organ and the atmosphere). As the rate and depth of breathing increase, more CO_2 than usual is blown off, so less H_2CO_3 than normal is added to the body fluids.

- Conversely, when arterial $[\text{H}^+]$ falls (pH increases), ventilation is reduced. As a result of slower, shallower breathing, metabolically produced CO_2 diffuses from the cells into the blood faster than it is removed from the blood, so higher-than-usual amounts of acid-forming CO_2 accumulate in the blood, restoring $[\text{H}^+]$ toward normal.

Interestingly, insects regulate pH in very similar ways. The opening and closing of spiracles and abdominally driven breathing are both controlled by the pH of the hemolymph. Insects may even have feedforward regulation of this in anticipation of high activity.

Water Breathers In fishes, kidneys play a minor role in acid-base adjustments, leaving the gills with the primary responsibility. Acid loads are primarily handled by membrane transporters in the gills rather than by alterations in breathing (ventilation). Since these are essentially excretory mechanisms, they are discussed later.

Respiratory Diseases When changes in $[\text{H}^+]$ occur because of fluctuations in $[\text{CO}_2]$ that arise from respiratory abnormalities, the respiratory mechanism cannot contribute at all to the control of pH; for example, if acidosis exists because of CO_2 accumulation caused by gill or lung disease, the impaired organs are clearly not compensating properly. The buffer systems (other than the CO_2 - HCO_3^- pair) plus renal regulation are the only mechanisms available for defending against respiratory-induced acid-base abnormalities. Let's now turn to renal regulation.

Excretory systems are a powerful third line of defense that aid acid-base balance by controlling both $[\text{H}^+]$ and $[\text{HCO}_3^-]$ in the ECF

Excretory organs are the third line of defense against changes in $[\text{H}^+]$ in body fluids, although they require hours to days to compensate for changes in body fluid pH. Note that gills in fishes and many crustaceans serve both as excretory and respiratory organs. Gill transporters serving as excretory mechanisms include H^+ V-ATPases (p. 85) to remove protons, an Na^+/H^+ antiport (which takes up one sodium ion for each proton excreted), and a $\text{Cl}^-/\text{HCO}_3^-$ antiport that may help remove excess base. Skin breathers such as frogs may also have similar transporters.

In some animals, nonrenal excretory organs contribute significantly to acid-base balance. The bladder fluid of reptiles can be acidified by an H^+ ATPase that is activated in response to high CO_2 levels. In insects, the hindgut is the key excretory organ for acid-base regulation. For example, the mosquito *Aedes dorsalis* can live in alkaline brine lakes in Africa at pH 10.5 while maintaining a hemolymph pH of 7.6. Bicarbonate is actively excreted by the hindgut in this process.

Here we focus on mammals, in which the kidneys are the most potent acid-base regulatory mechanism. Not only can they vary removal of H^+ from any source, but they can

also variably conserve or eliminate HCO_3^- , depending on the acid-base status of the body. For example, during renal compensation for acidosis for each H^+ excreted in the urine, a new HCO_3^- is added to the plasma. By simultaneously removing acid (H^+) from and adding base (HCO_3^-) to the body fluids, the kidneys can restore the pH toward normal more effectively than the lungs, which can adjust only the amount of H^+ -forming CO_2 in the body. Indeed, kidneys can return the pH almost exactly to normal. In contrast, when some nonrespiratory abnormality has altered the $[\text{H}^+]$, the mammalian respiratory system alone can return the pH to only 50 to 75% of the way toward normal; this is because the driving force governing the compensatory ventilatory response is diminished as the pH moves toward normal. In comparison, the kidneys continue to respond to a change in pH until compensation is essentially complete.

The kidneys control the pH of the body fluids by adjusting three interrelated factors: (1) H^+ excretion, (2) HCO_3^- excretion, and (3) ammonia (NH_3) secretion.

Hydrogen Ion Excretion Since lungs can adjust pH only by eliminating CO_2 , the task of eliminating H^+ derived from sulfuric, phosphoric, lactic, and other acids rests with the kidneys in mammals.

Almost all the excreted H^+ enters the urine by means of secretion. Recall that the filtration rate of H^+ equals plasma $[\text{H}^+]$ times GFR (p. 593). Because plasma $[\text{H}^+]$ is quite low (less than in pure H_2O except during extreme acidosis), the filtration rate of H^+ is likewise extremely low. The majority of excreted H^+ gains entry into the tubular fluid by being secreted by the proximal and distal tubules and collecting ducts (p. 571). Because the kidneys normally excrete H^+ , urine is usually acidic, having an average pH of 6.0.

The H^+ secretory process begins in the tubular cells with CO_2 arising from three sources: (1) diffusing in from plasma, (2) diffusing in from tubular fluid, or (3) metabolically produced within the tubular cells, where carbonic anhydrase (CA) catalyzes the conversion of CO_2 and H_2O into H^+ and HCO_3^- (p. 639). An energy-dependent carrier in the apical (luminal) membrane then transports H^+ out of the cell into the tubular lumen. The types of carriers differ in different parts of the nephron as follows:

- **Proximal tubule:** In this tubule, H^+ is secreted by primary active transport via H^+ ATPase pumps and by secondary active transport via Na^+/H^+ antiporters as in fish gills (see p. 643).
- **Distal and collecting tubules:** Recall that two types of cells are located in the distal and collecting tubules, *principal cells* and *intercalated cells* (p. 587). Principal cells are the ones crucial for Na^+ , Cl^- , and K^+ balance under the influence of aldosterone and maintenance of H_2O balance under the influence of vasopressin. Intercalated cells, which are interspersed among the principal cells, are involved in fine regulation of acid-base balance. There are two types of intercalated cells, Type A and Type B:
 1. **Type A intercalated cells** are H^+ -secreting, HCO_3^- -reabsorbing, K^+ -reabsorbing cells. They actively secrete H^+ into the tubular lumen via H^+/K^+ ATPase (which secrete H^+ in exchange for the uptake of K^+) and H^+ ATPase pumps. Both of these carriers are in the apical membrane (Figure 13-20a). The HCO_3^-

FIGURE 13-20 Renal ion secretion. (a) Hydrogen ion secretion coupled with bicarbonate reabsorption in a Type A intercalated cell. The H^+ -secreting pumps are located at the luminal membrane, and the HCO_3^- -reabsorbing antiporters are located at the basolateral membrane. Because the disappearance of a filtered HCO_3^- from the tubular fluid is coupled with the appearance of another HCO_3^- in the plasma, HCO_3^- is considered to have been “reabsorbed.” (b) Bicarbonate secretion coupled with hydrogen ion reabsorption in a Type B intercalated cell. The HCO_3^- -secreting antiporters are located at the luminal membrane and the H^+ -reabsorbing pumps are located at the basolateral membrane.

© Cengage Learning, 2013

generated in the process of H^+ formation from CO_2 under the influence of carbonic anhydrase enters the blood in exchange for Cl^- at the basolateral membrane via $\text{Cl}^-/\text{HCO}_3^-$ antiporters.

2. **Type B intercalated cells** are HCO_3^- -secreting, H^+ -reabsorbing, K^+ -secreting cells, just the opposite of the Type A cells. In the Type B cells, the active H^+ ATPase pumps and H^+/K^+ ATPase pumps are in the basolateral membrane and the $\text{Cl}^-/\text{HCO}_3^-$ antiporters are in the apical membrane. In this case, when H^+ and HCO_3^- are generated from the hydration of CO_2 under the influence of carbonic anhydrase, HCO_3^- is secreted into the tubular lumen in exchange for Cl^- , and H^+ is reabsorbed into the plasma in exchange for K^+ (Figure 13-20b). (Even though K^+ is actively secreted by the Type B cells, quantitatively much more

K^+ is actively secreted by the principal cells under the control of aldosterone.)

Type A intercalated cells are more active than Type B intercalated cells under normal circumstances, and their activity increases even more during acidosis. Type B intercalated cells become more active during alkalosis.

Bicarbonate Excretion Before being eliminated by the kidneys, the H^+ generated from noncarboxylic acids is buffered to a large extent by plasma HCO_3^- . Appropriately, therefore, renal handling of acid–base balance also involves the adjustment of HCO_3^- excretion, depending on the H^+ load in the plasma.

The kidneys regulate plasma $[\text{HCO}_3^-]$ by three interrelated mechanisms: (1) variable reabsorption of filtered HCO_3^-

FIGURE 13-21 Hydrogen ion secretion and excretion coupled with the addition of new HCO_3^- to the plasma. Secreted H^+ does not combine with filtered HPO_4^{2-} and is not subsequently excreted until all the filtered HCO_3^- has been “reabsorbed,” as depicted in Figure 13-20a. Once all the filtered HCO_3^- has combined with secreted H^+ , further secreted H^+ is excreted in the urine, primarily in association with urinary buffers such as basic phosphate. Excretion of H^+ is coupled with the appearance of new HCO_3^- in the plasma. The “new” HCO_3^- represents a net gain rather than merely a replacement for filtered HCO_3^- .

© Cengage Learning, 2013

back into the plasma in conjunction with H^+ secretion, (2) variable addition of new HCO_3^- to the plasma in conjunction with H^+ secretion, and (3) variable secretion of HCO_3^- in conjunction with H^+ reabsorption. The first two mechanisms of renal handling of HCO_3^- are inextricably linked with H^+ secretion, primarily by proximal tubular cells and to a lesser extent by Type A intercalated cells. Every time an H^+ is secreted into the tubular fluid, an HCO_3^- is simultaneously transferred into the peritubular capillary plasma. Whether a filtered HCO_3^- is reabsorbed or a new HCO_3^- is added to the plasma in accompaniment with H^+ secretion depends on whether filtered HCO_3^- is present in the tubular fluid to react with the secreted H^+ , as follows.

Bicarbonate is freely filtered, but because the apical membranes of tubular cells are impermeable to filtered HCO_3^- , it cannot diffuse into these cells. Therefore, reabsorption of HCO_3^- must occur indirectly. We will use the Type A intercalated cell as an example (Figure 13-20a). A hydrogen ion secreted into the tubular fluid combines with filtered HCO_3^- to form H_2CO_3 . Under the influence of carbonic anhydrase, which is present on the surface of the apical membrane, H_2CO_3 becomes CO_2 and H_2O within the filtrate. Unlike HCO_3^- , CO_2 can easily penetrate tubular cell membranes. Within the cells, CO_2 and H_2O , under the influence of intracellular carbonic anhydrase, form H^+ and HCO_3^- . Because HCO_3^- can permeate these tubular cells' basolateral membrane by means of the $\text{Cl}^-/\text{HCO}_3^-$ antiporter, it diffuses out of the cells and into the peritubular capillary plasma. Meanwhile, the generated H^+ is actively secreted (Figure 13-21). Because the disappearance of an HCO_3^- from the tubular fluid is coupled with the appearance of another HCO_3^- in the plasma, an HCO_3^- has, in effect, been “reabsorbed.” Even though the HCO_3^- entering the plasma is “new,” that is, not the same ion that was filtered, the net result is the same as if HCO_3^- were directly reabsorbed. Meanwhile, the secreted H^+ combines with urinary buffers such as phosphate (HPO_4^{2-}) and is excreted (Figure 13-21).

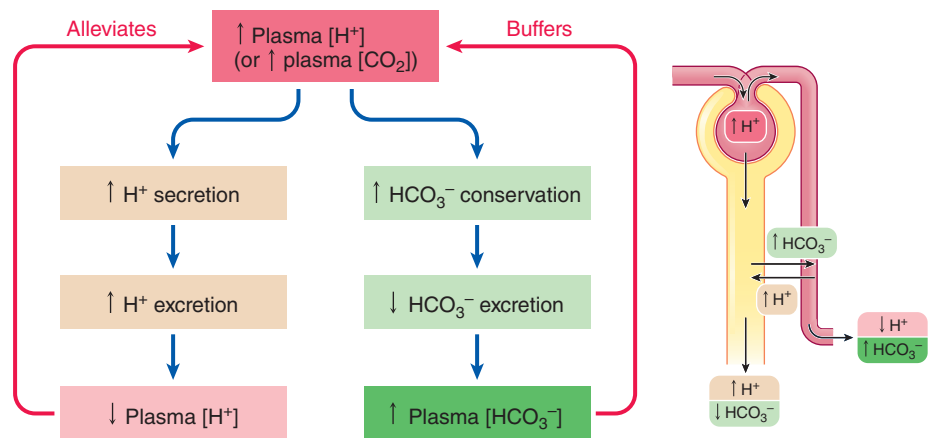

FIGURE 13-22 Control of the rate of tubular H^+ secretion and HCO_3^- reabsorption (mammalian kidney).

© Cengage Learning, 2013

The same steps are involved in HCO_3^- reabsorption in the proximal tubular cells, except in addition to having basolateral $\text{Cl}^-/\text{HCO}_3^-$ antiporters, these cells also have more abundant basolateral $\text{Na}^+/\text{HCO}_3^-$ symporters that simultaneously reabsorb Na^+ and HCO_3^- .

Renal Handling of H^+ during Acidosis and Alkalosis The kidneys are able to exert a fine degree of control over body pH. Renal handling of H^+ and HCO_3^- depends primarily on a direct effect of the plasma's acid-base status on the kidney's tubular cells. Under normal circumstances, the proximal tubular cells and Type A intercalated cells are predominantly active, promoting net H^+ secretion and HCO_3^- reabsorption. This pattern of activity is adjusted when pH deviates from the set point. Let's look first at the influence of acidosis and alkalosis on H^+ secretion (Figure 13-22):

- When the $[\text{H}^+]$ of the plasma passing through the peritubular capillaries is elevated above normal, the proximal tubular cells and Type A intercalated cells respond by secreting greater-than-usual amounts of H^+ from the plasma into the tubular fluid to be excreted.

- Conversely, when plasma $[H^+]$ is lower than normal, the kidneys conserve H^+ by reducing its secretion by proximal cells and Type A intercalated cells. Also, Type B intercalated cells become more active to compensate for alkalosis by increasing H^+ reabsorption. Together, these actions decrease H^+ excretion.

Because chemical reactions for H^+ secretion begin with CO_2 , the rate at which they proceed is also influenced by $[CO_2]$.

- When plasma $[CO_2]$ increases, the rate of H^+ secretion speeds up (Figure 13-22).
- Conversely, the rate of H^+ secretion slows when plasma $[CO_2]$ falls below normal.

These responses are especially important in renal compensations for acid–base abnormalities involving a change in H_2CO_3 caused by respiratory dysfunction. Thus, the kidneys can adjust H^+ excretion to compensate for changes in both carbonic and noncarbonic acids.

Renal Handling of HCO_3^- during Acidosis and Alkalosis When plasma $[H^+]$ is elevated during acidosis, more H^+ is secreted than normal. At the same time, less HCO_3^- is filtered than normal because more of the plasma HCO_3^- is used up in buffering the excess H^+ in the ECF. This greater-than-usual inequity between filtered HCO_3^- and secreted H^+ has two consequences. First, more of the secreted H^+ is excreted in the urine because more hydrogen ions are entering the tubular fluid at a time when fewer are needed to reabsorb the reduced quantities of filtered HCO_3^- . In this way, extra H^+ is eliminated from the body, making the urine more acidic than normal. Second, because excretion of H^+ is linked with the addition of new HCO_3^- to the plasma, more HCO_3^- than usual enters the plasma passing through the kidneys. This additional HCO_3^- is available to buffer excess H^+ present in the body.

In the opposite situation of alkalosis, the rate of H^+ secretion diminishes, while the rate of HCO_3^- filtration increases compared to normal. When plasma $[H^+]$ is below normal, a smaller proportion of the HCO_3^- pool is tied up buffering H^+ , so plasma $[HCO_3^-]$ is elevated above normal. As a result, the rate of HCO_3^- filtration correspondingly increases. Not all the filtered HCO_3^- is reabsorbed, because HCO_3^- ions are in excess of secreted H^+ ions in the tubular fluid and HCO_3^- cannot be reabsorbed without first reacting with H^+ . Excess HCO_3^- is left in the tubular fluid to be excreted in the urine, thus reducing plasma $[HCO_3^-]$ while making the urine alkaline. Furthermore, Type B intercalated cells come into play during alkalosis, further decreasing the excess HCO_3^- load in the body by secreting HCO_3^- into the urine.

Ammonia Secretion The energy-dependent H^+ carriers in the tubular cells can secrete H^+ against a concentration gradient until the tubular fluid (urine) becomes 800 times more acidic than the plasma. At this point, further H^+ secretion ceases because the gradient becomes too great for the secretory process to continue. It is impossible for kidneys of most mammals to acidify the urine beyond a gradient-limited urinary pH of 4.5. If left unbuffered as free H^+ , only about 1% of the excess H^+ typically excreted daily would produce a urinary pH of this magnitude at normal urine flow rates, and elimination of the other 99% of the usually secreted H^+ load would be prevented, a situation that would be intolerable. For H^+

secretion to proceed, the majority of secreted H^+ must be buffered in the tubular fluid so that it does not exist as free H^+ and, accordingly, does not contribute to the tubular acidity.

Bicarbonate cannot buffer urinary H^+ as it does the ECF, because HCO_3^- is not excreted in the urine simultaneously with H^+ . There are, however, two critical urinary buffers: (1) filtered phosphate buffers (p. 586) and (2) (the more important one) secreted ammonia (NH_3):

- **Phosphate as urinary buffer:** Normally, secreted H^+ is first buffered by the phosphate buffer system, which is in the tubular fluid because excess ingested phosphate has been filtered but not reabsorbed (Figure 13-21). The basic form of phosphate, HPO_4^{2-} , binds with secreted H^+ . Basic phosphate is present in the tubular fluid by virtue of dietary excess, not because of any deliberate mechanism to buffer secreted H^+ . When H^+ secretion is high, the buffering capacity of urinary phosphates is exceeded, but the kidneys cannot respond by excreting more basic phosphate. As soon as all the basic phosphate ions that are coincidentally excreted have “soaked up” H^+ , the acidity of the tubular fluid quickly rises as more H^+ ions are secreted. Without additional buffering capacity from another source, H^+ secretion would soon be halted abruptly as the free $[H^+]$ in the tubular fluid quickly increased to a critical limiting threshold.
- **Ammonia as urinary buffer:** The enzyme *glutaminase* in proximal tubular cells generates NH_3 from the amino acid *glutamine*. When acidosis exists, NH_3 enables the kidneys to continue secreting additional H^+ ions because NH_3 combines with free H^+ to form ammonium ion (NH_4^+):

The tubular membranes transport both NH_3 and NH_4^+ into the lumen by membrane proteins (including *Rh* types; see p. 573). Since membranes are not very permeable to NH_4^+ , these ions remain in the tubular fluid and are lost in the urine, each one taking an H^+ with it. Thus, NH_3 during acidosis serves to buffer excess H^+ in the tubular fluid, so that large amounts of H^+ can be secreted into the urine before the pH falls to the limiting value of 4.5. The rate of NH_3 secretion is related to the amount of excess H^+ to be transported in the urine. When an individual mammal has been acidotic for more than two or three days, the rate of NH_3 production increases substantially due to increased protein breakdown (to yield amino acids), glutamine uptake, and glutaminase activity (the regulatory signals for this are not fully known). This extra NH_3 provides additional buffering capacity to allow H^+ secretion to continue after the normal buffering capacity of phosphate is overwhelmed during renal compensation for acidosis.

What is the role of ammonia in renal regulation of acid–base balance?

13.8 Acid–Base Imbalances: Respiratory, Environmental, and Metabolic Disturbances

So far, we have mentioned some disturbances that alter body pH. Let's now look at these systematically. Deviations from normal acid–base status are divided into six general categories, depending on the source and direction of the abnormal change in $[H^+]$. These categories are *respiratory*, *metabolic*, and *environmental acidosis* and *respiratory*, *metabolic*, and *environmental alkalosis*.

Recall that changes in $[H^+]$ are reflected by changes in the ratio of $[HCO_3^-]$ to $[CO_2]$. Recall that the normal ratio is 20:1 ($pH = 7.4$; note these are mammalian values). Determinations of $[HCO_3^-]$ and $[CO_2]$ provide more meaningful information about the underlying factors responsible for a particular acid–base status than do direct measurements of $[H^+]$ alone. The following rules of thumb apply when examining acid–base imbalances *before any compensation take place*:

1. A change in pH that has a respiratory cause is associated with an abnormal $[CO_2]$, giving rise to a change in carbonic acid–generated H^+ . Most environmental causes also involve abnormal $[CO_2]$. In contrast, a pH deviation of metabolic origin is associated with an abnormal $[HCO_3^-]$ as a result of the participation of HCO_3^- in buffering abnormal amounts of H^+ generated from non-carbonic acids.
2. Anytime the $[HCO_3^-]/[CO_2]$ ratio falls below 20:1, an acidosis exists. The log of any number lower than 20 is less than 1.3 and, when added to the pK of 6.1, yields an acidotic pH below 7.4. Anytime the ratio exceeds 20:1, an alkalosis exists. The log of any number greater than 20 is more than 1.3 and, when added to the pK of 6.1, yield an alkalotic pH above 7.4. (Note these are mammalian values.)

We next examine each of the six imbalances separately in more detail in terms of possible causes and the compensations that occur. The “balance beam” concept, presented in Figure 13-23 in conjunction with the Henderson-Hasselbalch equation, may help you better visualize the contributions of lungs and kidneys to the causes and compensations of various acid–base disorders. The normal situation is represented in Figure 13-23a.

Respiratory acidosis arises from an increase in $[CO_2]$

Respiratory acidosis is the result of abnormal CO_2 buildup in body fluids, typically arising from hypoventilation (see p. 542). As less-than-normal amounts of CO_2 are lost through the lungs (or gills), the resultant increase in H_2CO_3 leads to an elevated $[H^+]$. Possible causes include lung or gill disease, depression of the respiratory center by drugs or disease, nerve or muscle disorders that reduce respiratory muscle ability, or (transiently) even the simple act of holding one's breath.

In uncompensated respiratory acidosis (Figure 13-23b), $[CO_2]$ is elevated (in our example, it is doubled) while $[HCO_3^-]$ is normal, so the ratio is 20:2 (10:1) and pH is reduced. Let us clarify a potentially confusing point. You

might wonder why when $[CO_2]$ is elevated and drives the reaction $CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$ to the right, we say that $[H^+]$ becomes elevated but $[HCO_3^-]$ remains normal, although the same quantities of H^+ and HCO_3^- are produced when CO_2 -generated H_2CO_3 dissociates. The answer lies in the fact that normally the $[HCO_3^-]$ is 600,000 times the $[H^+]$ in a mammal. For every one hydrogen ion and 600,000 bicarbonate ions present in the ECF, generating one additional H^+ and one HCO_3^- doubles the $[H^+]$ (a 100% increase) but only increases the $[HCO_3^-]$ 0.00017% (from 600,000 to 600,001 ions). Therefore, an elevation in $[CO_2]$ brings about a pronounced increase in $[H^+]$, but $[HCO_3^-]$ remains essentially normal.

Compensatory measures act to restore pH to normal:

- The chemical buffers immediately take up additional H^+ , but the respiratory mechanism usually cannot respond with compensatory increased ventilation, because an impairment in respiratory activity is the problem in the first place. Also, if high environmental CO_2 is the cause, increasing ventilation only makes the problem worse because the gradient favors inward diffusion of the gas.
- Thus, in mammals, the kidneys are most important in compensating for respiratory acidosis. They conserve all the filtered HCO_3^- and add new HCO_3^- to the plasma while simultaneously secreting and, accordingly, excreting more H^+ . As a result, HCO_3^- stores become elevated. In our example (Figure 13-23b), the plasma $[HCO_3^-]$ is doubled, so the $[HCO_3^-]-[CO_2]$ ratio is 40:2 rather than 20:2 as it was in the uncompensated state. A ratio of 40:2 is equivalent to a normal 20:1 ratio, so the pH is once again the normal 7.4. Enhanced renal conservation of HCO_3^- has fully compensated for CO_2 accumulation, restoring the pH to normal, although both the $[CO_2]$ and the $[HCO_3^-]$ are now distorted.

Note that maintenance of normal pH depends on preserving a normal ratio between $[HCO_3^-]$ and $[CO_2]$, no matter what the absolute values of each of these buffer components are. (Compensation is never fully complete because the pH can be restored close to but not precisely to normal. In our examples, however, we assume full compensation for ease in mathematical calculations. Also bear in mind that the values used are only representative. Deviations in pH actually occur over a range, and the degree to which compensation can be accomplished varies.)

Respiratory alkalosis usually arises from a decrease in $[CO_2]$

The primary defect in respiratory alkalosis is excessive loss of CO_2 from the body as a result of hyperventilation. When pulmonary ventilation increases out of proportion to the rate of CO_2 production, too much CO_2 is blown off. Consequently, less H_2CO_3 is formed and $[H^+]$ decreases. Possible causes of respiratory alkalosis include fever, anxiety, and ingested toxins, all of which excessively stimulate ventilation without regard to the status of O_2 , CO_2 , or H^+ in the body fluids. Respiratory alkalosis also occurs as a result of physiological mechanisms at high altitude. When the low concentration of O_2 in the arterial blood reflexly stimulates ventilation in an attempt to obtain more O_2 for the body, too much CO_2 is blown off in the process, inadvertently

(e) Metabolic alkalosis

FIGURE 13-23 Relationship of $[\text{HCO}_3^-]$ and $[\text{CO}_2]$ to pH in various acid-base statuses, shown visually as a balance beam and mathematically as a solution to the Henderson-Hasselbalch equation.

Note that the lengths of the arms of the balance beams are not to scale.

(a) When acid-base balance is normal, the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio is 20:1. Each of the four types of acid-base disorders has an uncompensated state and a compensated state. (b) In uncompensated respiratory acidosis, the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio is reduced (20:2) because CO_2 has accumulated. In compensated respiratory acidosis, HCO_3^- is retained to balance the CO_2 accumulation, which restores the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio to a normal equivalent (40:2). (c) In uncompensated respiratory alkalosis, the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio is increased (20:0.5) by a reduction in CO_2 . In compensated respiratory alkalosis, HCO_3^- is eliminated to balance the CO_2 deficit, which restores the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio to a normal equivalent (10:0.5). (d) In uncompensated metabolic acidosis, the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio is reduced (10:1) by an HCO_3^- deficit. In compensated metabolic acidosis, HCO_3^- is conserved, which partially makes up for the HCO_3^- deficit, and CO_2 is reduced; these changes restore the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio to a normal equivalent (15:0.75). (e) In uncompensated metabolic alkalosis, the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio is increased (40:1) by excess HCO_3^- . In compensated metabolic alkalosis, some of the extra HCO_3^- is eliminated, and CO_2 is increased; these changes restore the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio to a normal equivalent (25:1.25).

leading to an alkalotic state (see p. 542), which causes constriction of blood vessels going to the brain. This can cause fainting or even death. Interestingly, blood flow to the brain does not drop in birds hyperventilating. The mechanisms are not known but are essential for flight at high altitudes.

If we look at the biochemical abnormalities in uncompensated respiratory alkalosis (Figure 13-23c), the increase in pH reflects a reduction in $[\text{CO}_2]$ (half the normal value in our example) while the $[\text{HCO}_3^-]$ remains normal. This yields an alkalotic ratio of 20:0.5, which is comparable to 40:1.

Compensatory measures in mammals act to shift the pH back toward normal:

- The chemical buffer systems liberate H^+ to diminish the severity of the alkalosis.
- As plasma $[\text{CO}_2]$ and $[\text{H}^+]$ fall below normal because of excessive ventilation, two of the normally potent stimuli for driving ventilation are removed. This effect tends to “put brakes” on the extent to which some non-respiration-related factors such as fever or anxiety can overdrive ventilation. In those cases, hyperventilation does not continue unabated.
- If the situation continues for a few days, the kidneys compensate by conserving H^+ and excreting more HCO_3^- . If, as in our example (Figure 13-23c), the HCO_3^- stores are reduced by half by loss of HCO_3^- in the urine, the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio becomes 10:0.5, equivalent to the normal 20:1. Therefore, the pH is restored to normal by reducing the HCO_3^- load to compensate for the CO_2 loss.

Metabolic acidosis is associated with a reduction in plasma $[\text{HCO}_3^-]$

Metabolic acidosis encompasses all types of acidosis besides that caused by excess CO_2 in the body fluids. In the uncompensated state (Figure 13-23d), metabolic acidosis is always characterized by a reduction in plasma $[\text{HCO}_3^-]$ (in our ex-

ample it is halved), while $[\text{CO}_2]$ remains normal, producing an acidotic ratio of 10:1. The problem may arise from the body's excessive loss of fluids rich in HCO_3^- or from an accumulation of noncarbonic acids. In the latter case, plasma HCO_3^- is used up in the process of buffering the additional H^+ .

This type of acid-base disorder is the one more frequently encountered. The following are the most common causes in mammals:

1. *Severe diarrhea.* During digestion, a bicarbonate-rich digestive juice is normally secreted into the digestive tract from the pancreas and is subsequently reabsorbed back into the plasma when digestion is completed. During diarrhea, this HCO_3^- is lost from the body rather than being reabsorbed. The reduction in plasma $[\text{HCO}_3^-]$ without a corresponding reduction in $[\text{CO}_2]$ lowers the pH. That is, loss of HCO_3^- shifts the $\text{H}^+ + \text{HCO}_3^- \leftrightarrow \text{CO}_2 + \text{H}_2\text{O}$ reaction to the left to compensate for the HCO_3^- deficit, increasing $[\text{H}^+]$ above normal in the process.
2. *Diabetes mellitus ketoacidosis.* Abnormal fat metabolism resulting from the inability of cells to preferentially use glucose in the absence of insulin results in the formation of excess *keto acids* whose dissociation causes an increase in plasma $[\text{H}^+]$.
3. *Strenuous activity.* When muscles resort to anaerobic glycolysis during strenuous activity (see p. 55), excess lactate is produced, leading to a rise in plasma $[\text{H}^+]$. In exercising alligators, for example, plasma pH may drop from 7.4 to 7.0, then take two hours to recover.
4. *Uremic acidosis.* In severe renal failure (uremia), the kidneys cannot rid the body of even the normal amounts of H^+ generated from the noncarbonic acids formed by the body's ongoing metabolic processes, so H^+ starts to accumulate in the body fluids. Also, the kidneys cannot conserve an adequate amount of HCO_3^- to be used for buffering the normal acid load. The resultant fall in $[\text{HCO}_3^-]$ without a concomitant reduction in $[\text{CO}_2]$ is correlated with a decline in pH to an acidotic level.

Except in uremic acidosis, metabolic acidosis is compensated for by both respiratory and renal mechanisms as well as by chemical buffers:

- The buffers take up extra H^+ .
- The lungs blow off additional H^+ -generating CO_2 .
- The kidneys excrete more H^+ and conserve more HCO_3^- .

In our example (Figure 13-23d), these compensatory measures restore the ratio to normal by reducing $[\text{CO}_2]$ to 75% of normal and by raising $[\text{HCO}_3^-]$ halfway back toward normal (up from 50 to 75% of the normal value). This brings the ratio to 15:0.75 (equivalent to 20:1).

Note that in compensating for metabolic acidosis, the lungs deliberately displace $[\text{CO}_2]$ from normal in an attempt to restore $[\text{H}^+]$ toward normal. Whereas in respiration-induced acid-base disorders, an abnormal $[\text{CO}_2]$ is the cause of the $[\text{H}^+]$ imbalance, in metabolic acid-base disorders, $[\text{CO}_2]$ is intentionally shifted from normal as an important compensation for the $[\text{H}^+]$ imbalance.

When kidney disease is the cause of metabolic acidosis, complete compensation is not possible, because the renal mechanism is not available for pH regulation. Recall that the respiratory system can compensate only up to 75% of the

TABLE 13-6 Summary of $[\text{CO}_2]$, $[\text{HCO}_3^-]$, and pH in Uncompensated and Compensated Respiratory and Metabolic Acid–Base Abnormalities

Acid–Base Status	pH	$[\text{CO}_2]$ (compared to normal)	$[\text{HCO}_3^-]$ (compared to normal)	$[\text{HCO}_3^-]/[\text{CO}_2]$
Normal	Normal	Normal	Normal	20/1
Uncompensated Respiratory Acidosis	Decreased	Increased	Normal	20/2 (10/1)
Compensated Respiratory Acidosis	Normal	Increased	Increased	40/2 (20/1)

way toward normal. Uremic acidosis is very serious, because the kidneys cannot restore the pH all the way to normal.

Metabolic alkalosis is associated with an elevation in $[\text{HCO}_3^-]$

Metabolic alkalosis is a reduction in plasma $[\text{H}^+]$ caused by a relative deficiency of noncarbonic acids. This acid–base disturbance is associated with an increase in $[\text{HCO}_3^-]$, which, in the uncompensated state, is not accompanied by a change in $[\text{CO}_2]$. In our example (Figure 13-23e), $[\text{HCO}_3^-]$ is doubled, producing an alkalotic ratio of 40:1. This condition arises most commonly in mammals from *vomiting*, which results in abnormal loss of H^+ from the body as a result of loss of acidic gastric juices. Hydrochloric acid is secreted into the stomach lumen during the process of digestion. Bicarbonate is added to the plasma during gastric HCl secretion. This HCO_3^- is neutralized by H^+ as the gastric secretions are eventually reabsorbed back into the plasma, so normally there is no net addition of HCO_3^- to the plasma from this source. However, when this acid is lost from the body during vomiting, not only is plasma $[\text{H}^+]$ decreased, but also reabsorbed H^+ is no longer available to neutralize the extra HCO_3^- added to the plasma during gastric HCl secretion. Thus, loss of HCl in effect increases plasma $[\text{HCO}_3^-]$.

In metabolic alkalosis:

- The chemical buffer systems immediately liberate H^+ .
- Ventilation is reduced so that extra H^+ -generating CO_2 is retained in the body fluids.
- If the condition persists for several days, the kidneys conserve H^+ and excrete the excess HCO_3^- in the urine.

The resultant compensatory increase in $[\text{CO}_2]$ (up 25% in our example—Figure 13-23e) and the partial reduction in $[\text{HCO}_3^-]$ (75% of the way back down toward normal in our example) together restore the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio back to the equivalent of 20:1 at 25:1.25.

Overview of Compensated Acid–Base Disorders Clearly, an animal's acid–base status cannot be assessed on the basis of

pH alone. Uncompensated acid–base abnormalities can readily be distinguished on the basis of deviations of either $[\text{CO}_2]$ or $[\text{HCO}_3^-]$ from normal (Table 13-6). When compensation has been accomplished and the pH is essentially normal, determinations of $[\text{CO}_2]$ and $[\text{HCO}_3^-]$ can reveal the presence of an acid–base disorder. Note, however, that in both compensated respiratory acidosis and compensated metabolic alkalosis, $[\text{CO}_2]$ and $[\text{HCO}_3^-]$ are both above normal. With respiratory acidosis, the original problem is an abnormal increase in $[\text{CO}_2]$, and a compensatory increase in $[\text{HCO}_3^-]$ restores the $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio to 20:1. Metabolic alkalosis, in contrast, is characterized by an abnormal increase in $[\text{HCO}_3^-]$ in the first place; then $[\text{CO}_2]$ is deliberately increased to restore the ratio to normal. Similarly, compensated respiratory alkalosis and compensated metabolic acidosis share similar patterns of $[\text{CO}_2]$ and $[\text{HCO}_3^-]$. Respiratory alkalosis starts out with a reduction in $[\text{CO}_2]$, which is compensated by a reduction in $[\text{HCO}_3^-]$. With metabolic acidosis, $[\text{HCO}_3^-]$ falls below normal, followed by a compensatory decrease in $[\text{CO}_2]$.

Environmental acidosis arises from natural and anthropogenic increases in environmental $[\text{CO}_2]$ and sulfuric acid

Finally, let's turn to environmental disturbances. Acidosis can arise from CO_2 and acids in the environment. One example would be a human or pet exposed to output from a CO_2 -based fire extinguisher. Other environmental acids include sulfuric acid derived from sulfur compounds in emissions from volcanoes and coal-burning power plants. Sulfuric acid is a major cause of *acid rain* that can fall downwind of some power plants or volcanoes and damage aquatic ecosystems. And there is anthropogenic (human-made) atmospheric CO_2 .

Ocean Acidification In terms of environmental acidosis, the greatest concern is the increase of CO_2 in Earth's atmosphere as a result of human burning of fossil fuels. The gas has increased in the air from 280 ppm (parts per million) to nearly 387 ppm (as of 2009) since the Industrial Revolution began.

In addition to the “greenhouse” warming effect of CO_2 (see Chapter 15), up to half of the excess is dissolving in the oceans and thus, through the bicarbonate reaction, acidifying them. The oceans have had a consistent pH of about 8.2 for millennia, but by 2008, they had dropped below 8.1. Since pH is logarithmic, this is a 25% increase in $[\text{H}^+]$!

The most direct impact of this *ocean acidification* is a weakening of shells and coral skeletons, whose CaCO_3 matrix cannot form properly if water is too acidic. Recent studies show that some animals are already being affected by this, including:

- **Corals:** Glenn De’ath and colleagues reported in 2008 that growth of some corals on the Great Barrier Reef has declined by 13% since 1990, in correlation with rising acidity. Another study in 2011 on Indonesian coral reefs near natural CO_2 seeps reveals that coral diversity drops as pH falls from 8.1 to 7.8 and that coral growth stops at pH 7.7.
- **Bivalves:** Stephanie Talmage and Christopher Gobler reported in 2010 that larvae of two commercially important bivalves grew faster and developed thicker shells when grown at pre-industrial CO_2 /pH levels than when grown under current conditions. And at an oyster hatchery in Oregon, acidic ocean water entering the tanks in 2008 and 2009 killed most of the oyster larvae.
- **Fish:** Fisheries biologists of the National Oceanic and Atmospheric Administration tested pH effects on young pollock (a commercially important bony fish) in Oregon. The fish were found to compensate for increased acidity by boosting bicarbonate buffer in their blood, but this could harm their growth since that process presumably costs energy.

One possible result of such effects is rather dramatic: The density of marine jellies is increasing worldwide, choking the waters in some places like the Mediterranean and Japan Seas. At the same time, other organisms such as fishes are declining. Increasing acidity is thought to be one cause because—unlike the declining organisms—jellies so far appear to thrive in these changing ocean conditions that harm other animals. However, the role of pH in this trend remains controversial.

Some people have proposed that excess atmospheric CO_2 be dumped into the deep sea, where low temperatures and high pressures convert the gas into a liquid. Unfortunately, fish placed in cages next to experimental liquid CO_2 dumps died from acidosis as the liquid gas slowly dissolved into seawater.

Paul Yancey

Corals in Hawai’i. These corals are being threatened worldwide due to ocean acidification.

Environmental alkalosis arises from basic minerals

Environmental alkalosis is not common but can arise from basic minerals like sodium carbonate in water. In Chapter 12, you learned about the excretory adaptations of tilapia living in the highly alkaline Lake Magadi in Africa (p. 561). Another example, Pyramid Lake in Nevada, has been slowly drying up for many years, and the resulting concentration of sodium carbonate is continuously increasing the lake’s alkalinity (now at pH 9.4). There is concern that this threatens the resident cutthroat trout. In laboratory studies, trout exposed to water at pH 10 suffered a 0.25-pH-unit increase in blood pH, and over half of the fish died after 72 hours. The fish had excessively high levels of plasma ammonia and low levels of plasma Na^+ and Cl^- , suggesting that excretion and ion regulation were inhibited.

What are the causes of the six categories of acid–base imbalances?

Why is uremic acidosis so serious?

making connections

How Fluid and Acid–Base Regulation Contribute to the Body as a Whole

Homeostasis depends on maintaining a balance between the input and output of all constituents present in the internal fluid environment. Regulation of fluid balance involves two separate components: control of salt balance and control of H_2O balance. Control of H_2O balance is important in preventing changes in both ECF volume and osmolarity. Volume changes affect blood pressure, while osmolarity changes can induce detrimental osmotic shifts of H_2O between the cells and the ECF. Such shifts of H_2O into or out of the cells would cause the cells to swell or shrink, respectively. Cells, especially brain neurons, do not function normally when swollen or shrunken. In marine osmoconformers, the ICF has organic osmolytes to control osmotic pressure, and sometimes to protect proteins from destabilizing effects of urea and other stressors. In osmoregulators such as bony fishes and mammals, ECF salt, osmolarity, and volume are kept relatively constant.

A balance between input and output of H^+ is also critical to maintaining a body’s acid–base balance within the narrow limits compatible with life. Deviations in the internal fluid environment’s pH lead to altered neuromuscular excitability, to changes in enzymatically controlled metabolic activity, and to K^+ imbalances, which can cause cardiac arrhythmias. Hydrogen ions are uncontrollably and continually being added to body fluids as a result of metabolic activities, yet the ECF’s pH must be kept relatively constant (at a slightly alkaline level of 7.4 for optimal function in mammals). In vertebrates, control of ECF pH by the kidneys is the main effector for achieving H^+ balance. Assisting the kidneys are the lungs, and buffers, which provide temporary pH stability in both ECF and ICF. Buffering mechanisms take up or liberate H^+ , thereby transiently keeping its concentration constant within the body until its output can be brought into line with its input.

Chapter Summary

- If water–solute balance is to be maintained, input must equal output. Body water is distributed between the intracellular and extracellular fluid compartments (plasma, lymph, and interstitial and transcellular fluids). In vertebrates, the plasma and interstitial fluid are similar in composition, but the ECF and ICF are markedly different in all animals, with NaCl dominating in the ECF and K^+ and organic molecules in the ICF.
- Osmotic problems that threaten cells and animals include salinity, evaporation, ingestion and excretion, freezing, and certain pathologies. Animals have evolved two strategies to cope with osmotic challenges: osmoconforming and osmoregulating.
- Osmoconformers, which have internal osmolarities equal to that of the environment, use compatible and counteracting organic osmolytes in their cells. These include certain small carbohydrates, free amino acids, methylamines, methylsulfonium solutes, and urea. Compatible osmolytes do not perturb membranes and macromolecules, unlike high salt levels. Counteracting solutes offset factors that perturb macromolecules and membranes.
- Strict osmoconformers include most marine nonvertebrates and hagfish, which have ECF compositions similar to that of seawater but ICFs dominated by compatible organic osmolytes such as glycine and taurine. Stenohaline species cannot tolerate major changes in external salinity, while euryhaline ones can, by regulating cellular osmolytes to match ECF and external osmolarity. Hypo-ionic osmoconformers, with ECF salt levels less than seawater's, include marine chondrichthyans and coelacanths, which use the protein–destabilizing osmolyte urea counteracted by the protein–stabilizing osmolyte trimethylamine oxide (TMAO).
- Osmoregulators, which maintain a consistent internal osmolarity, rely on special transport epithelia. Hypo-osmotic regulators include most marine vertebrates and some arthropods, which use ion-excretion tissues such as gills. Some osmoregulating vertebrates have high levels of organic osmolytes, such as TMAO in deep-sea fishes and urea in estivating lungfish and frogs.
- Hyperosmotic regulation is found in all freshwater animals, and involves ion-uptake tissues such as gills, hypotonic urines, and impermeable integuments. Some animals such as salmon alternate between hyper- and hypo-osmotic regulation.
- Many terrestrial animals osmoregulate in the face of both low water and salt availability, using a variety of physiological (e.g., renal) and behavioral mechanisms.
- Fluid balance in mammals involves regulation of ECF volume and osmolarity. Control of ECF osmolarity prevents changes in ICF volume from hyper- or hypotonicity. Control of ECF volume is important in the long-term regulation of blood pressure and is adjusted in the short term through the baroreceptor reflex and plasma–interstitial fluid shifts. Both osmolarity and volume regulation are based on water and salt balances.
- Water balance depends on input from food, drink, and metabolism, and output via urine, feces, and insensible and sensible cutaneous and respiratory losses. Control of water balance by means of vasopressin and thirst is of primary importance in regulating ECF osmolarity.
- Long-term salt balances, which are more critical for volume regulation than water balance, depend on GFR changes and the renin–angiotensin–aldosterone system. During hemorrhagic shock, circulatory functions and fluid balance are coordinately regulated by many of these and other systems.
- Acid–base balance—the regulation of free hydrogen ions (H^+) in body fluids—is crucial to survival. Acids liberate free hydrogen ions, whereas bases accept them. The pH designation is used to express hydrogen ion concentration. Fluctuations in $[H^+]$ alter nerve, enzyme, and K^+ activity. Hydrogen ions are continually being added to body fluids from metabolic activities.
- Chemical buffer systems act as the first line of defense against changes in $[H^+]$ by binding with or releasing free H^+ . Buffering is described by the Henderson-Hasselbalch equation; for example, $pH = pK + \log [HCO_3^-]/[CO_2]$
- The CO_2 – HCO_3^- buffer system is the primary ECF buffer for non-carbonic acids. The peptide and protein buffer system, including hemoglobin in erythrocytes, is primarily important intracellularly. Buffers are a temporary mechanism because they do not eliminate excess $[H^+]$, necessitating the second and third lines of defense.
- Respiratory systems as a second line of defense regulate $[H^+]$ through adjustments in ventilation. Increased breathing removes CO_2 , while decreased breathing retains it.
- Excretory systems are a third line of defense that aid acid–base balance by controlling both $[H^+]$ and $[HCO_3^-]$ in the ECF. Mammalian kidneys, for example, have cells that can secrete H^+ and reabsorb HCO_3^- , and other cells to do the reverse. In acidosis, some cells secrete NH_3 , which can trap H^+ as NH_4^+ .
- Respiratory acidosis arises from an increase in $[CO_2]$, typically from hypoventilation. Respiratory alkalosis usually arises from a decrease in $[CO_2]$, such as in hyperventilation.
- Metabolic acidosis is associated with a reduction in plasma $[HCO_3^-]$, caused by severe diarrhea, diabetes, strenuous activity, and uremia. Respiratory alkalosis usually arises from a decrease in $[CO_2]$, such as in hyperventilation. Metabolic alkalosis is associated with an elevation in $[HCO_3^-]$, and can result from vomiting.
- Environmental acidosis arises from natural and anthropogenic increases in environmental $[CO_2]$ and sulfuric acid. Anthropogenic CO_2 is already acidifying the oceans and harming some organisms, especially those with $CaCO_3$ shells and skeletons. Environmental alkalosis arises from basic minerals, as in some alkaline lakes.

Review, Synthesize, and Analyze

1. What is *anhydrobiosis*? What are some animal examples, and how do they survive?
2. Compare the use of *counteracting* organic osmolytes in marine Chondrichthyes, deep-sea fishes, and (from Chapter 12) the mammalian kidney.
3. If a horse loses 10 liters of salt-rich sweat and drinks 7 liters of water during the same time period, what will happen to vasopressin and aldosterone secretion? Why is it important to replace both the water and the salt?
4. If a solute that can penetrate the plasma membrane, such as dextrose (a type of sugar), is dissolved in sterile water at a concentration equal to that of normal body fluids and then is injected intravenously, what is the impact on the body's fluid balance?
5. Describe the effects of *hemorrhage* on fluid balance and the ensuing compensatory responses.
6. A pet cat has had pronounced diarrhea for more than a week as a result of having acquired a bacterial intestinal infection. What impact has this prolonged diarrhea had on its fluid and acid–base balance? In what ways has the cat's body been trying to compensate for these imbalances?
7. Describe the three lines of defense against changes in $[H^+]$ in terms of their mechanisms and speed of action.
8. Given that mammalian plasma pH = 7.4, arterial P_{CO_2} = 40 mm Hg, and each mm Hg partial pressure of CO_2 is equivalent to a plasma $[CO_2]$ of 0.03 mM, what is the value of plasma $[HCO_3^-]$?
9. Death of most mammals occurs if plasma pH falls outside the range of 6.8 to 8.0 for an extended time. What is the concentration range of H^+ represented by this pH range?

The rumen of a Scottish Highland cow enables it to survive under conditions of low food quality and availability.

Digestive Systems

14.1 Introduction: Feeding Strategies and Evolution

To maintain homeostasis, nutrient molecules are needed for two purposes. First, some are used as “fuel” for energy production and must continually be replaced by new, energy-rich nutrients. Second, nutrient molecules such as amino acids are needed as “building blocks” for ongoing synthesis of new cells and cell components in the course of tissue turnover and growth. Similarly, water and electrolytes must be replenished regularly. The digestive system contributes to homeostasis by transferring nutrients, water, and electrolytes from the external environment to the internal environment. Because living cells depend on a continuing flow of nutrients to sustain their metabolic needs, most animals commit considerable time and energy to acquiring and digesting food. Carbohydrates, fats, and proteins represent the main fuels; they are broken down into absorbable units (specifically simple sugars, fatty acids, and amino acids), which an animal’s individual cells can use to produce ATP to carry out their particular energy-dependent activi-

ties, such as active transport, contraction, synthesis, and secretion. The units can also be used as building blocks. However, the digestive system does not directly regulate the concentration of any of these constituents in the internal environment; rather, it optimizes conditions for ingesting needed materials (food, water, and so forth), then digests and absorbs what is ingested.

We first provide an overview of digestive systems, examining the common features of the various components, before we begin a detailed tour of the tract from beginning to end.

Animal digestion evolved from an intracellular to an extracellular process in a specialized sac or tube connected to the environment

Digestion of food inside the body but outside the cell is accomplished by a digestive tract. Intracellular digestion is limited because only food items small enough to be internalized by the cells can be digested, whereas extracel-

lular digestion permits an animal to store and break down larger varieties and quantities of food items. The first digestive systems probably evolved as an infolding of the epidermis into an interior sac to trap food, providing the ability to capture much larger quantities of food. This is seen in Cnidaria (*knidos*, “stinging nettle” in Greek; jellies, corals, and their relatives), which are composed of an outer epidermis and an inner endoderm or *gastrodermis* (“stomach skin”) lining a blind-end sac. In later animal groups, the sac fused with the opposite end of the body to form a complete tube with an entrance (mouth) and exit (anus). Cells lining this digestive tube could evolve specialized functions; for example, cells responsible for acidic digestion could be compartmentalized and separated from those involved in alkaline digestion. Other parts of the tube could be specialized for receiving and storing food and processing wastes (Figure 14-1). Indigestible items could remain outside and not take up space within cells.

FIGURE 14-1 A generalized digestive tract. A digestive tract with one-way passage of food allows simultaneous operation of sequential stages in the processing of food and reduces mixing of digested and undigested matter. The crop is a storage region found in some animals.

© Cengage Learning, 2013

Thus, an animal's digestive tract can be thought of as a hollow sac or a tube with an entrance and exit, lying within the body and specialized for the initial processing of food items. At the openings, the tract is in direct contact with the outside world, so the lumen of the tract, although within the animal's body, is also technically part of the external environment. Until nutrients are actually absorbed across this tube, they cannot be considered "inside" the body. Conventionally, the gut tube in most animals can be divided into three specific regions: the **foregut**, **midgut**, and the **hindgut** (Figure 14-1).

Animals can be classified according to their primary feeding methods

Numerous methods for obtaining food have evolved. These include:

- **Filter or suspension feeders**, which range from sponges to baleen whales, trap organic material suspended in water (which may include dead particles, bacteria, algae,

protozoa, and small animals). An example of a filtering device can be seen in Figure 11-5, a polychaete's ciliated tentacles (the baleen mechanism will be described later).

- **Detritivores, or deposit feeders**, such as earthworms, many sea cucumbers and mites, feed on dead and living material in sediments.
- **Fluid feeders**, such as mosquitoes and vampire bats, which suck or lick fluids of a larger animal without ingesting the whole animal. Some fluid feeders are termed **parasites** if they remain attached to or within a host animal for long periods. A key example is the tapeworm, which has no digestive tract and lives within host intestines, where it absorbs small organic molecules through its body wall.
- **Carnivores** primarily eat other animals. They specialize in capturing live prey or rely on their abilities to locate carrion, and typically eat a high-energy, high-protein diet because of the high percentage of muscle tissue ("meat") in most animals.
- **Herbivores** depend on the intake of algal or plant materials, such as kelp blades and plant leaves, fruits, or seeds. Some of these materials have comparatively little directly available energy, and herbivores eating them have two options. The first, as seen in the dairy cow and the deer, uses **pregastric fermentation** (the processing of foodstuffs by microbes) as a means to break down plant material into absorbable units. In these animals the foregut is modified such that microorganisms can proliferate in a fermentation vat, the *rumen*. In a second type of herbivore, those with simple stomachs such as the horse and rabbit, microbial digestion occurs in the *hindgut*, which includes the *colon* and *cecum*. Herbivores either can be nonselective in their choice of food items or, as in the case of the panda, with its dependence on bamboo, can be highly selective. Herbivorous fish may feed on the fruits, seeds, flowers, and leaves of trees, whereas others may feed on algae.
- **Omnivores** such as humans, monkeys, and pigs can eat both animals and other organisms such as plants or fungi, and have digestive tracts more similar to carnivore tracts that rely on enzymatic digestion of foodstuffs. Because of seasonal changes in food availability, gut size adapts to low-quality feeds by increasing in length. For example, the starling is primarily a carnivore during the warmer months when insects and worms are available, but during the harsh winter months it is forced to become a herbivore and consume low-quality foods (buds, and so forth). In response, gut length increases a remarkable 450%.
- **Symbiotic autotroph-bearing** animals in the oceans require little or no external organic food (autotrophs are primary producers, namely photosynthesizers and chemosynthesizers). Key examples are (1) reef-building corals (Cnidarians) with photosynthesizing dinoflagellate symbionts that provide food molecules in addition to those ingested; and (2) vestimentiferan annelid worms living at hydrothermal vents (p. 741) and hydrocarbon (petroleum and natural gas) seeps. These worms use food molecules solely produced by symbiotic chemosynthesizing bacteria.

Depending on the life cycle of some animals, feeding specializations can be related to a particular stage of devel-

opment (as the vestimentiferan worm illustrates). Insect larvae normally have completely different food habits and digestive systems than adults. Tadpoles of some frog species are herbivorous and have a longer and more complex intestine than does the adult, which is carnivorous. And young mammals shift from milk to an adult diet.

External food supply ultimately represents one of the key factors that determines animal survivability, the others being predation, parasitism, disease, competition, and beneficial symbioses (such as microbes in ruminants' digestive tracts and algae in coral Cnidarians). The reproductive success of many species can also be linked to food availability. Rainfall, light, and temperature determine plant and algal growth and consequently the amount of food available to herbivores (and therefore the rest of the food chain). Plant material also varies in composition during the course of a year. Immature grasses and leaves are characterized by a higher content of protein compared with other nutrients than later in the season. In the oceans, the amount of particulate food generally decreases with depth and also varies according to location and season. In environments characterized by seasonal variation in climate, natural selection favors reproductive cycles that can best exploit these limiting resources.

Describe the different modes of animal feeding.

14.2 General Aspects of Digestion

Now let's turn to general features of digestive systems common to most animals.

Digestive systems perform four basic digestive processes

There are four basic digestive processes: *motility*, *secretion*, *digestion*, and *absorption*.

Motility The term **motility** refers to the muscular contractions within the gut tube that mix and move forward the contents of the digestive tract. However, some worm-shaped animals rely on muscular contractions of the body to indirectly force food through the gut tube. Although the smooth muscle in the walls of digestive tracts is typically *phasic* smooth muscle (p. 376) that displays action potential-induced bursts of contraction, it also maintains a constant low level of contraction known as **tone**. Tone is important in maintaining a steady pressure on the digestive tract contents as well as in preventing the walls of the digestive tract from remaining permanently stretched following distension.

Two basic types of digestive motility are superimposed on this ongoing tonic activity:

- **Propulsive movements** propel, or push, the contents through the digestive tract at varying speeds, with the rate of propulsion dependent on the functions accomplished by the different regions; that is, food is moved forward in a given segment at an appropriate velocity to

allow that segment to “do its job.” For example, transit of food through the foregut of arthropods and esophagus of vertebrates is rapid, which is appropriate because these structures merely serve as a passageway from the mouth to the stomach or midgut. In comparison, in the small intestine—the major site of digestion and absorption—the contents move slowly, allowing sufficient time for the breakdown and absorption of food. Propulsive movements are often thought of as being unidirectional from the mouth to anal sphincter; however, antiperistaltic contractions also occur in some species, especially birds.

- **Mixing movements** serve a twofold function. First, by mixing food with the digestive juices, movements promote digestion of the food. Second, they facilitate absorption by exposing all portions of the intestinal contents to the digestive tract's absorbing surfaces.

Motility in the digestive tract is mainly due to smooth muscle within the walls of the digestive organs; this muscle is controlled by complex autonomic (“involuntary”) mechanisms. Exceptions include the ends of the mammalian tract—the mouth and some or all of the esophagus (see p. 662) at the beginning and the external anal sphincter at the end—where motility may involve skeletal muscle. Accordingly, the acts of chewing, swallowing (rumination), and defecation have motor cortex control (“voluntary,” p. 192).

Secretion A number of digestive juices are secreted into the digestive tract lumen by exocrine glands located along the route, each with its own specific secretory product(s). Each secretion consists of water, electrolytes, and specific organic constituents that are important in the digestive process, such as enzymes, bile salts, or mucus. The secretory cells extract large volumes of water and those raw materials necessary to produce their particular secretion from blood. Secretion of all digestive juices requires energy, both for active transport of some of the raw materials into the cell (others diffuse in passively) and for synthesis of secretory products by the endoplasmic reticulum. On appropriate neural or hormonal stimulation, the secretions are released into the digestive tract lumen. Normally, the digestive secretions are reabsorbed in one form or another (back into the blood in vertebrates) after they participate in digestion. Failure to do so (because of vomiting or diarrhea, for example) results in loss of this fluid that has been “borrowed” from the plasma.

Digestion Digestion is the process whereby the structurally complex foodstuffs of the diet are broken down into smaller, absorbable units by enzymes produced within the digestive system. Complex carbohydrates, proteins, and fats are large molecules unable to cross plasma membranes intact. So, to be absorbed from the lumen of the digestive tract into the blood or lymph, they must be broken down into smaller nutrient molecules (although some animals use endocytosis, for example, of whole proteins in neonatal mammals). Digestion begins in the anterior regions of animal tracts and is accomplished for all nutrients with enzymatic **hydrolysis** (“breakdown by water”). Hydrolytic enzymes (**hydrolases**) add H₂O at the bond site, thereby breaking down the bonds that hold the small molecular subunits within the nutrient molecules together, thus setting the small molecules free (Figure 14-2a). These small subunits were originally joined

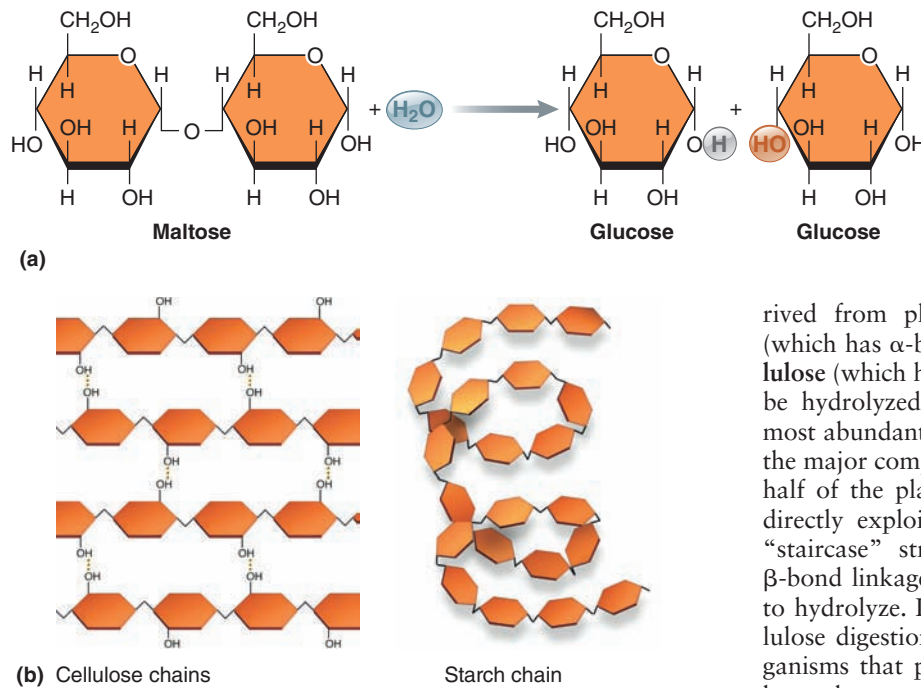

FIGURE 14-2 Structure and hydrolysis of common dietary carbohydrates. (a) An example of hydrolysis. In this example, the disaccharide maltose (the intermediate breakdown product of polysaccharides) is broken down into two glucose molecules by the addition of H_2O at the bond site. (b) Hydrogen bonding relationships for glucose units in cellulose and starch. In cellulose, hydrogen bonds form between glucose chains. This pattern stabilizes the chains and permits them to become tightly bundled. In amylose, a form of starch, the bonds form between units within a chain, which permits the glucose units to coil.

Source: C. Starr. (2000). *Biology: Concepts and Applications*, 4th ed., Belmont, CA: Brooks/Cole, p. 39, Figure 3.7.

to form nutrient molecules by the removal of H_2O at the bond sites. All digestive enzymes are hydrolytic, and the remarkable similarity of enzymes used by different animal species attests to their appearance early in evolution. Digestive enzymes are specific in the bonds they can hydrolyze. As food moves through the tract, it is subjected to various enzymes, each of which breaks down the food molecules even further. In this way, large food molecules are converted to simple absorbable units in a progressive, stepwise fashion as the tract contents are propelled forward. The major molecules are as follows:

1. **Carbohydrates** include the following:
 - a. **Monosaccharides** (“one-sugar” molecules), such as **glucose**, **fructose**, and **galactose**, very few of which are normally found in most diets. They are the absorbable units.
 - b. **Disaccharides** (“two-sugar” molecules) are another source of dietary carbohydrate and include **sucrose** (table sugar, which consists of one glucose and one fructose), **trehalose** (the most important carbohydrate for flight in insects, made up of two glucose molecules in opposite orientations), **maltose** (also made of two glucose molecules but in the same orientation), and **lactose** (milk sugar, made up of

one glucose and one galactose). They are hydrolyzed into monosaccharides in digestive tracts synthesizing the appropriate enzymes.

c. **Polysaccharides** (“many-sugar” molecules), which consist of chains of interconnected monosaccharide molecules, are the most common carbohydrates of animal diets. The most common polysaccharides that are derived from plant sources (Figure 14-2b) are **starch** (which has α -bonds between the glucose units) and **cellulose** (which has β -bonds). To be usable, they also must be hydrolyzed into monosaccharides. Cellulose is the most abundant organic molecule in the biosphere and is the major component of plant material, comprising over half of the plant cell wall. However, few animals can directly exploit this energy source. Given the fibrous “staircase” structure of cellulose resulting from its β -bond linkages (Figure 14-2b), it is extremely difficult to hydrolyze. In animals that use cellulose for fuel, cellulose digestion is accomplished by symbiotic microorganisms that proliferate in the digestive tract and that have the necessary enzymes—**cellulases**—to hydrolyze cellulose. These microbes may be housed in a specific area of the gut or in special organs connected to the gut, as in the case of termites and many wood-boring beetles. Some termites and wood wasps actually culture fungi that produce cellulase. **Chitin** is the principal component of the hard exoskeleton of arthropods and, like cellulose, is indigestible by most vertebrates. **Glycogen** represents the polysaccharide storage form of glucose in animals. After digestion of a meal, unused glucose is stored as glycogen (in liver and muscle in vertebrates; p. 26). *Cecropia*, a bamboolike tree, is the only plant known to synthesize glycogen. A particularly aggressive ant, *Azteca*, consumes the glycogen and, in turn, protects the tree from potential agents that could damage it.

2. **Proteins** are the second category of foodstuffs, which consist of various combinations of **amino acids** held together by peptide bonds. Through the process of digestion, proteins are degraded primarily into their constituent amino acids as well as a few **polypeptides** (several amino acids linked together by peptide bonds), both of which are the primary absorbable units for digested protein.
3. **Fats** represent the third category of foodstuffs. In most terrestrial food chains, dietary fat is in the form of **triglycerides**, which are neutral fats, each consisting of a combination of glycerol with three **fatty acid** molecules attached. During digestion, two of the fatty acid molecules split off, leaving a **monoglyceride**, a glycerol molecule with one fatty acid molecule attached. Thus, the end products of fat digestion are monoglycerides and free fatty acids, which are the absorbable units of fat. However, in ruminant species the triglycerides are degraded mostly to free fatty acids and glycerol, with the glycerol being fermented. For this reason glycerol synthesis must occur to a greater extent than in other species. In marine food chains, **waxes** (a fatty alcohol and fatty acid linked together) are common lipids. Waxes are hydrolyzed by the activity of esterases synthesized in microorganisms.

4. **Nucleic acids** can also form a significant portion of ingested nitrogen. Pancreatic nucleases, *RNase* and *DNase*, split the nucleic acids into their component nucleotides. The *duodenum* of ruminants is particularly effective in digesting nucleic acids because approximately 20% of the nitrogen entering the *abomasum* (acid-secreting portion of the stomach) originates from the microorganisms spilled from the rumen.

Absorption After digestion is completed, the process of absorption occurs in the middle to posterior sections of most digestive systems (such as the small intestine in vertebrates). Here the small, absorbable units that result from digestion, along with water, vitamins, and electrolytes, are transferred from the digestive tract lumen into the blood or hemolymph or body cavity. Specialized transporters in the epithelial cells carry the hydrophilic units through the membrane. The uptake of amino acids and/or glucose depends on cotransport with Na^+ . To enhance this process (in accordance with Fick's law of diffusion, p. 76), *surface area* is often greatly increased by folds. For example, in annelids (such as earthworms) and mollusks, long folds forming ridges called **typhlosoles** line parts of the tract (Figure 14-3a). You will see later how *villi* increase surface area in vertebrate intestines.

The ocean contains large amounts of dissolved organic matter, including sugars and amino acids. Some aquatic species can also absorb these nutrients through their gills (as in the mussel *Mytilus*), or through the epidermis (as in many marine nonvertebrates including annelids and echinoderms).

The digestive tract and accessory digestive organs make up digestive systems

The digestive system of an animal consists of the digestive tract plus the accessory digestive organs. In addition to its role in the digestive process, additional functions of the tract include osmoregulation, endocrine secretions, immune function, and the elimination of toxins.

In annelids and arthropods the foregut is referred to as the **stomodaeum**, the midgut as the **mesenteron**, and the hindgut as the **proctodaeum** (Figure 14-3b). Insect stomodaea and proctodaea are lined internally with a thin layer of cuticle, the **intima**, which is shed along with the outer skeleton during molt. The stomodaeum, which is specialized for the reception of food, consists of the *pharynx*, *esophagus*, *crop*, and *proventriculus*. The **stomodael valve** regulates the passage of food between the foregut and the midgut. The midgut is an elongated tube and generally consists of two or more sections. The midgut of most insects, for example, contains **diverticula** (blind tubules), which arise from the main passage and contain the **gastric caecae** (saclike structures, open at only one end) near the anterior end. The

FIGURE 14-3 Comparison of mollusk and insect digestive tracts. (a) A bivalve mollusk tract. Many bivalve and some gastropod mollusks have a crystalline style, which is rotated by cilia and the head of which grinds food against a hard shield in the stomach. The style also contains enzymes that are released by grinding. (b) Tract of a typical insect.

Sources: (a) V. Pearse, J. Pearse, M. Buchsbaum, & R. Buchsbaum. (1987). *Living Invertebrates*. Palo Alto, CA: Blackwell Scientific, p. 352, top left. (b) Modified from R. L. Patton. (1963). *Introductory Insect Physiology*. Philadelphia: Saunders, 1963, p. 31, Figure 3-1.

midgut is specialized for storing and digesting food items and subsequent midgut absorption of nutrients. In some cases, the same cell can carry out secretion and absorption. The hindgut extends from the **pyloric valve**, which separates the midgut from the hindgut, to the anus. The hindgut consists of two sections, the anterior *intestine* and the posterior *rectum*. Recall that the Malpighian tubules, which function as excretory organs (p. 563), empty their contents into the anterior end of the hindgut.

The digestive (or *gastrointestinal*) tract of most vertebrates includes the following organs (Figure 14-4): *mouth*; *pharynx* (throat); *esophagus*; *stomach* (and *rumen* in ruminants), or *proventriculus-gizzard complex* in birds; *small intestine*; *large intestine*; and *anus*. Note that these organs are continuous with each other and are discussed as separate entities only because of their regional modifications, which allow them to specialize in particular digestive activities.

FIGURE 14-4 Vertebrate digestive tracts showing progressive anatomic specialization for digestion (stomach and accessory digestive glands such as pancreas and liver) and absorption surface area of small intestine.

Source: D. C. Withers, (1992). *Comparative Animal Physiology*. Fort Worth, TX: Saunders, p. 925, Figure 18-28.

In addition to the specialized gut tubes, many phyla have **accessory organs** that aid digestion. The accessory digestive organs of most vertebrates include the *salivary glands*, the *exocrine pancreas*, and the *biliary system*, which consists of the *liver* and, in some species, the *gallbladder* (Figure 14-4). (Most metazoans have salivary glands; see

Figure 14-3). These exocrine organs are located outside of the wall of the digestive tract and empty their secretions through ducts into the digestive tract lumen. They develop from outpocketings of the embryonic digestive tube and maintain their connection with the digestive tract through the ducts that are formed.

Some smooth muscles of digestive tracts have autonomous activity

Digestive motility and secretion are carefully regulated to maximize digestion and absorption of the ingested food. First let's examine local action of the smooth muscles.

Autonomous Smooth-Muscle Function As we discussed in Chapter 8, some smooth muscle cells do not have a constant resting potential but rather display rhythmic, spontaneous variations in membrane potential. The prominent type of self-induced electrical activity in vertebrate digestive smooth muscle are *slow-wave* potentials (Figure 8-31), here referred to as the **basic electrical rhythm (BER)**. The BER is initiated by “pacesetter” cells, musclelike but noncontractile cells known as the **interstitial cells of Cajal**, located at the boundary between the *longitudinal* and *circular* smooth muscle layers (described on p. 671). These cells periodically produce electrical signals that spread to the adjacent contractile smooth-muscle cells as the BER. Recall that sheets of smooth muscle cells are connected by gap junctions; thus, the whole muscle sheet behaves like a functional *syncytium* (p. 378). Recall also that slow waves are not action potentials and do not directly induce muscle contraction; they are fluctuations in membrane potential that cyclically bring the membrane closer to or farther from threshold. These oscillations are believed to be due to cyclical variations in Ca^{2+} release from the endoplasmic reticulum and Ca^{2+} uptake by the mitochondria of the pacesetter cell.

Whether threshold for an action potential is reached depends on the effect of various mechanical, nervous, and hormonal factors that influence the “resting” potential, or the starting point around which the BER oscillates. If the starting point is nearer the threshold level, as when food is present in the digestive tract, the depolarizing slow-wave peak reaches threshold, triggering a volley of action potentials and its accompanying contractile activity. Conversely, if the starting point is farther from threshold, as when an animal is hungry or starved, there is less likelihood of reaching threshold, so contractile activity is reduced or eliminated.

The *rate* (frequency) of rhythmic digestive contractile activities—such as *peristalsis* in the stomach or rumen (p. 668), *segmentation* in the small intestine (p. 693), and *haustral* contractions (p. 703) in the large intestine—depends on the inherent rate established by the involved pacesetter cells. Specific details about these rhythmic contractions are discussed later, when we examine the organs involved. The *intensity* of these contractions depends on the number of action potentials that occur when the slow-wave potential reaches threshold, which in turn depends on how long threshold is sustained. At threshold, voltage-gated Ca^{2+} channels are activated, resulting in Ca^{2+} influx into the smooth muscle cell. The level of contractility can range from low-level tone to vigorous mixing and propulsive movements by varying the cytosolic Ca^{2+} concentration.

Furthermore, the intensity of the contraction also depends on the number of muscle fibers in the organ. Species vary tremendously in muscle mass within the walls of digestive tract organs. For example, the thick and thin muscle pairs lining the *gizzard* (organ of mastication) (p. 681) of a ruffed grouse can crack the shell of an acorn, whereas these muscle pairs are absent in most carnivorous birds, whose stomach is more similar to that of mammalian carnivores.

Feng Bin Wang and Terry L. Powley, Dept. of Psychological Science, Purdue University–West Lafayette

FIGURE 14-5 The enteric (intrinsic) nervous system of a rat's stomach. By injecting a tracer derived from a horseradish enzyme into the vagus nerve, which connects the brain to the esophagus and stomach, researchers were able to reveal the extent of the nerve network. As nerve fibers fray out into the tiny endings across the stomach, information concerning food volume, hunger, discomfort, and satiety are sent back to the brain.

Regulation of digestive functions is synergistic and occurs both intrinsically and extrinsically

Although pacesetters may produce routine muscle action, digestive functions are also regulated by intrinsic (Figure 14-5) and extrinsic nerves and hormones. As in most regulatory systems, there are sensors, integrators, and effectors.

Sensors and Effectors The digestive tract wall contains three different types of sensory receptors that respond to local chemical or mechanical changes in the digestive tract: (1) *chemoreceptors* sensitive to chemical components within the lumen, (2) *mechanoreceptors* (pressure receptors) sensitive to stretch or tension within the wall, and (3) *osmoreceptors* sensitive to the osmolarity of the luminal contents. Stimulation of these receptors elicits neural reflexes or secretion of hormones by endocrine cells, both of which alter the level of activity in the digestive system's effector cells. These effector cells are smooth muscle cells (for modifying motility) and exocrine gland cells (for controlling secretion of digestive juices) (Figure 14-6).

Now let's look at the integrators and their reflex pathways.

FIGURE 14-6 Summary of pathways controlling digestive system activities. Receptor proteins bind with and respond to gastrointestinal hormones, neurotransmitters, and local chemical mediators.

© Cengage Learning, 2013

Intrinsic Nerve Plexuses In vertebrates, the **intrinsic nerve plexuses** (*plexus*, “network”) are the two major networks of nerve fibers—the **myenteric plexus** and the **submucous plexus**—located entirely within the digestive tract wall and running its entire length. A nerve plexus is a type of nerve net (p. 151). Thus, unlike any other organ system, the digestive tract has its own intramural (“within wall”) nervous system, which contains as many neurons as the spinal cord and endows the tract with a considerable degree of self-regulation (a prime example of hierarchic distributed regulation, p. 19). In vertebrates, the two plexuses together are often termed the **enteric nervous system** (Figure 14-5). Insects have an analogous system, the **stomatogastric nervous system**, a network of peripheral ganglia along the gut.

The intrinsic plexuses influence all facets of digestive tract activity. Various types of neurons are present in the intrinsic plexuses. Some are afferent sensory neurons, which have receptors that respond to specific local stimuli in the digestive tract. Efferent local neurons innervate the smooth muscle cells and exocrine and endocrine cells of the digestive tract to directly affect digestive tract motility, secretion of digestive juices, and secretion of gastrointestinal hormones. As with the central nervous system, these input and output neurons of the enteric nervous system are linked by integrating interneurons. Some of the output neurons are excitatory, and some are inhibitory. For example, vertebrate enteric

neurons that release *acetylcholine* (*ACh*) as a neurotransmitter promote contraction of digestive-tract smooth muscle, whereas the neuromodulators *nitric oxide* and *vasoactive intestinal peptide* act in concert to cause its relaxation. These intrinsic nerve networks are primarily responsible for coordinating local activity within the digestive tract. To illustrate, if a large chunk of food gets stuck in the esophagus, local contractile responses coordinated by the intrinsic plexuses are initiated to push the food forward.

Extrinsic Nerves In hierarchical fashion, extrinsic neural and hormonal regulation can modulate the nerve plexuses, or, in some cases, can act directly on the smooth muscle and glands. Extrinsic nerves in vertebrates are the nerve fibers from both branches of the autonomic system that originate outside the digestive tract and innervate the various digestive organs. Recall that in general, the sympathetic and parasympathetic nerves supplying any given tissue exert opposing actions on that tissue (p. 159): The “fight-or-flight” sympathetic system inhibits or slows down digestive tract blood flow and motility, while the “rest-and-digest” parasympathetic system dominates in quiet, relaxed situations, when general maintenance activities such as digestion can proceed optimally. Accordingly, the parasympathetic nerve fibers supplying the digestive tract, which arrive primarily by way of the *vagus nerve*, increase smooth muscle motility and

promote secretion of digestive enzymes and hormones. Unique to the parasympathetic nerve supply to the digestive tract, the postganglionic parasympathetic nerve fibers are actually a part of the intrinsic nerve plexuses. They are the ACh-secreting output neurons within the plexuses. Accordingly, ACh is released in response to local reflexes coordinated by the intrinsic plexuses as well as to extrinsic vagal stimulation, which acts through the plexuses.

In addition to being called into play during generalized sympathetic or parasympathetic discharge, the autonomic nerves supplying the digestive system can be discretely activated to modify only digestive activity. One of the major purposes of specific activation of extrinsic innervation is the coordination of activity between different regions of the digestive system; for example, the act of chewing reflexly increases not only salivary secretion but also stomach, pancreatic, and liver secretion via vagal reflexes in *anticipation* of the arrival of food. Another anticipation mechanism is a pathway by which factors outside of the digestive system can influence digestion, as, for example, with a vagally mediated increase in digestive juices that occurs before eating when an animal sees or smells food.

Gastrointestinal Hormones Tucked within the mucosa of certain regions of the digestive tract are endocrine gland cells that, on appropriate stimulation, release hormones into the blood. These **gastrointestinal hormones**, some of which we will discuss later, are carried through the blood to other areas of the digestive tract, where they exert either excitatory or inhibitory influences on smooth muscle and exocrine gland cells. Interestingly, many of these same hormones are released from neurons in the brain, where they act as neurotransmitters and neuromodulators. During embryonic development, certain cells of the developing neural tissue migrate to the digestive system, where they become endocrine cells.

Reflex Pathways Now let's summarize intrinsic and extrinsic regulatory actions. Receptor activation may bring about two types of neural reflexes—*short* reflexes and *long* reflexes. When the intrinsic plexuses respond to local stimulation and alter effectors, all elements of the reflex are located within the wall of the digestive tract itself; that is, a **short reflex** takes place. Extrinsic nervous activities, which can be superimposed on the local controls to modify smooth muscle and glandular responses for coordination and anticipation, are known as **long reflexes** because they involve the long pathways between the central nervous system and digestive system.

In addition to the sensory receptors within the digestive tract wall that monitor luminal content and wall tension, the plasma membranes of the digestive system's effector cells have receptor proteins that bind with and respond to gastrointestinal hormones, neurotransmitters, and local chemical mediators.

From this overview, it is clear that regulation of gastrointestinal function is very complex, being influenced by many synergistic, interrelated pathways that evolved to ensure that the appropriate responses occur to digest and absorb the ingested food. Nowhere else is such a level of overlapping control exercised.

We are now going to take a “tour” of the digestive tract, beginning with the mouth and ending with the rectum, focusing primarily on vertebrates and insects.

Describe the four basic digestive processes.

List the three categories of energy-rich foodstuffs and the absorbable units of each. Which polysaccharide is the most common storage form in animals? Why is this so?

List the common components of a representative digestive system, and describe its cross-sectional anatomy and its neural–hormonal features.

14.3 Mouth

There is considerable diversity in the mechanisms and behaviors for obtaining food because of the enormous variety of animal diets. Let's examine some examples.

Obtaining and Receiving Food Animals may use shredding and cutting devices, such as bony *teeth* in many vertebrates, or specialized appendages that can tear food items into smaller pieces prior to ingestion, as in many arthropods. For example, many insects (such as locusts) have *mandibles* adapted for cutting and grinding. Other mouthparts associated with reducing food size include chisels and chitinous teeth. Liquid food such as nectar does not require reduction and is typically obtained by suction. External parasites have modified mouthparts adapted to feeding on the blood or other body fluids of a suitable host. The mosquito, for example, pierces the skin of its prey with an array of six needlelike mouthparts. One of these injects an anticoagulant (p. 400), which leads to the uncomfortable itch that follows the bite. It is through this route that foreign organisms such as those causing malaria, encephalitis, and yellow fever gain entry to the body. Only the egg-laying females (who have a greater protein requirement) are the nuisances, because the males dine exclusively on nectar.

Other body parts can aid in food acquisition, the hands of primates being obvious examples. As another example, Lophiiformes—a marine group that includes goosefishes, frogfishes, and anglerfishes—use modifications in their first dorsal fin to function as a lure to attract potential prey. The fin is used to dangle a lure that may resemble a source of live food immediately above their upwardly directed mouths. In deep-sea anglers, the lure contains symbiotic bioluminescent bacteria, whose glow attracts prey animals to investigate.

The **mouth** (or **oral cavity**) itself, which initially receives the food entering the gut, may also be specialized. The mouth of a snake, for example, requires unique adaptations to swallow a meal up to 1.5 times the snake's own body weight. A snake's jaw can open to an angle of up to 130 degrees, whereas a human's jaw can be opened only 30 degrees. Snakes have a hinged jaw as opposed to the single bone found in mammals. The snake's lower jaw is also split into two parts, with the halves connected by an elastic ligament, which permits the snake to completely stretch its head around its victim's body. Powerful muscles in the cheek and throat steadily push its prey head first toward the esophagus helped in part by the backward curvature of the teeth. Among modern-day sharks, such as the white-tipped reef shark, courtship rituals include the male biting the female's back, neck, and then the pectoral fin, a move that enables him to hold onto the female while copulating. Based on this observa-

Hilar Klandorf

A male Atlantic puffin demonstrates its hunting prowess to female puffins. The specialized beak can hold a dozen or more fishes inside. It has backward-pointing spikes in its interior, which hold fish in place while other fish are being hunted.

tion, John Long speculated that jaws may have first evolved to improve mating success and not for chewing food.

Although ancient birds had teeth (found as fossils), modern birds lack them, but their beaks are often specialized for toothlike functions. The beak represents one of the more evolutionarily plastic components of the avian digestive system, having been molded to conform to particular feeding habits. In herbivorous birds, the beak is an enlarged, crushing forceps, whereas in carnivorous birds the beak is a sharp-edged tearing instrument. The beaks (bills) of some birds, including ducks and geese, are richly innervated with sensory endings. The density of mechanoreceptors along the edges and at the tip of the bill is actually greater than in the fingertips of a human's index finger. Interestingly, as sophisticated beaks evolved, key genes controlling teeth development became pseudogenes (p. 33), although genes for constructing teeth remain intact in avian genomes. Given exposure to a tooth-inducing tissue from a mouse embryo, a chicken embryo's beak tissue will produce crocodilian-like teeth, and the *Talpid2* mutant strain of chicken is an example of a bird that makes such teeth.

In mammals, the mouth is ringed by the muscular **lips**, which aid in **prehension**, the seizing and conveying of food to the mouth. For example, the horse uses its lips to move foodstuffs into the mouth. The lips also serve nondigestive functions. They are important in communication; for example, facial expression and the articulation of many sounds depend on a particular lip formation.

The **palate**, which forms the arched roof of the oral cavity, separates the mouth from the nasal passages. Its presence allows breathing and chewing or sucking to take place simultaneously. Toward the front of the mouth, the palate is made of bone, forming what is known as the **hard palate**. There is no bone in the portion of the palate toward the rear of the mouth; this region is called the **soft palate**. However, in most avian species there is no soft palate, but the hard palate is separated by a median slit that permits direct communication with the nasal cavities. The floor of the avian mouth is membranous and, in some species such as pelicans, serves a storage

capacity. In some primates, including humans, hanging down from the soft palate at the rear of the throat is a dangling projection, the **uvula**, which plays an important role in sealing off the nasal passages during swallowing (p. 667).

The **tongue**, which forms the floor of the oral cavity, consists of voluntarily controlled skeletal muscles that form a *muscular hydrostat* (see p. 357). Methods of obtaining food and drink vary considerably; for example, the ballistic tongue of most lizards relies on simple surface tension (stickiness created when a wet tongue contacts dry prey) to catch prey. However, the tongue pouch of the chameleon functions more like a suction cup as it is capable of consuming prey much larger than what simple surface tension could handle. In ruminant mammals, the tongue is the organ of prehension because the lips have limited motility and the upper incisor teeth are absent. A giraffe can wrap its 46-cm (18-inch) tongue around a leafy branch and tear the leaves off into its mouth. Tongues can also be used for drinking. Cats and dogs, for example, curl their tongues downward into water, then pull it up rapidly to create a rising column of water. The jaws then snap over the column to engulf it before it falls back. A domestic cat can do this four times per second!

Movements of the tongue are important in guiding food within the mouth during chewing and swallowing, and also play an important role in vocalization. Embedded within the tongue are the *taste buds* (p. 234), which are also dispersed in the soft palate, throat, and linings of the cheeks. The tongue also continually synthesizes an *antimicrobial peptide* (p. 467). For this reason, tongues are rarely infected and heal quickly after injury.

Mastication The first step in the digestive process is **mastication** (chewing), the motility of the mouth that involves slicing, tearing, grinding, and mixing ingested foods by specialized mouthparts such as teeth. The purposes of mastication are (1) to grind and break food up into smaller pieces to facilitate swallowing and to increase the food surface area on which salivary enzymes will act, (2) to mix food with saliva, and (3) to stimulate the taste buds, which reflexly increases salivary, gastric, pancreatic, and bile secretion to prepare for the arrival of food in the lower digestive tract. However, carnivores normally swallow food without chewing and mixing the contents with saliva. Ruminants chew the feed only briefly before swallowing, sufficiently grinding the forage into particles just small enough to be formed into a food bolus. Only when ruminants regurgitate (movement of a food bolus from the stomach back to the mouth) is the food then thoroughly masticated. In contrast, the horse thoroughly masticates its food prior to swallowing.

The act of chewing in vertebrates is normally regulated by a chewing center in the medulla oblongata. The presence of food in the oral cavity activates mechanoreceptors that, via afferent pathways to this center, activate motor neurons that open the oral cavity while inhibiting the neurons that cause the closure of the cavity.

Let's look at functions of teeth, which are firmly embedded in and protrude from the jawbones. The exposed part of a tooth is covered by **enamel**, the hardest structure in most vertebrates. Enamel forms before the tooth's eruption by special cells that are lost as the tooth erupts. Teeth in fish, amphibians, and reptiles are specialized for holding and tearing food. **Polyphyodontia**, the replacement of teeth throughout an animal's lifetime, occurs in dinosaurs, sharks, and nonavian

reptiles. Tooth replacement varies considerably among species and age. For example, it occurs every two weeks in most sharks, but about every two years in an adult crocodile.

Mammals have **incisors** (cutting teeth) in front to grab and hold food and flat **molars** in the back for grinding fibrous material. Carnivorous mammals are noted for sharp **canines** (next to incisors) for seizing, piercing, and tearing prey. Finally there are **premolars** between canines and molars, with intermediate properties. As an example, all Old World primates (including humans) have 8 incisors, 4 canines, 8 premolars, and 12 molars. The extent to which molars are used varies between species and is related to the composition of the diet. Simple up-and-down movements of molars in carnivores and omnivores are inadequate to grind tough, coarse feeds, so herbivores make lateral grinding movements of the jaw. The upper jaw is slightly wider than the lower jaw, and the animal masticates on one side of the mouth at a time. Because of the lateral jaw movement, premolars may develop sharp edges that interfere with chewing or may injure the tongue or cheeks. This problem in domestic herbivores can be corrected by “floating the teeth,” that is, filing the projections down. Herbivores also have a long **diastema**, or gap, between the front teeth and the premolars on each side that allow ready manipulation of food by the tongue. Ruminants have a unique dentition; the upper incisors and canines are absent, while the lower incisors bite against a hard gum or dental pad in the upper jaw. They manipulate forage into the mouth with the tongue and lips and then cut or tear it with their lower incisors and dental pads. The teeth of rabbits, and the lower incisors of possums, koalas and rodents, grow continually throughout their lifetime, a consequence of abrasive high fiber diets, which continually wear down the enamel coating.

Teeth can evolve other roles, such as prey-paralyzing venomous fangs in snakes. Recent research has revealed that the first snake fangs evolved about 60 million years ago from the posterior tooth-forming layer in the upper jaw. At some point that layer became detached from the rest of the jaw and so became free to evolve independently of other teeth.

Not all vertebrates rely on teeth. Teeth in embryonic baleen whales (Mysticeti) are vestigial and are reabsorbed and replaced with long plates of **baleen** (parallel, fused filaments of *keratin*, the protein of hair) that hang from the jaws in place of teeth. These are used as straining devices for filter feeding, primarily on small marine animals such as krill (crustaceans) and fish. Such filtering is highly efficient: Recent energy estimates suggest that baleen whales gain at least 90 times more energy than they expend when filtering schools of prey such as krill. This may explain why blue whales can achieve body masses of 100,000 kg or more. In contrast, energy calculations predict that carnivores such as polar bears, which target large single prey, cannot obtain enough energy if they exceed 1,100 kg in size. Indeed, no such carnivores (living or extinct) exceed that limit.

Saliva aids in mastication but plays a more important role in lubricating food boluses before swallowing

Saliva, the secretion associated with the mouth, is produced by salivary glands, which are located outside the oral cavity and discharge saliva through short ducts into the mouth. The functions of saliva include the following:

1. **Moistening:** Saliva facilitates swallowing by moistening food particles, thereby holding them together, and (in vertebrates but not insects) by providing lubrication through the presence of mucus. Saliva keeps the oral cavity moist (and aids in vocalization by facilitating movements of the lips and tongue). In insects saliva provides lubrication of the mouthparts.
2. **Digestion:** In most animals (excluding ruminants), saliva begins digestion of starch in the mouth through action of **salivary amylase**, an enzyme that breaks down starches into maltose, a disaccharide consisting of two glucose molecules. In insects both the salivary gland and midgut cells can secrete amylases and various proteases. In some species of bees, the salivary gland secretes **invertase** (an enzyme that breaks down sucrose), which is taken into the body with the ingested nectar. Some insect and mammalian saliva also contains the lipid-splitting enzyme *lingual lipase*.
3. **Defense:** Saliva in many vertebrates exerts some antibacterial action by means of a twofold effect—first by *lysozyme*, an enzyme that lyses certain bacteria by breaking down their cell walls; second, by *salivary agglutinin*, a glycoprotein that complexes with IgA antibodies (p. 475) and then binds to bacteria; third, by *lactoferrin*, which tightly binds to iron needed for bacterial multiplication (p. 469); and fourth, by rinsing away material that may serve as a food source for bacteria.
4. **Taste:** Saliva is a solvent for molecules that stimulate the taste buds. Only molecules in solution can react with taste bud receptors. You can demonstrate this for yourself: Dry your tongue and then drop some sugar on it; you cannot taste the sugar until it is moistened.
5. **Neutralization:** Saliva is often rich in bicarbonate buffers, which neutralize acids in food as well as acids produced by bacteria in the mouth. In ruminants, salivary bicarbonate is responsible for neutralizing the pH of rumen fluid and is an important buffering system for maintaining the acid–base equilibrium of the rumen contents.
6. **Thermoregulation:** Saliva can also be used as a means of temperature control in animals without sweat glands. In fact, most mammals and birds have no sweat glands and rely on panting as a means of evaporative cooling (Chapter 15). Kangaroos actually spread saliva over their bodies when outside temperatures approach lethal limits.
7. **Poisons:** Venomous reptiles have special oral glands (associated with fangs) that produce highly toxic secretions, which, once injected into prey, exert **hemotoxic** (affecting the circulatory system), **neurotoxic** (affecting the nervous system and brain), or **myotoxic** (muscle necrosis) effects. Venoms are approximately 90% proteins (dry weight) and most are enzymes. These components act rapidly to prevent the prey from escaping. Some nonvertebrates such as spiders also have saliva with poisons for immobilizing or killing prey.
8. **Anticoagulation:** recall the secretion of anticoagulants in blood-sucking vampire bats, insects, and leeches (pp. 400 and 459). Mosquito saliva glands secrete **apyrase**, which breaks down ADP, and so prevents platelet aggregation (see p. 395).

9. *Silk*: In Lepidoptera, Hymenoptera, and Trichoptera, the glands secrete silk proteins for constructing cocoons and shelters, and net-spinning caddis flies use silk for food gathering.
10. *Pheromones*: The salivary glands of many insects and some vertebrates release these external hormones. For example, male boars stimulated by a receptive female will produce copious amounts of saliva laden with androsterones. These stimulate the female to take a mating posture and may warn off other boars. (You will see examples in insects shortly.)

Let's now look more closely at saliva in insects and vertebrates.

Insects In insects there are up to four pairs of salivary glands associated with the oral cavity, each of which is named after its associated mouthpart: the *mandibular*, *maxillary*, *hypopharyngeal*, and *labial* glands (Figure 14-3b). Of note, a particular gland may be present in only one of its life stages. For example, in Lepidoptera (moths and butterflies) the mandibular glands are present in the larval stage but not in the adult. In young worker honey bees, the mandibular gland produces a pheromonal secretion called *royal jelly* that is fed to larvae to control their development, whereas in older workers, the mandibular gland produces an alarm pheromone. In insects, ducts from paired salivary glands extend forward and unite into a common duct that opens near the base of the *labium* or *hypopharynx* mouthparts. Generally, these salivary glands have a secretory region that produces the primary saliva and a reabsorptive region that reabsorbs ions from the saliva. Both exchange regions are characterized by deep infoldings to increase surface area and numerous mitochondria to fuel the active transport of these ions. During feeding, a valve on the hypopharynx is opened as the hypopharynx is raised, thus permitting the release of saliva. However, when the insect is not feeding, the hypopharynx remains in a lowered position, which shuts off the valve and permits the saliva to be stored in the respective glands. Regulation of these glands is not as well known as in vertebrates, but in the American cockroach, serotonin induces the secretion of proteinaceous saliva, whereas dopamine induces the release of protein-free saliva.

Vertebrates Salivary glands in many vertebrates combine two cell types: One type produces a wetting *serous* (watery) fluid that is high in enzyme content, whereas the other produces *mucus*, which is thick and slippery for lubrication. Fish and chickens do not have serous cells, so their total daily output of saliva is comparatively small, and it lubricates the food in preparation for swallowing; wetting occurs later, in the crop. The salivary glands of many swifts and swallows can actually increase in size during nest-building season. For example, the glands of the edible-nest swiftlet, *Collocalia fuciphaga*, enlarge approximately 50-fold because their nests consist entirely of cemented saliva, the primary ingredient of “bird’s nest soup,” a Chinese delicacy.

In mammals saliva consists of about 99.5% H₂O and 0.5% electrolytes and protein. There are three major glands: the *parotid* for serous secretions, the *sublingual* for mucus secretions, and the *submandibular*, which makes both types. The salivary NaCl concentration is only one seventh of that in the plasma, which is important in perceiving salty tastes. Similarly, glucose is absent from saliva so that discrimina-

tion of sweet tastes is not impaired. Depending on the species of animal, the osmolality of saliva compared to blood plasma can range from hypotonic to hypertonic. However, saliva is always isotonic in ruminants and generally hypotonic in dogs and cats.

The salivary glands of ruminants produce copious amounts of alkaline saliva. When swallowed, this saliva enables selective compartments of its stomach to house a population of microbes capable of digesting dietary cellulose. Salivary bicarbonates and phosphates buffer the acids produced during fermentation and maintain the pH of the *rumenoreticulum* (compartment of a ruminant’s stomach; see p. 707) within a narrow range. Urea is also recycled via the salivary glands back to the rumen microbes for protein synthesis. In nonruminant mammals, saliva is ultimately not as critical for digesting and absorbing foods, because enzymes produced by the pancreas and small intestine can digest food even in the absence of salivary and gastric secretion.

The continuous low level of salivary secretion can be increased by simple and conditioned reflexes

Salivary secretion in vertebrates is the only digestive secretion entirely under neural control. Both nervous system reflexes and hormones regulate all other secretions. One exception is the ruminants, where the parotid gland secretes saliva spontaneously in the absence of any neural stimuli.

Saliva in mammals is continuously secreted, even in the absence of apparent stimuli, because of constant low-level stimulation by the parasympathetic nerve endings that terminate in the salivary glands. This basal secretion is important in keeping the mouth and throat moist at all times. The basal rate of salivary secretion in humans is about 0.5 mL/min, which can increase to 5 mL/min in response to a potent stimulus such as sucking on a lemon. Remarkably, salivary secretion in ruminants is of such a magnitude that it can be regarded as a second circulatory system for body fluids and electrolytes. Cattle produce approximately 140 liters of saliva per day, whereas sheep and ponies secrete around 10 liters per day. Almost 50% of the total extracellular sodium in the animal may be found in the rumen contents at any one time, whereas half of the total body water passes through the salivary glands into the rumen every day.

In addition to a continuous low-level secretion, salivary secretion may be enhanced by two different types of salivary reflexes (Figure 14-7):

1. The **simple**, or **unconditioned**, **salivary reflex** occurs when chemoreceptors and pressure receptors within the oral cavity respond to the presence of food. On activation, these receptors initiate impulses in afferent nerve fibers that carry the information to the **salivary center** located in the medulla oblongata, as are all the brain centers that control digestive activities. The salivary center, in turn, sends impulses via the extrinsic autonomic nerves to the salivary glands to promote increased salivation.
2. The **acquired**, or **conditioned**, **salivary reflex** occurs without oral stimulation. A zoo mammal hearing the sound of a food cart, or a dog watching the preparation of a meal, initiates salivation through this reflex. All of us have experienced such “mouth watering” in anticipa-

tion of something to eat. This reflex is a learned response based on previous experience and is an example of feed-forward or anticipation regulation. Inputs that arise outside the mouth and are mentally associated with eating act through the cerebral cortex to stimulate the medullary salivary center.

Autonomic Influence on Salivary Secretion

Unlike the autonomic nervous system elsewhere in the vertebrate body, sympathetic and parasympathetic controls from the salivary center to the salivary glands are not antagonistic. Instead, both act to *increase* salivary secretion, but the quantity and consistency of saliva change with the needs of the animal. The rate of saliva secretion depends on the quantity of food in the mouth, whereas its consistency depends on the composition of the food consumed. Both the amount and quality of saliva are commensurate with the need for sensory evaluation of the food as well as the need for lubrication of dry foodstuffs. Parasympathetic stimulation, which exerts the dominant role, increases blood flow through the glands and is accompanied by a prompt and abundant flow of serous saliva. Normally, sympathetic stimulation reduces blood flow but allows a continued saliva output of smaller volume of mucus saliva. Because sympathetic stimulation in humans elicits a smaller volume of saliva, the mouth is drier than usual during circumstances when the sympathetic system is dominant, such as stress situations. Thus, people experience a dry feeling in the mouth when they are nervous about giving a speech. Cats, in contrast, secrete voluminous watery saliva in response to sympathetic stimulation.

Digestion in the mouth is minimal

Most digestion of foodstuffs in vertebrates is accomplished farther down the tract after the swallowing. Stomach acid inactivates amylase, but in the center of the food mass, where acid has not yet reached, salivary amylase can continue to function for several hours. **Lingual lipase** (a fat-hydrolyzing salivary enzyme) is, however, activated by the low pH in the stomach.

Cats have a strong aversion to diets containing medium-chain triglycerides or hydrogenated coconut oil. Presumably lingual lipase breaks down some triglycerides into fatty acids in their mouths, which then activates specific taste receptors and produces the finicky response.

14.4 Pharynx, Esophagus, and Crop

The **pharynx** (throat) is the cavity at the rear of the oral cavity. In vertebrates, it acts as a common passageway for both the digestive system (by serving as the link for passing food between the mouth and esophagus) and the respiratory system (as a path for water moving across gills, or by providing access between the nasal passages and trachea for air). This arrangement necessitates mechanisms (described shortly) to guide food and air into the proper passageways beyond the pharynx. Some species of insects have *pharyngeal* and *cibarial* pumps that suction up their food and help it move into the esophagus.

Swallowing in vertebrates is a sequentially programmed all-or-none reflex

The motility associated with the pharynx and esophagus is **swallowing**, or **deglutition**. Most of us think of swallowing as the act of moving food out of the mouth and into the esophagus. However, swallowing actually is the entire process of moving food from the mouth through the esophagus into the stomach.

Swallowing in a vertebrate is initiated when a **bolus**, or ball of food, is forced by the tongue to the rear of the mouth into the pharynx. The pressure of the bolus in the pharynx stimulates pharyngeal pressure receptors, which send afferent impulses to the **swallowing center** located in the medulla. This center then reflexly activates, in the appropriate sequence, the muscles that are involved in swallowing. Swallowing is an example of a sequentially programmed all-or-none reflex in which multiple responses are triggered in a specific timed sequence; that is, a number of highly coordinated activities are initiated in a regular pattern over a period of time to accomplish the act of swallowing. Once initiated, swallowing cannot be stopped.

FIGURE 14-8 Oropharyngeal stage of swallowing in humans. (a) Position of the oropharyngeal structures at rest. (b) Changes that occur during the oropharyngeal stage of swallowing to prevent the bolus of food from entering the wrong passageways.

© Cengage Learning, 2013

During the oropharyngeal stage of swallowing, food is directed into the esophagus and prevented from entering the wrong passageways

Swallowing is arbitrarily divided into two stages: the *oropharyngeal stage* and the *esophageal stage*. The **oropharyngeal stage** consists of moving the bolus from the mouth through the pharynx and into the esophagus. When the bolus enters the pharynx during swallowing, it must be directed into the esophagus and prevented from entering the other openings that communicate with the pharynx. In other words, food must be prevented from reentering the mouth, from entering the nasal passages, and from entering the trachea (where it causes choking). All this is accomplished by the following coordinated activities (Figure 14-8 for a human):

- The position of the tongue against the hard palate prevents food from reentering the mouth during swallowing.
- The *uvula* is elevated and lodges against the back of the throat, sealing off the nasal passage from the pharynx so that food does not enter the nose.
- Food is prevented from entering the trachea primarily by elevation of the larynx and tight closure of the vocal folds across the laryngeal opening, or **glottis**. The first portion of the mammalian trachea is the *larynx* (see Figure 11-18, p. 518), across which are stretched the *vocal folds*. During swallowing, the vocal folds serve a purpose unrelated to vocalization. Contraction of laryngeal muscles aligns the vocal cords in tight apposition to each other, sealing the glottis entrance. Also, the bolus tilts a small flap of cartilaginous tissue, the *epiglottis* (*epi*

means “upon”), backward down over the closed glottis as further protection from food entering the respiratory airways. In some animals, such as horses, the nasal and tracheal tubes line up so precisely that they can breathe and drink at the same time, with the water passing to the left and right of the respiratory connection.

- Because the respiratory passages must be temporarily sealed off during swallowing, respiration in humans is briefly inhibited so that futile respiratory efforts are not attempted.
- With the larynx and trachea sealed off, pharyngeal muscles contract to force the bolus into the esophagus.

That the air and food passageways cross over in air-breathing vertebrates, necessitating these elaborate mechanisms to prevent choking, seems to be an evolutionary accident. Air breathing first evolved in some fishes as ventral lungs (filled by gulping) that developed in embryos as evaginations off the digestive tract. A dorsal tube from the same tract, with nostrils, evolved later from the tract upward for obtaining air independently of the mouth, creating the crossover.

The esophagus is a muscular tube guarded by sphincters at both ends

The **esophagus** is a fairly straight, muscular tube that extends between the pharynx and stomach (Figures 14-1, 14-3, and 14-4). In ruminants and dogs the entire musculature of the esophagus is skeletal, whereas in birds and humans it is entirely smooth muscle. In the horse and cat, the bottom third of the esophagus is smooth muscle. Lying for

FIGURE 14-9 Peristalsis in the esophagus. As the wave of peristaltic contraction sweeps down the esophagus, it pushes the bolus into the relaxed area ahead of it, propelling the bolus toward the stomach.

© Cengage Learning, 2013

the most part in the thoracic cavity, the esophagus joins the stomach in the abdominal cavity.

The esophagus is guarded at the upper end by the **pharyngoesophageal sphincter** and at the lower end by the **gastroesophageal sphincter** (or cardiac sphincter). These sphincter muscles, when closed, prevent passage through the tube.

Because the esophagus in most air-breathing vertebrates is exposed to subatmospheric intrapleural pressure as a result of respiratory activity (see p. 517), a pressure gradient exists between the atmosphere and the esophagus. Except during a swallow, the pharyngoesophageal sphincter remains closed as a result of neurally induced tonic contraction of the sphincter's circular skeletal muscle. This keeps the entrance to the esophagus closed to prevent large volumes of air from entering the esophagus and stomach during breathing. Otherwise, the digestive tract would be subjected to large volumes of gas, which would lead to excessive **eructation** (burping). During swallowing, this sphincter opens and allows the bolus to pass into the esophagus. Once the bolus has entered the esophagus, the pharyngoesophageal sphincter closes, the respiratory airways are opened, and breathing resumes.

Ruminants have another valve. On average, rumen gases consist of approximately 65% CO₂, 27% methane, 7% nitrogen, 0.5% oxygen, and 0.2% hydrogen, in addition to a trace amount of hydrogen sulfide. Most of these gases are diverted from the rumen into the trachea by the closing of the **nasopharyngeal sphincter**, the junction between the nasal cavity and the throat. Most of the gases are ultimately expelled with normal respiratory activity. (Gases produced by ruminants are currently of global concern: See *Challenges and Controversies: Global Warming and the Rumen*.)

Peristaltic waves push the food through the esophagus

After the oropharyngeal stage, the **esophageal stage** of the swallow begins once the food bolus contacts the pharyngeal mucosa. The swallowing center initiates a **primary peristaltic** wave that sweeps from the beginning to the end of the

esophagus, forcing the bolus ahead of it through the esophagus to the stomach. The term **peristalsis** refers to ringlike contractions of the circular smooth muscle that move progressively forward, pushing the bolus ahead of the contraction (Figure 14-9). Food and liquid can be propelled to the stomach even when an animal's head is lower than its body. The duration of the peristaltic wave depends on the length of the esophagus, and in humans requires about 5 to 9 seconds to reach the lower end. Progression of the wave is controlled by the swallowing center via the vagus nerve.

If a large or sticky swallowed bolus fails to be carried along to the stomach by the primary wave of peristalsis, the lodged bolus distends the esophagus, stimulating pressure receptors within its walls and thus initiating a second, more forceful peristaltic wave that is mediated by the intrinsic nerve plexuses at the site. These **secondary peristaltic** waves do not involve the swallowing center. Distension of the esophagus also reflexly increases salivary secretion. The trapped bolus is eventually dislodged and moved forward through the combination of lubrication by the extra swallowed saliva and the forceful secondary waves.

The gastroesophageal sphincter prevents reflux of gastric contents

Except during swallowing, the gastroesophageal sphincter remains contracted, to maintain a barrier between the stomach and esophagus, reducing the possibility of reflux of acidic gastric contents into the esophagus. If gastric contents do flow back into the esophagus despite the sphincter, the acidity of these contents irritates the esophagus, causing the esophageal discomfort known in humans as **heartburn**. (The heart itself is not involved at all.) The gastroesophageal sphincter relaxes reflexly as the peristaltic wave sweeps down the esophagus so that the bolus can pass into the stomach. After the bolus has entered the stomach, the gastroesophageal sphincter again contracts.

Achalasia is a condition that occurs commonly in dogs (and in humans) in which the lower esophageal sphincter fails to relax during swallowing but instead contracts more vigorously. Food accumulates in the esophagus, which enormously distends the esophagus when the food's passage into the stomach is greatly delayed. The underlying defect is apparently the result of damage to the **myenteric** nerve plexus (p. 661) in the region of the gastroesophageal sphincter.

Esophageal secretion is entirely protective

In most vertebrates, mucus is secreted throughout the length of the entire digestive tract. This lubricates the food, lessens the likelihood that the esophagus will be damaged by any sharp edges in the newly entering food, and protects the esophageal wall from acid and enzymes in gastric juice if gastric reflux occurs.

The crop is a modified section of the esophagus and functions mainly as a storage organ

The **crop**, a saclike outpouching of the esophagus, is commonly found in a number of animals including snails, insects (Figure 14-3b), and annelids; in vertebrates only some species of birds (and dinosaurs) have this structure (Figure 14-4e). The crop mainly serves a storage function that is par-

Challenges and Controversies

Global Warming and the Rumen

In ruminants, eructation helps relieve the pressure of the gases generated during the fermentation process. For example, in a 24-hour period, a cow belches (ejecting gas spasmodically from the rumen) approximately 500 liters of methane and 1,050 liters of CO₂. Approximately 2 to 12% of the ingested energy consumed by cattle is thus lost as methane. This represents an important loss of an energy source, as well as a factor that contributes to global warming. Global warming results from gases (primarily carbon dioxide and methane) in the upper atmosphere that trap heat (infrared) radiation that is leaving Earth. Methane affects climate directly through its interaction with long-wave infrared energy and indirectly through atmospheric oxidation reactions that produce CO₂. Atmospheric concentrations of methane had remained fairly stable at 750 ppm until approximately 100 years ago, when concentrations began to rise to their present levels of 1,800 ppm. (Similarly, atmospheric CO₂ has risen from about 280 ppm to about 390 ppm.) More than 500 million metric tons of methane enter the atmosphere annually, which ex-

ceeds the capacity of the atmosphere to oxidize it. At this rate, methane will contribute 14 to 17% of the factors leading to global warming in the next 50 years.

There are two significant sources of methane production, those of fossil origin, which contributes 20 to 30%, and those that yield contemporary carbon and produce 70 to 80%. Examples of the former include gas drilling, mining, and wetland emissions that contain methane that has been stored for thousands of years, whereas enteric fermentation from ruminants and insects (termites in particular), natural wetlands, biomass burning, oceans and lakes, and waste treatment are examples of the latter. Cattle are expected to contribute about 2% to global warming over the next 50 years.

Strategies to reduce methane emissions by livestock are thus of international importance. Scientists know that the type of carbohydrate fermented determines the level of methane production, both by affecting rumen pH in addition to the ruminal population. For example, the fermentation of cell wall fiber in coarse diets results in

higher methane production than do concentrate diets high in soluble carbohydrates, where methane losses may drop to as little as 3% of the ingested energy. Grinding and pelleting forages can also decrease methane production, but doing so decreases ruminal pH, which can lead to ruminal acidosis. Beef cattle are increasingly reared in feedlots and given methane-inhibiting substances (such as ionophores and dicarboxylic acids). It is thus possible to assume modest reductions in methane emissions of livestock while enhancing productivity by modifying diet quality. Although methane production is largely dependent on diet quality and feed intake, differences in methane emissions (per kg dry matter intake between animals) of 40 to 50% have been reported. This suggests that methane production is heritable, and current research (mainly in Australia and New Zealand) is focused on genetic selection for low-methane-emitting animals. Future technologies may develop methods to alter the microbial population in ways that would benefit the animal without negatively impacting the environment.

ticularly important in fluid-feeding insects, which have relatively large crops for storing blood or nectar. In some insects, the crop is a simple enlargement of the foregut, or, as in mosquitoes and Lepidoptera, a lateral diverticulum off the digestive tract. The crop in domestic fowl is structurally identical to that of the esophagus except for a scarcity of mucus glands. Mucus glands are also relatively sparse in the region of the esophagus below the crop because movement of the bolus largely involves prewetted material from the crop. Granivorous (“grain-eating”) and fish-eating birds have comparatively large crops for food storage, whereas carnivorous and insectivorous birds have limited need for a crop, which therefore are considerably reduced in size or are absent.

A food bolus moving down the esophagus in crop-bearing animals has two possibilities. It can either continue on to the *proventriculus-gizzard* organ(s) (in oligochaete worms, numerous arthropods, and most birds; Figures 14-3b and 14-4e), or it can enter the crop for temporary storage. The stored food is moistened by water as the animal drinks, but essentially no digestion occurs here. While empty, the crop of birds contracts once per minute, but if food is present in the proventriculus, then there is a complete inhibition of this contractile activity and the food remains within. The motility of the crop is regulated by vagal impulses. Motility and emptying are coordinated so as to release ingesta at a rate matching the emptying rate of the proventriculus and gizzard. If the

food bolus is too large for the gizzard, contractions subside and return the excess portion to the crop. We’ll examine details of avian proventriculus and gizzard later (p. 681).

The epithelial cells in the crop of some birds, including pigeons and doves, are sensitive to the hormone *prolactin*, the same hormone that promotes milk synthesis in mammals (p. 296). In both males and females, the increase in prolactin secretion during incubation of the eggs results in a marked proliferation of this tissue. Crop epithelia synthesize large stores of lipid material. Once the eggs hatch, these cells are sloughed off and mixed with food already present in the adult crop. This nutritive secretion, known as **crop milk**, is regurgitated into the esophagus of the squabs (chicks). In another species of bird, the **hoatzin** (*Opisthocomus hoazin*), the crop and esophagus function as a modified rumen (see p. 705), because this storage vat contains bacteria capable of digesting cellulose and detoxifying harmful plant alkaloids. Leafy plant material ferments in a large *double crop*, producing volatile fatty acids as smelly fermentation by-products, which gives the hoatzin a musky odor. The anterior sternum is markedly reduced in size to accommodate the voluminous fermentation structures, thus considerably reducing the area for flight muscle attachment. Nestlings can also be fed this regurgitated material. The highly developed digestive strategy of the hoatzin may have arisen from an evolutionary trade-off between detoxification of plant

chemical defenses and enhanced use of cellulosic leaf-cell wall as a nutritional resource.

Bees, too, can regurgitate the contents of their crops. As in birds, the proventriculus controls the movement of food from the crop but can also selectively remove pollen from a nectar suspension in the crop. The lips of the proventriculus are modified so that they can strain out the pollen grains for digestion while leaving the nectar in the crop for eventual regurgitation and processing into honey.

14.5 Stomach or Midgut

In most animals, the midgut or **stomach** provides for the initial digestion (beyond the minor salivary contribution) and storage of ingested food items. We will examine these roles primarily in insects and vertebrates.

Digestion in many insect midguts is aided by peritrophic membranes and filter chambers

In arthropods, the midgut is also referred to as the **mesenteron**. In many species of insects, the midgut is mildly acidic in the anterior two thirds and more alkaline in the posterior third. For example, the anterior midgut of the American cockroach (*Periplaneta americana*) is acidic (pH ~5.7), whereas the posterior midgut is slightly less (pH ~6.1). (Note that insect midguts are not nearly as acidic as vertebrate stomachs, and thus cannot use acid-activated pepsinlike enzymes.)

In numerous species of insects, a **peritrophic membrane** separates the midgut epithelium from the food. Structurally it is a permeable (porous) network of chitin fibrils set in a matrix of protein and mucopolysaccharides (proteins with attached chains of repeating sugar units). The role of the peritrophic membrane has not been established but is believed to include the following:

- **Protection:** It may protect the epithelial cells of the midgut from abrasion by the food.
- **Motility:** It may help move food through this region of the gut tube.
- **Defense:** It may inhibit the movement of some pathogens from the food into the insect's tissues. Although the pore size is normally smaller than the size of most bacteria, many bacterial enzymes and toxins can traverse the membrane and damage the midgut. However, large-molecular-weight tannins, which are toxic, cannot penetrate the pores of the peritrophic membrane.
- **Digestion:** It compartmentalizes the midgut lumen into an **ectoperitrophic** (*ecto*, “outer”) and **endoperitrophic** (*endo*, “inner”) space within which specialized digestive functions can occur. Trypsin and amylase are localized to the endoperitrophic space, where they begin the initial digestion of food. Aminopeptidase and trehalase are localized to the ectoperitrophic space, where they complete the process of digestion.

The **filter chamber** represents an additional variation in midgut structure. In Homoptera—insects like aphids that feed on large quantities of plant juices—the filter chamber permits water from the ingested sap to pass directly from the anterior region of the midgut to the hindgut. In this manner the sap is concentrated before being digested in the posterior region of the midgut. The excess fluid is released from the hindgut as **honeydew**, which in turn is a food for other insects. To produce this secretion, the midgut actually loops back onto itself and becomes internalized along with the Malpighian tubules.

Diverticula (small outpocketings or folds) often supplement or replace the midgut of many other nonvertebrates (including tunicates, echinoderms, mollusks, and crustaceans) and function in enzymatic digestion and absorption.

The vertebrate stomach stores food, begins protein digestion, and forms chyme

In vertebrates, only some species of bony fish, lampreys, hagfishes, and larval toads completely lack a stomach, with the esophagus opening directly into the intestine. For example, parrot fish (*Scaridae*) grind their algal food between heavy pharyngeal plates to disrupt the algal cell walls, the finely ground material then passing directly into the moderately alkaline intestine.

In monogastric mammals, the stomach is a simple, muscular, saclike chamber lying between the esophagus and small intestine. Generally the stomach of amphibians, fish, reptiles, and most mammals is a simple tubular expansion of the digestive tract. In humans it is arbitrarily divided into three sections based on anatomic, histologic, and functional distinctions (Figure 14-10). The dorsal region, or the **fundus**, is responsible for the storage of ingested food and adaptation to changes in volume. The middle, or main, part of the stomach is the body or **corpus**. Here the digesta is mixed with gastric secretions. The smooth muscle layers in the fundus and corpus are relatively thin, but the lower portion of the stomach, the **antrum**, has a much heavier musculature that is used to regulate expulsion of food into the small intestine as well as mix the contents. The terminal portion of the stomach consists of the **pyloric sphincter**, which acts as a barrier between the stomach and the upper part of the small intestine, the **duodenum**.

Variations between different animal groups with simple stomachs are based on the distribution and composition of the epithelium lining of the stomach. There are also glandular differences in the mucosa of these regions, as described later. Some species may have a more complex, multichambered stomach. The stomach of rats, for example, is divided into separate compartments. Voluminous chambers that are compartmentalized and perform separate functions characterize the digastric stomach of ruminants. As we noted earlier, some species of fish, such as the carp, completely lack a stomach, and food enters the small intestine directly.

The stomach performs three main functions:

1. **Storage:** The most important function is to store ingested food until it can be emptied into the small intestine at a rate appropriate for optimal digestion and absorption. In only a matter of minutes carnivores can consume a meal that then takes hours to digest and absorb. Because the small intestine is the primary site for this digestion and absorption, it is important that the stomach store the

FIGURE 14-10 Anatomy of the stomach (mammalian; shown for a human). The stomach is divided into three sections based on structural and functional distinctions—the fundus, body, and antrum. The mucosal lining of the stomach is divided into the oxyntic mucosa and the pyloric gland area based on differences in glandular secretion. © Cengage Learning, 2013

food and meter it into the duodenum at a rate that does not exceed the small intestine's capacities.

2. **Digestion:** The stomach secretes hydrochloric acid (HCl) and enzymes that begin protein digestion.
3. **Chyme formation:** Through mixing movements, the ingested food is pulverized and mixed with gastric secretions to produce a thick, liquid mixture known as **chyme**. The stomach contents must be converted to chyme before they can be emptied into the duodenum.

We now discuss how the stomach accomplishes these functions as we examine the four basic digestive processes—motility, secretion, digestion, and absorption—as they relate to the stomach. The details are primarily for mammals, but other animals are noted where comparison is illustrative. Starting with motility, gastric motility is complex and subject to multiple regulatory inputs. The four aspects of gastric motility are (1) gastric filling, (2) gastric storage, (3) gastric mixing, and (4) gastric emptying. We begin with gastric filling.

Gastric filling involves receptive relaxation

Stomachs can have a remarkable ability to accommodate significant changes in volume. Consider the blood-sucking leech, which feeds only once during its life and ingests the equivalent of nine times its body weight in about 30 minutes. Distension of the body eventually causes the animal to cease feeding. By comparison, the empty human stomach has a volume of about 50 mL, but it can expand to a capacity of about 1 liter (1,000 mL) during a meal. The mammalian stomach can accommodate such a 20-fold change in volume with little tension in its walls and little rise in intragastric pressure through the following mechanism. The interior of the stomach is thrown into deep folds. During a meal, the folds

get smaller and flatten out as the stomach relaxes slightly with each mouthful. This reflex relaxation of the stomach as it is receiving food is called **receptive relaxation**; it enables the stomach to accommodate the extra volume of food with little rise in stomach pressure. Receptive relaxation is triggered by the act of eating and is mediated by the vagus nerve.

Gastric storage takes place in the body of the stomach

A group of pacesetter cells (interstitial cells of Cajal) located in the upper fundus region of the mammalian stomach generate BERs (p. 660) that sweep down the length of the stomach toward the pyloric sphincter at a rate of a few per minute. This occurs continuously and may or may not be accompanied by contraction of the stomach's circular smooth muscle layer. Depending on the level of excitability in the smooth muscle, it may be brought to threshold by this flow of current and undergo action potentials, which in turn initiate peristaltic waves that sweep over the stomach in pace with the BER. Once initiated, the peristaltic wave spreads over the fundus and body to the antrum and pyloric sphincter. Because the muscle layers are thin in the fundus and body, the peristaltic contractions in this region are weak. When the waves reach the antrum, they become much stronger and more vigorous because the muscle there is much thicker.

Because only feeble mixing movements occur in the body and fundus, food emptied into the stomach from the esophagus is stored in the relatively quiet body without being mixed. The fundic area usually does not store food but contains only a pocket of gas. Food is gradually fed from the body into the antrum, where mixing does take place.

Gastric mixing takes place in the antrum of the stomach

The strong antral peristaltic contractions are responsible for mixing food with gastric secretions to produce chyme. Each antral peristaltic wave propels chyme forward toward the pyloric sphincter. Tonic contraction of the pyloric sphincter normally keeps it almost, but not completely, closed. The opening is large enough for water and other fluids to pass through with ease but too small for the thicker chyme to pass through except when a strong antral peristaltic contraction pushes it through. Even then, usually only a few milliliters of antral contents are forced into the duodenum with each peristaltic wave. Before more chyme can be squeezed out, the peristaltic wave reaches the pyloric sphincter and causes it to contract more forcefully, sealing off the exit and blocking further passage into the duodenum. The bulk of the antral chyme that was being propelled forward but failed to be pushed into the duodenum is abruptly halted at the closed sphincter and tumbled back into the antrum, only to be propelled forward and tumbled back again as the new peristaltic wave advances (Figure 14-11). This tossing back and forth, called **retropulsion**, thoroughly mixes the chyme in the antrum.

Gastric emptying is largely controlled by factors in the duodenum

In addition to accomplishing gastric mixing, the antral peristaltic contractions provide the driving force for gastric emptying. The amount of chyme that escapes into the

1 A peristaltic contraction originates in the upper fundus and sweeps down toward the pyloric sphincter.

2 The contraction becomes more vigorous as it reaches the thick-muscled antrum.

3 The strong antral peristaltic contraction propels the chyme forward.

4 A small portion of chyme is pushed through the partially open sphincter into the duodenum. The stronger the antral contraction, the more chyme is emptied with each contractile wave.

5 When the peristaltic contraction reaches the pyloric sphincter, the sphincter is tightly closed and no further emptying takes place.

6 When chyme that was being propelled forward hits the closed sphincter, it is tossed back into the antrum. Mixing of chyme is accomplished as chyme is propelled forward and tossed back into the antrum with each peristaltic contraction.

FIGURE 14-11 Gastric emptying and mixing as a result of antral peristaltic contractions (mammalian stomach, shown for a human).

© Cengage Learning, 2013

duodenum with each peristaltic wave before the pyloric sphincter closes tightly depends largely on the strength of peristalsis and on the particle size of the ingested material. During the digestive phase of gastric motility, only particles less than 2 mm in diameter escape through the pyloric sphincter. The intensity of antral peristalsis can vary markedly under the influence of different signals from both the stomach and the duodenum; thus, gastric emptying is regulated by both gastric and duodenal factors. These factors influence the stomach's excitability by slightly depolarizing or hyperpolarizing the gastric smooth muscle. This excitability in turn is a determinant of the degree of antral peristaltic activity. The greater the excitability, the more frequently the BER generates action potentials, the greater the degree of peristaltic activity in the antrum, and the faster the rate of gastric emptying (Table 14-1).

Factors in the Stomach that Influence the Rate of Gastric Emptying The main gastric factor that influences the strength of contraction is the amount of chyme, as well as the chyme's fluidity, in the stomach. Other things being equal, the stomach empties at a rate proportional to the volume of chyme in it at any given time. Distension of the stomach triggers increased gastric motility through a direct effect of stretch on the smooth muscle as well as through involvement of the intrinsic plexuses, the vagus nerve, and the stomach hormone *gastrin*. (The control and other functions of this hormone, which is secreted by special endocrine cells in the antrum, are described later.)

Factors in the Duodenum that Influence the Rate of Gastric Emptying Despite these gastric influences, factors in the duodenum are of primary importance in controlling the rate of gastric emptying. The duodenum must be ready to receive the chyme and can act to delay gastric emptying by reducing peristaltic activity in the stomach until the duodenum is ready to accommodate more chyme. Even if the stomach is distended and its contents are in a liquid form, it cannot empty until the duodenum is ready to process the chyme.

The four most important factors in the duodenum that influence gastric emptying are *fat*, *acid*, *hypertonicity*, and *distension*. The presence of one or more of these stimuli in the duodenum activates appropriate duodenal receptors, triggering either a neural or hormonal response that slows gastric motility by reducing the excitability of the gastric smooth muscle. The subsequent reduction in antral peristaltic activity slows down the rate of gastric emptying.

- The *neural response* is mediated through both the intrinsic nerve plexuses (short reflex) and the autonomic nerves (long reflex). Collectively, these reflexes are called the **enterogastric reflex** (*entero* means “intestine”).
- The *hormonal response* involves the release from the duodenal mucosa of several hormones collectively known as **enterogastrones**. The blood carries these hormones to the stomach, where they inhibit antral contractions to reduce gastric emptying. Three of these enterogastrones have been positively identified: *secretin*, *cholecystokinin* (CCK), and *gastric inhibitory peptide*.

TABLE 14-1 Factors Regulating Gastric Motility and Emptying (Vertebrate)

Factors	Mode of Regulation	Effects on Gastric Motility and Emptying
Within the Stomach		
<i>Volume of chyme</i>	Distension has a direct effect on gastric smooth muscle excitability, as well as acting through the intrinsic plexuses, the vagus nerve, and gastrin	Increased volume stimulates motility and emptying
<i>Degree of fluidity</i>	Direct effect; contents must be in a fluid form to be evacuated	Increased fluidity allows for more rapid emptying
Within the Duodenum		
<i>Presence of fat, acid, hypertonicity, or distension</i>	Initiates the enterogastric reflex or triggers the release of enterogastrones (secretin, cholecystokinin)	These factors in the duodenum inhibit further gastric motility and emptying until the duodenum has coped with factors already present
Outside the Digestive System		
<i>Emotion</i>	Alters autonomic balance	Stimulates or inhibits motility and emptying
<i>Intense pain</i>	Increases sympathetic activity	Inhibits motility and emptying
<i>Decreased glucose use in the hypothalamus</i>	Increases vagal activity	Stimulates motility; accompanied by hunger pangs

© Cengage Learning, 2013

(or *glucose-dependent insulinotropic peptide*). **Secretin** is produced by endocrine cells known as **S cells** and **CCK** by endocrine cells known as **I cells** in the duodenal and jejunal mucosa. Secretin was the first hormone discovered, by Bayliss and Starling in 1902. Because it was a secretory product that entered the blood in response to an increase in acidity in the duodenum, it was termed *secretin*. The name **cholecystokinin** derives from the fact that this same hormone also governs contraction of the bile-containing gallbladder (*chole* means “bile,” *cysto* means “bladder,” and *kinin* means “contraction”). The name **gastric inhibitory peptide** is self-explanatory; it is a peptide hormone that inhibits the stomach (but see the hormone summary at the end of this chapter for an explanation of its new name, *glucose-dependent insulinotropic peptide*). A possible fourth intestinal hormone, **neurotensin**, inhibits both gastric acid secretion as well as motility of the small intestine. Birds have a unique hormone **avian pancreatic polypeptide (APP)** that also is effective in reducing gastric motility.

Let’s examine why it is important that each of these stimuli in the duodenum (fat, acid, hypertonicity, and distension) delays gastric emptying (acting through the enterogastric reflex or one of the enterogastrones).

- **Fat:** Fat is digested and absorbed more slowly than the other nutrients. Furthermore, fat digestion and absorption take place only within the small-intestine lumen. Therefore, when fat is already present in the duodenum, further gastric emptying of more fatty stomach contents into the duodenum is prevented until the small intestine has processed the fat already there. In fact, fat is the most potent stimulus for inhibition of gastric motility. This is evident in humans when you compare the rate of emptying of a high-fat meal (after six hours, some of a

bacon-and-eggs meal may still be in the stomach) to that of a protein-and-carbohydrate meal (lean meat and potatoes may require only three hours to empty).

- **Acid:** Because the stomach secretes hydrochloric acid (HCl), highly acidic chyme is emptied into the duodenum, where it is neutralized by sodium bicarbonate (NaHCO_3) secreted into the duodenal lumen from the pancreas. Unneutralized acid irritates the duodenal mucosa and inactivates the pancreatic digestive enzymes that are secreted into the duodenal lumen. Appropriately, therefore, unneutralized acid in the duodenum inhibits further emptying of acidic gastric contents until complete neutralization is accomplished.
- **Hypertonicity:** As molecules of protein and starch are digested in the duodenal lumen, large numbers of amino acid and glucose molecules are released. If absorption of these amino acid and glucose molecules does not keep pace with the rate at which protein and carbohydrate digestion proceeds, these large numbers of molecules remain in the chyme and increase the osmolarity of the duodenal contents. Osmolarity depends on the number of molecules present, not on their size (recall colligative properties, p. 79), and one protein molecule may be split into several hundred amino acid molecules, each of which has nearly the same osmotic activity as the original protein molecule. The same holds true for one large starch molecule, which yields many smaller but equally osmotically active glucose molecules. Because water is freely diffusible across the duodenal wall, water enters the duodenal lumen from the plasma as the duodenal osmolarity rises. Large volumes of water entering the intestine from the plasma lead to intestinal distension, and, more importantly, circulatory disturbances ensue because of the reduction in plasma volume. To prevent these effects, gastric emptying is reflexly inhibited when

the osmolarity of the duodenal contents starts to rise. Thus, the amount of food entering the duodenum for further digestion into a multitude of additional osmotically active particles is reduced until absorption processes have had an opportunity to catch up.

Emptying and stress can influence gastric motility

In conjunction with the sensation of hunger, peristaltic contractions begin some time after the stomach empties, sweeping over the nearly empty antrum. This arousal of stomach motility appears to be mediated by increased parasympathetic activity. An animal may experience the sensation of hunger pangs when these peristaltic contractions are occurring, but the contractions themselves are not responsible for the sensation.

Other factors unrelated to digestion, such as stress, also can alter gastric motility by acting through the autonomic nerves to the smooth muscles. Even though the effect of emotions on gastric motility varies from one animal to another and is not always predictable, fear generally tends to decrease motility, whereas aggression tends to increase it. In addition to these influences, intense pain from any part of the body tends to inhibit motility, not just in the stomach but also throughout the digestive tract. Most of these responses are brought about by increased sympathetic activity and a corresponding decrease in parasympathetic activity.

The act of vomiting is powered by respiratory muscles, not the stomach

Vomiting, or **emesis**, the forceful expulsion of gastric contents out through the mouth, is generally perceived as being caused by abnormal gastric motility. However, animals with simple stomachs do not vomit by reverse peristalsis, as might be predicted. Actually, the stomach itself does not actively participate in the act of vomiting. The stomach, the esophagus, the esophageal sphincters, and the pyloric sphincter are all relaxed during vomiting. The major force for expulsion comes, perhaps surprisingly, from contraction of the respiratory muscles—namely, the diaphragm (the major inspiratory muscle) and the abdominal muscles (the muscles of active expiration) (see Figure 11-14, p. 511). Vomiting, however, is unusual in horses because the tone of the gastroesophageal sphincter is so great that it limits regurgitation of materials into the esophagus. Rats, too, cannot vomit and are careful to taste novel foods in small quantities.

Some species of birds, particularly carnivores, can “vomit” or **egest** indigestible foodstuffs. Owls, for example, egest the bones, feathers, and fur of their prey in the form of pellets. The presence of nutrients in the digesta inhibits egestion, but once digestion of the meal is complete, the rate and frequency of gastric contractions then increase. This compacts and shapes the pellet. Continued contractions move the pellet into the lower esophagus, where it is egested by rapid reverse peristalsis. Other birds such as penguins egest food to feed their young, while birds such as the fulmar and petrel can spew oil by-products at potential predators.

Vomiting in mammals begins with a deep inspiration and closure of the glottis. The contracting diaphragm descends downward on the stomach while simultaneous con-

traction of the abdominal muscles compresses the abdominal cavity, increasing the intra-abdominal pressure and forcing the abdominal viscera upward. As the flaccid stomach is squeezed between the diaphragm from above and the compressed abdominal cavity from below, the gastric contents are forced into the esophagus and out through the mouth. The glottis and uvula (in some primates) move to their blocking positions to prevent vomited material from entering the respiratory airways.

This complex act of vomiting is coordinated by a **vomiting center** in the medulla of the brain stem. Vomiting can be initiated by afferent input to the vomiting center from a number of receptors throughout the body. The causes of vomiting include (1) irritation or distension of the stomach and duodenum, and (2) chemical agents, including drugs or noxious substances that initiate vomiting (that is, **emetics**) either by acting in the upper portions of the gastrointestinal tract, or by stimulating chemoreceptors in a specialized **chemoreceptor trigger zone** in the medulla. Activation of the trigger zone initiates the vomiting reflex.

With excessive vomiting an animal experiences considerable losses of secreted fluids and acids that normally would be reabsorbed. The resultant reduction in plasma volume can lead to dehydration and circulatory problems, whereas loss of acid from the stomach can lead to metabolic alkalosis (see p. 650). However, limited vomiting brought about by irritation of the digestive tract can provide a useful service in removing noxious material from the stomach. Snakes, for example, that swallow too large a prey item are sometimes forced to vomit the remains before they putrefy inside their guts.

Gastric digestive juice is secreted by glands located at the base of gastric pits

The rate and the amount of gastric juice secretion are dependent on the frequency of feeding. For example, gastric juice production is continuous in ruminants and unpredictable in reptiles (carnivorous reptiles are dependent on prey availability and environmental temperature for digestion to occur). Once under way, gastric secretion in a snake carries on for up to six days to completely digest a rat, whereas in hibernators digestive functions virtually come to a standstill during hibernation.

The cells responsible for gastric secretion in a mammal are located in the lining of the stomach, the gastric mucosa, which is divided into two distinct areas whose distribution varies between species: (1) the **oxyntic mucosa**, which lines the body and fundus, and (2) the **pyloric gland area (PGA)**, which lines the antrum. The luminal surface of the stomach is pitted with deep pockets formed by infoldings of the gastric mucosa. The invaginations in this first portion are called **gastric pits**, at the base of which lie the **gastric glands**. A variety of secretory cells line these invaginations, some exocrine and some endocrine or paracrine (Table 14-2). Two types of glands normally line the proventriculus of birds: simple mucosal glands that secrete mucus in addition to compound submucosal glands that secrete HCl and **pepsinogen** (see p. 677). Interestingly, unlike in mammals, both HCl and pepsinogen are synthesized within the same cell—the chief or **oxynticopeptic cell**. Oxynticopeptic cells also line the stomach of fish.

© Cengage Learning, 2013

FIGURE 14-12 Mechanism of HCl secretion. The stomach's parietal cells actively secrete H^+ and Cl^- by the actions of two separate pumps. Hydrogen ion is secreted into the lumen by a primary H^+/K^+ ATPase active transport pump at the parietal cell's luminal border. The K^+ transported into the cell by the pump promptly exits through a luminal K^+ channel, thus being recycled between the cell and lumen. The secreted H^+ is derived from the breakdown of H_2O into H^+ and OH^- . Catalyzed by carbonic anhydrase, the OH^- combines with CO_2 (that is either metabolically produced in the cell or diffuses in from the plasma) to form HCO_3^- . Chloride is secreted by secondary active transport. Driven by the HCO_3^- concentration gradient, a Cl^-/HCO_3^- antiporter in the basolateral membrane transports HCO_3^- down its concentration gradient into the plasma and simultaneously transports Cl^- into the parietal cell against its concentration gradient. Chloride secretion is completed as the Cl^- that entered from the plasma moves out of the cell down its electrochemical gradient through a luminal Cl^- channel into the lumen.

Gastric Exocrine Secretory Cells Three types of secretory cells are found in the walls of the pits in the oxyntic mucosa:

- **Mucous cells** line the gastric pits and the entrance of the glands. They secrete a thin, watery *mucus*. (*Mucous* is the adjective; *mucus* is the noun.)
- Chief and parietal cells line the deeper portions of the gastric glands. The more numerous **chief cells** secrete the enzyme precursor *pepsinogen*.
- The **parietal** (or **oxyntic**) cells, which secrete *HCl* and *gastric intrinsic factor*. The parietal cells are located on the outer wall of the gastric pits and do not come into

contact with the pit lumen. (*Parietal* means “wall,” a reference to the location of these cells. *Oxyntic* means “sharp,” a reference to these cells’ potent *HCl* secretory product.)

These exocrine secretions are all released into the gastric lumen. Collectively, they make up the gastric digestive juice.

A few stem cells are also found in the gastric pits. These cells rapidly divide and serve as the parent cells of all new cells of the gastric mucosa. The daughter cells that result from cell division either migrate out of the pit to become surface epithelial cells or migrate down into the deeper parts of the pit to differentiate into chief or parietal cells. Through this activity, the entire stomach mucosa is regularly replaced (every three days in humans).

Between the gastric pits, the gastric mucosa is covered by **surface epithelial cells**, which secrete a thick, viscous, alkaline mucus that forms a visible protective layer several millimeters thick over the surface of the mucosa.

Gastric Endocrine and Paracrine Secretory Cells

Other secretory cells in the gastric mucosa release endocrine and paracrine regulatory factors instead of products involved in the digestion of nutrients in the gastric juice lumen. These are as follows:

- **Enterochromaffin-like (ECL) cells** dispersed among the parietal and chief cells in the gastric glands of the oxyntic mucosa secrete the paracrine *histamine*.
- The gastric glands of the PGA primarily secrete mucus and a small amount of pepsinogen; no acid is secreted in this area, in contrast to the oxyntic mucosa. More importantly, endocrine cells known as **G cells** in the PGA secrete the hormone *gastrin* into the blood.
- **D cells**, which are scattered in glands near the pylorus but are more numerous in the duodenum, secrete the paracrine *somatostatin*.

Let’s examine each of these secretory products in more detail, looking first at the exocrine products and their role in digestion, then at the exocrine secretions, among other actions.

Hydrochloric Acid Secretion The parietal cells actively secrete *HCl* into the lumen of the gastric pits, which in turn empty into the lumen of the stomach. The pH of the luminal contents of most vertebrates may fall to as low as 2 as a result of this *HCl* secretion. Hydrogen ion (H^+) and chloride ion (Cl^-) are actively transported by separate pumps in the parietal cell’s plasma membrane. Hydrogen ion is actively transported against a tremendous concentration gradient, with the H^+ concentration being as much as 3 to 4 million times greater in the lumen than in the blood. Because of the high-energy expenditure needed to move H^+ against such a large gradient, parietal cells have an abundance of mitochondria.

The secreted H^+ is not transported from the plasma but is derived instead from metabolic processes within the parietal cell (Figure 14-12). Specifically the H^+ to be secreted is derived from the breakdown of H_2O molecules into H^+ and OH^- within the parietal cells. This H^+ is secreted into the

stomach lumen by H^+/K^+ ATPase in the parietal cell's luminal membrane. This primary active transport carrier also pumps K^+ into the cell from the lumen. The transported K^+ then passively leaks back into the lumen through luminal K^+ channels, thus leaving K^+ levels unchanged by the process of H^+ secretion.

Chloride is also actively secreted but against a much smaller concentration gradient of only 1.5 times. The process begins with the enzyme *carbonic anhydrase* (ca in Figure 14-12; see also p. 541), which parietal cells contain in abundance. In the presence of carbonic anhydrase, OH^- readily combines with CO_2 , which either has been produced within the parietal cell by metabolic processes or has diffused in from the blood. The combination of OH^- and CO_2 form HCO_3^- . The reduction in OH^- causes H_2O to split into more H^+ and OH^- . The generated H^+ in essence replaces the one secreted.

The generated HCO_3^- is moved into the plasma down its electrochemical gradient by the Cl^-/HCO_3^- antiporter in the basolateral membrane of the parietal cells and simultaneously transports Cl^- from the plasma into the parietal cell against its electrochemical gradient. By building up Cl^- inside the parietal cell, the Cl^-/HCO_3^- antiporter establishes a Cl^- concentration gradient between the parietal cell and gastric lumen. Because of this concentration gradient and because the cell interior is negative compared to the luminal contents, the negatively charged Cl^- now moves out of the cell down its electrochemical gradient through Cl^- channels in the luminal membrane into the gastric lumen, completing the Cl^- secretory process. In the meantime, the blood leaving the stomach is alkaline, the so-called **alkaline tide**, because HCO_3^- has been added to it. The alkaline tide is greatest in the alligator (*Alligator mississippiensis*) in which the pH increases from 7.4 to 7.6, a change of 0.2 pH units. Comparably the change in pH units in *Rana catesbeiana* is 0.1; *Bufo marinus*, 0.05; and the python (*Molurus*), 0.02.

Although HCl does not actually digest anything and is not absolutely essential to gastrointestinal function, it does perform several functions. Specifically, HCl:

- Activates the enzyme precursor pepsinogen to an active enzyme, pepsin, and provides an acid medium that is optimal for pepsin activity.
- Aids in the breakdown of connective tissue and muscle fibers, thereby reducing large food particles into smaller particles.
- Denatures protein; that is, it uncoils proteins from their tertiary structure, thus exposing more of the peptide bonds for enzymatic attack.
- Along with salivary lysozyme, kills most microorganisms ingested with the food (although some resistant ones may escape and continue to grow and multiply in the intestine).

Pepsinogen, once activated, begins protein digestion

The major digestive constituent of gastric secretion is **pepsinogen**, an inactive enzymatic molecule produced in all vertebrates having stomachs except cyclostomes. (In stomachless pufferfish, the gene is not expressed in the gut, though it is in the skin.) Moreover, in animals lacking highly acidic digestive regions (such as insects), no equivalent en-

FIGURE 14-13 Pepsinogen activation in the stomach lumen (vertebrate). In the lumen, hydrochloric acid (HCl) activates pepsinogen to its active form, pepsin, by cleaving off a small fragment. Once activated, pepsin autocatalytically activates more pepsinogen and begins protein digestion. Secretion of pepsinogen in the inactive form prevents it from digesting the protein structures of the cells in which it is produced.

zyme has evolved. Pepsinogen is stored in the chief cell's cytoplasm within secretory vesicles known as **zymogen granules**, from which it is released by exocytosis (p. 41) on appropriate stimulation. When pepsinogen is secreted into the gastric lumen, HCl cleaves off a small fragment of the molecule, converting it to the active form of the enzyme, **pepsin** (Figure 14-13). Once formed, pepsin acts on other pepsinogen molecules to produce more pepsin. A mechanism such as this, whereby an active form of an enzyme activates other molecules of the same enzyme, is referred to as an **autocatalytic** ("self-activating") process and is another example of positive feedback. Only when there is no more protein in the stomach does the secretion of pepsinogen cease.

Pepsin initiates protein digestion by splitting certain amino acid linkages in proteins to yield peptide fragments

(small amino acid chains); it works most effectively in a low-pH environment. Because pepsin can digest protein, it must be stored and secreted in an inactive form, so it does not digest proteins such as cytoskeletons in the cells in which it is formed. While inside the cell, therefore, pepsin is maintained in the inactive form of pepsinogen until it reaches the gastric lumen, where it is activated by HCl.

Stomach mucus is protective

The surface of the gastric mucosa is covered by a layer of mucus, which serves as a protective barrier against several forms of potential injury to the gastric mucosa:

- By virtue of its lubricating properties, mucus protects the gastric mucosa against mechanical injury.
- Mucus helps protect the stomach wall from self-digestion because pepsin is inhibited when it comes in contact with the mucus coating the stomach lining. (However, mucus does not affect pepsin activity in the lumen, where digestion of dietary protein proceeds without interference.)
- Being alkaline, mucus helps protect against acid injury by neutralizing HCl in the vicinity of the gastric lining, but it does not interfere with the function of HCl in the lumen. Whereas the pH in the lumen may be as low as 2, the pH in the mucus layer adjacent to the mucosal cell surface is about 7.

Four chemical messengers primarily influence the secretion of gastric digestive juices. Parietal cells have separate receptors for each of these messengers. Three of them—acetylcholine (ACh), gastrin, and histamine—are stimulatory. They bring about increased secretion of HCl by promoting the insertion of additional H^+/K^+ ATPases into the parietal cell's plasma membrane. The fourth regulatory agent—somatostatin—inhibits acid secretion. Gastrin and ACh also increase pepsinogen secretion through their stimulatory effect on the chief cells. We now consider each of these chemical messengers in further detail:

- **Acetylcholine** is a neurotransmitter released from the intrinsic nerve plexus in response to vagus stimulation. ACh stimulates the parietal and chief cells as well as the G cells and ECL cells. It is the most important trigger of HCl secretion in fishes.
- The G cells secrete the hormone **gastrin** into the blood in response to protein products in the stomach lumen as well in response to ACh. Like secretin and CCK, gastrin is a major gastrointestinal hormone. After being carried by the blood back to the body and fundus of the stomach, gastrin stimulates (that is, it is *tropic*) the parietal and chief cells, promoting secretion of a highly acidic gastric juice. In addition to directly stimulating the parietal cells, gastrin also indirectly promotes HCl secretion by stimulating the ECL cells to release histamine. Gastrin is the main factor responsible for increasing HCl secretion during digestion of a meal. Gastrin is also *trophic* (growth promoting) to the mucosa of the stomach and small intestine, thereby maintaining their secretory capabilities.
- **Histamine**, a paracrine, is released from the ECL cells in response to gastrin and ACh. Histamine acts locally on nearby parietal cells to increase the rate of HCl secre-

tion and potentiates the actions of ACh and gastrin.

Histamine and gastrin are the most important triggers of HCl secretion in frogs and mammals.

- **Somatostatin** is released from the D cells in response to acid. It acts locally as a paracrine, in negative-feedback fashion, to inhibit secretion by the parietal cells, G cells, and ECL cells, thus turning off the HCl-secreting cells and their most potent stimulatory pathway.

ACh and gastrin both operate through IP_3/Ca^{2+} second-messenger pathways; histamine activates cAMP to bring about its effects. These messengers all bring about increased secretion of HCl by promoting the insertion of additional H^+/K^+ ATPases into the parietal cells' plasma membrane. A pool of these pumps is stored within the parietal cell in intracellular vesicles, which fuse with the luminal membrane via exocytosis to add more of these active carriers to the membrane as needed to increase HCl secretion (recall that renal aquaporins are similarly regulated; p. 585).

From this list, it is obvious not only that multiple chemical messengers influence the parietal and chief cells but also that these chemicals also influence each other. Next, as we examine the phases of gastric secretion, you will see under what circumstances each of these regulatory agents is released.

Control of gastric secretion involves three phases

The rate of gastric secretion can be increased by (1) factors arising before food ever reaches the stomach, (2) factors resulting from the presence of food in the stomach, and (3) factors originating in the duodenum after food has left the stomach. Accordingly, gastric secretion is divided into three phases—the cephalic, gastric, and intestinal phases (Table 14-3).

Cephalic Phase The **cephalic phase** of gastric secretion refers to the increased secretion of HCl and pepsinogen that occurs in feedforward (anticipatory) fashion in response to stimuli acting in the head even before food reaches the stomach (*cephalic* means “head”). As we noted earlier, response to food-related stimuli (anticipating a meal, odor, chewing and swallowing) gastric secretion is increased by the vagus nerve. Recall that vagal stimulation results in two effects: (1) It promotes increased secretion of ACh, by intrinsic plexuses, which in turn leads to increased secretion of HCl and pepsinogen by the secretory cells. (2) It triggers G cells to release of gastrin, which in turn further enhances secretion of HCl and pepsinogen, with the effect on HCl being potentiated by gastrin promoting the release of histamine. The secretion of gastric juice in response to cephalic stimuli does not occur in ruminants because of the lack of association between the ingestion of food and the appearance of the ingesta in the compartmentalized ruminant stomach.

Gastric Phase The **gastric phase** of gastric secretion begins when food actually reaches the stomach. Stimuli acting in the stomach—namely *protein*, especially peptide fragments; *distension*; *caffeine*; and *alcohol*—increase gastric secretion by overlapping efferent pathways. For example, protein in the stomach, the most potent stimulus, stimulates chemoreceptors that activate the intrinsic nerve plexuses, which in

Cornell University, College of Veterinary Medicine

The photo above is of Stella, the successor to Ellie, the first cow at the Cornell College of Veterinary Medicine, to be fitted with a fistula (portal in the side) that functioned as a “window” into ruminant digestion. Ellie, born in 1988, died of old age in 2002; she outlived most of the other Holsteins. The removable cap on the fistula fitting allowed veterinary students to sample her digestive fluids and determine the rate of digestion of various foodstuffs. This fistula also allowed her to donate rumen fluid to other, less healthy cows, whose digestive systems needed a boost.

turn stimulate the secretory cells. Furthermore, protein brings about activation of the extrinsic vagal fibers to the stomach, enhancing the events of the cephalic phase. Through these synergistic and overlapping pathways, protein induces the secretion of a highly acidic, pepsin-rich gastric juice, which continues the digestion of the protein that first initiated the process.

Cephalic- and gastric-phase events have been tested as follows. First, if an animal (non ruminant) is fitted with an **esophageal fistula** (tube connecting the esophagus with the outside world) such that any ingested food is diverted from the stomach into a collecting port, there is an increase in secretion of HCl and pepsinogen in the animal’s stomach when the animal is eating due to cephalic stimulation. Alternatively, if a region of the stomach is experimentally denervated and pinched off with an opening to the outside world (a **Heidenhain pouch**) such that acid secretion can be measured, there is still acid secretion in the pouch as soon as food is put into it. Because the animal did not “see” the food, no cephalic phase is triggering the stomach. Rather, when food is placed in the stomach, gastric secretion is increased by the processes of the gastric phase.

Pioneering studies of gastric function were performed by William Beaumont, the “father of gastric physiology,” on a patient who retained a hole in his stomach after an accident. Beaumont would tie a piece of food to a string, insert it through the hole into the stomach, and at various intervals would remove the string and observe how much food remained. This led to the observation that it was primarily stomach secretions and not the mixing process that resulted in the digestion of the food item. Thus, digestion was understood to be primarily a chemical process and not simply a mechanical one.

Intestinal Phase The intestinal phase of gastric secretion encompasses the factors originating in the small intestine that influence gastric secretion, as with gastric emptying. Even if the stomach is completely isolated from the intestinal tract, placement of food into the upper part of the duodenum can still induce acid secretion in the stomach. Several important factors that originate in the small intestine influence gastric secretion. The intestinal phase has both an excitatory and an inhibitory component.

To a limited extent, the presence of the products of protein digestion in the duodenum stimulates further gastric secretion by triggering the release of **intestinal gastrin** that is carried by the blood to the stomach. This is the *excitatory component* of the intestinal phase of gastric secretion. It is as if the small intestine, on noting the arrival of protein fragments from the stomach, offers the stomach a “helping hand” in digesting the protein by enhancing gastric secretion.

The *inhibitory* component of the intestinal phase of gastric secretion is dominant over the excitatory component, as we will examine next.

Gastric secretion gradually decreases as food empties from the stomach into the intestine

You now know what factors turn on gastric secretion before and during a meal, but how is the flow of gastric juices shut off as chyme begins to be emptied from the stomach into the small intestine? Gastric secretion is gradually reduced by three different means as the stomach empties (Table 14-4):

- **Emptying:** As food is gradually emptied into the duodenum, the major stimulus for enhanced gastric secretion—the presence of protein in the stomach—is withdrawn.
- **Somatostatin:** After foods leave the stomach and gastric juices accumulate to such an extent that gastric pH falls very low (pH less than 3), somatostatin is released, inhibiting gastric secretion.
- **The inhibitory component of the intestinal phase of gastric secretion:** The same stimuli that inhibit gastric motility (fat, acid, hypertonicity, or distension in the duodenum brought about by stomach emptying) inhibit gastric secretion as well. The enterogastric reflex and the enterogastrones suppress the gastric secretory cells, while they simultaneously reduce the excitability of the gastric smooth muscle cells. For example, when the pH of the intestine becomes too low, *enteroglucagon* is released into the circulation and “shuts off” the flow of gastric juices.

The stomach lining is protected from gastric secretions by the gastric mucosal barrier

How can the stomach contain strong acid contents and proteolytic enzymes without destroying itself? We have already learned that mucus provides a protective coating. Furthermore, the surface mucus-secreting cells secrete HCO_3^- that is trapped in the mucus and neutralizes acid in the vicinity. In addition, other barriers to acid damage of the mucosa are provided by the mucosal lining itself. First, the luminal membranes of the gastric mucosal cells are almost impermeable to H^+ , so acid cannot penetrate *into* the cells and thus cause cell damage. Furthermore, the lateral edges of these

cells are joined together near their luminal borders by tight junctions (see p. 66), so acid cannot diffuse or conduct *between* the cells from the lumen into the underlying submucosa. Cardiac glands in some mammals (such as swine) secrete bicarbonate ion into the overlying mucus to protect the epithelial cells from H⁺. The properties of the gastric mucosa that enable the stomach to contain acid without injuring itself constitute the **gastric mucosal barrier** (Figure 14-14). These protective mechanisms are further enhanced by the fact that the entire stomach lining is replaced (every three days in humans) before they are irreparably damaged by the wear and tear of harsh gastric conditions.

Despite these protections (Figure 14-14), the barrier occasionally is broken so that the gastric wall is injured by its acidic and enzymatic contents. When this occurs, an erosion, or **peptic ulcer**, of the stomach wall results. A major contributor in humans is *Helicobacter pylori*, a bacterium that tolerates stomach. (Excessive gastric reflux into the esophagus and dumping of excessive acidic gastric contents into the duodenum, as well as *H. pylori*, can lead to peptic ulcers in

these locations as well.) Pigs are notable for their susceptibility to stomach ulcers, particularly in the esophageal area. Generally, there is a higher incidence in barrows (male pigs that have been castrated before reaching puberty) than gilts (female pigs that have not given birth), with both crowding and heat stress increasing the severity of the lesion.

Carbohydrate digestion continues in the body of the stomach, whereas protein digestion begins in the antrum

Two separate digestive processes take place within the stomach. Food in the body of the stomach remains a semisolid mass because peristaltic contractions in this region are too weak for mixing to occur. Because food is not mixed with gastric secretions in the body of the stomach, very little protein digestion occurs here. Acid and pepsin can attack only the surface of the food mass. Carbohydrate digestion, however, continues in the interior of the mass under the influ-

FIGURE 14-14 Gastric mucosal barrier.

© Cengage Learning, 2013

The components of the gastric mucosal barrier enable the stomach to contain acid without injuring itself:

- 1 The luminal membranes of the gastric mucosal cells are impermeable to H⁺ so that HCl cannot penetrate into the cells.
- 2 The cells are joined by tight junctions that prevent HCl from penetrating between them.
- 3 A mucus coating over the gastric mucosa serves as a physical barrier to acid penetration.
- 4 The HCO₃⁻-rich mucus also serves as a chemical barrier that neutralizes acid in the vicinity of the mucosa. Even when luminal pH is 2, the mucus pH is 7.

ence of salivary amylase. Even though acid inactivates salivary amylase, the unmixed interior of the food mass is free of acid.

Digestion by the gastric juice itself is accomplished in the antrum of the stomach, where the food is thoroughly mixed with HCl and pepsin, initiating protein digestion.

In most vertebrates, at this point, fat digestion has not even begun. Although it is possible for fat molecules, which are lipid soluble, to pass through the lipid portions of the cell membranes that line the stomach, this does not occur to any appreciable extent, because dietary fat in the gastric lumen separates into large fat droplets that float in the chyme. However, in some species lingual lipase (p. 664) has begun the process of lipid digestion.

The proventriculus and gizzard begin the process of digestion in birds and insects

Animals that possess gizzards include birds, which have no stomach per se, but rather an organ is divided into two components we noted earlier (p. 660): the **proventriculus**, which serves as the “glandular stomach,” and a separate **gizzard**, which serves as the “muscular stomach” to macerate and grind the ingesta. The proventriculus is comparatively small in herbivorous birds and is considerably larger in aquatic carnivores, which also use it as a storage space for captured prey. Motility functions of the proventriculus are to expel ingesta and digestive secretions into the gizzard.

Two pairs of smooth muscle groups, the *thin* (*musculi intermedii*) and *thick* (*musculi laterales*) encircle the gizzard and act in opposition to each other. Most birds cannot chew their food, so the gizzard, which contains **grit** (swallowed pebbles and small stones), is responsible for the mechanical breakdown of ingesta. The mucosal lining of the gizzard is covered by a coating, **koilin**, a tough protein-polysaccharide complex that has an amino acid composition similar to that of feather protein (keratin). Structurally, koilin is a composite of filaments formed in tubular glands lining the gizzard. This

hard filament eventually forms a rod that protrudes through the luminal surface of the mucosa and forms the *gizzard teeth* (the abrasive lining of the gizzard’s surface).

The gizzard is a comparatively large organ evolved to develop high pressures for particle size reduction. In birds the myoglobin content of the gizzard is approximately 100-fold greater than in the breast muscle, and mitochondrial numbers are also elevated, indicating a high aerobic capacity. Digesta from the gizzard is refluxed back into the proventriculus for further digestion and mixed with gastric secretions. Movement of digesta from the gizzard back into the proventriculus allows feed to be exposed to digestive enzymes and low pH for extended times, consequently improving digestive efficiency and increasing gut health. Gut health improvements are also associated with the acidic destruction of pathogenic bacteria that are ingested with feed.

In domestic poultry, gastroduodenal motility is tightly coordinated and begins with contraction of the thin, circular muscles lining the gizzard, followed by several waves of peristalsis in the duodenum. A powerful contraction of the thick muscles then precedes peristalsis of the proventriculus. Contractions of the proventriculus and duodenum are generated by intrinsic neural connections originating from the gizzard and are not significantly affected by loss of extrinsic innervation. At the end of the contraction of the thin muscles, ingesta flows from the gizzard into the duodenum, whereas after contraction of the thick muscles, the ingesta flows into the proventriculus. Contraction of the proventriculus then forces material back into the gizzard. In poultry, these cycles are normally repeated two to three times per minute, with food deprivation decreasing the frequency of contractions.

Gizzards are also found in alligators, crocodiles, and in several species of fish, including the mullet, which is found in estuarine waters worldwide. The gizzard also occurred in herbivorous dinosaurs. Many annelids, mollusks, and arthropods also have (nonhomologous) gizzards: In cockroaches, for example, six cutting edges or plates are arranged

radially around the gizzard such that when compressed together, they form a powerful grinding tool to macerate digesta. Only when food particles are sufficiently ground can they continue their passage from the foregut into the midgut. This function helps limit the amount of food leaving the crop and entering the midgut.

What enzyme is produced in the stomach, and how is it activated?

How does the parietal cell accomplish the production of HCl?

What are the functions of the proventriculus and gizzard?

14.6 Digestive Accessory Organs: Pancreas, Liver, Gallbladder, Fat Body

When gastric contents are emptied into the vertebrate small intestine, they are mixed not only with juice secreted by the small-intestine mucosa but also with the secretions of the exocrine pancreas and liver that are emptied into the duodenal lumen. We discuss the roles of each of these accessory digestive organs before we examine the small intestine itself.

The (hepato)pancreas is a mixture of exocrine and endocrine tissue

The **pancreas** in most vertebrates is a mixed gland that contains both exocrine and endocrine tissue (Figure 14-15). Approximately 98% of the vertebrate pancreas is committed to its exocrine function. The predominant exocrine portion consists of grape-like clusters of secretory cells that form sacs known as **acini**, which connect to ducts that eventually empty into the duodenum. The smaller endocrine portion consists of isolated islands of endocrine tissue, the **islets of Langerhans**, which are dispersed throughout the pancreas. The most important hormones secreted by the islet cells are *insulin* and *glucagon* (p. 316). In most species the islets are unequally distributed throughout the gland. For example, the splenic lobe of the avian pancreas is approximately 4 to 5% endocrine in function, compared to less than 0.5% for the remaining three lobes. The exocrine and endocrine tissues of the pancreas are derived from different tissues during embryonic development and share only their location in common. Although both are involved with the metabolism of nutrient molecules, they have different functions under the control of different regulatory mechanisms.

The **hepatopancreas** of crustaceans, gastropods, and fishes contains cells with functions comparable to those found in the mammalian pancreas and liver. Structurally the crustacean hepatopancreas consists of numerous blind ended tubules lined with epithelium that secrete various digestive enzymes. Ducts from the hepatopancreas are connected to

the anterior midgut where they are refluxed back to the proventriculus. Alternatively chyme from the midgut enters the hepatopancreas where it is further digested and eventually absorbed. Cells in this organ can store both lipids and glycogen generated from the digestive processes. The organ also has endocrine functions.

The exocrine pancreas secretes digestive enzymes and an aqueous alkaline fluid

The **exocrine pancreas** in most vertebrates secretes a pancreatic juice consisting of two components: (1) *pancreatic enzymes* actively secreted by the *acinar cells* that form the acini and (2) an *aqueous alkaline solution* actively secreted by the *duct cells* that line the pancreatic ducts. The aqueous (watery) alkaline component is rich in sodium bicarbonate (NaHCO_3). Pancreatic secretions show various adaptations to the diet of the animal as well as the feeding strategy.

Like pepsinogen, pancreatic enzymes are produced and stored within zymogen granules and are released by exocytosis as needed. The acinar cells secrete different types of pancreatic enzymes that can digest foodstuffs. In nonruminants, these pancreatic enzymes are important because they can almost completely digest food in the absence of all other digestive secretions. The principal types of vertebrate pancreatic enzymes are (1) *proteolytic enzymes*, which are involved in protein digestion; (2) *pancreatic amylase* and *chitinase* (in some vertebrates), which contributes to carbohydrate digestion; and (3) *pancreatic lipase*, for fat digestion.

Pancreatic Proteolytic Enzymes The three major proteolytic enzymes secreted by the vertebrate pancreas are *trypsinogen*, *chymotrypsinogen*, and *procarboxypeptidase*, each of which is secreted in an inactive form. When **trypsinogen** is secreted into the duodenal lumen, it is activated to its active enzyme form, **trypsin**, by **enterokinase**, an enzyme embedded in the luminal border of the cells that line the duodenal mucosa. Trypsin then autocatalytically activates more trypsinogen. Like pepsinogen in the chief cells of the stomach, trypsinogen must remain inactive within the pancreas to prevent this proteolytic enzyme from digesting the cells in which it is formed. As further protection, the pancreatic tissue also produces a chemical known as **trypsin inhibitor**, which blocks trypsin's actions if activation of trypsinogen inadvertently occurs within the pancreas.

Chymotrypsinogen and **procarboxypeptidase**, the other pancreatic proteolytic enzymes, are converted by trypsin to their active forms, **chymotrypsin** and **carboxypeptidase**, respectively, within the duodenal lumen. Thus, once enterokinase has activated some of the trypsin, trypsin then governs the rest of the activation process.

Each of these proteolytic enzymes attacks different peptide linkages. The end products that result from this action are a mixture of amino acids and small peptide chains. Mucus secreted by the intestinal cells protects against digestion of the small-intestine wall by the activated proteolytic enzymes.

Pancreatic Amylase Like salivary amylase, pancreatic amylase plays an important role in carbohydrate digestion by converting polysaccharides into disaccharides. Amylase is secreted in the pancreatic juice in an active form because active amylase does not present a danger to the secretory cells. These cells do not contain any polysaccharides.

FIGURE 14-15 Schematic representation of the exocrine and endocrine portions of the mammalian pancreas (shown for a human). The exocrine pancreas secretes into the duodenal lumen a digestive juice composed of digestive enzymes secreted by the acinar cells and an aqueous NaHCO_3 solution secreted by the duct cells. The endocrine pancreas secretes the hormones insulin and glucagon into the blood.

© Cengage Learning, 2013

Pancreatic Chitinase If cellulose is the most common biological polysaccharide, then what is the second? It is *chitin*, a compound found in the cuticle of arthropods and in cell walls of fungi where it serves a structural function comparable to that of cellulose. **Chitin** consists of chains of glucose molecules, each linked by β -bonds, and each of which has an acetamino group ($-\text{N}-\text{CO}-\text{CH}_3$) in place of a hydroxyl ($-\text{OH}$) group on the second carbon. Compared to cellulose, this is a more digestible nutrient for vertebrates, although only fish and some species of marine birds have a pancreatic chitinase that breaks down chitin into N-acetyl-glucosamine.

Pancreatic Lipase In vertebrates pancreatic lipase is extremely important because it is the principal enzyme that can digest fat. Pancreatic lipase (like salivary lipase) hydrolyzes dietary triglycerides into monoglycerides and free fatty acids, which are the absorbable units of fat. Like amylase, lipase is secreted in its active form because there is no risk of

pancreatic self-digestion by lipase. When pancreatic enzymes are deficient, digestion of food is incomplete. Because the pancreas is the only significant source of lipase, pancreatic enzyme deficiency results in serious maldigestion of fats. The principal clinical manifestation of pancreatic exocrine insufficiency in mammals is **steatorrhea**, or excessive undigested fat in the feces. Up to 60 to 70% of the ingested fat may be excreted in the feces. Digestion of protein and carbohydrates is less impaired because salivary, gastric, and small-intestinal enzymes contribute to the digestion of these two foodstuffs.

Pancreatic Aqueous Alkaline Secretion Pancreatic enzymes function best in a neutral or slightly alkaline environment, yet the highly acidic gastric contents are emptied into the duodenal lumen in the vicinity of pancreatic enzyme entry into the duodenum. This acidic chyme must be quickly neutralized in the duodenal lumen, not only to allow optimal functioning of

the pancreatic enzymes but also to prevent acid damage to the duodenal mucosa. The alkaline (NaHCO_3 -rich) fluid secreted by the pancreas into the duodenal lumen serves the important function of neutralizing the acidic chyme as the latter is emptied into the duodenum from the stomach. This aqueous NaHCO_3 secretion is by far the largest component of pancreatic secretion. The volume of pancreatic secretion ranges between 1 and 2 liters per day in humans to as high as 12 liters per day in a pony, depending on the types and degree of stimulation.

All of the details of pancreatic NaHCO_3 secretion are not known, but carbonic anhydrase (see Figure 14-12, p. 676) is involved and the Na^+/K^+ pump provides the driving energy for secondary active transport. According to the current model, under the influence of carbonic anhydrase, CO_2 in the pancreatic duct cell combines with OH^- generated from H_2O to produce HCO_3^- , which exits across the luminal membrane to enter the duct lumen via a $\text{Cl}^-/\text{HCO}_3^-$ antiporter. Sodium moves through the “leaky” tight junctions into the lumen. Together these actions accomplish NaHCO_3 secretion. The H^+ generated from H_2O within the duct cell enters the blood across the basolateral border either by active transport or an Na^+/H^+ antiporter. Thus, the pancreatic duct cells secrete HCO_3^- and absorb H^+ , whereas the gastric parietal cells secrete H^+ and absorb HCO_3^- , so the overall acid–base status of the body is not altered by digestive secretion.

Pancreatic exocrine secretion is hormonally regulated to maintain neutrality of the duodenal contents and to optimize digestion

Pancreatic exocrine secretion is regulated primarily by hormonal mechanisms. A small amount of cholinergic-induced (parasympathetic) pancreatic secretion occurs during the cephalic phase of digestion, with a further token increase occurring during the gastric phase in response to gastrin. However, the predominant stimulation of pancreatic secretion occurs during the intestinal phase of digestion, when chyme is in the small intestine. The release of the two major enterogastrones, secretin and cholecystokinin (CCK), in response to chyme in the duodenum plays the central role in the control of pancreatic secretion (Figure 14-16).

Role of Secretin in Pancreatic Secretion Of the factors that stimulate enterogastrone release (fat, acid, hypertonicity, and distension), the primary stimulus for secretin release is acid in the duodenum. Secretin, in turn, is carried by the blood to the pancreas, where it stimulates the duct cells to markedly increase their secretion of a NaHCO_3 -rich aqueous fluid into the duodenum. Even though other stimuli may

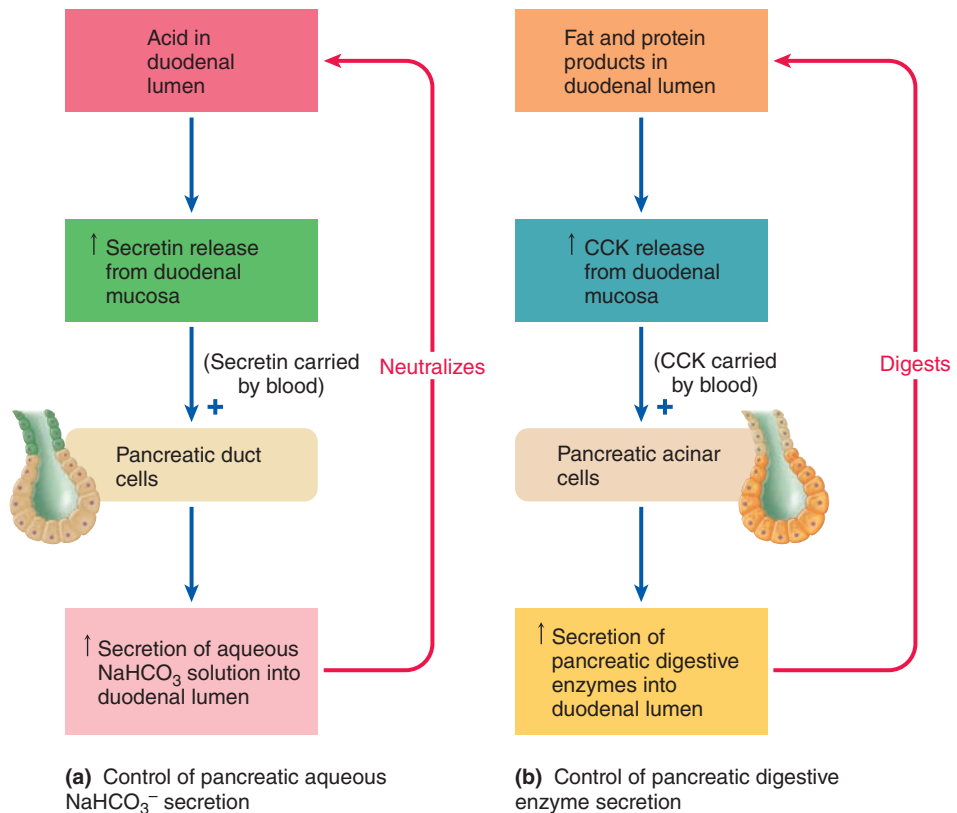

FIGURE 14-16 Hormonal control of pancreatic exocrine secretion (mammal).

© Cengage Learning, 2013

cause the release of secretin, it is appropriate that the most potent stimulus is acid, since the result is pancreatic secretion that neutralizes the acid. This mechanism provides a control system for maintaining neutrality of the chyme in the intestine, and is thus another example of negative feedback. The amount of secretin released is proportional to the amount of acid that enters the duodenum, so the amount of NaHCO_3 secreted parallels the duodenal acidity.

Role of CCK in Pancreatic Digestion Cholecystokinin is important in the regulation of pancreatic digestive enzyme secretion. The main stimulus for release of CCK from the duodenal mucosa into the blood is the presence of fat in the lumen and, to a lesser extent, protein products. The circulatory system transports CCK to the pancreas, where it stimulates the pancreatic acinar cells to increase digestive enzyme secretion.

All three types of pancreatic enzymes are packaged together in the zymogen granules, so all the pancreatic enzymes are released together on exocytosis of the granules. Therefore, even though the total amount of enzymes released varies depending on the type of meal consumed (the most being secreted in response to fat), the proportion of enzymes released does not vary on a meal-to-meal basis. That is, a high-protein meal does not cause the release of a greater proportion of proteolytic enzymes. Evidence suggests, however, that long-term adjustments in the proportion of the types of enzymes produced may occur as an adaptive response to a prolonged or seasonal change in diet. For example, a greater proportion of proteolytic enzymes are produced with a long-term switch to a high-protein feed. CCK may play a role in pancreatic enzyme adaptation to changes in diet.

Just as gastrin is trophic (“nourishing”) to the stomach and small intestine, CCK and secretin exert trophic effects on the exocrine pancreas to maintain its integrity.

We now look at the contributions of the remaining vertebrate accessory digestive units, the liver and gallbladder.

The vertebrate liver performs various important functions, including bile production, nutrient processing, and detoxification

Besides pancreatic juice, the other secretory product that is emptied into the duodenal lumen is **bile**. The **biliary system** includes the *liver*, the *gallbladder*, and associated ducts. Bile is continuously secreted in ruminants, horses, and pigs, whereas in most animals that feed at infrequent intervals, such as the dog and cat, bile is stored in the gallbladder until periods of feeding and digestion.

Liver Functions The liver is the largest and most important metabolic organ in the vertebrate body; it can be viewed as the body’s major “biochemical factory.” The liver performs a wide variety of functions, including the following:

- *Secretion of bile salts* for the digestive tract.
- *Metabolic processing of the major categories of nutrients* (carbohydrates, proteins, and lipids) after their absorption from the digestive tract, including *gluconeogenesis*—the process of converting noncarbohydrate nutrients into glucose.
- *Detoxification or degradation* of body wastes and hormones as well as drugs and other foreign compounds.
- *Synthesis of plasma (lipo)proteins*, including those necessary for the clotting of blood, and those that transport steroid and thyroid hormones, and phospholipids and cholesterol in the blood (see Figure 9-4).
- *Storage* of glycogen, fats, iron, copper, and many vitamins.
- *Activation of vitamin D*, which the liver accomplishes in conjunction with the kidneys.
- *Removal of bacteria and worn-out red blood cells*, thanks to its resident macrophages known as **Kupffer cells**.
- *Secretion of the hormones thrombopoietin* (stimulates platelet production; p. 393), *hepcidin* (inhibits iron uptake from the intestine), *insulin-like growth factor-I* (stimulates growth; p. 292), and *angiotensinogen* (important in salt regulation; p. 587).
- *Excretion of cholesterol, biliverdin, and bilirubin* (p. 688), the latter two being breakdown products derived from the destruction of worn-out red blood cells.
- *Synthesis of ascorbic acid* (vitamin C) in some species of mammals (excluding primates and guinea pigs) and birds.
- *Buoyancy* in sharks because of high amounts of low-density lipids.

Given this wide range of complex functions, there is amazingly little specialization of cells within the liver. Each liver cell, or **hepatocyte** (*hepato*, “liver”) performs the same wide variety of metabolic and secretory tasks. The specialization comes from the highly developed organelles within each hepatocyte. The only liver function not accomplished by the hepatocytes is the phagocytic activity carried out by Kupffer cells.

In some species the liver performs additional functions during particular stages of development. For example, the size of the liver is increased in some animals engaged in reproduction. Synthesis of egg constituents (lipogenesis for yolk and some albumin synthesis) is carried out in the avian liver. As a consequence, fatty livers are a common problem in laying hens. Fat content of the liver can increase from 5 to 50% and can markedly increase mortality rate. **Fatty liver syndrome** arises when carbohydrate intake exceeds the liver’s ability to synthesize lipoproteins for secretion into the plasma. However, there is not a corresponding increase in fat content of mammalian livers, because both the fetus and the mammary gland contribute to the metabolic demands associated with carbohydrate intake.

Liver Blood Flow To carry out these wide-ranging tasks, the anatomic organization of the liver permits each hepatocyte to be in direct contact with blood from two sources: venous blood coming directly from the digestive tract and arterial blood coming from the aorta. Venous blood enters the liver by means of a unique and complex vascular connection between the digestive tract and the liver, known as the **hepatic portal system** (Figure 14-17). The veins draining the digestive tract do not directly join the inferior vena cava, the large vein that returns blood to the heart. Instead, the veins from the stomach and intestine enter the hepatic portal vein, which carries the products absorbed from the digestive tract directly to the liver for processing, storage, or detoxification before they gain access to the general circulation. Within the liver, the portal vein once again breaks up into a capillary network called **sinusoids** to permit exchange between the blood and hepatocytes before draining into the hepatic vein, which joins the inferior vena cava. The hepatocytes also are provided with fresh arterial blood, which supplies their oxygen and delivers bloodborne metabolites and toxins for hepatic processing.

The liver lobules are delineated by vascular and bile channels

The liver is organized into functional units known as **lobules**, which are hexagonal arrangements of tissue surrounding a central vein (Figure 14-18a). At the outer edge of each “slice” of the lobule are three vessels: a branch of the hepatic artery, a branch of the portal vein, and a bile duct. Blood from the branches of both the hepatic artery and the portal vein flows from the periphery of the lobule into large, expanded sinusoids, which run between rows of liver cells to the central vein like spokes on a bicycle wheel (Figure 14-18b). The Kupffer cells line the sinusoids and engulf and destroy old red blood cells and bacteria that pass through in the blood. The hepatocytes are arranged between the sinusoids in plates two cell layers thick, so that each lateral edge faces a sinusoidal pool of blood. The central veins of all the liver lobules converge to form the hepatic vein, which carries the blood away from the liver. A thin, bile-carrying channel, a **bile canaliculus**, runs between the cells within each hepatic plate. Hepatocytes continuously secrete bile into these thin channels, which carry the bile to a bile duct at the periphery of the lobule. The bile ducts from the various lobules converge to eventually form the hepatic duct, which transports the bile from the liver to the duodenum. Each hepatocyte is in contact with a sinusoid on one side and a canaliculus on the other side.

The liver receives blood from two sources:

1a Arterial blood, which provides the liver's O_2 supply and carries bloodborne metabolites for hepatic processing, is delivered by the **hepatic artery**.

1b Venous blood draining the digestive tract is carried by the **hepatic portal vein** to the liver for processing and storage of newly absorbed nutrients.

2 Blood leaves the liver via the **hepatic vein**.

FIGURE 14-17 Schematic representation of liver blood flow (human).

Bile is continuously secreted by the vertebrate liver and is diverted to the gallbladder between meals

The opening of the bile duct into the duodenum is guarded by the **sphincter of Oddi**, which prevents bile from entering the duodenum except during digestion of meals (Figure 14-19). When this sphincter is closed, most of the bile secreted by the

liver is diverted back up into the **gallbladder**, a small, saclike structure tucked beneath the liver. Those vertebrates with a gallbladder can concentrate the bile salts approximately 10- to 20-fold by selectively removing electrolytes and water. Bile is subsequently stored and concentrated in the gallbladder between meals. After a meal, bile enters the duodenum as a result of the combined effects of gallbladder emptying and increased bile secretion by the liver. The amount of bile secreted per day in humans ranges from 250 mL to 1 liter, depending on the degree of stimulation. In birds, two bile ducts exit the liver, one from each lobe. The cystic duct is either connected to the gallbladder or directly to the small intestine, whereas the hepatic duct directly communicates with the small intestine. Animals without a gallbladder include the rat, horse, pigeon, deer, giraffe, elephant, and camel.

Bile salts are recycled through the enterohepatic circulation

Bile contains several organic constituents, namely *bile salts*, *cholesterol*, *lecithin*, and *bilirubin* or *biliverdin*, all derived from hepatocyte activity. These are released in an aqueous alkaline fluid (added by the duct cells) similar to the pancreatic $NaHCO_3$ secretion. Even though bile does not contain any digestive enzymes, it is important for the digestion and absorption of fats, as we will describe shortly.

Bile salts are derivatives of cholesterol. To reduce their toxicity, mammals conjugate bile acids with either *taurine* or *glycine*, whereas birds and fish form only the taurine conjugate. (Steroid bile salts have not been identified in any non-vertebrates.) Bile salts are actively secreted into the bile and eventually enter the duodenum along with the other biliary constituents. Following their participation in fat digestion and absorption, most bile salts are reabsorbed back into the blood by special active-transport mechanisms located in the mammalian terminal ileum, the last portion of the small intestine. (In birds, the majority of absorption takes place in the jejunum, the second intestinal segment.) From here the bile salts are returned via the hepatic portal system to the liver, which resecretates them into the bile. This recycling of bile salts (and some of the other biliary constituents) between the small intestine and liver is referred to as the **enterohepatic circulation** (Figure 14-19).

On average, bile salts cycle between the liver and small intestine twice during the digestion of a typical meal. Approximately 5% of the secreted bile salts ultimately escape into the feces daily. These lost bile salts are replaced by new bile salts synthesized by the liver; thus, the size of the pool of bile salts is kept constant.

Bile salts aid fat digestion and absorption through their detergent action and micellar formation, respectively

Bile salts aid fat digestion through their detergent action (*emulsification*) and facilitate fat absorption through their participation in the formation of *micelles*. Both functions are related to the structure of bile salts. Let's see how.

Emulsification by Bile Salts Emulsification refers to bile salts' ability to convert large fat globules into a **lipid emulsion** that consists of many small fat droplets suspended in

FIGURE 14-18 Anatomy of the mammalian liver.

© Cengage Learning, 2013

the aqueous chyme, thus increasing the surface area available for attack by pancreatic lipase. Fat globules, no matter their size, are made up primarily of undigested triglyceride molecules. For lipase to digest fat, it must come into direct contact with the triglyceride molecules. Because fat molecules are not soluble in water, they tend to aggregate into large droplets in the aqueous environment of the small-intestine lumen. If bile salts did not emulsify these large droplets, lipase could act on the lipids only at the surface of the large droplets, and triglyceride digestion would be greatly prolonged.

Bile salts act like the detergent you use to break up grease when you wash dishes. Bile salt molecules and detergents are **amphipathic**: Each contains a hydrophobic (lipid-soluble) portion (a steroid derived from cholesterol) plus a negatively charged, hydrophilic (water-soluble) portion (from taurine or glycine). Bile salts *adsorb* on the surface of a fat droplet; that is, the lipid-soluble portion of the bile salt interacts with the fat droplet, leaving the charged portion projecting from the surface of the droplet to dissolve in water (Figure 14-20a). Intestinal mixing movements break up large fat droplets into smaller ones. These small droplets would quickly recombine were it not for adsorbed bile salts creating a “shell” of water-soluble negative charges on the surface of each little droplet. Because like charges repel, these negatively charged groups on the droplet surfaces cause the fat droplets to repel each other (Figure 14-20b). This prevents the small droplets from recombining into large fat droplets, producing a lipid emulsion that increases the surface area available for lipase action. The small emulsified fat droplets range in diameter from 200 to 5,000 nm.

Although bile salts increase the surface area available for attack by pancreatic lipase, lipase alone cannot penetrate

the layer of bile salts adsorbed on the surface of the small emulsified fat droplets. To solve this dilemma, the pancreas secretes the polypeptide **colipase** along with lipase. Like bile salts, colipase is amphipathic; it displaces some bile salts and lodges at the surface of the fat droplets, where it binds to lipase, thus anchoring this enzyme to its site of action amid the bile-salt coating.

During digestion of a meal, when chyme reaches the small intestine, the presence of food, especially fat products, in the duodenal lumen triggers the release of CCK. This hormone stimulates contraction of the gallbladder and relaxation of the sphincter of Oddi, so bile is discharged into the duodenum, where it appropriately aids in the digestion and absorption of the fat that initiated the release of CCK. A similar process happens in the small intestine of fish with a gastrin/CCK-related peptide that stimulates gallbladder contraction.

Micellar Formation Bile salts—along with cholesterol and lecithin, which are also constituents of bile—play an important role in facilitating fat absorption through micellar formation. Like bile salts, **lecithin** (a phospholipid used in nonstick cooking sprays) is amphipathic, whereas cholesterol is almost totally insoluble in water. In a **micelle**, the bile salts and lecithin aggregate in small clusters with their fat-soluble portions huddled together in the middle to form a hydrophobic core, while their water-soluble portions form an outer hydrophilic shell (Figure 14-21). A micelle is 3 to 10 nm in diameter, compared to an average diameter of 1,000 nm for an emulsified lipid droplet. Micelles are water soluble by virtue of their hydrophilic shells, but they can dissolve water-insoluble (and hence lipid-soluble) substances in their lipid-soluble cores. Micelles thus provide a handy

FIGURE 14-19 Enterohepatic circulation of bile salts (human). The majority of bile salts are recycled between the liver and small intestine through the enterohepatic circulation, designated by the blue arrows. After participating in fat digestion and absorption, most bile salts are reabsorbed by active transport in the terminal ileum and returned through the hepatic portal vein to the liver, which resecreted them in the bile.

© Cengage Learning, 2013

vehicle for carrying water-insoluble substances through the watery luminal contents. The most important lipid-soluble substances thus carried are the products of fat digestion (monoglycerides and free fatty acids) as well as fat-soluble vitamins, which are all transported to their sites of absorption by means of the micelles. If they did not hitch a ride in the water-soluble micelles, these nutrients would float on the surface of the aqueous chyme (just as oil floats on top of water), never reaching the absorptive surfaces of the small intestine.

Biliverdin and bilirubin are waste products of hemoglobin excreted in the bile

Biliverdin (in most vertebrates) and *bilirubin* (in mammals), the other major constituents of bile, do not play a role in digestion at all but instead are two of the few waste products excreted in the bile. Worn-out red blood cells are removed from the blood by macrophages in the spleen (p. 392) and

other areas in the body. Kupffer cells degrade these worn-out red blood cells to yield heme (iron-containing portion of the hemoglobin). Heme, which is toxic, is converted to **biliverdin** (green in color), releasing *carbon monoxide* (CO) in the process. (CO, although toxic at high levels, may have a physiological role at low concentrations as a paracrine vasodilator to boost local blood flow.) Amphibians and reptiles (including birds) excrete biliverdin as the major means of pigment elimination, with the result that the color of their bile is dark green. The excretion rate of bile pigment is greater in birds than mammals because of the much shorter life of avian red blood cells (see p. 392).

In mammals, biliverdin is transformed by a uniquely mammalian enzyme into bilirubin (yellow in color) and then released into the lobule sinusoid. Bilirubin synthesis may have evolved because the molecule is a potent antioxidant, reverting to biliverdin as it scavenges free radicals (perhaps replacing uric acid, p. 565). Excess bilirubin is toxic, however, and much is extracted from the blood by the hepatocytes and actively excreted into the bile. A small amount of bilirubin is normally reabsorbed by the small intestine back into the blood, and when it is eventually excreted in the urine, it is largely responsible for the urine's yellow color. If bilirubin is formed more rapidly than it can be excreted, it accumulates in the body and causes **jaundice**, Mammals with this condition appear yellowish, with this color being most apparent in the whites of their eyes. Human babies with jaundice are exposed to fluorescent light, which helps break down bilirubin in the skin.

The fat body of insects plays a major role in intermediary metabolism and is the central storage depot of nutrients and energy reserves

The insect **fat body** houses the analogues of the vertebrate liver, hematopoietic and immune systems, and adipose tissue in a single functional unit. The fat body is analogous to the vertebrate liver because it plays a role in intermediary metabolism, is regulated by hormones, and serves as a storage place for food reserves. Because lipids can be accumulated in such massive quantities in the fat body, it appears as a diffuse organ of fat located throughout the **hemocoel** (body cavity filled with blood) and abdomen of insects. Structurally, the fat body is arranged in thin lobes that are bathed by the hemolymph. The vast majority of the cells in the fat body that perform metabolic functions are termed **adipocytes**, which (like vertebrate adipose cells) are characterized by the presence of numerous lipid droplets. Another fat body cell type includes **urate cells**, which are involved in storing uric acid crystals in species lacking Malpighian tubules (see p. 566). The fat body is structurally organized to maximize exchange with the hemolymph, which is the

(a) Structure of bile salts and their adsorption on the surface of a small lipid droplet

FIGURE 14-20 Schematic structure and function of bile salts. (a) A bile salt consists of a lipid-soluble part that dissolves in the fat droplet and a negatively charged, water-soluble part that projects from the surface of the droplet. (b) When a large fat droplet is broken up into smaller fat droplets by intestinal contractions, bile salts adsorb on the surface of the small droplets, creating shells of negatively charged, water-soluble bile salt components that cause the fat droplets to repel one another. This emulsifying action holds the fat droplets apart and prevents them from recoalescing, increasing the surface area of exposed fat available for digestion by pancreatic lipase.

FIGURE 14-21 A micelle. Bile constituents (bile salts, lecithin, and cholesterol) aggregate to form micelles that consist of a hydrophilic (water-soluble) shell and a hydrophobic (lipid-soluble) core. Because the outer shell of a micelle is water soluble, the products of fat digestion, which are not water soluble, can be carried through the watery luminal contents to the absorptive surface of the small intestine by dissolving in the micelle's lipid-soluble core. This figure is not drawn to scale compared to the lipid emulsion droplets in Figure 14-20b. An emulsified fat droplet ranges in diameter from 200 to 5,000 nm (average 1,000 nm) compared to a micelle, which is 3 to 10 nm in diameter.

carrier for products taken up or released by the fat body. For example, during feeding cycles, the fat body synthesizes lipids, carbohydrates, and proteins, whereas during strenuous activity, it mobilizes the release of lipids and carbohydrates (see Figure 9-4, p. 390).

Locomotion and contraction of the flight muscles in insects depends on the oxidation of substrates, mainly carbohydrates and lipids, although in tsetse flies and certain beetles, the amino acid proline can be metabolized. During a short flight, proline is utilized as an energy source, whereas during a long, flight triglycerides are mobilized. These substrates are mobilized from their storage sites and provided to the flight muscles by the action of small peptide hormones synthesized in the insect's *corpora cardiaca* (CC; p. 280). These hormones are generically known as **adipokinetic** (AKH; “lipid-mobilizing”), **hypertrehalosemic** (HrTHs) (“increasing the hemolymph sugar trehalose”), or **hyperprolinemic** hormones. Their contribution to hemolymph sugar homeostasis is comparable to that of the vertebrate hormone *glucagon* (p. 320). After release of these neuropeptides from the CC into the hemolymph during flight, they bind to G-protein coupled receptors, which are only known from a very limited number of insects to date, and activate either a triacylglycerol (TAG) lipase or a glycogen phosphorylase in the fat body. In addition, AKH activates phospholipase C to induce the release of Ca^{2+} from intracellular Ca^{2+} stores. Interestingly, the insect AKH receptors are structurally and evolutionarily related to the GnRH receptors of mammals.

Nutrient sensing also appears to be in the domain of the fat body. Studies of the laboratory fruit fly *Drosophila melanogaster* and, more recently, mosquitoes have shown that the fat body can express specific amino acid transporters, which can function as nutrient sensors. The amount of nutrient reserves stored in the fat body ultimately modulates several important events in the insect's life such as the rate of growth, the timing of metamorphosis, and egg development. The fat body coordinates insect growth with metamorphosis or reproduction by storing or releasing components essential to these events. For example, the synthesis of the egg protein **vitellogenin** (see p. 765) in the fat body of *Aedes aegypti* female mosquitoes is transcriptionally up-regulated after a blood meal. A cascade of reactions is then initiated that begin at the fat body plasma membrane, where specific amino acids present in the hemolymph are “sensed” by amino acid transporters. This signal activates an evolutionarily conserved nutritional signaling cascade that results in the translation of a transcriptional activator of vitellogenin gene expression. In response, the synthesis of vitellogenin is stimulated, which reaches a peak ~30 hours after ingestion of the blood meal.

unanswered Questions | A solar-powered hornet?

Biological dogma states that plants obtain metabolic energy from the sun, while animals do so from organic molecules (food). In 2008, that dichotomy was partly demolished by the discovery of a seaslug that has obtained photosynthesis genes from algae (p. 34). More recently, a hornet that may also utilize solar energy for specific metabolic functions has been described. The oriental hornet *Vespa orientalis* has a cuticle with a bright yellow abdomi-

nal stripe. Jacob Ishay, Marian Plotkin, and colleagues found that shining light on the abdomen generates several hundred millivolts of potential across the cuticle. Analysis of cuticle microstructure revealed that the cuticles reflect very little light, but instead capture and channel light waves into a yellow pigment, *xanthopterin*, which generates electric currents when activated by light energy. What does the wasp use this electricity for? We do not know, but intriguingly, the researchers found that the yellow stripe has enzymes normally found in the fat body, and that shining light on the stripes alters the activities of those enzymes. Thus, these hornets may have a solar-powered metabolic tissue! <<

check your understanding 14.6

What are the contributions of the accessory digestive organs in vertebrates and insects? What are the nondigestive functions of the liver?

What is the principal function of bile salts?

14.7 Small Intestine

The **small intestine** is a tube that lies coiled within the abdominal cavity, extending between the stomach and the large intestine. It is somewhat arbitrarily divided into three segments in most terrestrial vertebrates: the **duodenum**, the **jejunum**, and the **ileum**. In birds, **Meckel's diverticulum**, a vestige of the yolk sac, lies approximately midway along the small intestine. The small intestine is the site at which most digestion and absorption of nutrients takes place in vertebrates (recall that in arthropods, the midgut and hindgut are the sites of most digestion and absorption). An alternative strategy relies on the pregastric absorption of some nutrients through the lining of the ruminoreticulum (see discussion of ruminants, p. 705). In addition, some animal groups can ferment cellulose postgastrically and absorb nutrients through the lining of the colon and/or the cecum (see p. 704).

The digestive tract wall has four layers: mucosa, submucosa, muscularis externa, and serosa

The digestive tract wall has the same general structure throughout most of its length from the esophagus to the anus, with some local variations characteristic for each region. A cross section of the small intestine (Figure 14-22) reveals four major tissue layers. From the innermost layer of the tract outward, they are the *mucosa*, the *submucosa*, the *muscularis externa*, and the *serosa*:

1. The **mucosa** lines the luminal surface of the digestive tract. It is divided into three layers:
 - a. A **mucous membrane**, an inner epithelial layer that serves as a protective surface as well as being modified in particular areas for secretion and absorption. It contains *exocrine cells* for secreting digestive juices, *endocrine cells* for secreting gastrointestinal hormones, and *epithelial cells* specialized for absorbing digested nutrients.

FIGURE 14-22 Tissue structure of the mammalian digestive tract. (a) Generalized layers of the digestive tract wall, consisting of four major layers: from innermost out, the mucosa, submucosa, muscularis externa, and serosa. (b–d) The mammalian small intestine: (b) One of the circular folds of the small-intestine mucosa, which collectively increase the absorptive surface area threefold. (c) Microscopic fingerlike projection known as a *villus*. Collectively, the villi increase the surface area another 10-fold. (d) A villus epithelial cell, depicting the presence of microvilli on its luminal border to form a *brush border*; the microvilli increase the surface area another 20-fold. Altogether, these surface modifications increase the small intestine's absorptive surface area 600-fold.

© Cengage Learning, 2013

- b. The **lamina propria**, a thin middle layer of connective tissue on which the epithelium rests. Small blood vessels, lymph vessels, and nerve fibers pass through the lamina propria, and it houses the *gut-associated lymphoid tissue (GALT)*, which is important in the defense against intestinal bacteria (p. 467).
- c. The **muscularis mucosa**, a sparse outer layer of smooth muscle that lies adjacent to the submucosa.
2. The **submucosa** is a thick layer of connective tissue that provides the digestive tract with its distensibility and elasticity. It contains the larger blood and lymph vessels, both of which send branches inward to the mucosal layer and outward to the surrounding thick muscle layer. Also, a nerve network known as the *submucosal plexus* lies within the submucosa.
3. Surrounding the submucosa is the **muscularis externa**, the major smooth-muscle coat of the digestive tube. In most parts of the tract, it consists of two layers: an inner circular layer and an outer longitudinal layer. Contraction of the inner circular fibers, which run around the circumference of the tube, constricts the lumen at the point of contraction. Contraction of the fibers in the outer layer, which run longitudinally along the length of the tube, shortens the tube. Together, contractile activity of these smooth-muscle layers produces the propulsive and mixing movements. Lying between the two muscle layers is another nerve network, the *myenteric plexus*, which, along with the submucosal plexus, helps regulate local gut activity.
4. The **serosa** is the outer connective tissue covering of the digestive tract, which secretes a serous fluid that lubricates and prevents friction between the digestive organs and surrounding viscera. Throughout much of the tract, the serosa is continuous with the **mesentery**, which suspends the digestive organs from the inner wall of the abdominal cavity like a sling (Figure 14-22a). This attachment provides relative fixation, supporting the digestive organs in proper position, while still allowing them freedom for mixing and propulsive movements.

The mucous lining of the small intestine is remarkably well adapted to its special absorptive function, for two reasons: (1) It has a very *large surface area*, and (2) the epithelial cells in this lining have a variety of *specialized transport mechanisms*.

Adaptations that Increase the Small Intestine's Surface Area

The following three modifications of the small-intestine mucosa greatly increase the surface area available for absorption (Figure 14-22b, c, d):

1. **Folds:** The inner surface of the small intestine is arranged in circular folds that are visible to the naked eye and that increase the surface area threefold.
2. **Villi:** Projecting from this folded surface are microscopic, fingerlike projections known as **villi**, which give the lining a velvety appearance and increase the surface area by another 10 times (Figure 14-22b, c). Epithelial cells cover the surface of each villus. Villi are dynamic and readily change dimensions in response to numerous dietary factors. For example, the mass of a python's small intestine increases two- to threefold overnight after swallowing its prey, associated with a 60-fold increase in enzyme content. Each epithelial cell lining the small intestine increases in size and develops longer projections, adaptations that enable the ingesta to be digested more quickly. Interestingly, the energetic cost to the python for adapting its small intestine to the arrival of food is approximately a third to a half of the energy derived from its prey.
3. **Microvilli:** Even smaller, hairlike projections known as **microvilli** arise from the luminal surface of these epithelial cells (Figure 14-22d), increasing the surface area another 20-fold in a formation called the **brush border**. Each epithelial cell has as many as 3,000 to 6,000 of these microvilli, which are visible only with an electron microscope. Generally, villi are longest in the jejunum and progressively decrease in length through the ileum. It is within the membrane of this brush border that the enzymes of the small intestine perform their functions. Arising from the surface of the microvilli is the **glycocalyx**, a meshwork of carbohydrate-rich filaments. These filaments are components of the digestive enzymes that project into the lumen of the small intestine.

Altogether the folds, villi, and microvilli provide the small intestine with a luminal surface area about 600 times greater than it would have if it were a tube of the same length and diameter lined by a flat surface. In fact, if the surface area of the human small intestine were spread out flat, it would cover an entire tennis court.

Structure of a Villus Absorption across the digestive tract wall involves transepithelial transport similar to movement of material across the kidney tubules (see p. 583). Each villus has the following major components (Figure 14-22c):

- **Epithelial cells that cover the surface of the villus.** The epithelial cells are joined at their lateral borders by tight junctions, which limit passage of luminal contents between the cells, although the tight junctions in the small intestine are “leakier” than those in the stomach. These epithelial cells have, within their luminal brush borders, carriers for absorption of specific nutrients and electrolytes from the lumen as well as the brush-border digestive enzymes that complete carbohydrate and protein digestion.
- **A capillary network.** Each villus is supplied by an arteriole that breaks up into a capillary network within the villus. The capillaries rejoin to form a venule that drains away from the villus.

FIGURE 14-23 Segmentation. Segmentation consists of ringlike contractions along the length of the vertebrate small intestine. Within a matter of seconds, the contracted segments relax and the previously relaxed areas contract. These oscillating contractions thoroughly mix the chyme within the small-intestine lumen.

© Cengage Learning, 2013

- **A terminal lymphatic vessel.** Each villus is supplied by a single, blind-ended lymphatic vessel known as the **central lacteal**, which occupies the center of the villus core.

During the process of absorption, digested substances enter the capillary network or the central lacteal. To be absorbed, a substance must pass completely through the epithelial cell, diffuse through the interstitial fluid within the connective tissue core of the villus, and then cross the wall of a capillary or lymph vessel. Like renal transport (see Chapter 12), intestinal absorption may be an active or passive process, with active absorption involving energy expenditure during at least one of the steps in the transepithelial transport process.

Segmentation contractions mix and slowly propel the chyme

Segmentation, the small intestine's primary method of motility, both mixes and slowly propels the chyme. Segmentation consists of oscillating, ringlike contractions of the circular smooth muscle along the length of the small intestine; between the contracted segments are relaxed areas containing a small bolus of chyme. The contractile rings occur every few centimeters apart, dividing the small intestine into segments like a chain of sausages. These contractile rings do not sweep along the length of the intestine as peristaltic waves do. Rather, after a brief period of time the contracted segments relax, and ringlike contractions appear in the previously relaxed areas (Figure 14-23). The new contraction forces the chyme in a previously relaxed segment to move in both directions into the now relaxed adjacent segments. A newly relaxed segment therefore receives chyme from both the contracting segment immediately ahead of it and the one immediately behind it. Shortly thereafter, the areas of contraction and relaxation alternate again. In this way, the chyme is chopped, churned, and thoroughly mixed. These contractions can be compared to squeezing a pastry tube

with your hands to mix the contents. This mixing serves the dual functions of mixing the chyme with the digestive juices secreted into the small-intestine lumen and exposing all the chyme to the absorptive surfaces of the small intestine mucosa.

Initiation and Control of Segmentation

Segmentation contractions are initiated by the small intestine's pacesetter cells, which produce a basic electrical rhythm (BER; p. 660) similar to the gastric BER responsible for peristalsis in the stomach. If the small-intestine BER brings the circular smooth-muscle layer to threshold, segmentation contractions are induced, with a frequency following the frequency of the BER.

The circular smooth muscle's degree of responsiveness and thus the intensity of segmentation contractions can be influenced by distension of the intestine, by the hormone gastrin, and by extrinsic nerve activity. All these factors influence the excitability of the small-intestine smooth-muscle cells by moving the "resting" potential around which the BER oscillates closer to or farther from threshold. Segmentation is slight or absent between meals but becomes very vigorous immediately after feeding. Both the duodenum and ileum start to segment simultaneously when the digesta first enters the small intestine. The duodenum starts to segment primarily in response to local distension caused by the presence of chyme. Segmentation of the empty ileum, in contrast, appears to be brought about by gastrin, which is secreted in response to the presence of chyme in the stomach, a mechanism known as the **gastroileal reflex**. Extrinsic nerves can modify the strength of these contractions. Parasympathetic stimulation enhances segmentation, whereas sympathetic stimulation depresses segmental activity.

Segmentation not only accomplishes mixing but also is the primary factor responsible for slowly moving chyme through the small intestine. How can this be, when each segmental contraction propels chyme both forward and backward? The chyme slowly progresses forward because the frequency of segmentation declines along the length of the small intestine. The pacesetter cells in the duodenum spontaneously depolarize at a faster rate than those farther down the tract, with the pacesetter cells in the terminal ileum exhibiting the slowest rate of spontaneous depolarization. For example, the rate of segmentation in the human duodenum is 12/min, compared to a rate of only 9/min in the terminal ileum. As a result, more chyme on average is pushed forward than is pushed backward, so chyme is moved very slowly down the small intestine while being shuffled back and forth to accomplish thorough mixing and absorption. This slow movement is advantageous because it allows ample time for the digestive and absorptive processes to take place. The contents usually take three to five hours to move through the human small intestine.

FIGURE 14-24 Control of the ileocecal valve/sphincter (shown for a human). The juncture between the ileum and large intestine consists of the ileocecal valve, which is surrounded by thickened smooth muscle, the ileocecal sphincter. Pressure on the cecal side pushes the valve closed and contracts the sphincter, preventing the bacteria-laden colonic contents from contaminating the nutrient-rich small intestine. The valve/sphincter opens and allows ileal contents to enter the large intestine in response to pressure on the ileal side of the valve and to the hormone gastrin secreted as a new meal enters the stomach.

The migrating motility complex sweeps the intestine clean between meals

When most of the meal has been absorbed, segmentation contractions cease and are replaced by the **migrating motility complex**, or "intestinal housekeeper." This between-meal motility consists of weak, repetitive peristaltic waves that move a short distance down the intestine before dying out. These short waves start at the stomach and take about 100 to 140 minutes in humans to gradually migrate from the stomach to the end of the small intestine, with each contraction "sweeping" any remnants of the preceding meal plus mucosal debris and bacteria forward toward the colon, just like a good housekeeper. After the end of the small intestine is reached, the cycle begins again and continues to repeat itself until the next meal. The hormone *motilin* (p. 712), released by intestinal *crypt* cells, plays a role in stimulating this migrating motility complex. When the next meal arrives, segmental activity is triggered again, and the migrating motility complex ceases.

The ileocecal juncture prevents contamination of the small intestine by colonic bacteria

At the juncture between the small and large intestines, the last portion of the ileum empties into the *cecum* (Figure 14-24). Two factors contribute to this region's ability to act as a barrier between the small and large intestines. First, the anatomic arrangement is such that valvelike folds of tissue protrude from the ileum into the lumen of the cecum. When the ileal contents are pushed forward, this **ileocecal valve** is

easily pushed open, but the folds of tissue are forcibly closed when the cecal contents attempt to move backward. Second, the smooth muscle within the last several centimeters of the ileal wall is thickened, forming a sphincter that is under neural and hormonal control. Most of the time this **ileocecal sphincter** remains at least mildly constricted. Pressure on the cecal side of the sphincter causes it to contract more forcibly; distension of the ileal side causes the sphincter to relax, a reaction that is mediated by the intrinsic plexuses in the area. Relaxation of the sphincter is enhanced through the release of gastrin at the onset of a meal, when increased gastric activity is taking place. This relaxation allows the undigested fibers and unabsorbed solutes from the preceding meal to be moved forward as the new meal enters the tract.

The digestive tract of numerous carnivorous mammals, including some species of bats and marsupials, lack a constriction or valve between the small and large intestine. In fact, there is very little distinction between the small and the large intestinal tracts, and generally these animals also lack a cecum. For example, the short terminal segment of the large intestine of a mink is slightly larger than the small intestine and lacks a sphincter or valve at the junction between the two segments. In the horse, there is a sphincter at both the *ileocecal* and the *cecocolic* junction that ensures that the intestinal contents enter the cecum before passage through the colon. The ceca are paired in birds, although they are not present in all avian species.

Small-intestine secretions do not contain any digestive enzymes

Each day the exocrine glands located in the small-intestine mucosa secrete into the lumen large volumes of an aqueous salt and mucus solution known as the **succus entericus** (*succus*, “juice”; *entericus*, “of the intestine”; about 1.5 liters in humans). However, no digestive enzymes are secreted into this intestinal juice. The small intestine synthesizes digestive enzymes, but they function within the borders of the epithelial cells that line the lumen instead of being secreted directly into the lumen. As in other parts of the tract, mucus in the secretion provides protection and lubrication. Furthermore, this aqueous secretion provides an abundance of H₂O to participate in the enzymatic digestion of food, which proceeds most efficiently when all the reactants are in solution.

The regulation of small-intestine secretion is not clearly understood. As well, the factors that specifically alert the intestine of the upcoming meal are not completely known. However, the secretion of succus entericus does increase after a meal. The most effective stimulus for secretion appears to be local stimulation of the mucosa by the presence of chyme.

Small-intestine enzymes complete the process of digestion at the brush border membrane

Digestion within the small-intestine lumen is accomplished by the pancreatic enzymes, with fat digestion being enhanced by bile secretion. As a result of those enzymes' actions, fats are completely reduced to their absorbable units of monoglycerides and free fatty acids, proteins are broken down into small peptide fragments and some amino acids, and carbohydrates are reduced to disaccharides and some monosaccharides. Thus, fat digestion is completed within

the small-intestine lumen, but carbohydrate and protein digestion have not been brought to completion.

Recall that the luminal surface of the mammalian small-intestine epithelial cells has a *brush border* (see p. 692). This contains different categories of enzymes:

1. **Enterokinase**, which activates the pancreatic enzyme trypsinogen.
2. The **disaccharidases** (**maltase**, **sucrase**, **lactase**, and **trehalase**), which complete carbohydrate digestion by hydrolyzing the remaining disaccharides (*maltose*, *sucrose*, *lactose*, and *trehalose*) into their constituent monosaccharides.
3. The **aminopeptidases**, which hydrolyze the small peptide fragments into their amino acid components, thereby completing protein digestion. Thus, carbohydrate and protein digestion are completed at the brush border. (Table 14-5 summarizes the digestive processes for the three major categories of nutrients.)

Not all vertebrate groups express each of these enzymes in their brush border. For example, birds have no need of lactase but do have an intestinal amylase. Many passerine songbirds lack sucrase, whereas hummingbirds, with a sucrose-rich nectar diet, express sufficient sucrase activity in their intestines. Because the microbes in the reticulorumen of a ruminant scavenge most of the carbohydrates, the concentrations of disaccharidases in the small intestine are low, with sucrase not synthesized at all. Vertebrates whose diet normally contains chitin have evolved a chitinase enzyme. Bats, rodents, turtles, and insectivorous lizards synthesize substantial quantities of chitinase in their gastric mucosa. Similarly, many species of fish and birds produce chitinase in their pancreas, whereas other species rely on intestinal bacteria to synthesize this enzyme. Gut microflora of some species may contain chitinase as well as cellulase.

The small intestine is highly adaptable for its primary role in absorption

Normally, all products of carbohydrate, protein, and fat digestion, as well as most of the ingested electrolytes, vitamins, and water, are absorbed by the small intestine indiscriminately. Usually only the absorption of calcium and iron is adjusted to an individual animal's needs in the short run. Thus, the more food that is consumed, the more that is digested and absorbed. However, this does not mean food absorption capacity is static. In many vertebrates, the length of the intestine and the density of its transporters can be altered. You have already seen how a python's small intestine can change radically and quickly in mass. In other animals, changes can occur during long-term dietary changes. For example, in omnivores the glucose transporter is up-regulated on a prolonged high-carbohydrate diet (a form of acclimatization; p. 16).

The lengths of the small intestine and the types and densities of its transporters are remarkably matched to typical diets of species. For instance, herbivores typically have a higher density of intestinal glucose transporters than do carnivores. Cats require taurine and arginine in their diet because they cannot synthesize them and can suffer from even short-term deficits in these amino acids. Taurine is essential for neural development, osmotic balance of neural and renal tissues, and other functions that are poorly understood. Arginine is used in the production of urea (see Figure 12-2), which carnivores produce in high amounts because of

TABLE 14-5 Digestive Processes for the Three Major Categories of Nutrients (Mammals)

Nutrients	Enzymes for Digesting Nutrient	Source of Enzymes	Site of Action of Enzymes	Action of Enzymes	Absorbable Units of Nutrients
Mammals					
<i>Carbohydrate</i>	Amylase	Salivary glands	Mouth and body of stomach Small-intestine lumen	Hydrolyzes polysaccharides to disaccharides	Monosaccharides, especially glucose

their high protein intake. To ensure adequate intake, cats have exceptionally high levels of intestinal taurine and arginine transporters.

Most absorption occurs in the duodenum and jejunum; very little occurs in the ileum, not because the ileum does not have absorptive capacity but because most absorption has already been accomplished before the intestinal contents reach the ileum. The small intestine has an abundant reserve absorptive capacity. In fact, about 50% of the small intestine can be removed with little interference to absorption—with at least two exceptions. If the terminal portion of the ileum is removed, vitamin B₁₂ and bile salts are not properly absorbed, because the specialized transport mechanisms for these two substances are located only in this region. All other substances can be absorbed throughout the length of the small intestine.

The mucosal lining experiences rapid turnover

Dipping down into the mucosal surface between the villi are shallow invaginations known as the **crypts of Lieberkühn** (Figure 14-22c). Unlike the gastric pits, these intestinal crypts do not secrete digestive enzymes, but they do secrete water and electrolytes, which, along with the mucus secreted

by the cells on the villus surface, constitute the succus entericus. They also secrete the hormone motilin (p. 712).

Furthermore, the crypts function as stem cell “nurseries.” The epithelial cells lining the small intestine slough off and are replaced at a rapid rate as a result of high mitotic activity in the crypts. New cells that are continually being produced at the bottom of the crypts migrate up the villi and, in the process, push off the older cells at the tips of the villi into the lumen. In this manner, more than 100 million intestinal cells are shed per minute. In humans, the entire trip from crypt to tip averages about three days, so the epithelial lining of the small intestine is replaced approximately every three days. Because of this rapid growth, John Gurdon in 1962 used nuclei from adult frog intestines in the first successful animal cloning experiment, in which adult nuclei were transplanted into an egg that had its own nucleus destroyed.

The new cells undergo several changes as they migrate up the villus. The concentration of brush border enzymes increases and the capacity for absorption improves, so the cells at the tip of the villus have the greatest digestive and absorptive capability. Just at their peak, these cells are pushed off by the newly migrating cells. Thus, the luminal contents are constantly exposed to cells that are optimally equipped to complete the digestive and absorptive functions.

Furthermore, just as in the stomach, the rapid turnover of cells in the small intestine is essential because of the harsh luminal conditions. Dogs infected with canine *parvovirus* exhibit a high mortality because the virus attacks and destroys the rapidly dividing cells found in the crypts. Bacteria residing in the intestine can then cross into the blood stream, causing **sepsis**, a systemic inflammatory state.

In addition to the stem cells, **Paneth cells** are found in the crypts. They serve a defensive function, safeguarding the stem cells. They produce two chemicals that thwart bacteria: (1) *lysozyme*, the bacterial-lysing enzyme also found in saliva, and (2) *defensins*, small antimicrobial proteins (p. 467).

Let's now turn our attention to the mechanisms through which the specific dietary constituents are normally absorbed.

Energy-dependent Na^+ absorption drives passive H_2O absorption

Sodium may be absorbed both passively and actively. When the electrochemical gradient favors movement of Na^+ from the lumen to the blood, passive diffusion of Na^+ can occur *between* the intestinal epithelial cells through the “leaky” tight junctions into the interstitial fluid within the villus. Movement of Na^+ *through* the cells is energy dependent and involves at least two different carriers, similar to the process of Na^+ reabsorption across the kidney tubules (see p. 562). Sodium enters the epithelial cells across the luminal border either by itself passively through Na^+ channels or in the company of another ion or a nutrient molecule by secondary active transport via three different carriers: Na^+/Cl^- symporter, Na^+/H^+ antiporter, or Na^+ -glucose (or amino acid) symporter. Sodium is actively pumped out of the cell by the Na^+/K^+ pump at the basolateral membrane into the interstitial fluid in the lateral spaces between the cells where they are not joined by tight junctions.

As with the renal tubules in the early portion of the nephron, the absorption of Cl^- , H_2O , glucose, and amino acids from the small intestine is linked to this energy-dependent Na^+ absorption. Chloride passively follows down the electrical gradient (through *CFTR* channels; p. 561) created by Na^+ absorption, resulting in a concentrated area of high osmotic pressure in a localized region between the cells, similar to the situation in the kidneys (see Figure 12-3, p. 562). As a result, H_2O is drawn osmotically from the lumen into the lateral space where it is picked up by the capillary network. Meanwhile, more Na^+ is pumped into the lateral space to encourage more H_2O absorption.

Carbohydrate and protein are both absorbed by secondary active transport and enter the blood

Absorption of the digestion end products of both carbohydrates and proteins involves special carrier-mediated transport systems that require energy expenditure and Na^+ cotransport, and both categories of end products are absorbed into the blood.

Carbohydrate Absorption Dietary carbohydrate is presented to the small intestine for absorption mainly in the forms of the disaccharides maltose (the product of polysaccharide digestion), sucrose, and lactose (Figure 14-25a). The disaccharidases located in the brush borders of the small-intestine cells

further reduce these disaccharides into the absorbable monosaccharide units of glucose, galactose, and fructose.

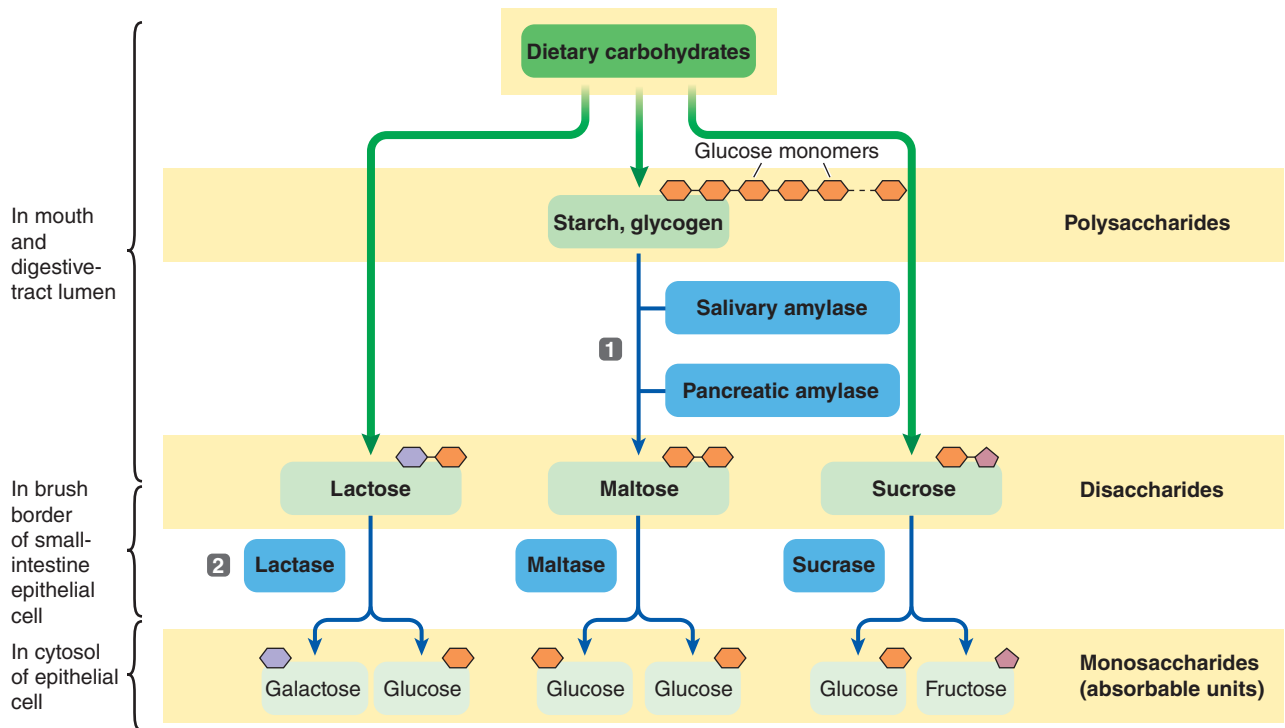

Glucose and galactose are both absorbed by secondary active transport, in which symport carriers, such as the *sodium-glucose cotransporter* (*SGLT*; see Figure 14-25b) on the luminal membrane transport both the monosaccharide and Na^+ from the lumen into the interior of the intestinal cell. Recall that the operation of these carriers, which do not directly use energy themselves, depends on the Na^+ concentration gradient established by the energy-consuming basolateral Na^+/K^+ pump (see p. 84). Glucose (or galactose), having been concentrated in the cell by these symporters, leaves the cell down its concentration gradient by facilitated diffusion (passive carrier-mediated transport; see p. 318) via the *glucose transporter* *GLUT-2* in the basal border to enter the blood within the villus. In addition to glucose being absorbed through the cells by means of the symporter, recent evidence suggests that a significant amount of glucose crosses the epithelial barrier through the leaky tight junctions between the epithelial cells. *Fructose* is absorbed into the blood solely by facilitated diffusion. It enters the epithelial cells from the lumen via *GLUT-5* and exits these cells to enter the blood via *GLUT-2* (Figure 14-25b).

Protein Absorption The protein presented to the small intestine for absorption is primarily in the form of amino acids and a few small peptide fragments (Figure 14-26a). Amino acids are absorbed across the intestinal cells by symporters, similar to glucose and galactose absorption (Figure 14-26b). The amino acid symporters are selective for different amino acids. Small peptides gain entry by means of yet another Na^+ -dependent carrier in a process known as **tertiary active transport** (*tertiary*, “third”). In this case, the symporter simultaneously transports both H^+ and the peptide from the lumen into the cell, driven by H^+ moving down its concentration gradient and the peptide moving against its concentration gradient (Figure 14-26b). The H^+ gradient is established by an antiporter in the luminal membrane that is driven by Na^+ moving into the cell down its concentration gradient and H^+ moving out of the cell against its concentration gradient. The Na^+ concentration gradient that drives the antiporter in turn is established by the energy-dependent Na^+/K^+ pump at the basolateral membrane. Thus, glucose, galactose, amino acids, and small peptides all get a “free ride” on the energy expended for Na^+ transport. The small peptides are broken down into their constituent amino acids by the aminopeptidases in the brush border membrane or by intracellular peptidases (Figure 14-25a). Like monosaccharides, amino acids enter the capillary network within the villus.

In addition to dietary proteins, in nonruminants some endogenous proteins that have entered the intestinal lumen from the three following sources are digested and absorbed as well:

1. Digestive enzymes, all of which are proteins that have been secreted into the lumen.
2. Proteins within the cells that are pushed off from the villi into the lumen during the process of mucosal turnover.
3. Small amounts of plasma proteins that normally leak from the capillaries into the digestive tract lumen.

About 20 to 40 g of endogenous proteins enter the lumen of humans each day from these three sources. All

(a) Carbohydrate digestion

(b) Carbohydrate absorption

1 The dietary polysaccharides starch and glycogen are converted into the disaccharide maltose through the action of salivary and pancreatic amylase.

2 Maltose and the dietary disaccharides lactose and sucrose are converted to their respective monosaccharides by the disaccharidases (maltase, lactase, and sucrase) located in the brush borders of the small-intestine epithelial cells.

3 The monosaccharides glucose and galactose are absorbed into the epithelial cells by Na⁺- and energy-dependent secondary active transport (via the symporter SGLT) located at the luminal membrane.

4 The monosaccharide fructose enters the cell by passive facilitated diffusion via GLUT-5.

5 Glucose, galactose, and fructose exit the cell at the basal membrane by passive facilitated diffusion via GLUT-2.

6 These monosaccharides enter the blood by simple diffusion.

(a) Protein digestion

(b) Protein absorption

1 Dietary and endogenous proteins are hydrolyzed into their constituent amino acids and a few small peptide fragments by gastric pepsin and the pancreatic proteolytic enzymes.

2 Many small peptides are converted into their respective amino acids by the aminopeptidases located in the brush borders of the small-intestine epithelial cells.

3 Amino acids are absorbed into the epithelial cells by means of Na^+ - and energy-dependent secondary active transport via a symporter. Various amino acids are transported by carriers specific for them.

4 Some small peptides are absorbed by a different type of symporter driven by H^+ , Na^+ , and energy-dependent tertiary active transport.

5 Most absorbed small peptides are broken down into their amino acids by intracellular peptidases.

6 Amino acids exit the cell at the basal membrane via various passive carriers.

7 Amino acids enter the blood by simple diffusion. (A small percentage of di- and tripeptides also enter the blood intact.)

KEY

FIGURE 14-26 Protein digestion (a) and absorption (b), for vertebrate small intestine.

endogenous proteins must be digested and absorbed along with the dietary proteins to prevent depletion of the body's protein stores. The amino acids absorbed from both food and the endogenous protein are used primarily to synthesize new protein in the body.

An exception to the need to digest proteins is found in neonatal mammals. Their intestines can accomplish limited uptake of whole proteins via the active process of endocytosis (see p. 44). This is primarily used to absorb whole antibodies of the IgA class (see p. 475) from maternal milk, and helps protect the young animal from pathogens while its immune system is still developing. There is also some evidence that large protein molecules are absorbed intact into an animal's bloodstream through a process termed *persorption*. This form of passage occurs between the cells and is possible wherever single-layered epithelium covers the mucosa of the gastrointestinal tract. Researchers have shown that ingested proteins, which were radioactively labeled, reach peak concentrations in the blood of a rabbit within 2 hours. Absorption rates ranged from 1 to 10% of the ingested protein.

Fat Absorption Fat absorption is quite different from carbohydrate and protein absorption because the insolubility of fat in water presents a special problem. Fat must be transferred from the watery chyme through the watery body fluids even though it is not water soluble. Therefore, fat must undergo a series of transformations to circumvent this problem during its digestion and absorption (Figure 14-27).

When the stomach contents are emptied into the duodenum, the ingested fat is aggregated into large, oily, triglyceride droplets that float in the chyme. Recall that through the bile salts' detergent action in the small intestine, the large droplets are dispersed into a lipid emulsification of small droplets, thereby exposing a much greater surface area of fat for digestion by pancreatic lipase. The products of lipase digestion (monoglycerides and free fatty acids) are also not very water soluble, so very little of these end products of fat digestion can diffuse through the aqueous chyme to reach the absorptive lining. However, biliary components facilitate absorption of these fatty end products by forming micelles, as you learned earlier (p. 686). Once these micelles reach the luminal membranes of the epithelial cells, the monoglycerides and free fatty acids passively diffuse from the micelles through the lipid component of the epithelial cell membranes to enter the interior of these cells. As these fat products leave the micelles and are absorbed across the epithelial cell membranes, the micelles can pick up more monoglycerides and free fatty acids, which have been produced from digestion of other triglyceride molecules in the fat emulsion.

Bile salts continuously repeat their fat-solubilizing function down the length of the small intestine until all the fat is absorbed. Then, the bile salts themselves are reabsorbed in the terminal ileum by special active transport. This is an efficient process because relatively small amounts of bile salts can facilitate digestion and absorption of large amounts of fat, with each bile salt performing its ferrying function repeatedly before it is reabsorbed.

Once within the interior of the epithelial cells, the monoglycerides and free fatty acids are resynthesized into triglycerides. These triglycerides conglomerate into droplets and are coated with a layer of lipoprotein (synthesized by the endoplasmic reticulum of the epithelial cell), which ren-

ders the fat droplets water soluble. The largest of the lipoproteins, known as **chylomicrons** (p. 389), are extruded by exocytosis from the epithelial cells into the interstitial fluid within the villus. In mammals the triglyceride-rich chylomicrons are secreted into the central lacteals and enter lymphatic vessels, whereas in birds they are absorbed into capillaries of the villi. Fatty acids with short- or medium-length carbon chains also enter the blood.

The actual transfer of monoglycerides and free fatty acids from the chyme across the apical membranes of the intestinal epithelial cells is a passive process because the lipid-soluble fatty end products merely dissolve in and pass through the lipid portions of the membrane. Fat absorption is therefore considered to be a passive process. However, the overall sequence of events necessary for fat absorption does require energy. For example, bile salts are actively secreted by the liver, the resynthesis of triglycerides and formation of chylomicrons within the epithelial cells are active processes, and the exocytosis of chylomicrons requires energy.

Vitamin absorption is largely passive

Water-soluble vitamins (B complex vitamins and vitamin C) are primarily absorbed passively with water, whereas fat-soluble vitamins (vitamins A, D, E, and K) are carried in the micelles and absorbed passively with the end products of fat digestion. Carriers, if necessary, can also accomplish absorption of some of the vitamins. Vitamin B₁₂ is unique in that it must be combined with *gastric intrinsic factor* from stomach parietal cells (p. 676 and Table 14-2) for absorption by special transport in the terminal ileum.

Most absorbed nutrients immediately pass through the liver for processing

Recall that the venules that leave the small-intestine villi, along with those from the remainder of the digestive tract, empty into the portal vein (Figure 14-17), which carries the blood to the liver. Consequently, anything absorbed into the digestive capillaries first must pass through the hepatic biochemical factory before entering the general circulation. Thus, the products of carbohydrate and protein digestion are channeled into the liver, where many of these energy-rich products are subjected to immediate metabolic processing. Furthermore, the liver detoxifies harmful substances that may have been absorbed from the gut. Only after this processing does the venous blood that began in the intestine rejoin the general circulation.

Recall that fat in the form of chylomicrons is picked up by the central lacteal and enters the lymphatic system instead, thereby bypassing the hepatic portal system. Contractions of the villi, accomplished by the muscularis mucosa, periodically compress the central lacteal and "milk" the lymph out of this vessel. The lymph vessels eventually converge to form the *thoracic duct*, a large lymph vessel that empties into the venous system within the chest. By this means, fat ultimately gains access to the circulatory system. Therefore, the liver does have a chance to act on the digested fat, but not until the fat has been diluted by the blood in the general circulatory system and has been somewhat reduced by uptake into adipose cells (see p. 389). This dilution of fat presumably protects the liver from being inundated with more fat than it can handle at one time.

FIGURE 14-27 Fat digestion and absorption (vertebrate small intestine).

The liver plays an important role in lipid transport by synthesizing three types of plasma lipoproteins. The first studies to characterize these plasma lipoproteins were conducted in the 1920s on horse serum. Liver-produced lipoproteins were named on the basis of their density of protein as compared to lipid. High-density lipoprotein (HDL) was isolated first. With the advent of analytical high-speed ultracentrifuges, subse-

quent studies identified low-density lipoprotein (LDL), which contains less protein and more cholesterol, and very-low-density lipoprotein (VLDL), which contains the least protein and most lipid. As you saw in Chapter 9 (p. 389), the LDLs and HDLs transport primarily cholesterol (and phospholipid) for cell membrane production. VLDLs are rich in triglycerides, which are used for energy storage in adipose tissue.

Extensive absorption by the small intestine keeps pace with secretion

The small intestine of humans normally absorbs about 9,000 mL of water per day, which contains the absorbable units of nutrients, vitamins, and electrolytes. How can that be, when humans normally ingest only about 1,250 mL of fluid and 1,250 g of solid food (80% of which is H₂O) per day? Table 14-6 illustrates the tremendous daily absorptive accomplishments performed by the small intestine. Each day, about 9,500 mL of H₂O and solutes enter the small intestine. Note that of this 9,500 mL, only 2,500 mL are ingested from the external environment. The remaining 7,000 mL of fluid consist of digestive juices that are essentially derived from plasma. Considering that the entire plasma volume is only about 2,750 mL, it is obvious that absorption must closely parallel secretion to prevent the plasma volume from falling sharply. Of the 9,500 mL of fluid entering the small-intestine lumen per day, about 95%, or 9,000 mL of fluid, is normally absorbed by the small intestine into the plasma, with only 500 mL of the small-intestine contents passing on into the colon. Thus, most digestive juices are not lost from the body. After the constituents of the juices are secreted into the digestive tract lumen and perform their function, they are returned to the plasma. The only secretory product that escapes from the body is bilirubin (p. 688).

Biochemical balance among the stomach, pancreas, and small intestine is normally maintained

Because the secreted juices are normally absorbed back into the plasma, the acid–base balance of the body is not altered by digestive processes. Within the small-intestine lumen, the HCl secreted by the parietal cells of the stomach is neutralized by the NaHCO₃ secreted by the pancreatic duct cells:

The resultant H₂CO₃ decomposes into CO₂ + H₂O:

The end products of these reactions—Na⁺, Cl[−], CO₂, and H₂O—are all absorbed by the intestinal epithelium into the blood. Thus, through these interactions, the body normally does not experience a net gain or loss of acid or base during digestion.

Diarrhea results in loss of fluid and electrolytes

When vomiting or diarrhea occurs, these normal neutralization processes cannot take place. We have already described vomiting and the subsequent loss of acidic gastric contents leading to metabolic alkalosis in the section on gastric motility. The other common digestive disturbance that can lead to a loss of fluid and an acid–base imbalance is **diarrhea**. This condition is characterized by passage of a highly fluid fecal matter, often with increased frequency of defecation. Just as with vomiting, the effects of diarrhea can be either beneficial or harmful. Diarrhea is beneficial when rapid emptying of the intestine hastens the elimination of harmful material from the animal's body, which happens frequently in domestic dogs, which are prone to eat such materials. However, not only are

TABLE 14-6 Volumes Absorbed by the Small and Large Intestine per Day (Human)

Volume entering the small intestine per day			
Sources	Ingested	Food eaten	1,250 g ^a
		Fluid drunk	1,250 mL
	Secreted from the plasma	Saliva	1,500 mL
		Gastric juice	2,000 mL

© Cengage Learning, 2013

some of the ingested materials lost, but some of the secreted materials that normally would have been reabsorbed are lost as well. Excessive loss of intestinal contents causes dehydration, loss of nutrient material, and metabolic acidosis resulting from the loss of HCO₃[−] (see p. 649). The abnormal fluidity of the feces in diarrhea usually occurs because the intestine cannot absorb fluid as extensively as normal. This extra unabsorbed fluid passes out in the feces. Diarrhea is the leading cause of death of human children worldwide.

The most common cause of diarrhea is excessive intestinal motility, which arises either from local irritation of the gut wall caused by bacterial or viral infection of the intestine or from emotional stress. Rapid transit of the intestinal contents does not allow sufficient time for adequate absorption of fluid to occur.

How is the biochemical balance in pH between the stomach and small intestine maintained?

Describe how the three major categories of nutrients are digested in the small intestine.

14.8 Hindgut/Large Intestine

We now turn to the final segments of the digestive tract.

The hindgut of insects actively transports nutrients and may house symbionts

The hindgut of insects is divided into two predominant regions: the intestine, or **ileum** (anterior region), and the **rectum** (posterior region). In contrast to vertebrates, the hindgut of

Molecular Biology and Genomics

Big Bugs Have Little Bugs...

Many insects are similar to ruminant mammals in that they rely on symbiotic bacteria in their digestive tracts (p. 707). One well-studied model animal is the pea aphid *Acyrtosiphon pisum*, which feeds on plant sap that is poor in several nutrients. In special cells around the aphid's digestive tract, symbiotic bacteria (*Buchnera*) manufacture key nutrients, especially several amino acids that the aphid cannot make (known as *essential amino acids*). Until recently, it has been difficult to study these endosymbionts, because they do not grow in the laboratory. However, genetic analysis is shedding some light on the relationship and its evolution. By comparing the genome of free-living *Buchnera* with that of the symbiont, researchers discovered that the lat-

ter have lost most of the genes necessary for the microbes to live on their own. For example, genes for defensive cell wall proteins are absent. Furthermore, the genes for making essential amino acids for the host aphid have been duplicated manyfold and are located in *plasmids* (small circlets of

DNA separate from the main chromosome). Plasmids serve as dedicated factories producing RNA for the enzymes to make large quantities of the amino acids, which are exported to the host.

These studies reveal much about the genetic processes of evolution. First, because they have no selective benefit, genes that are no longer used mutate into unusable forms and may shrink as pieces are accidentally lost during DNA replication. Second, intimate symbioses such as these may be irreversible, with each partner no longer capable of living without the other. Finally, the process suggests how mitochondria and chloroplasts, which also have greatly reduced genomes, may have evolved from symbiotic microbes.

Pea aphid, *Acyrtosiphon pisum*.

insects constitutes the reabsorptive portion of both the digestive and excretory systems as ion and nutrient transport occurs in both regions. For example, the rectum in the hindgut of locusts has been demonstrated to transport some amino acids via an Na^+ -independent process. The rectum works in concert with the Malpighian tubules (see p. 566), which are excretory in function, as part of the excretory system.

As you will see for vertebrates shortly, hindguts often house beneficial symbiotic microbes. Cellulose-digesting anaerobic microorganisms are housed in special organs connected to the hindgut of wood-eating termites and the wood roach *Cryptocercus*. (See also *Molecular Biology and Genomics: Big Bugs Have Little Bugs...*)

The vertebrate hindgut or large intestine consists of the colon, cecum, and rectum or cloaca

The hindgut of vertebrates consists of the *colon*, *cecum*, and *rectum/cloaca* (Figure 14-28); however, in amphibians the hindgut is difficult to distinguish from the midgut, although the diameter is somewhat larger. In most species a valve or sphincter separates the two compartments. The cecum was described earlier (p. 693). The small, fingerlike projection at the bottom of the cecum in humans and some apes is the **vermiform appendix**, a lymphoid tissue that stores lymphocytes but that has no direct digestive function. It is thought to be a remnant of a larger cecum in ancestral primates and has long been thought to be vestigial. Recent studies indicate that it may serve as a refuge for symbiotic bacteria, which may repopulate the main tract if symbionts there have been killed off by diseases or toxins. However, since the appendix is prone to obstruction from trauma, infections, and foreign bodies—which can lead to lethal swelling and rupture—it is not an optimal adaptation (see p. 2).

The **colon**, which makes up most of the mammalian large intestine, varies considerably between animals in structure de-

pending on diet (as you will see later). Generally the colon of mammals shows a remarkable range of structural variation and tends to be proportionately longer than that of other vertebrates. In humans, there is a distinct *ascending colon*, *transverse colon*, and *descending colon*. The ascending colon of ruminants, pigs, and horses are dramatically modified in both size and structure. For example, in ruminants and pigs it is much elongated and organized into coils. In the horse it is markedly enlarged and occupies a considerable portion of the abdominal cavity. The transverse colon is comparatively short, whereas the descending colon is continuous with the **rectum** (*rectum* means “straight”). In amphibians, reptiles (including birds), and some mammals the hindgut terminates, along with the renal and reproductive systems, in a **cloaca**, whereas in fish the ducts from the urinary and genital tracts exit from the body separate from that of the digestive tract. In reptiles including birds, the cloaca is divided by ridges into three regions (Figure 12-10, p. 575). The anterior **coprodaeum** receives the excreta from the intestines; the middle **urodaeum** receives the fluid from the kidneys through the ureters, as well as the material from the oviduct; and the **proctodaeum** stores the excreta. The proctodaeum opens externally into the muscular anus. Lying on the dorsal wall of the urodaeum is the **bursa of Fabricius**, a lymphoid organ (p. 473) important in newly hatched birds.

The large intestine serves as a temporary storage site for excreta, functions in electrolyte and fluid balance, and harbors microbes for fermentation and production of volatile fatty acids

The colon of a human normally receives about 500 mL of chyme from the small intestine each day. Because most digestion and absorption have been accomplished in the small intestine, the contents delivered to the colon consist of indigestible food residues (such as cellulose), unabsorbed biliary compo-

nents, and the remaining fluid. The colon extracts more H_2O and salt from the contents, so it is important in fluid-electrolyte balance. Sodium is actively absorbed, Cl^- follows passively down the electrical gradient, and H_2O follows osmotically. What remains to be eliminated is known as *excreta* or *feces*. The primary function of the large intestine is to store this fecal material before defecation. Cellulose and other indigestible substances in the diet provide bulk and help maintain regular bowel movements by contributing to the volume of the colonic contents.

Symbiotic microbes live in the cecum and colon in most if not all species, where they synthesize some vitamins such as vitamin K (p. 710), although in nonruminants only vitamin K is produced in significant quantities. Microbes also make **volatile fatty acids (VFAs)**; fatty acids with 6 or fewer carbons). For example, acetate, butyrate, and propionate are produced by symbiotic bacteria in broiler chickens, in which these VFAs may provide usable nutrients to the chicken and inhibit growth of pathogenic bacteria.

Diet composition governs variation in structure of the large intestine

Carnivores (such as cats and dogs) tend to have the simplest digestive tracts, with comparatively short, unstructured colons. For example, carnivorous fish have gut lengths normally slightly greater than the length of their own body. In these animals there is little distinction between the small and large intestine and the cecum is either absent or marginal in its development. Thus, in carnivores, the major function of the colon is the absorption of electrolytes, water, and other materials that escaped absorption in the small intestine.

In omnivores and particularly in herbivores that ingest considerable amounts of complex polysaccharides, notably rabbits and horses, the structure of the large intestine tends to be more complex. Generally the ceca and/or the colon are **sacculated** (having expandable side sacs) and voluminous, providing a site for microbial digestion. Intestinal length is also longer in omnivorous fishes compared to carnivorous fishes. In herbivorous fishes, gut length can exceed 20 times body length. Exceptions include the kangaroo and sheep, whose cecum and colon are neither sacculated nor particularly enlarged. Sacculations are formed when the outer longitudinal smooth-muscle layer of the colon does not completely surround the large intestine. In these animals, it consists of separate, conspicuous, longitudinal bands of muscle, the **taeniae coli**, which run the length of the cecum and large intestine. Most animals with taeniae have three, but a horse has four. Approximately half of the proximal coiled region of the pig colon has two taeniae, whereas the remainder is without. These taeniae coli are actually shorter than the underlying circular smooth-muscle and mucosal layers would be if the latter were stretched out flat. Because of this, the underlying layers are gathered into pouches or sacs called **haustra**. The haustra are not merely passive gath-

FIGURE 14-28 Anatomy of the large intestine (mammal, shown for a human).

© Cengage Learning, 2013

ers, however; they actively change location as a result of contraction of the circular smooth-muscle layer.

Haustral contractions prolong the retention of digesta

Most of the time, movements of the large intestine are slow and nonpropulsive, as is appropriate for its absorptive and storage functions. The colon's primary method of motility are **haustral contractions** initiated by the autonomous rhythmicity of colonic smooth muscle cells. These contractions, which throw the large intestine into haustra, are similar to small-intestine segmentations but occur much less frequently. Whereas human small-intestine segmentation occurs at rates of between 9 and 12 contractions per minute, there may be 30 minutes between haustral contractions. The location of the haustral sacs gradually changes as a relaxed segment that has formed a sac slowly contracts while a previously contracted area simultaneously relaxes to form a new sac. These movements are nonpropulsive; they slowly shuffle the contents in a back-and-forth mixing movement that exposes the colonic contents to the absorptive mucosa. By prolonging the retention of the colonic contents, more time is made available for microbial digestion. This is particularly important in the pig and horse because they lack a rumen in which to digest dietary cellulose. Locally mediated reflexes involving the intrinsic plexuses largely control haustral contractions.

Peristaltic contractions also propel the flow of intestinal and cecal contents toward the rectum. A pacemaker in the midcolon region generates slow waves, which travel both directions along the colon, which contributes to the net

movement of ingesta along the colon. Birds rely primarily on peristaltic rather than haustral contractions for colon motility.

In addition to the haustral contractions, which impede the flow of ingesta, are the **antiperistaltic contractions**, which function primarily to fill the cecum. Generally they originate from pacemakers in the proximal region of the colon. These contractions are important in most herbivores and pigs, in which their mixing action enhances microbial digestion of cellulose and absorption of fermentation products, such as volatile fatty acids.

Because of this slow colonic movement, bacteria have time to grow and accumulate in the large intestine. In contrast, contents in the small intestine are normally moved through too rapidly for bacteria to proliferate. Not all ingested bacteria are destroyed by salivary lysozyme and gastric HCl, so the surviving anaerobic bacteria continue to thrive in the large intestine. Most colonic microorganisms are generally harmless in this location (and some are beneficial; p. 710), surviving on any remaining protein and polysaccharides in the digesta.

Postgastric fermentation is not as efficient as pregastric fermentation in obtaining nutrients

Postgastric fermentation occurs in all animals but is particularly well developed in some species such as the horse, whale, elephant, possum, and koala. The site of the fermentation chamber is the combined colon and upper cecum. By positioning the fermentation chamber after the stomach, the host animal has the first chance at the available carbohydrates and protein in the food but loses the opportunity to exploit the high-quality microbially synthesized protein. Further, the digestive capabilities of the stomach and small intestine cannot contribute to the digestion of microbial products. However, VFAs and some vitamins synthesized by the microbes in the cecum and colon are absorbed through the mucosa of the large intestine. In many species the cecal wall is arranged in spiral ridges, which increases the surface area available for absorption. Because the cecum and colon do not absorb nutrients as efficiently as the small intestine, the quality of these animals' diet is more important in sustaining normal metabolic activity. Recycling of nitrogen (see p. 709) is also less important in mammalian postgastric fermenters. Thus, when dietary sources become scarce, ruminants have a survival edge over nonruminant herbivores.

The environment within the colon/cecum of postgastric fermenters must be able to support a substantial microbe population in a buffered environment. In the horse, large quantities of bicarbonate and phosphate buffers are secreted by the ileum and transferred to the cecum, an action comparable to the role of the salivary gland in ruminants. The animal must also be able to absorb the products of fermentation as well as to reclaim as much fluid as possible from the digesta before it is excreted.

Herbivorous avian species such as the galliformes (chicken, turkeys, and so forth), ostriches, ducks, and geese have enlarged ceca. It has been shown in the galliformes that uric acid and urea from their urine passes down the ureters into the cloaca, then reflux antiperistaltically into the colon and ceca. Microbes decompose the urea and uric acid into ammonia, which may then be used by bacteria to synthesize amino acids. The microbes themselves primarily use these amino acids, but some are absorbed into the blood of the

host bird to meet its amino acid requirements. Ammonia is also absorbed directly from the ceca and is used to synthesize amino acids in the liver. Ammonia "recycling" is an important adaptation that permits the galliformes to exploit habitats otherwise unavailable to most animals.

Nutritional Benefit from the Reingestion of Feces A solution to obtaining nutritional benefit from protein and vitamin synthesis by microbes in the large intestine is the practice of **coprophagy** (Greek *copros* or "feces" and *phagein* "to eat"). Many species practice coprophagy for various reasons, some as normal practice (e.g., stink bugs) and others under specific conditions. For example, some species that lack a pregastric digestive system, such as rabbits, hamsters, and capybara, produce two types of fecal material. The soft fecal pellets produced in the nighttime are reingested, thus making the products of cecal fermentation available for digestion and absorption. Delivery of the soft feces is accomplished by inhibition of motility in the proximal colon associated with hyperactivity of the distal region close to the anus. In the rabbit, the soft fecal pellets contain over 50% bacteria and provide adequate intake of vitamin B₁₂. The second type of feces is a dark, hard pellet, which is not reingested.

Many hindgut digestors practice coprophagy when very young. Colts, young elephants, pandas, koalas, and hippos practice it in order to establish a microbe population in the hindgut, then abandon this practice as adults. Because chickens normally practice coprophagy, outbreaks of *coccidiosis* are relatively common in birds raised on litter. Coccidiosis is caused by single-celled protozoa (*Eimeria*) that colonize the large intestine. Affected animals may develop symptoms that include diarrhea, bloody droppings, and an abrupt decrease in food intake.

Mass movements propel colonic contents long distances

Generally after meals, a marked increase in motility takes place during which large segments of the colon contract simultaneously, driving the feces one third to three fourths of the length of the colon in a few seconds. These massive contractions, appropriately called **mass movements**, drive the colonic contents into the distal portion of the large intestine, where material is stored until defecation occurs. In the dog, mass movements originate near the ileocecal valve and can evacuate the ingesta the entire length of the colon, whereas in the cat the movements are generated lower in the colon.

When food enters the stomach, mass movements occur in the colon primarily by means of the **gastrocolic reflex**, which is mediated from the stomach to the colon by gastrin and by the extrinsic autonomic nerves. Thus, when a new meal enters the digestive tract, reflexes are initiated to move the existing contents farther along down the tract to make way for the incoming food. The gastroileal reflex moves the remaining small-intestine contents into the large intestine, and the gastrocolic reflex pushes the colonic contents into the rectum, triggering the defecation reflex.

Feces are eliminated by the defecation reflex

When mass movements of the colon move fecal material into the rectum, the resultant distension of the rectum stimulates stretch receptors in the rectal wall, thus initiating the

defecation reflex. This reflex causes the **internal anal sphincter** (which consists of smooth muscle) to relax and the rectum and sigmoid colon to contract more vigorously. If the **external anal sphincter** (which consists of skeletal muscle) is also relaxed, defecation occurs. Being skeletal muscle, the external anal sphincter is under voluntary control. The initial distension of the rectal wall is accompanied by the conscious urge to defecate. If circumstances are unfavorable for defecation, voluntary tightening of the external anal sphincter can prevent defecation despite the defecation reflex. Ground-nesting animals generally defecate at considerable distances from their young to decrease the likelihood of detection by a predator. If defecation is delayed, the distended rectal wall gradually relaxes, and the urge to defecate subsides until the next mass movement propels more feces into the rectum, once again distending the rectum and triggering the defecation reflex. During periods of inactivity, both anal sphincters remain contracted to ensure fecal continence.

When defecation does occur, voluntary straining movements that involve simultaneous contraction of the abdominal muscles and a forcible expiration against a closed glottis usually assist it. This maneuver brings about a large increase in intra-abdominal pressure, which helps eliminate the feces. Defecation is also a normal response to fear, presumably in response to activation of neural centers in the brain.

Large-intestine secretion is protective in nature

The large intestine does not secrete any digestive enzymes. Colonic buffers consist of an alkaline (HCO_3^- and PO_4^{3-}) mucous solution, whose function is to protect the large-intestine mucosa from mechanical and chemical injury. In the horse and pig, pancreatic HCO_3^- is of sufficient volume so as to contribute to the buffering capability in the colon. In ruminants, considerable amounts of PO_4^{3-} are secreted in the saliva, whereas in nonruminants, the source of PO_4^{3-} is the diet. The uptake of PO_4^{3-} is low in the intestine, with the result that its concentration increases as the colon absorbs fluid. The mucus provides lubrication to facilitate passage of the feces, whereas the buffers neutralize acids produced by local bacterial fermentation.

The large intestine converts the luminal contents into feces

Fecal material normally consists of undigested cellulose and other unabsorbed food residues, bilirubin (or biliverdin), small amounts of salt and water, and bacteria. Some of these items were never actually a part of the body. As we noted earlier, some absorption takes place within the vertebrate colon, but not to the same extent as in the small intestine. Because the luminal surface of the colon is fairly smooth, it has considerably less absorptive surface area than the small intestine. In many vertebrates, specialized transport mechanisms are not present in the colonic mucosa for absorption of glucose or amino acids, as there are in the small intestine. A notable exception is the colon of birds, where both glucose and amino acids are absorbed by secondary active transport. Thus, the glucose and amino acids not reabsorbed in the kidney can either be reabsorbed into the blood or used by the microorganisms in the ceca. When excessive small-intestine motility delivers the contents to the colon before absorption of nutrients has been completed,

the colon cannot absorb these materials, and they are lost in diarrhea.

check your understanding 14.8

Why is postgastric fermentation not as effective as pregastric fermentation?

What are the principal functions of the large intestine?

How do the principal functions of the large intestine differ among species?

14.9 Ruminant Digestion

Ruminants are a group of animals that have achieved the highest degree of specialization in fermenting plant material. Animals having a rumen can exploit the vast supplies of structural carbohydrates found in the plant cell wall and convert them into a source of nutrients. Ruminants, so named because they **ruminates** (chew the cud), also voluntarily regurgitate partially digested food back into the mouth to complete the mechanical grinding of the ingested plant material. This has often been thought of as an evolutionary development that has allowed ruminants (often prey animals) to consume feed in haste and later mechanically process their food during leisure times of safety. Ruminant species have evolved a stomach of sufficient size and motility to house a population of microbes able to break down cellulose and other complex polysaccharides into end products of fermentation, which meet the nutritional requirements of the host animal. Consequently, ruminants are among the most widely distributed groups of mammals on Earth, having adapted to Arctic, desert, and tropical environments.

The rumen is divided into separate compartments

The stomach of true ruminants (*Ruminantia*), which includes cattle, sheep, goats, deer, giraffe, and antelope, is divided into four compartments, which occupy approximately three quarters of the abdominal cavity. The **forestomach** (the pregastric region) consists of three chambers: the **rumen**, **reticulum**, and **omasum**, each of which is involved in the storage and passage of ingested food (Figure 14-29). *Pseudoruminants* (Tylpoda), including llamas and camels, have a three-compartment stomach, the omasum being absent.

The **rumen** and its continuation, the **reticulum**, also have an important role in the absorption of nutrients and simple molecules. It is in these two compartments that the bulk of anaerobic fermentation (see p. 47) of plant material occurs and cellulose is catabolized into digestible units. Energy is obtained through fermentation that would otherwise be lost to the host animal. However, the fermentative process requires specific temperatures, pH, motility, and secretions to maintain the microbial populations. In all ruminant animals, the rumen is the most spacious structure, followed by the abomasum. In a majority of ruminant species, the reticulum is greater in size than the omasum, which is the smallest of the four compartments. The variability in size of the latter two compartments is ultimately determined by the

(a)

FIGURE 14-29 Comparison of rumen structure and function in a selective versus a nonselective feeder.

(a) Stomach of a nonselective feeder, the ox. (b) Rumen function in an antelope stomach. Note that the relative size of the rumen is considerably smaller than in the ox. Food moves from the rumen and reticulum into the omasum for sorting. The abomasum is the acid-secreting region.

(b)

feeding strategies of the particular animal group as well as by seasonal changes in food availability.

Surrounding the ruminant stomach is an outer muscular layer, which consists of a thin sheet of longitudinally directed smooth muscle, whereas the inner layer is thick and circular in structure. The muscular layers mix the ingesta and provide for the progressive movement of this material through the stomach toward the small intestine. Rumen mixing also promotes the turnover of indigestible particles that would quickly clog the rumen if allowed to accumulate.

The ruminal cavity is divided into internal compartments by the presence of **pillars**. Longitudinal pillars partially divide the rumen into dorsal and ventral sacs. When contracted, these muscular folds enable the mixing and movement of large volumes of fluid. These pillars also help

stabilize the fluid contents of the ruminoreticulum and limit the movement of the digesta toward the reticulum. In deer, for example, rapid movements of the body would potentially result in a considerable displacement of ruminal fluid were it not for the limitations imposed by these structures. Because this volume may equal as much as 14% of an animal's body weight, it is vital that it be stabilized. Lining the rumen are fingerlike projections, the **papillae**, that increase the surface area available for absorption of nutrients. Feeding *high-concentrate diets* (replacing the roughage component of the diet with higher-energy grains) to cattle results in the gradual degradation of these structures. Starvation also decreases the size of the papillae.

The ruminal compartment is separated from the reticulum by the **ruminoreticular fold**. However, the separation

does not inhibit the free exchange of digesta between the two compartments. Within these two sacs occurs most fermentation and absorption of nutrients. Hardware and other foreign objects accumulate in the reticulum because of its position relative to the esophagus. **Hardware disease** occurs in ruminants when a foreign object, usually a piece of metal that has been swallowed, penetrates the reticulum. The condition is particularly common in cattle because they do not separate foreign objects—nails, wire, and so forth—from feed, and swallow everything before it is completely chewed. Penetration of the reticulum wall permits bacteria and partially digested food to spill out into the abdominal cavity, resulting in *peritonitis*.

The esophagus terminates at the junction between the reticulum and the rumen, the *cardia*, and opens directly over the cavity of the reticulum. It is encircled by strands of smooth muscle that are organized to form a *reticular groove*. The reticular groove extends from the opening of the esophagus to the *reticulo-omasal orifice*. The luminal surface of the reticulum is lined with ridges, which are thought to be involved in the sorting of particles that pass near the reticulo-omasal orifice. Ingesta ultimately entering the omasum are identical in consistency to that found in the ruminoreticulum.

The omasum provides a channel for the passage of ingesta from the reticulum into the glandular stomach, the abomasum. The luminal surface is characterized by the presence of leaflike structures that absorb water and nutrients as well as limit the passage of large particles. At the junction with the abomasum is the *omasoabomasal orifice*, a well-developed structure that lacks a sphincter to limit backflow. It also regulates the movement of materials from the omasum into the abomasum during digestion and inhibits the movement of ingesta from the omasum when the abomasum is full.

The abomasum is similar in function to the stomachs of nonruminants

The acid-secreting region of the stomach, the **abomasum**, functions in the digestion of protein and lysis of rumen microbes. It is structurally similar to that of stomachs of nonruminants except for the presence of relatively large spiral folds. It has a much larger fundic area and a larger pyloric region at the junction of the abomasum and small intestine. In ruminants that are fed coarse plant material, gastric juice secretion is continuous, whereas it is cyclic in animals provided concentrate diets at intervals during the day. **Displaced abomasum syndrome** results from feeding high-concentrate diets to dairy cattle as a consequence of the abomasum becoming enlarged with fluid and gas, which results in a shift of the abomasum from the right half of the abdominal cavity to either the left or the right.

Motility of the ruminant stomach is predominantly regulated by central nervous system reflex mechanisms

Vagal and splanchnic nerves innervate the ruminant stomach. Vagal motor nerve fibers originating in the gastric centers of the medulla oblongata in the brain stem can increase the rate at which the ruminoreticulum contracts. For example, excitatory input generated from the sight of food, the process of chewing or rumination itself, or an increase in the

distension of the ruminoreticulum all increase rumen motility. In contrast, input from the splanchnic nerve is inhibitory. Distension of the abomasum, for example, decreases the rate at which the ruminoreticulum contracts.

Rumination is the regurgitation, remastication, and reswallowing of ingesta

Rumination cycles (or “cud chewing”) are closely linked with ruminoreticular motility and last approximately a minute. Regurgitation is associated with an extra contraction of the reticulum followed by a primary contraction. The extra contraction is associated with a transient negative pressure created by closure of the glottis prior to an inspiratory cycle. The influx of digesta into the esophagus occurs simultaneously with the opening of the lower esophageal sphincter and a relaxing of the upper esophageal sphincter. The semiliquid digesta is propelled up the esophagus by reverse peristalsis. Once food enters the mouth the liquid portion is immediately reswallowed, but the particulate material remains in the mouth for maceration by the teeth and *reinsalivation*, mainly from the parotid gland on the side of chewing. Each rumination cycle is divided into a prolonged chewing phase followed by a short redeglutition phase. The food bolus is reformed and reswallowed. The amount of time spent ruminating depends on the species of animal as well as the composition of the food. In general, the greater the roughage content of the diet, the more time that is spent ruminating the digesta. Forages and hay require more chewing than do feed concentrates.

The environment of the rumen fosters the growth of anaerobic microbes

As we noted earlier, enhanced fermentation of plant material is the key to ruminants' success. Microorganisms contained in the rumen break down cellulose into short-chain fatty acids that are absorbed through the rumen wall. Most of these microorganisms are attached to partially digested feed particles (approximately 75%), whereas the remaining either adhere to the rumen wall or are present in the rumen fluid. The rumen is normally well buffered by the copious flow of saliva (which contains both bicarbonates and phosphates), production of short-chain organic acids, as well as the buffering capacity of the animal's diet. Further, the presence of ammonia in the rumen can limit decreases in rumen pH, which is optimally around 6.5 to 7.0, but due to the generation of VFAs is normally somewhat lower.

The microbial populations found in the rumen include anaerobic species of *bacteria*, *archaea*, *protozoa*, and *fungi*. Of these, bacteria are the greatest in number and diversity of species. Over 200 species of bacteria have been identified in concentrations of 10^9 to 10^{10} cells per gram of rumen contents. The predominant bacterial species found in rumen fluid from wild ruminants such as deer and moose are similar to those species identified in domesticated ruminants. Bacteria can be either liquid-associated and feed on soluble carbohydrates or proteins, or be solid-associated (adherent bacteria) and bound to food particles. The latter bacteria digest the insoluble polysaccharides as well as the less soluble proteins. Immediately after the animal's feeding, some of the adherent bacteria detach from the particulate matter and colonize the new feed particles. Soluble nutrients leaching from the cut ends of the plant material attract both microbes and protozoa

by chemotaxis. A third group of bacteria (*epimural bacteria*: *epi*-, “on”; *mural*, “wall”) is associated with the epithelial cells lining the rumen wall. These organisms use the O_2 that diffuses from the blood through the epithelial cells to the rumen fluid. In this manner, they help maintain the anaerobic environment of the rumen. These cells are also important in converting the urea that diffuses through the rumen wall into ammonia (via the enzyme *urease*) because very few microbe populations synthesize ureases. Epimural bacteria also digest the cells that are sloughed from the rumen wall. Were it not for these microbes, these highly keratinized cells (fibrous proteins) would be indigestible.

Protozoa numbers vary from 10^5 to 10^6 per gram of contents and include about 60 species in domestic animals. While the diversity of protozoa in wild ruminants is considerably less than in domestic ruminants, compartmentalization of protozoa is similar to that of bacteria in that there are liquid-associated, solids-associated, and epimural populations. Protozoa face a particular problem in that the time required to reproduce is longer than the time the ingesta remains in the rumen. For this reason protozoa must adhere to large feed particles or the rumen wall to avoid being washed out with the other digesta. Protozoa are particularly sensitive to the composition of an animal's diet. For example, in dairy cows the number of protozoa increases in proportion to the amount of grain fed. Protozoa feed on ruminal bacteria, fungal zoospores, and other readily digestible materials, including plant starch granules and some polyunsaturated fatty acids. Interestingly, certain species of methanogenic bacteria (those converting CO_2 to CH_4) colonize the cilia of protozoa. Thus, many feed-grade antibiotics such as *monensin* or *lasalocid* that target protozoal species often decrease methane production by reducing the methanogenic host.

Archaea contribute from 0.3 to 3.3% of the total ruminal microbe population. Ruminal archaea are strictly anaerobic methanogens, which survive by utilizing the electrons derived from H_2 or formate as energy sources to reduce CO_2 to methane.

At least 14 species of fungi have been identified, but a reliable estimate of their numbers has not been made. The vegetative stage of fungi is termed a *sporangium*. Sporangia generate flagellate, motile *zoospores* that remain in the fluid compartment until their attachment to a food particle. However, once they are attached to the digesta it is difficult to quantify population numbers. Fungal hyphae (filaments) penetrate deep into the plant cell walls and thus gain access to a pool of cellulose unavailable to protozoa and bacteria. Their weakening of the cell wall enables bacteria to eventually gain access and increase the rate of digestion of these insoluble plant fibers. Chemotaxis also plays a role in the location and colonization of plant material. Fungi secrete a more soluble form of cellulase than bacteria and are more successful in fermenting coarse particles, although their overall rate of digestion is slower compared to bacteria. Because of their attachment to large particles, both protozoa and fungi are cleared from the rumenoreticulum at relatively low rates, compared to bacteria.

Nutrients for the host ruminant are generated by anaerobic microbes

Fermentation is the most important process to occur in the rumen. It is also the first step in the generation of nutrients suitable for the host ruminant. Because the diet of ruminant animals contains varying proportions of insoluble celluloses,

hemicelluloses (structural component of plant cells), pectins (polysaccharide isolated from fruits), and starch (polysaccharide that stores energy in plants), these complex polysaccharides need to be converted into simpler forms to be metabolized by the ruminant microbes. Complicating this digestive process are the seasonal changes in the proportion of cellulose and hemicellulose as the herbage matures. Aging of plant walls is associated with an increase in the structural component, **lignin**, a noncarbohydrate polymer, which effectively resists degradation by most rumen microbes. Most bacteria attach to feed particles and digest the structurally complex polysaccharides via cellulase enzyme complexes tightly bound to the surface of the bacteria. Similar cellulase complexes are used by protozoa to digest engulfed feed particles, whereas fungi can digest polysaccharides by bound enzymes or by releasing the cellulases into the surrounding fluid. Starch and cellulose are degraded into glucose, whereas hemicellulose and pectin are converted into xylose (monosaccharide). Sugars and pectins are the most rapidly fermented, followed by starches and fiber. Most simple sugars do not accumulate in the rumen liquor, because they are taken up and metabolized by the microbes populating the forestomach, regardless of whether they participated in the initial hydrolysis of the complex polysaccharides. However, depending on the rate and extent of digestion, some carbohydrates escape the rumen. For example, most fiber, considerable starch, and some simple sugars escape the rumen environment.

Generation of Volatile Fatty Acids by Microbes The metabolism of glucose and xylose by the microbes is similar to that of cells in the animal (Figure 14-30). These simple sugars are anaerobically metabolized through the glycolytic pathway into the intermediate *phosphoenolpyruvate* (PEP). Methane, CO_2 , acetate, and some butyrate are generated from PEP. Alternatively, PEP can be further metabolized into pyruvate, which ultimately leads to generation of the short-chain fatty acids propionate and butyrate. Under normal conditions, the rumen fluid content is approximately 60 to 70% acetate, 14 to 20% propionate, and 10 to 14% butyric acid. If the diet contains high concentrations of soluble carbohydrates or starch, the concentration of propionic and lactic acids increase, whereas high-fiber diets cause increases in acetic acid and declines in propionate and lactate.

The VFAs acetate, propionate, and butyrate are the most important product of the microbial fermentation process because they can be directly used as a source of energy by the host animal. Propionate is particularly important because it is the only VFA that can be used to synthesize glucose. Under normal conditions, approximately 70% of the ruminant's glucose and glycogen is generated from propionate, whereas the catabolism of protein contributes only about 20%. The other VFAs provide energy by entering the TCA cycle as acetyl CoA, with the excess energy stored as body fat in the tissues. These end products become milk fat and lactose in a lactating ruminant. Acetate, in particular, is important in the synthesis of milk fat in the udder and body fat. Other aromatic compounds can enter the vascular system and reach the mammary gland. For example, digestion of onions, garlic, and leek in the rumen generates VFAs that eventually flavor the milk.

VFAs produced by the rumen microbes are passively absorbed through the rumen wall. The rate of absorption is dependent on chain length, pH, concentration, and osmolarity. For example, as the osmotic pressure in the rumen in-

FIGURE 14-30 Fermentation pathways in the ruminant. Excretory products in a lactating ruminant also include ketones.

Source: J. Bryant and B. R. Moss, Montana State University.

creases, absorption of VFAs from the rumen decreases. Osmotic pressure in the rumen averages 280 mOsm, but pressures above 350 mOsm can completely stop rumination. Between the pHs of 4.5 and 6.5, the rates of VFA absorption are butyrate > propionate > acetate, whereas the rates are similar when rumen pH is above 6.5. Low pHs are also associated with a diminished attachment of rumen microbes to fiber particles, which reduces the microbial degradation of cellulose. At pH levels lower than 5.0, there is a complete cessation of fiber digestion in addition to a decline in the number of cellulolytic (cellulose-digesting) microbes.

Protein Metabolism by Microbes Each of the microbial populations in the rumen can hydrolyze protein into constituent polypeptides and amino acids and use these products as a source of nitrogen for their own growth (Figure 14-31). Although most bacterial proteases (protein-digesting enzymes) remain bound to the cell, some species liberate their proteases into the rumen fluid to generate polypeptides. Polypeptides up to six amino acids long can be absorbed by the rumen bacteria and further hydrolyzed to end products such as amino acids, or are deaminated (the nitrogenous amine group is removed) to produce ammonia. Ammonia as well as amino acids are readily absorbed through the lining of the ruminoreticulum and omasum. Deamination of some amino acids such as valine and leucine is responsible for the generation of **isoacids**, or branched-chain fatty acids. These isoacids are essential in small amounts for the growth of cellulolytic microbes. Peak ammonia production occurs about one to two hours after feeding, although the appearance of free amino acids and ammonia occurs within minutes after feeding. Rumen microbes use the ammonia along with some amino acids and polypeptides to synthesize their own microbial protein. Once these bacteria are swept into the abomasum, their cell proteins are digested and eventually absorbed through the small intestine. The synthesis of microbial protein also ensures that the host is

supplied with essential as well as nonessential amino acids. Approximately 30 to 40% of the dietary protein entering the rumen is not degraded and is classified as **rumen-undegradable protein**. However, the gastrointestinal proteolytic enzymes readily hydrolyze these proteins.

Ammonia generated in the ruminoreticulum is either converted into microbial protein or converted to urea in the liver. Some of this urea is returned to the forestomach directly through the wall of the ruminoreticulum or through the salivary glands. High urease (urea-digesting) activity is found along the ruminal wall and is responsible for the rapid degradation of urea to ammonia for metabolism into microbial protein. Recall that presence of urease in the rumen permits the incorporation of urea in the diet of ruminants. However, feeding ruminants a diet too high in urea or rapidly hydrolyzed protein can lead to ammonia toxicity.

Wild herbivores experience marked changes in food quality and quantity throughout the year. When environmental conditions become sufficiently harsh and the only herbage available is deficient in protein, the concentration of ammonia in the rumen is low, as are the number of rumen microbes, thus slowing the breakdown of cellulose. However, the total amount of nitrogen returned to the rumen as urea exceeds that absorbed from the rumen as ammonia. Nitrogen recovered from this process is converted to microbial protein. Ultimately, the total amount of protein arriving in the intestine can be greater than that in the original food. A wild ruminant can conserve an important nitrogen source by returning to the rumen urea that would otherwise have been excreted in its urine. Alternatively, under conditions when protein degradation is greater than its synthesis, such as in animals fed protein-rich concentrates, ammonia can potentially accumulate in the rumen fluid. Under these circumstances, some of the ammonia that is converted to urea in the liver is excreted in the urine and thus wasted.

FIGURE 14-31 Protein pathways in the ruminant. NPN is nonprotein nitrogen.

Rumen microbes synthesize vitamins for their host and detoxify some ingested toxins

One important by-product of fermentation is the synthesis of all B vitamins. Rumen microorganisms, if enough cobalt is available, even synthesize the vitamin B₁₂ complex. The microbes responsible for this process require many of the B vitamins. Thus, ruminants do not require a dietary source of these vitamins.

Regardless of the location of microbes in an animal's digestive tract, these microorganisms can also protect the host animal from some toxins that are ingested in the diet. Microbes are thus sometimes considered the *first line of defense* against dietary toxins and nutritional limiting compounds. Livestock are more likely to consume poisonous plants when pasture is short, a consequence of restricted grazing practices, drought, or late-season grazing. Most poisonous plants are unpalatable and, if there is something better to eat, are usually not eaten in quantities sufficient to become toxic. Consumption of various poisonous molecules, such as oxalates (in rhubarb leaves), can be neutralized by rumen microbes into harmless by-products. Protozoa and bacteria can convert another poison, nitrate, in foodstuffs. Often some plants store minerals such as calcium and phosphorous in complexes known as **phytate**. This phytate complex is resistant to normal mammalian digestion and often additional dietary phosphorous is necessary to meet a monogastric's (swine and poultry) phosphorous requirements. Ruminants, however, due to their microbial inhabitants, are able to utilize these minerals because of microbial degradation of the phytate complex. Some species of baleen whales can survive the ingestion of pollutant-laden krill (a tiny crustacean). Anaerobic microorganisms found in the ceca of bowhead whales (though not ruminants) can degrade PCBs, anthracene, and naphthalene, major constituents of oil spills.

Some ruminants are selective in what they eat, whereas others simply graze the available forage

Cattle are representative of a group of herbivores that are relatively nonselective in their consumption of forage. They intensively consume forage at limited periods during the day, followed by intense periods of rumination. In general, the larger the animal, the more likely it can be classified within this grouping. Ruminants with a larger forestomach have a greater digestive capacity in which to ferment lower-quality plant material. The ability to digest fiber is also associated with an increase in total intestinal length and a reduction in transit time through the intestine. A slower rate of passage improves nutrient absorption by increasing time of contact with absorptive cells and increases digestibility of dietary fiber by allowing more time for microbial fermentation. However, management practices of the beef cattle industry include the feeding of concentrate diets to enhance growth rate. Because these animals are slaughtered for meat, they normally do not live long enough to develop diet-related problems associated with this feeding practice.

At the other end of the spectrum are the *selective feeders* that consume only the most nutritious parts of the herbage. This activity normally requires more effort and time and so tends to be employed by smaller ruminants that need less total energy consumption. Associated with the high-quality diet is an increased rate of VFA production. Their rumens are more highly folded, which increases the available surface area for absorption of amino acids and VFAs. Selectors tend to have smaller rumens relative to body size as well as shorter total intestinal lengths. The pillars and ruminal structure have evolved to increase the passage rate of digesta. Antelopes are examples of ruminants that require frequent meals and whose forestomachs are comparatively less developed. The turnover of material in the rumen of these animals is faster than in their nonselective counter-

parts. Concentrate selectors such as whitetail and roe deer can exploit the seasonal variability in plant growth and show marked increases in food intake during the summer months, when food sources are plentiful. The increase in turnover of rumen contents at this time permits them to store the excess energy as fat reserves to help them through the winter season. Rumen capacity in deer is also increased by 50% during the summer months, which lets the animal accommodate a greater digesta load. Goats and caribou are examples of intermediate feeders and show a less marked increase in food intake and rumen size during the summer.

What compound(s) can be absorbed from the rumen?

14.10 Overview of the Gastrointestinal Hormones

Throughout our discussion of digestion, we have repeatedly mentioned different functions of the several major gastrointestinal hormones in vertebrates, especially gastrin, secretin, and cholecystokinin (CCK). Let's now fit all these functions together so that you can appreciate the overall adaptive importance of these interactions. Furthermore, we now introduce more recently identified hormones as gastrointestinal hormones. All of these are small peptides, and most perform their functions by binding to G-protein coupled receptors on their target cells to bring about the desired responses (via second messengers; see Figure 3-17c, p. 95). This list is far from complete; at least 20 possible signal peptides have been isolated from the mammalian digestive tract, and the functions of many of these remain uncertain.

Gastrin Protein in the stomach stimulates the release of gastrin, which has the following functions:

1. It stimulates parietal and chief cells to increase secretion of HCl and pepsinogen, two substances of primary importance in initiating digestion of the protein that promoted their secretion.
2. It enhances gastric motility, stimulates ileal motility, relaxes the ileocecal sphincter, and induces mass movements in the colon—functions that are all aimed at keeping the contents moving through the tract on the arrival of a new meal.
3. It is trophic (see p. 272) not only to the stomach mucosa but also to the small-intestine mucosa, helping maintain a well-developed, functionally viable digestive tract lining.

Predictably, gastrin secretion is inhibited by an accumulation of acid in the stomach and by the presence in the duodenal lumen of acid and other constituents that necessitate a delay in gastric secretion.

Secretin As the stomach empties into the duodenum, the presence of acid in the duodenum stimulates the release of

secretin into the blood, which performs the following inter-related functions:

1. It inhibits gastric emptying to prevent further acid from entering the duodenum until the acid that is already present is neutralized.
2. It inhibits gastric secretion to reduce the amount of acid being produced.
3. It stimulates the pancreatic duct cells to produce a large volume of aqueous NaHCO_3 secretion, which is emptied into the duodenum to neutralize the acid.
4. It stimulates secretion by the liver of a NaHCO_3 -rich bile, which likewise is emptied into the duodenum to assist in neutralization of the acidic chyme. This helps prevent damage to the duodenal walls and provides a suitable environment for the optimal functioning of the pancreatic digestive enzymes, which are inhibited by acid.
5. Secretin and CCK are both trophic to the exocrine pancreas.

CCK As chyme is emptied from the stomach, fat and other nutrients enter the duodenum. These nutrients, especially fat and to a lesser extent protein products, cause the release of cholecystokinin (CCK) which performs the following inter-related functions:

1. It inhibits gastric motility and secretion, allowing adequate time for the nutrients already in the duodenum to be digested and absorbed.
2. It stimulates the pancreatic acinar cells to increase secretion of pancreatic enzymes, which continue the digestion of these nutrients in the duodenum. (This action is especially important for fat digestion because pancreatic lipase is the only enzyme that digests fat.)
3. It causes contraction of the gallbladder and relaxation of the sphincter of Oddi so that bile is emptied into the duodenum to aid fat digestion and absorption. Bile salts' detergent action is particularly important in enabling pancreatic lipase to perform its digestive task. Once again, the multiple effects of CCK are remarkably well adapted to dealing with the fat and other nutrients whose presence in the duodenum triggered this hormone's release.
4. CCK has also been implicated in long-term adaptive changes in the proportion of pancreatic enzymes produced in response to seasonal changes in diet.
5. Besides facilitating the digestion of ingested nutrients, CCK is an important regulator of food intake. It plays a key role in satiety or fullness (see Chapter 15, p. 727).

GIP A more recently recognized hormone released by the duodenum, GIP, helps promote metabolic processing of the nutrients once they are absorbed. This hormone was originally named *gastric inhibitory peptide* (GIP) for its presumed role as an enterogastrone. It was believed to inhibit gastric motility and secretion, similar to secretin and CCK. GIP does this, but only weakly; we now know that this hormone's main role is to stimulate insulin release by the pancreas. So it is now called **glucose-dependent insulinotropic peptide** (once again, GIP). Again, this is remarkably adaptive in anticipation or “feedforward” fashion (p. 16). As soon as the meal is absorbed, the body has to shift its metabolic gears to use and store the newly arriving nutrients. The

metabolic activities of this postabsorptive phase are largely under the control of insulin. Stimulated by the presence of a meal, especially glucose, in the digestive tract, GIP initiates the release of insulin *before* the absorption of the meal. Insulin is especially important in promoting the uptake and storage of glucose in the muscle and liver.

GIP structure has evolved interesting differences. Consider the Gila monster, a venomous lizard of the Sonoran desert, which eats only a few times a year. Its salivary glands and digestive tract release a very potent form of GIP that stimulates insulin rapidly during one of these rare large meals to both slow intestinal absorption (to prevent a blood glucose spike) and stimulate insulin production for better glucose postabsorptive processing. Gila monster GIP is now being used by some Type II diabetic humans (p. 323) whose pancreatic endocrine cells only weakly make insulin after a meal.

Motilin The hormone **motilin**, secreted by gland cells in the crypt of the small intestine, triggers peristaltic pumping in the mammalian intestine between meals. In support of its housecleaning function, motilin stimulates the contraction of the antrum and fundus of the stomach and accelerates gastric emptying.

Ghrelin and Obestatin The peptide hormone **ghrelin** (the “hunger hormone”) is secreted by epithelial cells lining the stomach fundus, primarily during fasting periods just before normal mealtimes (in rats and humans). It stimulates release of growth hormone from the anterior pituitary, and—perhaps most importantly—greatly increases appetite. The gene that encodes ghrelin also expresses the opposing hormone **obestatin** (the “fullness hormone”), whose function may be to decrease appetite. The roles of these two hormones in food intake and energy balance are further discussed in Chapter 15.

PYY₃₋₃₆ The recently discovered peptide **PYY₃₋₃₆** is secreted by cells lining the ileum and colon. It is released in proportion to the amount of food inside it. Locally, like CCK, it inhibits gastric motility and stimulates bile and pancreas secretion. It also travels to the brain (hypothalamus), where it suppresses appetite. Its role in food intake and energy balance is further discussed in Chapter 15.

Nefstatin-1 The peptide **nefstatin-1** was discovered in 2006 as an appetite suppressant in fish and mammals. More recently it has been found in gastric mucosa and pancreas, although its function there is unclear. Its role in the brain is covered in Chapter 15.

This overview of the multiple, integrated, adaptive functions of the gastrointestinal hormones provides an excellent example of the remarkable efficiency of an animal’s body, and the remarkable nature of the vertebrate’s “second brain” and its associated endocrine system located in the gut. Much remains for science to learn about these regulatory functions.

How Digestive Systems Contribute to the Body as a Whole

To maintain constancy in the internal environment, materials that are used up in the body (such as nutrients and O₂) or uncontrollably lost from the body (such as evaporative H₂O loss from the airways or salt loss in sweat) must constantly be replaced by new supplies of these materials from the external environment. All these replacement supplies except O₂ are acquired through the digestive system in most animals. The large, complex food that is ingested is broken down by the digestive system into small units, which are then absorbed. If excess nutrients are ingested and absorbed, the extra is placed in storage, such as in the insect fat body and vertebrate adipose tissue (fat), for later use; or it is metabolized, so that the blood level of nutrient molecules is kept relatively constant. In a sense, *the entire digestive system is an effector for energy, mineral, and water homeostasis.*

Unlike most body systems, regulation of digestive-system activities themselves is not aimed at maintaining homeostasis. The quantity of nutrients and H₂O ingested is subject to control, but the quantity of ingested materials absorbed by the digestive tract is not subject to control, with few exceptions. The hunger mechanism governs food intake to help maintain energy balance (Chapter 15), and the thirst mechanism controls H₂O intake to help maintain H₂O balance (Chapter 13). Once these materials are in the digestive tract, the digestive system does not vary its rate of nutrient, H₂O, or electrolyte uptake according to body needs; rather, it optimizes conditions for digesting and absorbing what is ingested. Truly, except for indigestible and other unabsorbable items, what an animal consumes is what it gets.

Chapter Summary

- To maintain homeostasis, nutrient molecules used for energy production must continually be replaced by new, energy-rich nutrients. Thus, the digestive system contributes to homeostasis by transferring nutrients, water, and electrolytes from the external environment to the internal environment.
- Carbohydrates, fats, and proteins represent the main fuels; they are broken down into absorbable units (specifically simple sugars, fatty acids, and amino acids), which an animal’s individual cells can use as fuel or as “building blocks” to make their own, larger molecules.
- Animal digestion evolved from an intracellular to an extracellular process in a specialized sac or tube connected to the environment. Conventionally, the gut tube in most animals can be divided into three specific regions: the foregut, midgut, and hindgut.
- Animals can be classified according to their primary feeding methods, including filter-feeding, deposit feeding, herbivory, carnivory, and so forth.
- Digestive systems perform four basic digestive processes: motility, secretion, digestion, and absorption.

- The prominent type of self-induced electrical activity in digestive smooth muscle are slow-wave potentials: basic electrical rhythms (BER) or pacesetter potentials.
- In vertebrates, the intrinsic nerve plexuses are the two major networks of nerve fibers—the myenteric plexus and the submucous plexus—that are located entirely within the digestive tract wall and run its entire length.
- Saliva aids in mastication but plays a more important role in lubricating food boluses before swallowing.
- The esophagus is a fairly straight, muscular tube that extends between the pharynx and stomach and is guarded at both ends by sphincters. The crop is a modified section of the esophagus and functions mainly as a storage organ.
- In most animals, the midgut or stomach provides for the initial digestion (beyond the minor salivary contribution) and storage of food items. Strong antral peristaltic contractions are responsible for mixing food with gastric secretions to produce chyme. Before emptying, the stomach contents must be converted into a finely divided, thick liquid form.
- The four most important factors in the vertebrate duodenum that influence gastric emptying are fat, acid, hypertonicity, and distension.
- Gastric (stomach) digestive juice in mammals is secreted by glands located at the base of gastric pits. The major digestive constituent of gastric secretion is pepsinogen, an inactive enzymatic molecule produced by the stomach of all vertebrates.
- Mammalian parietal cells actively secrete HCl into the lumen of the gastric pits, which in turn empty into the lumen of the stomach. Intrinsic factor, a secretory product of the parietal cells (also secreted from the pylorus and beginning of the duodenum in pigs) is important in absorption of vitamin B₁₂. Gastric secretion gradually decreases as food empties from the stomach into the intestine.
- The vertebrate exocrine pancreas secretes a pancreatic juice consisting of two components: (1) pancreatic enzymes actively secreted by the acinar cells that form the acini and (2) an aqueous alkaline solution actively secreted by the duct cells that line the pancreatic ducts. Pancreatic exocrine secretion is hormonally regulated to maintain neutrality of the duodenal contents and to optimize digestion.
- The vertebrate liver performs various important biochemical functions, including bile production. Bile is continuously secreted by the vertebrate liver and is diverted to the gallbladder between meals. Bile salts aid fat digestion and absorption through their detergent action and micellar formation, respectively.
- The fat body of insects plays a major role in intermediary metabolism, and it is the central storage depot of nutrients and energy reserves. Nutrient sensing also appears to be in the domain of the fat body.
- The small intestine is the site at which most digestion and absorption of nutrients takes place in vertebrates. (In arthropods, the midgut and hindgut are the sites of most digestion and absorption.) Small-intestine enzymes complete the process of digestion at the brush border membrane. Carbohydrate and protein are both absorbed by secondary active transport and enter the blood. Extensive absorption by the small intestine keeps pace with secretion.
- The hindgut or large intestine functions in electrolyte and fluid balance, harbors microbes for fermentation and VFA production, and serves as a temporary storage site for excreta. Diet composition governs the variation in structure of the large intestine. The large intestine absorbs primarily salt and water, converting the luminal contents into feces.
- Ruminant species have evolved a stomach of sufficient size and motility to house a population of microbes able to break down cellulose and other complex polysaccharides into end products of fermentation, which meet the nutritional requirements of the host animal. Pregastric fermenters have a survival edge over monogastrics and hindgut fermenters in nutrient-limiting situations.
- Acetate, propionate, and butyrate are the most important volatile fatty acids of the microbial fermentation process because they can be directly used as a source of energy by the host animal. VFAs produced by the rumen microbes are passively absorbed through the rumen wall.
- There are numerous gastrointestinal hormones including gastrin, secretin, CCK, ghrelin, and GIP, each having important roles in regulating digestive-related processes.

Review, Synthesize, and Analyze

1. What four general factors are involved in regulating digestive system function? What is the role of each?
2. Describe the types of motility in each component of the digestive tract. What factors control each type of motility?
3. State the composition of the digestive juice secreted by each component of the digestive system. Describe the factors that control each digestive secretion.
4. List the enzymes involved in digesting each category of foodstuff. Indicate the source and control of secretion of each of the enzymes.
5. Describe the process of mucosal turnover in the stomach and small intestine.
6. Why are some digestive enzymes secreted in inactive form? How are they activated?
7. Speculate on why insects do not have a pepsin-type enzyme released from their gastric mucosa.
8. What absorption processes take place within each component of the digestive tract? What special adaptations of the small intestine enhance its absorptive capacity?
9. Describe the absorptive mechanisms for salt, water, carbohydrate, protein, and fat.
10. The number of immune cells in the *gut-associated lymphoid tissue (GALT)* housed in the mucosa is estimated to be equal to the total number of these defense cells in the rest of the body. Speculate on the adaptive significance of this extensive defense capability of the digestive system.

11. After bilirubin is extracted from the blood by the liver, it is conjugated (combined) with glucuronic acid by the enzyme glucuronyl transferase within the liver. Only when conjugated can bilirubin be actively excreted into the bile. For the first few days of life, the liver does not make adequate quantities of glucuronyl transferase. Explain how this transient enzyme deficiency leads to the common condition of jaundice in newborns.

12. Why might coprophagy be a better solution to the digestion of cellulose in rabbits than pregastric fermentation?

Energy Balance and Thermal Physiology

15.1 Introduction: Thermodynamics and Life

Each cell needs energy to perform the functions essential for its own survival and to carry out its specialized contribution toward maintaining homeostasis. All energy used by animal cells is ultimately provided by food (exogenous energy-rich nutrients), intake of which is regulated to maintain **energy balance**, the internal homeostasis of nutrients available for the cells. In this chapter, we show how this balance occurs. We also consider temperature, one of the key components of energy equations. Temperature profoundly affects the rate of chemical reactions within cells, and animals have evolved various strategies to cope with these effects. Compare, for example, the butterfly above with the hummingbird on the next page. Moreover, solid evidence shows that Earth's atmosphere and oceans have been warming at least in part due to anthropogenic CO₂, and effects of this rise on organisms are already being documented. Before we examine energy balance and temperature, however, let us set the stage by examining the key energy equations.

Life follows the laws of thermodynamics

Perhaps the most distinctive characteristic of life that delineates it from nonliving systems is the way it uses energy. Whereas nonliving energetic processes—volcanoes, earthquakes, storms, and so forth—create disorder, living systems somehow produce their own order unique to each individual. Yet all these processes (indeed, all known processes in the universe) obey fundamental laws regarding energy—the **laws of thermodynamics**. There are three of these laws, with two that are relevant to physiology:

- The *First Law of Thermodynamics* is that energy can be neither created nor destroyed. Therefore, energy is subject to the same kind of input–output balance as are the chemical components of life such as H₂O and salt (see p. 612). The First Law of Thermodynamics suggests that life might operate forever on its internal energy content, simply converting one form to an-

other as necessary. However, the Second Law says this is not possible.

- The *Second Law of Thermodynamics* is that the **entropy** (a measure of disorder or randomness) of a system *plus its surroundings* increases over time as the energy content degrades to unusable heat. This is expressed in the following equation, where Δ indicates change and S is entropy:

$$\Delta S_{\text{net}} = \Delta S_{\text{surroundings}} + \Delta S_{\text{system}} \\ > 0 \text{ for spontaneous reactions}$$

The Second Law of Thermodynamics is in many ways the most important physical law regarding life in the universe. Most people are aware that the universe seems to run down over time, and only by expending energy can we reverse this trend. But life itself seems to defy this decay (until death, at least), and indeed some people have suggested that life violates the Second Law. However, they are forgetting that the law covers a system *plus its surroundings*, not just a system

A hummingbird is endothermic: It regulates its internal body temperature primarily by internal metabolism. However, it is also heterothermic: At night, its metabolism and body temperature may decrease by many degrees to save energy.

by itself. The system called “life” does *not* violate the law, because the order it creates can arise only at the expense of its environment. That is, as life becomes more organized, the surrounding environment becomes even more disorganized. The net result—increased order in an organism, increased disorder in the surroundings—is *always* an increase in net disorder (entropy). Plants, for example, create order at the expense of the sun, which is creating enormous disorder as it radiates out light and particles. Animals create order at the expense of the local environment: They eat ordered molecules (food such as glucose) and release less ordered waste molecules (such as CO_2) and—perhaps most importantly—heat, which directly increases disorder. Thus, life must continuously extract energy from the environment to maintain itself, whereas the rest of the universe degrades even faster than it would on its own. In short, the “metabolic cost of living” is a constant struggle against entropy (a struggle that is ultimately lost through aging and death).

To compensate for entropy, animals require input of food energy, most of which is ultimately converted to heat output

Since energy cannot be created or destroyed, it is subject to the same kind of *input–output balance* we described for other body components such as water and salt (p. 612).

Energy Input *Input* energy is that in ingested foodstuffs for most animals. As you have just seen, nondormant organisms need ongoing energy input from the environment. Each cell in an animal needs energy to perform functions essential for its own survival (for example, reversing the effects of entropy by restoring ion gradients and repairing damaged structures) and to carry out its specialized contributions to-

ward maintenance of the whole animal. This requires food (from the environment, or in some animals, from internal symbionts). Chemical energy locked in the bonds that hold atoms together in food molecules is released when these molecules are broken down in the body. However (as a consequence of the Second Law of Thermodynamics), 100% of the food energy cannot be used usefully, because some energy is always lost to entropy.

Energy Output Energy *output* or *expenditure* falls into two categories (Figure 15-1). **External work** is the energy expended when skeletal muscles are contracted to move external objects or to move the body in relation to the environment. **Internal work** constitutes all other forms of biological energy expenditure that do not accomplish mechanical work outside the body. That is, it encompasses all the internal energy-expending activities that must go on all the time just to sustain life, such as skeletal muscle contractions associated with postural maintenance and shivering, the work of pumping blood and breathing, the energy required for active transport of critical materials across plasma membranes, and the energy used during synthetic reactions essential for the maintenance, repair, and growth of cell structures.

Although energy cannot be created or destroyed, it can be converted from one form to another. For example, **chemical energy** in ATP is converted into **kinetic energy** of locomotion by muscle contractile proteins. But not all energy in nutrient molecules can be harnessed to perform useful biological work like this (in accordance with the Second Law). The energy in nutrient molecules that is not used for work is transformed into **thermal energy**, or **heat**. During biochemical processing, only about 50% of the energy in nutrient molecules is transferred to ATP; the other 50% of nutrient energy is immediately lost as heat. During ATP expenditure by the cells, another 25% of the energy derived from ingested food becomes heat. Because animal bodies are not heat engines, they cannot convert heat into work. Therefore, not more than 25% of nutrient energy is available to accomplish work, whether external or internal. The remaining 75% is lost as heat during the sequential transfer of energy from nutrient molecules to ATP to cellular systems.

Furthermore, of the energy actually captured for use by animals, *almost all expended energy eventually becomes heat*. To exemplify, energy expended by a heart to pump blood is gradually changed into heat by friction as blood flows through vessels. Likewise, energy used in the synthesis of cellular structural protein initially reduces entropy, but it eventually appears as heat when that protein is degraded during the normal course of turnover of bodily constituents. Even in the performance of external work, skeletal muscles convert chemical energy inefficiently, with as much as 75% of the expended energy being lost as heat, and the 25% converted into kinetic energy being dissipated as heat when an animal stops moving. Thus, all energy that is liberated from ingested food but not used for net growth eventually becomes heat. This heat is not necessarily wasted energy, however, because it is used to maintain body temperature in some animals (which affects the rate at which chemical reactions can proceed), but not to do work.

Because most animal energy expenditure eventually appears as heat, energy is normally expressed in terms heat energy, the basic units of which are as follows:

FIGURE 15-1 Energy input and output.

© Cengage Learning, 2013

1. The **calorie** is the amount of heat required to raise the temperature of 1 g of H₂O by 1°C (specifically, from 14.5 to 15.5°C). This unit is too small to be convenient when discussing animals because of the magnitude of heat involved, so the **kilocalorie (kcal)** or **Calorie**, equal to 1,000 calories, is used. When nutritionists speak of “calories” in quantifying the energy content of food, they are actually referring to kilocalories or Calories.
2. The **joule**, the international unit for energy of any kind, is equal to 0.239 calories. The term **kilojoule (kJ)** (1,000 joules) is commonly used, again because of the magnitude of animal energies. *Most scientific research now uses the joule or kilojoule rather than the calorie*, but in the United States the Calorie is still used in human nutrition.

As a common example, 4.1 kcal or 17.1 kJ of heat energy are released when 1 g of glucose is oxidized or “burned,” whether the oxidation takes place inside or outside a body.

check your understanding 15.1

Describe the laws of thermodynamics and how they apply to life.

Define *internal* and *external work* in an animal and why heat is the primary output.

15.2 Energy Balance: General Principles

Now let’s examine how animals achieve energy balance as limited by thermodynamics.

Energy input must equal energy output, which is measured as metabolic rates of basal metabolism, activity, diet-induced thermogenesis, and production

Because energy cannot be created or destroyed, energy input *must* equal energy output (heat plus storage), as represented by the following equation (where E = energy):

$$E_{\text{input}} = E_{\text{output}}$$

Metabolic Rate and the “Animal Energy Equation” In the balance equation above, *output* energy (expenditures used for external and internal work) is generally measured as the

rate at which energy is expended. This is broadly termed the **metabolic rate**:

$$\text{Metabolic rate} = \frac{\text{energy expenditure}}{\text{unit of time}}$$

Rather than simply using internal and external work, physiologists break this rate into specific major expenditures, in what might be called “*the animal energy equation*”:

$$E_{\text{input}} - E_{\text{loss}} = E_{\text{SMR/BMR}} + E_{\text{activity}} + E_{\text{DIT}} + E_{\text{production}}$$

where *input* is the total food energy obtained and *loss* is that portion lost per unit time via feces, urine, skin sloughing, and so forth. Thus, the left side of the equation is *net energy intake*. The other four right-side components—the output expenditures—are as follows:

1. **SMR and BMR** are **standard and basal metabolic rates**. These internal-work expenditures are the “idling speed”: *the minimal amount of energy needed per unit time to sustain waking (nonsleep) life under optimal conditions*.
2. **Activity** energy is the cost per unit time of neuromuscular efforts above the SMR or BMR level. This involves both internal and external work.
3. **DIT** is **diet-induced thermogenesis** (*thermo-*, “heat”; *genesis*, “production”), also called **specific dynamic action (SDA)**, is an increase in metabolic rate above the SMR or BMR level that occurs as a consequence of food intake (internal work).
4. **Production** refers to the rate of energy storage, such as adipose deposition, net growth during development, and reproduction (all internal work). This is the only component that does not rapidly become heat (increasing entropy), but rather decreases entropy as an increase in body mass. However, it can also be negative when a fasting animal taps into its reserves for energy, and so this component effectively becomes energy input for the animal.

We will examine each of these expenditure components in detail, but first, let’s see how metabolic rates are measured.

Methodology The rate of energy use can be measured directly or indirectly.

1. **Direct calorimetry** assumes all energy ends up as heat and involves the cumbersome procedure of placing the subject in an insulated chamber with H₂O circulating through the walls. The difference in the temperature of the H₂O entering and leaving the chamber reflects the amount of heat liberated by the subject and picked up

**FIGURE 15-2** Measuring oxygen consumption by animals.

(a, b) Animals on treadmills, which force an animal to run at controlled speeds. The animal may be fitted with a mask for measuring gases in exhaled breath, or may be in an enclosed chamber from which gases are sampled. calorimetry for determining metabolic rates were developed for widespread use.

- In the **indirect respirometry method**, only the subject's O_2 uptake per unit of time (called the V_{O_2}) is measured, which is a straightforward task in most cases (Figure 15-2). Recall that food energy is liberated with the use of oxygen during aerobic metabolism. Accordingly, a direct relationship exists between the volume of O_2 used and the quantity of heat produced. This relationship also depends on the type of food being oxidized, with the following average values, known as the *physiological fuel values*:

Carbohydrates: $4.1 \text{ kcal/g} = 17.1 \text{ kJ}$

Proteins: $4.3 \text{ kcal/g} = 17.9 \text{ kJ}$

Fats: $9.3 \text{ kcal/g} = 38.9 \text{ kJ}$

An estimate, the **energy equivalent of O_2** , can be made of the quantity of heat produced per liter of O_2 consumed, using the animal's typical diet. For a typical human in North America, for example, the average is 4.8 kcal (20.0 kJ) per liter of O_2 consumed. Thus, in determining metabolic rate, a simple measurement of O_2 consumption can be used to reasonably approximate heat production by multiplying by this factor. However, for nonhuman animals the composition of the diet may not be easily obtained; thus, (1) metabolic rates may be reported simply as liters of oxygen consumed per unit time, or (2) an estimate may be made using the **respiratory quotient (RQ)**, the ratio of CO_2 produced to O_2 consumed. This requires measurements of carbon dioxide production (V_{CO_2}), an increasingly common technique. The RQ varies depending on the foodstuff consumed. When carbohydrate is being used, the RQ is 1; that is, for every molecule of O_2 consumed, one molecule of CO_2 is produced:

For fat use, the RQ is 0.7; for protein, it is 0.8. Using the RQ and the physiological fuel values, an energy equivalent of O_2 can be closely estimated. (Note that a slight correction is necessary to convert gas volumes to moles: 1 mole of $O_2 = 22.39 \text{ L}$, whereas 1 mole of $CO_2 = 22.26 \text{ L}$.)

On a diet consisting of a mixture of these three nutrients, resting O_2 consumption in a human averages about 250 mL/min, and CO_2 production averages about 200 mL/min, for an average RQ of 0.8:

$$RQ = \frac{CO_2 \text{ produced}}{O_2 \text{ consumed}} = \frac{200 \text{ mL/min}}{250 \text{ mL/min}} = 0.8$$

Measurement of RQ in a newly hatched or migrating bird or in a diving seal reveals a value closer to 0.7, indicating their reliance on fats during these energy-

by the H_2O as it passes through the chamber. Even though this method provides a direct measurement of heat production, it is not practical, because a calorimeter chamber can be costly, particularly for large animals. Therefore, other more practical methods of **indirect**

intensive activities. Conversely, because carbohydrates yield more energy per O_2 consumed, it is thought that high-altitude animals rely more on carbohydrate than fat compared to low-altitude relatives. Marie-Pierre Schippers and colleagues recently verified this for the Andean leaf-eared mouse.

3. The **doubly labeled water** method is another form of indirect calorimetry, in which animals (often captured in the wild) are given $D_2^{18}O$, water made from heavy hydrogen (deuterium D) and the oxygen isotope ^{18}O . Deuterium is eliminated from the body as water (D_2O), but ^{18}O is eliminated as both water ($D_2^{18}O$) and $C^{18}O_2$. Researchers measure the difference between the elimination rates of each, calculate CO_2 production rate, and convert it into energy expenditure using the RQ . This is the method used to measure **field metabolic rate (FMR)**, an average metabolic expenditure over the time of the analysis.

Now let's see how respirometry is used to measure minimal metabolic rates. An animal's metabolic rate varies, depending on a variety of factors, such as genetics, external temperature, exercise, food intake, shivering, and anxiety. To determine the minimal energy requirements for survival, metabolic rate must be measured under standardized conditions established to control the variables that can alter rate. It is measured under the following specified conditions:

1. To eliminate any nonresting muscular exertion, the animal should be quiescent and should have refrained from muscular activity for some time. (Note that metabolic rate during sleep is lower than the minimal rate as defined here.)
2. The animal should have minimal anxiety or stress levels. Stress usually increases metabolic rates in vertebrates; this is due to secretion of epinephrine, which increases heart rate (p. 416). For many animals this necessitates an acclimation period to laboratory conditions prior to the actual measurement. This factor has not been well studied.
3. The animal should not have eaten any food within an appropriate amount of time before the rate determination, to avoid diet-induced thermogenesis (DIT).
4. There should be no elevated energy costs of reproduction, such as pregnancy, egg brooding, lactation, or seasonal gamete production.
5. The measurement should be performed at an optimal temperature for that organism.

Regarding point 5, recall that animals fall into two broad categories of thermal adaptation: **ectotherms** (such as amphibians), which depend on external heat for their body temperatures, and **endotherms** (such as mammals), which use internal heat to regulate body temperatures (these are discussed in detail later in this chapter). Because of this difference, there are two types of this minimal metabolic rate:

- **Standard metabolic rate (SMR)** is an ectotherm's resting metabolic rate at a particular temperature, which may be the average temperature experienced naturally, the temperature the animal prefers if given a choice, or any temperature within its normal range. SMR values usually change dramatically with temperature, and thus the temperature of the test conditions must be reported.
- **Basal metabolic rate (BMR)** is an endotherm's resting metabolic rate in its **thermal neutral zone (TNZ)**, a

range of external temperatures that do not induce thermoregulatory processes by the animal. For example, the TNZ for lightly clothed humans lies around so-called room temperature. In the TNZ, there is no shivering, significant sweating, or other thermoregulatory processes that would raise the metabolic rate. (See TNZ later, p. 748.)

Measurements of BMR/SMR are difficult to make, and any exceptions to the conditions just listed must be reported. Another term is used if measurements are made under less-controlled conditions: the **resting metabolic rate (RMR)**, the rate of a quiescent animal in which all the strict conditions are not met. RMR values are typically 10 to 25% higher than the BMR but are often used because measurements in a controlled laboratory with all of the strict conditions are not always practical.

Let's now look at the four expenditure components in detail, beginning with $E_{\text{production}}$.

Energy of production determines net energy balance

The production component ($E_{\text{production}}$) leads to the concept of energy balance, the factor that determines whether an animal will be at a stable weight, losing weight, or gaining weight, and whether that individual is maintaining a mass* that is optimal or is over- or underweight. For example, gaining significant mass is normal in juvenile growth and in hibernators laying down internal stores for the winter, but in other cases it leads to **obesity**, defined as having a body mass that is high enough to impair health. Conversely, starvation in famines, as may occur in overpopulated deer, may lead to health-threatening low body mass. Thus, understanding of energy balance is of great importance not only for human health but also for health of all animals, domestic or wild. There are three possible states of balance:

- **Neutral energy balance.** If the net amount of energy in food intake (input minus losses) exactly equals the amount of energy expended (output) other than production, then body mass remains constant ($E_{\text{production}} = 0$).
- **Positive energy balance.** If the net energy intake exceeds the amount of nonproduction energy expended, and the extra energy taken in is not used immediately, but is stored (a for example, fat stored in adipose tissue or a growing fetus), then body mass increases ($E_{\text{production}}$ is positive).
- **Negative energy balance.** Conversely, if the net energy intake is less than the body's immediate nonproduction energy requirements, the animal must use its stored energy to supply energy needs, and, accordingly, body mass decreases ($E_{\text{production}}$ is negative).

Thus, the other expenditures—BMR/SMR, activity, and DIT—determine whether there is sufficient energy left over from net intake for production. Let's look at BMR/SMR next.

*Note that *mass* is a measure of the amount of material in an object, with units in grams. *Weight* is popularly used in the same way, but actually, it is the gravitational force acting on a mass, in units of newtons. We will generally use *mass* except for terms like *overweight*.

BMR and SMR are regulated in part by thyroid hormones

The BMR or SMR is not a constant for a species; for example, it can vary between individuals, life stages, and sexes. We do not know all of the factors that regulate the rate of BMR and SMR, but in vertebrates, thyroid hormones (p. 301) are the primary (though not sole) determinant: As thyroid hormones increase, the SMR or BMR increases correspondingly. For example, in an experiment on Western fence lizards (*Sceloporus occidentalis*), SMR fell 31% in animals with their thyroids removed, and SMR was restored to normal by injections of thyroid hormone (T_4) (p. 298). Other factors include stress production of epinephrine, which also increases metabolic rate.

Recent research has found that *bile acids*, which are released during fat digestion (p. 686), bind to receptors on adipose cells in mice and skeletal muscle in humans. The receptors activate a gene for an enzyme (deiodinase) that converts the inactive T_4 into the biologically active T_3 (p. 301). In this way, consuming excess fat may temporarily lead to increased basal metabolic rates.

BMR and SMR scale with body mass

BMR and SMR can also differ considerably among species; in particular, endotherms have much higher BMRs than the SMRs of ectotherms. We will examine this later in the section titled Thermal Physiology. Here we examine the phenomenon of *scaling*. As discussed in previous chapters (e.g., pp. 10, 155, 414, 505, and 601), some physiological features depend on the size of organisms because of scaled factors such as surface area and volume. Perhaps the most consistent, yet controversial, scaling relationship is that between BMR or SMR and body mass. Numerous studies have found that although larger animals certainly consume more energy than smaller animals (Figure 15-3a), they have lower metabolic rates *per unit mass* than smaller ones (Figure 15-3b). Basically, a gram of elephant costs much less energy to maintain than a gram of shrew!

The actual scaling factor (the rate at which metabolism changes with body size) is found by plotting the BMR values for whole animals against their body masses on a log–log plot (Figure 15-3a). A straight line with a positive slope is obtained, with the following formula:

$$M = aW^b$$

where M is metabolic rate, a is the metabolic rate per unit mass (usually rate per kg), W is the body mass, and b is the slope. Again, this plot shows that larger animals do use more energy. But the slope (b) is always less than 1, which signifies the lower metabolic rates (per unit mass) of larger animals (if b were 1, then all animals would use energy at the same rate per unit mass). In fact, for mammals, a *consistent slope (b) of about 0.75 (3/4)* has been obtained in numerous studies. Similar scaling is found for birds, again with a slope between 0.7 and 0.8. Other physiologic and anatomic features also scale to body mass with slopes of about 0.75, such as alveolar surface area (see p. 509).

Scaling and Thermoregulation Following the discovery of the 0.75 scaling by Max Kleiber in 1932, a widely accepted hypothesis was generated: Scaling reflects properties of the

ratio between surface area and volume with respect to temperature regulation by endotherms. The argument goes as follows: (1) Surface area increases as the square of the radius, whereas volume increases as the cube; therefore, smaller organisms have a higher ratio of surface area to volume (see Figure 1-4). Due to the square-cube difference, area/volume ratio scales by a power of $2/3$ (0.67), at least for spheres. (2) Endotherms produce heat by their volumes (mass) and lose it from their surface areas. (3) Therefore, a smaller endotherm must have a higher metabolic rate per unit mass to compensate for its higher rate of heat loss (via surface area). In fact, as this hypothesis predicts, metabolic rates within a single mammalian species do often scale with size by a factor of 0.67.

This hypothesis makes perfect physical sense, but it has two major flaws. First, the hypothesis predicts that BMR will scale with a slope of about 0.67, but instead a slope of 0.75 has been repeatedly found among species. Second, other studies have reported that ectotherms such as non-avian reptiles and fishes (and even unicellular organisms) have SMRs that scale by factors less than 1.0 (see Figure 15-3c for insects, showing a slope of 0.825). The hypothesis is irrelevant to most of these organisms, because most do not generate (and retain) body heat for the purposes of thermoregulation. So why does metabolism scale with an apparent $3/4$ factor among endotherms, and by slopes of less than 1 in animals in general? Neither of these flaws has been satisfactorily explained. See *Challenges and Controversies: A Universal Scale of Life?* (p. 722) for recent hypotheses.

Increased muscle activity is the factor that can most increase metabolic rate, as indicated by metabolic scope

The next expenditure category is neuromuscular *activity*. Expressed primarily as locomotion powered by skeletal muscles (external work) and breathing by respiratory muscles and circulatory flow from the heart (internal work), this is potentially the greatest energy usage for an animal, at least for short periods of time. Even slight increases in muscle tone notably elevate metabolic rate, and metabolic rates can increase manyfold during extreme activity. Table 15-1 shows examples for a human and a hummingbird. Note that the rates for the bird are much smaller than for the human, as befitting the bird's much smaller size. However, if we compare these animals on a per-kg basis, a very different perspective is found. The human marathon runner expends about 77 kJ/hr per unit kg, but the hovering hummingbird expends about 870! This is thought to be the maximum possible for vertebrate muscle (see the Suggested Reading by Suarez). And yet, the metabolic rate of a flying honeybee can be at least three times that of the hummingbird.

Metabolic Scope A convenient indicator of an animal's activity capacity is the ratio of metabolic rate at its highest level to the BMR or SMR—the **metabolic scope**. For example, the ratio for a human marathoner is about 17 (1,300/77 in kcal/hr, Table 15-1). **Aerobic scope** values are derived from activity measured using oxygen consumption. This has been done for many animals, using laboratory devices such as treadmills, wind tunnels, and water flumes (Figure 15-2). Aerobic scope values for terrestrial vertebrates (including

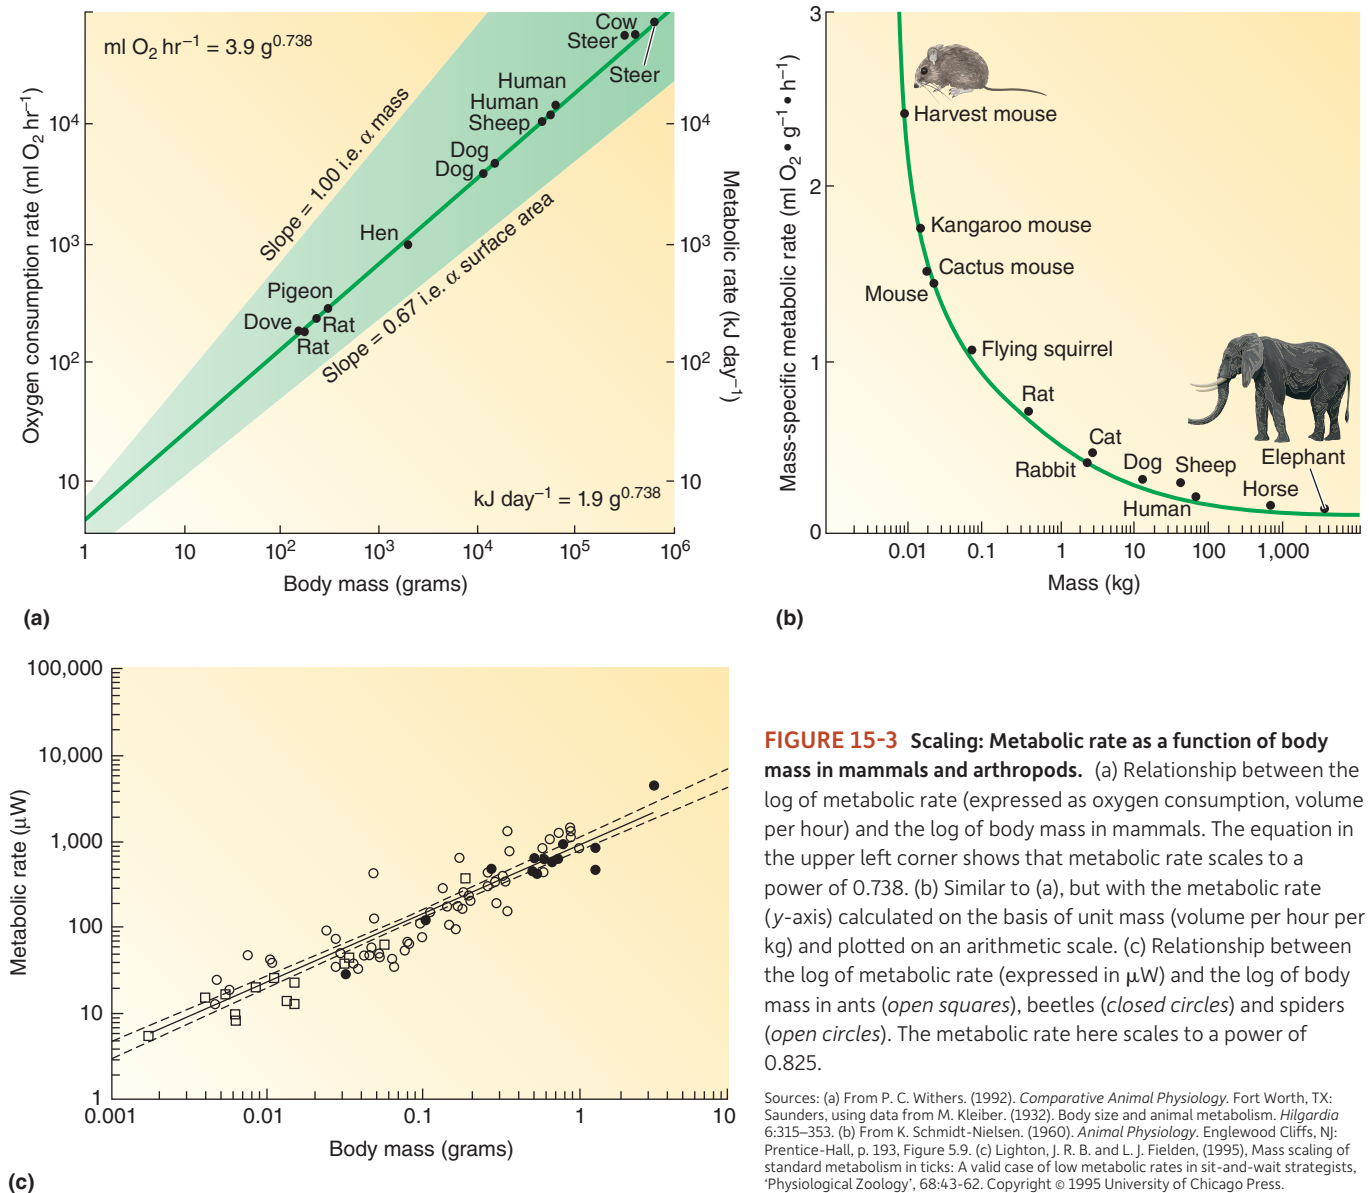

FIGURE 15-3 Scaling: Metabolic rate as a function of body mass in mammals and arthropods. (a) Relationship between the log of metabolic rate (expressed as oxygen consumption, volume per hour) and the log of body mass in mammals. The equation in the upper left corner shows that metabolic rate scales to a power of 0.738. (b) Similar to (a), but with the metabolic rate (y-axis) calculated on the basis of unit mass (volume per hour per kg) and plotted on an arithmetic scale. (c) Relationship between the log of metabolic rate (expressed in μW) and the log of body mass in ants (open squares), beetles (closed circles) and spiders (open circles). The metabolic rate here scales to a power of 0.825.

both ectotherms and endotherms) fall in the range of about 5 to 40, following a scaling pattern. That is, whole-animal aerobic metabolic rate can be elevated above the basal level by a factor of about 5 to 10 for a small vertebrate like a hummingbird, up to 24-fold in human medium-distance runners and cross-country skiers, and 40 or more in large mammalian runners like horses. In contrast, for some flying insects, the aerobic scope factor can be over 100!

Why is aerobic scope limited to the 5 to 40 range for so many vertebrates? The limit appears to be the delivery of oxygen by the circulatory system. There seems to be a strict limit to the rate of pumping through a network of narrow vessels. The values for some insects show that the insect respiratory system, with trachea that carry oxygen directly to muscles, may be much more effective (although limited by body size; see p. 505).

Locomotory Costs and Speed Metabolism during locomotion generally increases with speed, as you would expect,

but there are some interesting exceptions. For running mammals, the increase in metabolism is roughly linear with velocity (Figure 15-4a). For a swimming fish, the cost increases exponentially as drag from the environment begins to have more and more effect (Figure 15-4b) because water is so much more dense than air. Flight energetics show varying patterns: In some species, metabolic rate is independent of speed at medium to high levels, whereas in others metabolism actually *decreases* at medium speeds (Figure 15-4c). This is because at low speeds much energy is needed to overcome gravity when a bird is first ascending from a perch. Once airborne at medium speeds, a bird can save energy by *gliding*, using its forward momentum to generate lift with its wings to stay aloft. (Bird wings have an *aerofoil* shape: flat or slightly concave on the bottom and curved on the top so that air moving over the wing must travel a greater distance across the top than it does across the bottom. This creates negative pressure (lift) on the top relative to the bottom, drawing the wing up.)

Challenges and Controversies

A Universal Scale of Life?

Why is metabolism not linearly proportional to body mass? As discussed in the main text, the primary hypothesis has focused on heat and ratios of surface area to volume. But these do not explain why a relationship scaled to a $3/4$ power rather than a $2/3$ power is found among many forms of life. Indeed, some scientists have claimed that the $3/4$ power applies to all life from microbes to trees, and in some sense must represent a universal phenomenon of life. Because the heat loss hypothesis (see main text) cannot apply to ectothermic organisms, several other hypotheses have been generated. One of these might be called the *four-dimensional* or *fractal transport* hypothesis. Three researchers (Brian Enquist, James Brown, and Geoffrey West) noted that all organisms require a means of transporting and distributing internal nutrients, gases, and wastes. In multicellular organ-

isms, this usually involves networks of increasingly finer branching tubes, such as blood vessels, tracheae, and xylem (in plants). The researchers showed that any network that maximizes the packing of two-dimensional tubular surface areas in a three-dimensional space scales to a $3/4$ power. After joining the team, Jamie Gillooly showed that factoring in temperature could account for the fact that colder organisms have scaling lines that fall below the lines of warmer organisms. These ideas lead to their Metabolic Theory of Ecology, which states that temperature and metabolic rate govern most interactions and patterns in ecosystems.

This is the first hypothesis that seems to apply to many different kinds of organisms, and is thus attractive. But critics have pointed out that BMR is not limited by transport systems, because those systems

are only pushed to their limits at maximal metabolism. Also, some researchers are not convinced that all life forms follow the $3/4$ scaling pattern; for example, some ectotherms show scaling slopes considerably different from 0.75 (see Figure 15-3c). Moreover, recent studies have found that the slope varies among taxonomic groups from 0.4 to 1.0; the slope tends to be near 0.6 for smaller vertebrates and 0.87 for larger ones. Another study suggested that the true slope for mammals is actually close to 0.67, with the 0.75 value arising from large herbivores whose prolonged digestive processes (DIT) yield laboratory measurements of MR that are not true BMRs. Regardless, it does appear that larger organisms are more efficient than smaller ones. But the causes are likely to remain controversial for many years.

Finally, changes in **gait** (modes of limb use during locomotion) can alter the linear pattern. As you learned in Chapter 8, most terrestrial vertebrates have elastic tendons in their legs that can store energy each time a leg hits the ground. This energy can be released on the next step, so that much of the energy required to lift the limbs is not wasted. Horses also have tendons in their backs, which come into play during a gallop gait. The ultimate example is found in hopping kangaroos and wallabies, which have been found to have no increase in metabolism as they increase hopping velocity (although they do show the expected linear increase while walking). See Figure 15-4d, and p. 358 for details.

Actual metabolic rates during locomotion (as well as scope) are scaled with body size, so that larger animals use less energy per unit body mass to cover a given distance than do smaller animals (Figures 15-4a and b). That is, it costs much less to move a gram of dog than a gram of mouse the same distance. This appears to be true of insects as well as vertebrates. It is not readily apparent why this should be, although one of the current hypotheses to explain scaling suggests that it may reflect the scaling of oxygen delivery (see *Challenges and Controversies: A Universal Scale of Life?*).

Diet-induced thermogenesis occurs after eating in most animals

The third energy-expenditure category is *diet-induced thermogenesis* (DIT; or *specific dynamic action*, SDA), which manifests as a rise in metabolism and heat production for several hours after eating. DIT has two components.

1. **Obligatory DIT** is the result of the increased metabolic activity associated with the costs of obtaining and processing food, that is, gut motility, production of gut se-

cretions, nutrient uptake, biosynthesis of proteins, glycogen stores, and lipids, and excretion of wastes.

2. **Regulatory DIT** is increased heat production after a meal, largely for the purpose of removing excess nutrients, for example, “burning off” excess calories ingested (p. 729).

Obligatory DIT has been found in all phyla of animals tested; regulatory DIT has historically been studied in endotherms but may also occur in many types of animals. We examine the role of regulatory DIT in body mass control shortly.

Although the exact costs involved with DIT are not all certain, there are clear patterns. Within an individual, large and/or hard-to-digest meals induce a greater DIT than small and/or readily digested meals. Species differences are diverse; for example, DIT reaches a peak within a few hours in most endotherms, but it takes up to several days in sluggish ectotherms such as seastars. The extent of DIT also varies; for instance, humans show an increase of up to 50% in metabolism after a large meal, whereas other mammals, ectothermic vertebrates, and insects may exhibit 100% to 800% increases or more. The record may be held by the Burmese python, which shows a 4,400% increase in metabolism after swallowing a rodent! This animal (and other snakes that eat large, infrequent meals) actually undergoes *atrophy* of its digestive organs in between meals, presumably to save energy. This down-regulation is manifested as lower liver and intestinal masses and lower density of nutrient transporters in the intestine (see p. 692). Then, on ingesting its large but infrequent prey item, the snake restores all these atrophied features in concert with the movement of the load through the respective regions of the digestive tract. This up-regulation accounts for the enormous DIT.

Now that we have examined the details of energy balance and its components, we turn to its regulation.

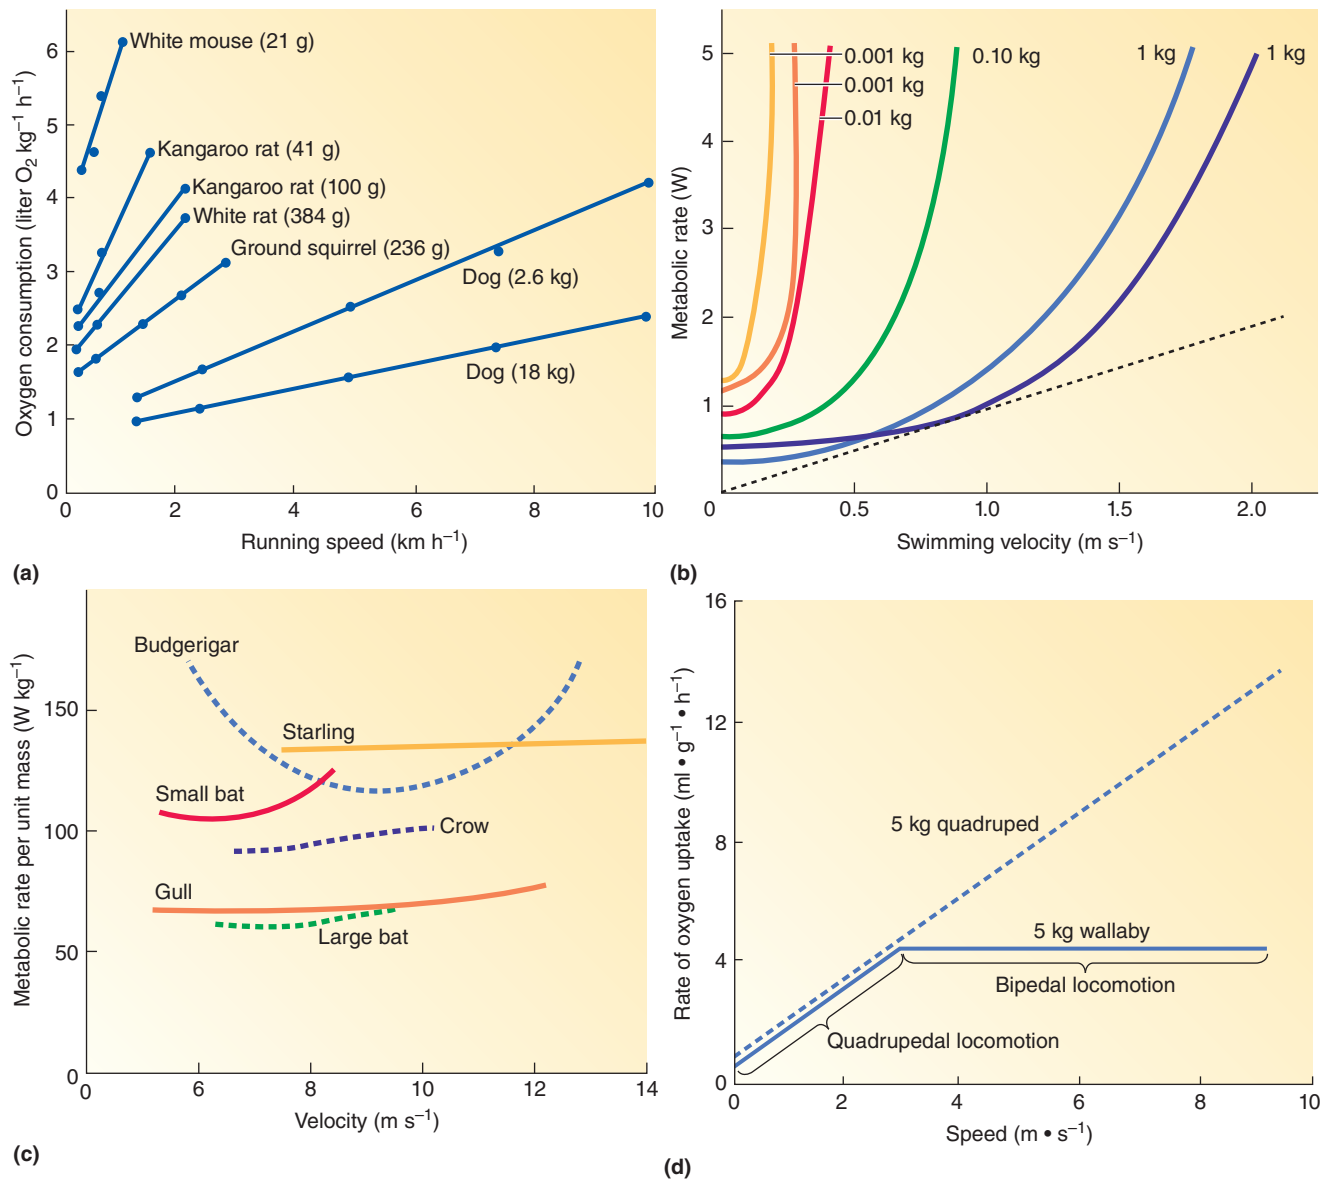

FIGURE 15-4 Metabolic rates (measured as oxygen consumption) as a function of animal locomotory speed. (a) Metabolic rates (per body mass) for running terrestrial mammals. Rate increases linearly with speed, with costs being higher in smaller mammals. (b) Metabolic rate (per whole animal) for a swimming fish. Rate tends to increase exponentially with speed. (c) Metabolic rate (per body mass) for flying birds and bats. A decrease in rate is seen at intermediate speeds due to gliding in some species. (d) Metabolic rate (per body mass) for a wallaby. When the animal uses all four limbs (quadrupedal locomotion), the rate increases linearly, as in part (a). But after the animal switches to bipedal hopping at higher speeds, rate becomes independent of speed.

15.3 Energy Balance: Regulation

Some adult animals maintain long-term neutral energy balance, while others undergo regulated periods of positive or negative energy balance

Physiologists have observed that many adult mammals, including humans, maintain a fairly constant mass (weight) over long periods of time. This implies that homeostatic mechanisms (with a set point) exist to maintain a long-term balance between energy intake and energy expenditure. Moreover, individuals may have different set points for body masses (you may have noticed that some humans stay lean no matter how much they eat, whereas other, overweight humans have great difficulty losing weight).

Conversely, periodic changes in body mass are adaptive in some animals. For example, hibernators (such as a marmot, Figure 15-5a) typically increase their body mass greatly during active (feeding) seasons and decrease during hibernation as they live off of their internal energy stores. Migratory birds may similarly gain and lose mass during premigration feeding and the migration itself, respectively. Reproductive

periods such as pregnancy also include periods of mass increases followed by decreases. Finally, long-term balance is not maintained in some adult animals; for example, many adult fish indefinitely grow larger if food supplies permit (see Chapter 7, pp. 291–292).

To achieve either a constant body mass (with the exception of minor fluctuations caused by changes in H₂O content) or adaptive changes in mass as in a hibernator, there must be regulatory mechanisms to control some or all components of the animal energy equation. How does this occur? There must be *sensors* to detect energy status, an *integrator* to receive and process energy information, *effectors* to make adjustments, and appropriate *signal mechanisms* among these components. Energy regulation has been most thoroughly studied in mammals, on which we focus this discussion. We begin with the integrator component.

Food intake in mammals is controlled primarily by the hypothalamus in response to numerous inputs

In mammals, control of food intake—the input side of the animal energy equation—has been found to be a function of a pair of **feeding**, or **appetite**, **centers** and another pair of **satiety centers**. These integrators are located in the **arcuate nucleus** of the hypothalamus, an arc-shaped collection of neurons located adjacent to the floor of the third ventricle. The functions of these areas have been elucidated by a series of experiments that involve either destruction or stimulation of these specific regions in laboratory rats. Stimulation of the clusters of nerve cells designated appetite centers makes the animal hungry, driving it to eat voraciously, whereas selective destruction of these areas suppresses eating behavior to the point that the animal starves itself to death. (Note that eating is a behavioral effector, a point we'll return to later on p. 728.) In contrast, stimulation of the satiety centers signals satiety, or the feeling of having had enough to eat. Consequently, the stimulated animal refuses to eat, even if previously deprived of food. As expected, destruction of this area produces the opposite effect—profound overeating and obesity—because the animal never achieves a feeling of being full (Figure 15-5b). Thus, the feeding centers tell animals when to eat, whereas the satiety centers tell them when they have had enough.

Although it is convenient to consider these specific areas as direct regulators of feeding behavior, this approach is too simplistic. Physiologists now know that complex systems and numerous signals provide information about the body's energy status. Recent studies have uncovered multiple, highly integrated, redundant pathways, crisscrossing into and out of the hypothalamus, that are involved in controlling food intake and maintaining energy balance. Integration of multiple molecular signals ensures that effector feeding behavior is synchronized with the body's immediate and long-term energy needs. Let's examine these, beginning with a closer look at the hypothalamic integrator.

Arcuate Nucleus: The Integrator The arcuate nucleus has two subsets of neurons that function in an opposing manner. One subset releases *neuropeptide Y*, and the other releases *melanocyte-stimulating hormones (MSHs)* derived from *pro-opiomelanocortin (POMC)*, a precursor molecule

(a)

(b)

FIGURE 15-5 “Fat” mammals. (a) The hoary marmot (*Marmota caligata*) of western North America. This heterotherm must build up large deposits of fat before winter, when it hibernates. (b) Comparison of a normal rat with a rat whose satiety center (in the hypothalamus) has been destroyed. Several months after destruction of the classical satiety center in the ventromedial area of the hypothalamus, the rat on the right had gained considerable mass as a result of overeating compared to its normal littermate on the left. Rats sustaining lesions in this area also display less grooming behavior, accounting for the soiled appearance of the fat rat.

(a) Paul Yancey, (b) Wilbert E. Gladfelter, Ph.D., Department of Physiology, School of Medicine, West Virginia University

that can be cleaved in different ways to produce several different hormones (see p. 271). **Neuropeptide Y (NPY)**, one of the most potent appetite stimulators ever found, leads to increased food intake, thus promoting mass gain. MSHs, a group of hormones known to be important in regulating skin color in some species (see p. 284), have been shown to exert an unexpected role in energy homeostasis in mammals. Most notably **α melanocyte-stimulating hormone (α -MSH)** suppresses appetite, thus leading to reduced food intake and mass loss.

Beyond the Arcuate Nucleus: Orexins and Others NPY and α -MSH are not the final signals in appetite control. These arcuate-nucleus chemical messengers, in turn, influence the release of neuropeptides in other parts of the brain that exert more direct control over food intake. Scientists are currently trying to unravel the other factors and regions that act upstream and downstream from arcuate nucleus to regulate appetite. Two such regions in the hypothalamus have been found to be richly supplied by axons from the NPY- and MSH-secreting neurons of the arcuate nucleus. These areas are the **lateral hypothalamic area (LHA)** and **paraventricular nucleus (PVN)**. In a recently proposed model, the LHA and PVN release chemical messengers in response to input from the arcuate nucleus neurons. These messengers act downstream from the NPY and α -MSH signals to regulate appetite. The LHA produces two closely related neuropeptides known as **orexins A and B**, which are potent stimulators of food intake (*orexis* means “appetite”). NPY stimu-

lates and α -MSH inhibit the release of orexins, thus regulating appetite and food intake. However, orexins (which are produced in a circadian rhythm) also increase wakefulness and physical activity, so are not committed to mass gain. By contrast, the PVN releases neuromodulators, for example, **corticotropin-releasing hormone (CRH)**, that decrease appetite and food intake. (As its name implies, CRH is better known for its role as a hormone; see p. 289.)

The release of all of these brain regulators requires sensory input that “informs” the hypothalamus of the body’s energy status for both long-term maintenance of energy balance and the short-term control of food intake. Let’s next look at the key input signals based on current research (Figure 15-6).

Leptin and insulin are signals of long-term energy balance

Scientists’ notion of fat cells (**adipocytes**) in adipose tissue as merely storage space for triglyceride fat underwent a dramatic change late in the last century with the discovery of their active role in energy homeostasis. Adipocytes secrete several hormones, collectively termed **adipokines**, that play important roles in energy balance and metabolism. Thus, adipose tissue is now considered an endocrine gland. For example, **adiponectin** increases sensitivity to insulin (which helps protect against Type II diabetes mellitus), decreases body mass, and exerts anti-inflammatory actions. Unfortunately, obesity suppresses adiponectin secretion. Here we

Molecular Biology and Genomics

Discovering the Obesity Gene

The discovery and characterization of the leptin gene in 1994 by Jeffrey Friedman illustrates the importance of genetics to physiology. Physiologists had known for decades that obesity has a genetic component because different animal individuals on the same diets could have very different—and stable—body masses, with an apparent set point that could vary widely among individuals. Furthermore, the propensity for obesity could be passed from one generation to the next. Manipulations of the hypothalamus showed appetite was controlled in that brain region. Researchers widely suspected that mammalian bodies must have feedback signals that would tell the hypothalamus about the energy status of the body.

But physiologists had no luck finding such a signal. Enter the geneticists in the 1980s. By then, several strains of obese mice were established, including the *ob* strain, weighing about three times more

than other mice. After eight years of genetic breeding and cloning experiments, Friedman and his colleagues showed that obesity was due to the functional absence of a single gene, dubbed the *ob* gene. They isolated and cloned the normal *ob* gene (in non-*ob* mice), and subsequent work showed that it codes for the protein hormone leptin, which has turned out to be one of the key energy signals in mammals. Without modern genetic methods, this might never have been discovered.

Using genome analysis and antibody detection, researchers have found leptin in most other vertebrates (reptiles including birds, and fishes). Leptin in broiler chickens is produced not only by adipose but also by liver tissue. The discovery of chicken leptin is being used to investigate methods for obesity control in these animals! Broiler chickens, as a source of human food, have been bred for maximal growth, but this has

produced obese parent birds with low reproductive rates. For this reason, these birds are placed on restricted diets from an early age: Even so, both egg production and fertility dramatically decline with age. Researchers hope to manipulate leptin concentrations to reduce adipose stores while enhancing lean meat production.

Leptin-related genes and proteins have been studied in a reptile (the fence lizard *Scolecopus undulatus*) and a fish (the green sunfish *Lepomis cyanellus*). As in mammals, fasting sunfish have lower levels of plasma leptin than fed sunfish. Injecting mouse leptin into these animals induced effects similar to that seen in mammals: The injected lizard raised its body temperature slightly and its RMR by 250%, and showed a reduced appetite, whereas the injected sunfish began to metabolize its adipose stores. Thus, leptin is an ancient vertebrate signal of energy balance.

will focus on **leptin** (*leptin*, “thin”), an adipocyte hormone essential for normal body-mass regulation in mammals. As a sensory process, the amount of leptin in the blood informs the brain of the total amount of triglyceride fat stored in adipose tissue: That is, the larger the fat stores, the more leptin released into the blood. This bloodborne signal, discovered in the mid-1990s by genetic analysis of obese laboratory mice, was the first molecular satiety signal found by genetics (see *Molecular Biology and Genomics: Discovering the Obesity Gene*).

The arcuate nucleus is the major site for leptin action. Acting in negative-feedback fashion, increased leptin from burgeoning fat stores serves as a “trim-down” signal. Leptin suppresses appetite, thus decreasing food consumption and promoting mass loss, by inhibiting hypothalamic output of appetite-stimulating NPY and stimulating output of appetite-suppressing α -MSH. Conversely, a decrease in fat stores and the resultant decline in leptin secretion bring about an increase in appetite, leading to mass gain. The leptin signal is generally considered the dominant factor responsible for the long-term matching of food intake to energy expenditure so that total body energy content remains balanced and body mass remains constant.

Interestingly, leptin has recently been shown to also be important in reproduction, for example, as one of the triggers for the onset of puberty through its effects on *kisspeptin* neurons (see p. 798). The importance of its role in energy balance, and how that affects survival, was shown in recent experiments on Siberian hamsters. Susannah French and colleagues used a pump to infuse leptin into pregnant hamsters to keep the hormone artificially high. These mothers had

significantly more offspring than mothers with a placebo treatment. Apparently, the treatment tricked the hypothalamus into “thinking” that energy was in excess, so the mother’s body diverted more energy to the growing embryos. But, following the principles of energy balance, this came at a cost: The treated mothers had weakened immune responses and were more prone to bacterial infections.

Leptin may also be involved in the annual cycle of hibernating mammals such as Arctic ground squirrels, animals that do not maintain constant mass year-round because they must store up large adipose deposits in the productive seasons and survive on them in the winter. Some studies suggest that the brain ignores leptin signals in the autumn, allowing the animals to gain mass, whereas during the winter hibernation, the high leptin output of the stored fat effectively suppresses appetite.

Another bloodborne signal besides leptin that plays an important role in long-term control of body mass is **insulin**, a hormone secreted by the pancreas in response to a rise in the concentration of glucose and other nutrients in the blood following a meal (p. 316). It stimulates cellular uptake, use, and storage of these nutrients. Thus, the increase in insulin secretion that accompanies nutrient abundance, use, and storage appropriately inhibits the NPY-secreting cells of the arcuate nucleus, thus suppressing further food intake.

Gastrointestinal Hormones: Signals of Short-Term Energy Balance In addition to insulin’s and leptin’s importance in the long-term regulation of body energy and mass, other factors are believed to play a role in controlling the timing and size of meals. Early proposals suggested that cues of

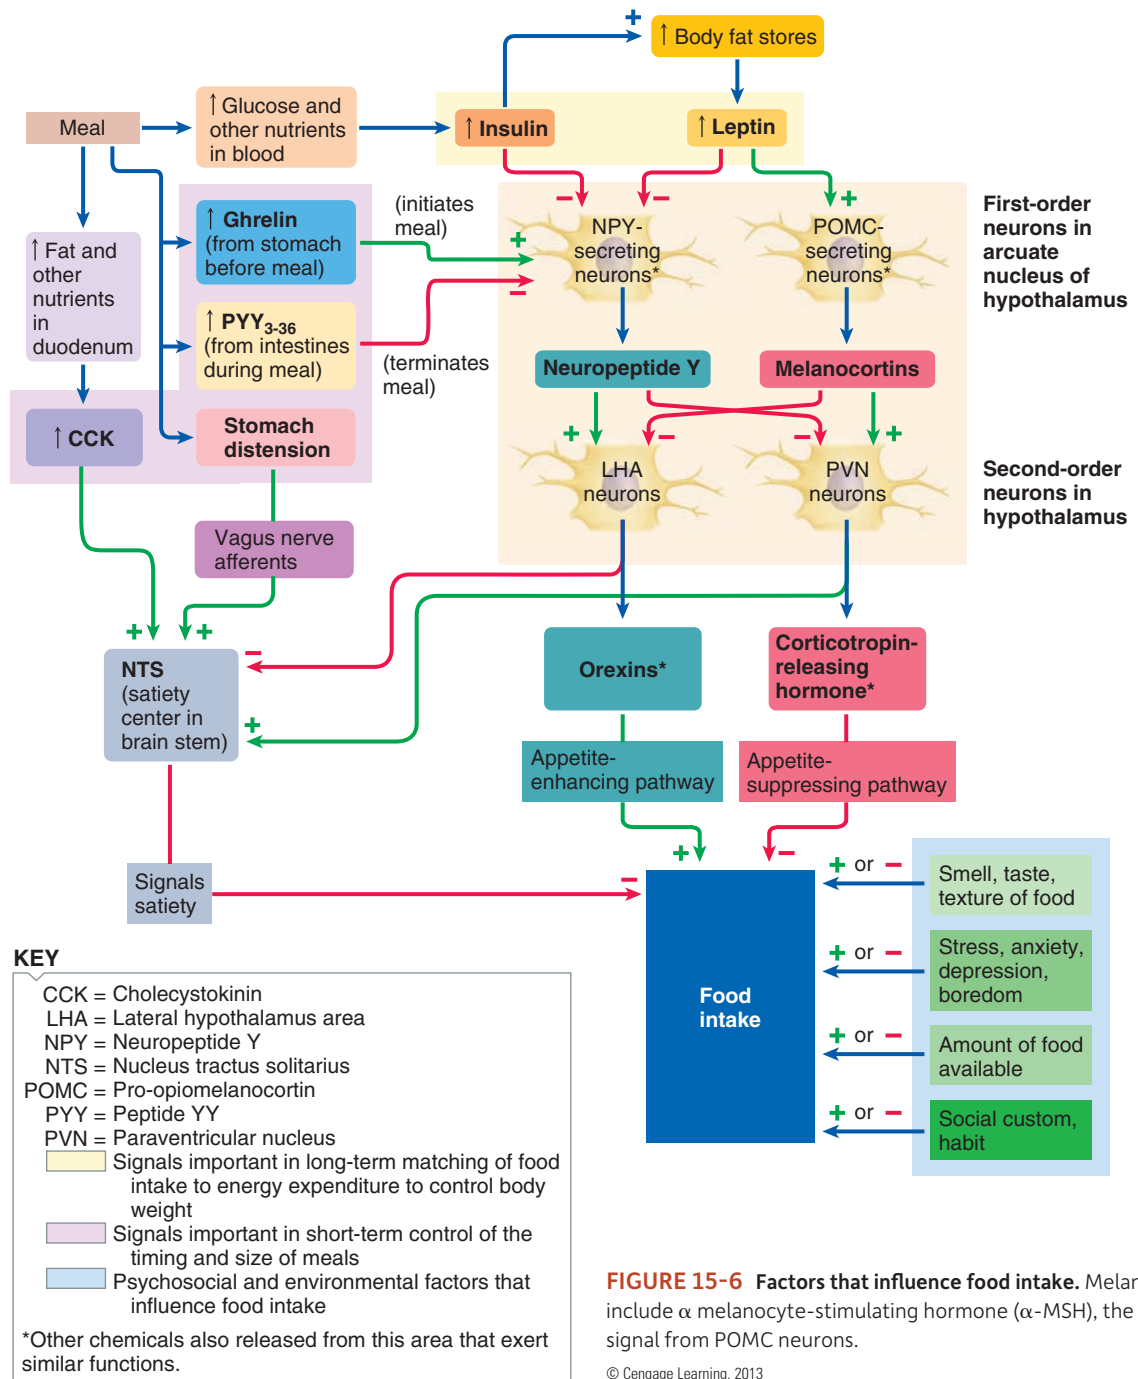

FIGURE 15-6 Factors that influence food intake. Melanocortins include α melanocyte-stimulating hormone (α -MSH), the primary signal from POMC neurons.

© Cengage Learning, 2013

emptiness or fullness of the digestive tract signaled hunger or satiety, respectively. For example, stimulation of gastric stretch receptors has been shown to suppress food intake. However, neural input arising from stomach distension plays a more important role in controlling the rate of gastric emptying than in signaling satiety (see p. 672). Recent studies have found that the digestive tract has food-sensing receptors similar or identical to those in the tongue's taste buds. There is now good evidence that the following internal bloodborne signals reflecting the depletion or availability of energy-producing substances, sensed by the gut, are important in the initiation and cessation of eating.

- **Cholecystikinin (CCK):** One of the gastrointestinal hormones released from the duodenal mucosa during digestion of a meal, CCK is an important satiety signal for regulating the size of meals. CCK is secreted in response to the presence of nutrients in the small intestine. Through multiple effects on the digestive system, CCK facilitates the digestion and absorption of these nutrients (see p. 684). It is appropriate that this bloodborne signal, whose rate of secretion is correlated with the amount of nutrients ingested, also contributes to the sense of being filled after a meal has been consumed but before it has actually been digested and absorbed.

- **Ghrelin, Obestatin, and PYY₃₋₃₆:** Three peptides involved in the short-term control of food intake have recently been identified: *ghrelin*, *obestatin*, and *peptide YY₃₋₃₆* (*PYY₃₋₃₆*). All are secreted by the digestive tract; moreover, ghrelin and obestatin arise from the same gene and its encoded protein, which breaks in half to form them. **Ghrelin** (Hindu for growth), the so-called hunger hormone (p. 712), is a potent appetite stimulator produced by the stomach and regulated by the feeding status. Secretion of this mealtime stimulator rises before and at the onset of meals and stimulates appetite behavior, then falls once food is eaten. Ghrelin stimulates appetite by activating the hypothalamic NPY-secreting neurons. Recent research suggests that ghrelin secretion can be activated indirectly by dietary fats entering the stomach. It may be that ghrelin informs the brain that fat-rich food is entering the gut and so appetite should be increased to take advantage of that food. **Obestatin**, conversely, has been called the “satiety hormone” as it appears to have effects opposite those of ghrelin. However its role in appetite regulation is still unsettled.
PYY₃₋₃₆ appears to be the main antagonist to ghrelin rather than obestatin. The secretion of PYY₃₋₃₆, which is produced by the small and large intestines, is at its lowest level before a meal but rises during meals and signals satiety. This peptide acts by inhibiting the appetite-stimulating NPY-secreting neurons in the arcuate nucleus. By thwarting appetite, PYY₃₋₃₆ is believed to be an important mealtime terminator.

Table 15-2 summarizes the effects of these gastrointestinal signals. These could explain why animals stop eating before the ingested food is actually digested, absorbed, and made available to meet the body’s energy needs. An animal may feel satisfied when adequate food to replenish the stores is in the digestive tract, even though the body’s energy stores are still low. This would help prevent the overshoot phenomenon (in this case, overeating) that characterizes simple negative-feedback systems (p. 16).

Effectors for energy balance are mechanisms to regulate eating and expenditures

The final components of a regulatory system are its effectors. Potentially any or all of the components of the animal energy equation could be regulated. Much remains to be learned about this, but a number of regulatory mechanisms are known. Let’s examine some of these.

Regulation of Food Intake (Eating) On the input side of the equations, you have already seen how eating, the behavioral effector controlled in part by the hypothalamus, is affected by sensory signals such as leptin and ghrelin. Over a 24-hour period the energy in ingested food rarely matches energy expenditure for that day. The correlation between total caloric intake and total nonproduction energy output is strong, however, over long periods of time for animals with long-term neutral energy balance.
However, that balance can be disrupted by psychosocial and other environmental influences. For example, the amount of pleasure derived from eating can reinforce feeding behavior. This has been demonstrated in an experiment in which

TABLE 15-2 Effect of Involuntary Regulatory Signals on Appetite

Regulatory Signal	Source of Signal	Effect of Signal on Appetite
Neuropeptide Y	Arcuate nucleus of hypothalamus	Increases
α-MSH	Arcuate nucleus of hypothalamus	Decreases
Leptin	Adipose tissue	Decreases
Insulin	Endocrine pancreas	Decreases
Ghrelin	Stomach	Increases

Orexins	Lateral hypothalamus	Increases*
Corticotropin-Releasing Hormone	Paraventricular nucleus of hypothalamus	Decreases
Cholecystokinin	Small intestine	Decreases
Stomach Distension	Stomach	Decreases

*Also increases in energy expenditures and wakefulness.

© Cengage Learning, 2013

rats were offered their choice of highly palatable human foods. They overate by as much as 70 to 80% and became obese. When the rats returned to eating their regular monotonous but nutritionally balanced rat chow, their obesity was rapidly reversed as their food intake was controlled once again by physiological drives rather than by urges for the apparently tastier offerings. Stress, anxiety, depression, and apparent boredom have also been shown to alter feeding behavior in ways that are unrelated to energy needs in experimental animals as well as humans. Some types of stress, particularly involving *cortisol* (p. 286), lead to overeating (as if the hypothalamus “thinks” it needs to prepare for future starvation), while other types lead to undereating.
There is no question that regulation of eating is the most important factor in the long-term maintenance of energy balance and body mass. However, in laboratory studies on different strains of rats, genetically lean mice eat as much or more than genetically obese mice while remaining much leaner. Thus, regulation of expenditures (output) must also be important.
Compensatory Changes in Expenditures in Response to Underfeeding Some studies suggest that after several weeks of eating less than normal (e.g., as a result of starvation, or deliberate “dieting” in a human), a mammal may initiate small counteracting decreases in BMR, possibly by reductions in thyroid hormones (p. 301), and/or decreases in muscular activity by uncertain mechanisms. This energy-saving effect partially explains why some humans or laboratory animals on a diet become stuck at a plateau after having shed the first grams easily.

Chronic underfeeding can also lead to suppression or even reversal of production output. For example, starvation (as well as some other stresses) in mammals can lead to lower gonadotropin output and thus reduced spermatogenesis and oogenesis. This may occur in part because declining leptin levels in starvation cause a decrease in the release of *kisspeptin*, a regulator of reproductive hormones (p. 798). Many vertebrates such as rodents and ovoviparous fishes actually reabsorb their internal embryos or fetuses. Some vertebrates will even eat developing eggs (oviparous animal) or newborns. Nonvertebrates also exhibit similar energy-saving reproductive adjustments. Starving aphids, for example, reabsorb their developing oocytes, while starving great pond snails (*Lymnaea stagnalis*) stop producing egg-laying hormone due to reduced neurosecretory output from the brain.

Compensatory Increases in Expenditures in Response to Overfeeding Conversely, physiological processes that “burn off” excess calories account in part for the inability of some mammals (including some humans) to gain much mass despite excessive food intake. These involve regulatory DIT and muscular activity.

1. *Increased regulatory DIT: Uncoupling proteins and brown adipose tissue.* Humans and laboratory mammals have been found to release “unwanted” calories by activating **uncoupling proteins (UCP)** in some tissues. UCPs are channels for protons (H^+) that let the H^+ gradients generated from food energy in mitochondria dissipate, with no ATP synthesis. A major site of UCPs is **brown adipose tissue (BAT)**, which probably evolved as a thermoregulatory organ in small and newborn mammals (as we will discuss later; p. 746). However, BAT can also be activated after a large meal (as regulatory DIT). BAT does not store fats but rather converts available energy in lipids into heat using **UCP-1**, and is now recognized as a major contributor to energy balance. Larger mammals were thought to lose their BAT as they aged, but new research shows that some lean humans have some BAT, while obese humans have little or none. White adipose tissue and skeletal muscle, containing UCP-2 and UCP-3, respectively, appear to be similarly used, and again, lean humans have higher densities of both UCPs than do obese individuals.

BAT is activated by the sympathetic nervous system. Interestingly, the ghrelin system may suppress BAT. Yuxiang Sun and colleagues created two groups of knock-out mice, one lacking ghrelin and the other missing the ghrelin receptor. The latter group, in contrast to the ghrelin knock-out or control animals, did not gain weight on a high-fat diet. The researchers found that BAT, lacking the ghrelin receptor, increased its levels of UCP-1 and thus its ability to “burn off” excess fat. Thus, the normal ghrelin receptor may favor fat storage.

2. *Increased exercise and non-exercise activity thermogenesis.* Muscular activity levels may also be regulated for disposal of excess energy. In humans, involuntary movements called “fidgeting,” like foot tapping, have been found to be more frequent in lean than in heavy individual humans. Lean rodents on a high-fat diet also exhibit purposeless repetitive movements. Such behavior is called **non-exercise activity thermogenesis (NEAT)**

and is regulated by the hypothalamus. Laboratory rodents injected with leptin into blood, or orexin-A into the PVN, show a spontaneous increase in muscular (including NEAT) activity, and either lose more mass or gain less than control animals. In humans, voluntary activities such as exercise are of course well known to contribute to energy balance.

Different energy-balance set points among species result from evolutionary adaptations to different food supplies

Clearly, even though many mammals maintain a relatively constant body mass, species and individuals vary greatly in the mass they actually maintain (as we noted earlier). This has led to the proposal that the hypothalamic centers determining long-term satiety can evolve different *set points* for energy balance, possibly for adipose storage in particular. The two extreme set points are often termed “lean” and “obese” (or “heavy”). Although humans in modern Western societies tend to attach positive and negative connotations to lean and obese states, respectively, physiologists view these in a different light. Both extremes (and set points in between) can be evolutionarily advantageous depending on the environment:

- Lean animals do better in habitats where food is plentiful year-round so that storing a high amount of body fat is unnecessary. The advantage here is that such animals are more agile than heavy ones, better able to avoid predators and (in some species) to obtain food in the first place. Thus, carnivores in the tropics (such as tigers) are lean. (Although the leanness may be attributed to high activity levels, many carnivores in fact are sedentary for much of the time.) The trade-off between storage and agility was revealed in zebra finches by researchers in Scotland, who videotaped and weighed numerous birds on a daily basis. Some finches had access to excessive calories from human sources. A mere 7% gain in body mass led to a 33% loss in speed and maneuverability, making these overfed birds easier prey for cats and sparrow hawks. Thus, an obese or heavy set point has negative consequences in a food-plentiful habitat, including increased cardiovascular and oxidative stresses causing internal health problems, as well as reduced maneuverability. Household pets, as well as humans themselves, often suffer from the consequences of obesity.
- Conversely, a high adipose set point has very clear advantages in “feast or famine” habitats, where food is only abundant at limited times of the year. A clear example is the mammalian hibernator (see Figure 15-5a). An Arctic ground squirrel must reach an “obese” state (up to 50% body fat) before winter sets in or it will not survive the eight months during which it hibernates in its burrow. Desert habitats that have abundant food only during short rainy seasons also select for this adaptation. Overall, it is now recognized that having a propensity toward being “overweight” is not necessarily an abnormal physiological state but may be an evolutionary adaptation for a particular environment.

Researchers do not yet fully understand what determines these different set points in the neurological structure

of the brain. But, as discussed earlier in this chapter, fat storage levels and the associated set point may be closely tied to leptin and how the hypothalamus reacts to it. The hypothalamus of a lean-adapted mammal reacts strongly to a modest rise in leptin, shutting off appetite and acting as if it had a low set point. The hypothalamus of “obese” mammals, conversely, reacts only to very high levels of leptin. Also, humans and laboratory animals appear to differ in the thermogenic activity of tissues with uncoupling proteins, correlating with lean or obese set points. Research is continuing on these numerous fronts.

15.4 Thermal Physiology: General Principles

We now turn to a major habitat factor intimately involved with energy. When physiological ecologists examine the distribution of species around the planet, noting that most species live in rather restricted ranges, they ask what factors are responsible for these restrictions. One of the most pervasive factors is temperature, which has direct and profound effects on biological functions.

Temperature alters rates of chemical reactions and denatures macromolecules

Temperature is a measure of heat energy, which in turn is manifested primarily in kinetic energy (movement) of molecules. The primary effects of this are shown in Figure 15-7, which shows a typical optimal curve of biological function and temperature. Basically, two different temperature effects create this curve:

1. **Kinetic energy of reactants:** On the left (up-trending) side of the plot, reaction rates increase with temperature simply from the increased kinetic energy of molecules. Reacting molecules (such as substrates and enzymes, for example) encounter each other more frequently. It has become customary to characterize this temperature response with a value called the Q_{10} , which is the ratio of a reaction rate (or metabolic process) at one temperature to the rate at 10°C cooler:

$$Q_{10} = \frac{\text{rate at temperature } T}{\text{rate at temperature } T_{-10}}$$

Q_{10} values are useful measures of the temperature sensitivity of a biological process (from single reactions to a

FIGURE 15-7 The relative activity of an enzymatic reaction as a function of temperature. The decrease in activity below 30°C is primarily due to reduced kinetic energy, while the decrease in activity above 50°C is due to disturbed protein structures, including denaturation.

Source: Modified from M. K. Campbell & S. Farrell. (2003). *Biochemistry*, 4th ed. Belmont, CA: Thomson, p. 137, Figure 5.2.

whole organism’s metabolism). In general, researchers have found that many reactions tend to double or triple for each 10°C rise, at least over a moderate range. However, at some point with rising temperature, the curve begins to flatten, reaches an optimum, and then declines.

2. **Denaturation of macromolecules.** Above the optimum (right side of the plot), rates of biological processes begin to decrease with temperature for one basic reason: The macromolecules (such as enzymes) responsible for the process begin to denature (that is, lose their tertiary levels of structure). As we discussed in Chapter 2 (p. 27), weak bonds stabilize many of these structures so that they can be flexible, but this makes them susceptible to loss of function at higher kinetic energies.

In general, this curve means that organisms cannot operate over a wide range of body temperatures. For animals, active metabolism seems to be restricted to a range from about –2°C (the freezing point of seawater) to 55 to 60°C. (A penguin living actively at –50°C air temperature in Antarctica does not violate this restriction, because its cells are warmed to about 40°C from internal heat production and retention.) This is a relatively narrow range, given that a temperature of –89.2°C (–128.5°F) has been recorded (in Antarctica) and hydrothermal vent temperatures may reach about 400°C (750°F)! Some animals have evolved ways to cope with body temperatures colder than freezing (as you will see), but metabolism in these animals is generally in a dormant state. At the other extreme, there is no convincing evidence of any animal tolerating over 55°C for anything but very brief periods (on some desert sands and at some

FIGURE 15-8 Schematic diagrams of membrane structures and their relationship to temperature. (a) Saturation level of membrane phospholipids changes with temperature adaptation. The *left* figure represents a warm-adapted membrane: The fatty-acid “tails” are highly saturated, allowing for close stacking of neighboring tails. This enhances thermostability at higher temperatures. The *right* figure represents a cold-adapted membrane: The fatty-acid “tails” are more unsaturated, creating double bonds that interfere with stacking of neighboring tails. This enhances flexibility at colder temperatures. (b) Stiffening of the membrane with cholesterol. Cholesterol reduces fluidity by stabilizing extended forms of the phospholipid tails. (c) The relationship between adaptation temperature and ratio of unsaturated phospholipid tails (phosphatidylethanolamine, PE) to saturated ones (phosphatidylcholine, PC) in gill membranes of rainbow trout transferred to different temperatures as shown.

marine hydrothermal vents; see p. 741). Ignoring long-term acclimatization for the moment, excessively high temperatures are usually more dangerous than cold ones. Many organisms can survive lower body temperatures temporarily because reactions merely slow down (although freezing can set a lower limit because of the lysis of cells from ice crystal formation in organisms that cannot prevent that), but excessive heat can irreversibly damage membranes and proteins.

Biomolecules can be altered to work optimally at different temperatures

For the most part, biological systems are subject to the optimal curve of Figure 15-7, but it is important to realize that *the optimum itself can change with different temperatures*. Changes can occur over two possible (and very different) time courses: within an organism’s lifetime in *acclimatization* processes, and over many generations by the process of mutation and natural selection, that is, *evolution*. Both categories are sometimes loosely called “adaptation” (see p. 17 for more details on terminology). If “adaptation” is used, it is crucial to carefully explain the time course.

Not all organisms can successfully acclimatize to different temperatures, nor can all species evolve to survive temperatures outside of their normal ranges. Indeed, changes in habitat temperatures may be a major cause of extinctions over geological time; moreover, the current rise in global air and water temperatures is already affecting organismal distributions and physiologies (as we will discuss later). Regardless, optima clearly differ among species and within some species experiencing different thermal habitats, in part because of changes in two critical classes of biomolecules—membranes and proteins.

Membranes and the Homeoviscous Adaptation Biological membranes are held weakly together by hydrophobic interactions between the fatty acid chains of its phospholipids (p. 71), giving them a certain *viscosity* or fluidity that is vital to functions such as transport and diffusion. However, the weak structure makes them very susceptible to temperature

changes. At low temperatures, viscosity increases and the membrane becomes too rigid for optimal function. At higher temperatures, membranes lose viscosity and become too fluid. If you have used butter from a refrigerator and also from a kitchen counter on a hot day, you are aware of these effects. As you saw in Chapter 3 (p. 72), a membrane can be changed to counter these effects by the length of the fatty acids and by the degree of *saturation* of its fatty acids (and, to some extent, by altering its cholesterol content). A hypothetical example is shown in Figures 15-8a and b, with a real

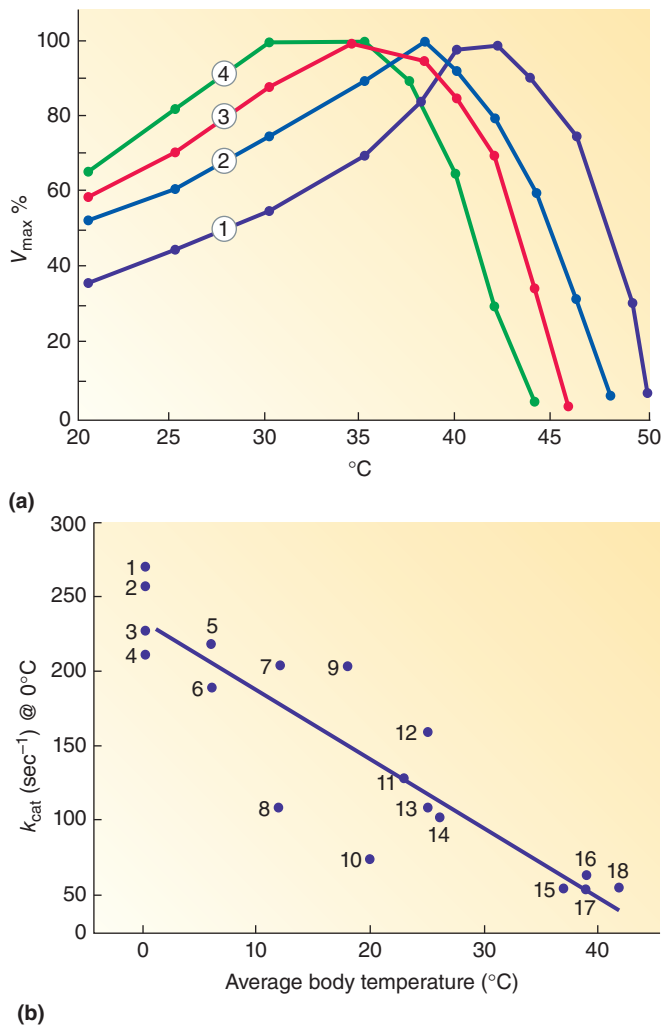

FIGURE 15-9 Relationship between enzyme activity and temperature in animals adapted to different temperatures. (a) The relative activity max (V_{\max}) of myosin ATPase of four lizards, showing that animals adapted to higher temperatures have enzymes with higher thermal optima. 1. *Dipsosaurus dorsalis*, which has a preferred body temperature of 38.8°C ; 2. *Uma notata*, preferred body temperature of 37.5°C ; 3. *Sclerophorus undulatus*, preferred body temperature of 36.3°C ; 4. *Gerrhonotus multicarinatus*, preferred body temperature of 30.0°C . (b) The enzyme catalytic rate constant (k_{cat}) for lactate dehydrogenases (LDH, A_4 type) from various vertebrates adapted to different temperatures, showing that, in general, animals adapted to higher temperatures have enzymes with lower catalytic rates. Antarctic notothenioid fishes are 1. *Lepidonotothen nudifrons*; 2. *Parachaenichthys charcoti*; 3. *Champscephalus gunnari*; 4. *Harpagifer antarcticus*. South American notothenioid fishes are 5. *Patagonotothen tessellata*; 6. *Eleginops maclovinus*. Temperate and subtropical fishes are 7. *Sebastes argentea* (rockfish); 8. *Hippoglossus stenolepis* (halibut); 9. *Sphyræna argentea* (barracuda); 10. *Squalus acanthias* (dogfish shark); 11. *Sphyræna lucasana* (barracuda); 12. *Gillichthys mirabilis* (goby); 13. *Thunnus thynnus* (bluefin tuna). A tropical fish is 14. *Sphyræna ensis* (barracuda). Terrestrial animals are 15. *Bos taurus* (cow); 16. *Gallus gallus* (chicken); 17. *Meleagris gallapavo* (turkey); and 18. *Dipsosaurus dorsalis* (desert iguana).

example in Figure 15-8c. First, consider a warm-adapted organism. Its membranes typically consist of *saturated fatty acids* (SFAs), in which the carbons in the “tails” are fully hydrogenated. This allows the tails to stack together tightly, giving the whole membrane enough viscosity to work properly at warm temperatures (Figure 15-8a, left). Cholesterol may be high as well, to further reduce fluidity (Figure 15-8b). However, these membranes become too rigid to work in the cold (as butter does in a refrigerator). Conversely, a cold-adapted organism typically has a higher proportion of *polyunsaturated fatty acids* (PUFAs), in which some carbons have fewer hydrogens and thus form double bonds with neighbor carbons. This puts “kinks” in the tails, making tight stacking impossible (Figure 15-8a, right). This makes the whole membrane less viscous and thus more fluid in the cold. But these membranes become too fluid to work in warm conditions. Thus, there is a trade-off between thermal stability and fluidity. Both membranes have approximately the same viscosity *when they are each measured at their adaptational temperatures*. Hence, the term **homeoviscous adaptation** was coined to refer to these saturation changes that preserve an optimal viscosity of the cell membrane.

Saturation levels are catalyzed by enzymes called **desaturases** (used in the cold to remove hydrogens) and **saturases** (used in warm conditions to add hydrogens). As noted, the time course of changes is critical when discussing this adaptation. In general, organisms from different thermal habitats have lipid compositions that follow the saturation principles just described. However, only some organisms can acclimatize (from winter to summer, for example) by regulating the saturases and desaturases and thus their membranes. In addition to the fish described in Chapter 3 (p. 72), an example is shown in Figure 15-8c.

Proteins and the “Homeoflexibility Adaptation” A similar type of change can occur with proteins, although generally only over evolutionary time. In this case, the trade-off is between *thermostability* and *protein flexibility* rather than fluidity. Recall from Chapter 2 (e.g., Figure 2-1) that many proteins need to be flexible to “do their job.” As you saw earlier, increased temperature can cause these flexible structures to denature (Figure 15-7), but lower temperatures can make an enzyme too rigid to function well. As shown in Figure 15-9a for myosin (the “motor” protein of muscle; see Chapter 8), optimal temperatures for functionality do vary among species. How does this occur? A major clue was found in studies of *catalytic rate constants* (k_{cat}) for some enzymes. These values indicate how fast an enzyme can catalyze a particular reaction. The studies revealed an initially surprising result: Enzymes of animals with warm bodies, such as mammals, have relatively inefficient (low k_{cat}) enzymes, whereas cold-bodied animals have faster (high k_{cat}) enzymes. As with membranes, there appears to be a trade-off between the flexibility needed for fast catalysis and the thermostability needed to resist heat.

One particular enzyme, **lactate dehydrogenase (LDH)**, has been analyzed in some detail. LDH is the final enzyme of anaerobic glycolysis, catalyzing the conversion of pyruvate and NADH to lactate and NAD^+ (p. 55), and its action is paramount to survival in anaerobic burst activity, such as pouncing on food or escaping a predator. As shown in Figure 15-9b, k_{cat} of LDHs is inversely related to an animal’s average body temperature. In its tertiary structure LDH has

FIGURE 15-10 Schematic diagram of the enzyme lactate dehydrogenase (LDH), which binds NADH and pyruvate and catalyzes their conversion into NAD^+ and lactate. The upper diagram shows the conformational changes that occur upon binding, as a flexible loop of the enzyme closes over the active site. The flexibility of this loop evolves to match a species' thermal habitat (greater flexibility in the cold). The lower diagram shows the active site itself and the amino acids (Histidine-193 and Arginine-171) that bind pyruvate. The binding ability of the histidine may be protected from thermal disturbances by an animal decreasing its fluid pH with rising temperature (see main text, p. 738).

a flexible loop, which opens and closes during its reaction (Figure 15-10). Warm-adapted LDHs have relatively stiff loops, rigid enough to resist denaturation at higher temperatures. But they are too inflexible to work at cold temperatures. Conversely, cold-adapted LDHs have relatively loose loops, able to open and close well in the cold. But they lose their structure more easily at higher temperatures.

Such differences in thermostability may evolve fairly straightforwardly, as revealed in recent studies on malate dehydrogenases (MDH, an enzyme of the citric-acid cycle, p. 50) in intertidal limpets of the western United States. Yunwei Dong and George Somero compared MDHs from *Lottia digitalis* of northern habitats and its close relative *L. austrodigitalis* of southern habitats. The MDH from the southern *L. austrodigitalis* is considerably more thermosta-

ble and can bind substrate more effectively at higher temperatures than the MDH of *L. digitalis* (northern). The differences are the result just one amino acid substitution. In the active site, MDH of *L. austrodigitalis* has a serine where *L. digitalis* MDH has a glycine. Importantly, serine allows for additional hydrogen bonding, improving binding at higher temperatures. Knowing such differences in thermal adaptation are critical to understanding the effects of global warming on species' distribution and survival.

The thermal adaptation strategies of animals depend on their primary source of heat

Let's now turn to the ways in which animals cope with environmental temperature changes that threaten their biomolecules. Recall that physiologists generally classify animals into two broad categories: **ectotherms** (*ecto*, “external”)—those dependent on external sources for body heat—and **endotherms** (*endo*, “internal”)—those more dependent on internal sources. Physiologists still frequently use a pair of older terms: **poikilotherms** (*poikilos*, “changeable”)—animals whose body temperatures vary with the environment—and **homeotherms**—animals with narrowly varying body temperatures (recall that *homeo* means “similar,” not “constant”). These terms often lead to confusion. Because we humans are mammals (endotherms) with fairly constant body temperatures (homeotherms), some people mistakenly believe the two terms are synonymous. But they are not, as we show in detail later. For now, consider an ectothermic lizard that can use sun and shade to keep its body temperature fairly constant (that is, it is homeothermic some of the time). Also consider a hibernating endotherm such as a marmot (p. 725): It is not homeothermic when considered on an annual basis. Rather it is an example of a **heterotherm**, an animal that has endothermy but is not fully homeothermic.

Note that there is no clear dividing line between a heterotherm and a homeotherm. For example, a camel in the desert absorbs a large heat load during the day, increasing its body temperature by several degrees (for example, from as low as 34°C to as high as 41°C) to avoid losing water by evaporative cooling. At night, it releases the heat and its body temperature drops. Does this level of change constitute homeothermy, or heterothermy? Some physiologists suggest that homeothermy be defined as internal temperature variations of no more than plus or minus 2°C, but in some ways the definitions do not matter. Rather, it is important to realize that there is a continuum of temperature regulation ranges and abilities, and that no endotherm has an absolutely constant internal temperature (hence the prefix *homeo* for “similar” rather than *homo* for “same”). Even your body temperature drops when you sleep and increases with heavy exercise and fever.

The internal body temperatures of both ectotherms and endotherms depend simply on the difference between heat input and heat output (Figure 15-11). *Heat input* occurs by gain from the external environment (which dominates in ectotherms) and from internal heat production (the most important source for endotherms). Conversely, *heat output* occurs by way of heat loss from exposed body surfaces to the external environment (in both ectotherms and endotherms). Let's first examine the inputs and outputs involving the environment.

Heat exchange between the body and the environment takes place by radiation, conduction, convection, and evaporation

Endotherms as well as ectotherms are influenced by heat exchanges with their environments, so it is important to understand how such exchanges occur. All heat loss or heat gain between the body and the external environment must take place between the body surface and its surroundings. The same physical laws of nature that govern heat transfer between inanimate objects also control the transfer of heat between the body surface and the environment. The temperature of an object may be thought of as a measure of the concentration of heat within the object. Accordingly, heat always moves down its “concentration” gradient, that is, down a **thermal gradient** from a warmer to a cooler region.

Organisms are subject to, and make use of, four mechanisms of heat transfer: *radiation*, *conduction*, *convection*, and *evaporation*.

1. **Radiation** refers to light energy, which exists as electromagnetic waves (and photons) that travel through space (Figure 15-12, step 1). Objects can both emit (source of heat loss) and absorb (source of heat gain) radiant energy. Heat is emitted from all objects (if not at absolute zero, -273°C) in the form of **infrared radiation** (wavelengths longer than red light). In the reverse direction, when radiant energy (especially infrared, but also visible light) strikes an object and is absorbed, the energy of the wave motion is transformed into heat within the object (manifested as increased vibrational energy within molecules). Whether a body loses or gains heat by radiation depends on the difference in temperature between the skin surface and the surfaces of various other objects in the body’s environment, and on the amount of direct sunlight striking the skin. Because net transfer of heat by radiation is always from warmer objects to cooler ones, a body gains heat by radiation from objects warmer than the skin surface, such as the sun, rocks, or soil in the sun, or burning wood. In contrast, an animal loses heat by radiation to objects in its environment whose surfaces are cooler than the surface of the skin, such as trees, soil in the shade, and so forth.
2. **Conduction** is the transfer of heat between objects of differing temperatures that are in direct contact with each other (Figure 15-12, step 2). Heat moves down its thermal gradient from the warmer to the cooler object by being transferred from molecule to molecule. Except at absolute zero, all molecules are constantly vibrating, with warmer molecules moving faster than cooler ones. When molecules of differing heat content touch each other, the faster-moving, warmer molecule agitates the cooler molecule into more rapid motion, “warming up” the cooler molecule. During this process, the original warmer molecule loses some of its thermal energy as it slows down and cools off a bit. Therefore, given enough time, the temperature of the two touching objects eventually equalizes. The rate of heat transfer by conduction depends on the *temperature difference* between the touching objects and the *thermal conductivity* of the substances involved (that is, how easily heat is conducted by the molecules of the substances).

FIGURE 15-11 Heat input and output.

© Cengage Learning, 2013

Heat can be lost or gained by conduction when the skin is in contact with a good conductor. When standing on snow, for example, an animal’s foot becomes cold because heat conducts from the foot to the snow. Conversely, when an animal sits on a rock warmed by the sun, heat is transferred directly from the rock to its body. Similarly, bodies lose or gain heat by conduction to the layer of air in direct contact with the body. Only a small percentage of total heat exchange between the skin and air takes place by conduction alone because air is not a very good conductor of heat. Heat is conducted much more rapidly between a body surface and water, a better conductor than air.

3. **Convection** refers to the transfer of heat energy by *currents* of air or water (the medium). Let’s follow an example for air next to skin, air that is warming from body heat. Because warm air is lighter (less dense) than cool air, the warmed air rises, and cooler air moves in next to the skin to replace the vacating warm air. The process is then repeated (Figure 15-12, step 3). Such movements in the external medium, known as *convection currents*, can carry heat away from a body. If it were not for convection currents, no further heat could be dissipated from the skin by conduction once the temperature of the layer of the medium immediately around the body equilibrated with skin temperature. The combined conduction–convection process of removing heat from a body is enhanced by forced movement of the medium across the body surface, either by external movements, such as those caused by wind and water currents, or by movement of the body through the medium, such as during locomotion.
4. **Evaporation** is the final method of heat transfer used by a body, but only in air. When water evaporates from the skin surface, such as that of a frog in air, the heat required to transform water from a liquid to a gaseous state is absorbed from the skin, thereby cooling the animal (Figure 15-12, step 4). Evaporative heat loss can occur from the linings of the respiratory airways as well as from the skin (*cutaneous* loss). Evaporation is particularly important for regulation if the air temperature rises above the temperature of skin. In that situation, the temperature gradient reverses itself so that heat is gained from the environment. Evaporation is the only means of heat loss under these conditions, and the pro-

FIGURE 15-12 Mechanisms of heat transfer.

© Cengage Learning, 2013

cess can be understood in terms of the fundamental entropy equation given earlier. Recall that

$$\Delta S_{\text{net}} = \Delta S_{\text{surroundings}} + \Delta S_{\text{system}} \\ > 0 \text{ for spontaneous reactions}$$

Here the system is the water droplet on the skin, and the surroundings are the body being cooled. When the air is hotter than the body, and yet the latter is being cooled, the $\Delta S_{\text{surroundings}}$ is thermodynamically unfavorable because entropy is actually decreasing during cooling against a heat gradient. However, the unfavorable factor is more than “paid for” by a **change of state** in water. During evaporation, water molecules go from a moderately ordered liquid state to a highly disordered vapor state, giving an enormously favorable ΔS_{system} . Essentially, the heat energy of the body is absorbed in the breaking of hydrogen bonds between water molecules as water vaporizes. This change of state, which is very effective, is exactly the process used in refrigerators and air conditioners, where liquid refrigerants vaporize in cooling coils, removing heat from the desired space. Energy in the form of a compressor motor must be used to reliquify the refrigerant, recycling this costly resource, whereas in organisms, the cooling fluid—water—is lost and must be replaced.

Evaporation cannot succeed, however, if the air is saturated with water vapor, that is, at 100% relative humidity (RH). At that point, the rate of water vapor reforming hydrogen bonds and thus condensing into liquid is equal to the reverse process. *If the air is hotter than an animal's body at 100% RH, then there is no physiological means for cooling off.* Animals must allow

their body temperatures to rise or must use behavioral mechanisms to avoid the situation.

Evaporation often occurs in a maladaptive way, that is, not for thermoregulation. A frog in a warm, dry area is in danger of dying from dehydration because it cannot stop cutaneous water loss. Inadvertent respiratory losses of water can also be dangerous; for example, exercising in cold, dry winter air can cause serious dehydration in humans.

Heat gain versus heat loss determines core body temperature, with mechanisms to gain external heat, retain internal heat, generate more internal heat, and lose excess heat

From a thermoregulatory viewpoint, an animal body may conveniently be viewed as a *central core* surrounded by an *outer shell*. The temperature within the inner core, which in a vertebrate consists of the abdominal and thoracic organs, the central nervous system, and the skeletal muscles, is the subject of regulation in animals that can thermoregulate, ectotherm and endotherm alike. That is, this internal **core temperature** remains fairly constant in homeotherms and may also vary less than environmental temperature in poikilotherms. The skin and subcutaneous fat constitute the outer shell. Temperatures within the shell may vary considerably more than in the core and are most often cooler than the core in endotherms.

The core temperature is a result of the difference between heat input and heat output (Figure 15-11). The means by which heat gains and heat losses can be balanced to regulate core body temperature generally fall into four broad

1 Radiation—the transfer of heat energy from a warmer object to a cooler object in the form of electromagnetic waves (“heat waves”), which travel through space.

2 Conduction—the transfer of heat from a warmer to a cooler object that is in direct contact with the warmer one. The heat is transferred through the movement of thermal energy from molecule to adjacent molecule.

3 Convection—the transfer of heat energy by air currents. Cool air warmed by the body through conduction rises and is replaced by more cool air. This process is enhanced by the forced movement of air across the body surface.

4 Evaporation—conversion of a liquid such as sweat into a gaseous vapor, a process that requires heat (the heat of vaporization), which is absorbed from the skin.

categories—in short, *gain*, *retain*, *generate*, and *lose* heat:

- *Gain external heat/avoid loss to cold environs* by using solar radiation, conduction from a warm surface or other source of environmental heat, and by avoiding cold areas. The heat gains are **ectothermic sources**, made use of primarily through specific thermoregulatory *behaviors* (such as solar basking), aided by *anatomic* features such as dark surfaces to absorb solar radiation effectively.
- *Retain internal heat*. Because of entropy, all metabolism produces some heat. This and any externally gained heat can be retained using *behavior* (such as entering an insulated burrow), *insulation* (such as hair), *reduced blood flow* to the integument to reduce losses, *countercurrent exchangers* in circulation that retain core heat, and *larger body sizes*. All these reduce heat loss via conduction, radiation, and sometimes convection and evaporation.
- *Generate more internal heat*. This is the definitive feature of **endothermy**, requiring significant heat-generating tissues.
- *Lose excess internal heat/avoid gains from hot environs* by *behavior* (such as seeking shade), *anatomy* (such as reflective white layers on the shell of an intertidal snail, and long, thin legs of desert insects which hold their bodies well above the hot ground), enhancing transfer via the integument through *increased blood flow*, and increasing *evaporation* (panting, sweating, cutaneous loss).

This list is only a brief overview; we now turn to the details for ectotherms.

check your understanding 15.4

Describe the basic effects of temperature on biological systems.

Discuss the evolutionary and functional aspects of homeoviscous adaptations of membranes and stability versus flexibility of proteins.

Define *endothermy*, *ectothermy*, *poikilothermy*, and *homeothermy*.

Discuss the features of the four heat transfer mechanisms: radiation, conduction, convection, and evaporation.

Discuss body heat balance and key features of “gain, retain, generate, and lose heat.”

15.5 Ectothermy

Body temperatures of ectotherms may follow the environment, or may be regulated by heat gains, retention, and losses

What happens to an ectotherm when the environmental temperature is not near the optimum for its molecular structures? There are two broad categories of response: *poikilothermy* and *ectothermic regulation*.

FIGURE 15-13 The body temperature of an intertidal mussel

(*Mytilus californianus*) when the tide is out. The temperature is measured with a thermistor inserted inside the shell (blue line). As the tide goes out, the body temperature soars more than the air temperature (green line). Upon reemersion, the temperature drops rapidly.

Source: Modified from T. Carefoot, (1977). *Pacific Seashores*. Seattle, WA: University of Washington Press by arrangement with J. J. Douglas, Vancouver Canada. p. 68, Figure 67.

Poikilothermy Poikilothermic ectotherms that live in thermally variable environments undergo variations in body temperatures as well. Metabolic rates in such animals typically decrease in the cold (thus saving energy) and speed up as the environment warms (thus becoming better able to obtain food, up to a point). Survival may depend on using behavior to avoid extreme temperatures and/or limited physiological heat-loss mechanisms such as evaporation. If extreme temperatures cannot be avoided, poikilotherms may enter dormancy during the extremes or compensate through changes in internal biochemical optima (as you will see later). Some poikilotherms have body temperatures essentially identical to that of the environment—especially aquatic animals, because of the high heat conductivity and specific heat of water. These animals are sometimes called pure *thermoconformers*. But some have body temperatures that, although not nearly constant, vary less than the environment. This is particularly true of many ectotherms in terrestrial habitats because air transfers heat much less effectively than water.

Most life on this planet is poikilothermic. An extreme example is given in Figure 15-13, showing a mussel on an intertidal rock on the West Coast of North America. When the tide is in, its body temperature will be the same as the ocean, which is usually cold (about 11°C in this case). When the tide is out on a hot summer day, the mussel’s body temperature soars and may reach 30°C or more. Some evaporative cooling may keep its temperature lower than it would be otherwise, but nevertheless it undergoes a large change in internal temperature.

Ectothermic Regulation An ectotherm in a constant environment, such as the cold deep sea or some polar ocean regions, is even more homeothermic (almost “homothermic”) than any mammal. However, these animals typically cannot cope with any significant temperature changes. For example,

FIGURE 15-14 Relationship between body temperature and air temperature for lizards. The dotted black line is the relationship for pure poikilothermy (equal body [T_b] and air [T_a] temperature). Thermoconforming lizards *Draco* and *Anolis* in shaded forest habitat show a similar pattern (red squares, orange circles, respectively), while thermoregulating lizards marine iguana and *Anolis* in open sun have flatter lines (green circles, purple triangles, respectively). Also shown is the relationship for a water-filled metal can in the sun (blue triangles).

Source: From P. C. Withers. (1992). *Comparative Animal Physiology*. Fort Worth, TX: Saunders, p. 140, Figure 5-13.

Antarctic fishes can suffer heat-associated mortality at 5°C! Of more interest are ectotherms that actively use external heat exchanges to maintain their body temperatures at or near an optimum. Well-studied examples include lizards and butterflies (see opening photograph of this chapter). Let's examine the four strategies of heat regulation in a lizard to illustrate (see Figure 15-14):

- **Gain external heat/avoid loss to cold environs.** On cold mornings, the lizard basks in sunlight, soaking up infrared radiation and heat via conduction from warmed surfaces. (It also basks for the purpose of vitamin D production; see p. 329.) Once warmed up to an optimal level, it becomes active, seeking food while using both behavioral and physiological mechanisms to maintain a consistent body temperature.
- **Retain internal heat.** The lizard may *vasoconstrict* blood vessels going to its skin to reduce heat loss. In very large ectotherms, a phenomenon called **gigantothermy** may occur, in which an animal like a large turtle may absorb heat and then easily retain it for some time in a cooler environment due to their comparatively low surface-area-to-volume ratio.
- **Generate more internal heat.** This does not occur significantly in pure ectotherms. However, some very large (varanid) lizards, such as the Komodo dragon, warm up temporarily from high locomotory activity, retaining heat again because of their low surface area to volume ratio.
- **Lose excess internal heat/avoid gains from hot environs.** Blood vessels in the lizard's skin may dilate to increase heat loss. Evaporation from the mouth also provides cooling (one lizard, the Gila monster of southwestern United States, evaporates water from its cloaca rather than its mouth). When it gets too hot, the animal seeks

shade. As another example, Sylvain Pincebourde and colleagues have recently shown that the intertidal ochre seastar (*Pisaster ochraceus* of the North American Pacific Northwest), instead of being a strict poikilotherm as long thought, can pump cold seawater into its coelom to lower its body temperature when overheating due to exposure to the sun at low tide. In order for certain animals to go outdoors during the colder winter temperatures, some zoos heat up the animal during the night so that they have sufficient heat to radiate during the daylight hours.

Using such mechanisms, some ectotherms can regulate body temperature as effectively as a mammal can, at least for some periods.

On a seasonal basis, some ectotherms can *migrate* to help minimize changes in body temperature. The monarch butterfly (p. 14), for example, spends summers in northern North America (such as Alaska and Canada) but joins a massive migration in the autumn to specific southern sites in California and Mexico for the winter months (as you will see later, such migrations are being altered by global warming). Some migratory fishes have similar behaviors; for example, the dogfish shark of the western Atlantic migrates between Florida in the winter and Maine in the summer.

Although these two categories of poikilothermy and ectothermic regulation are convenient, it is important to note that there is no distinct boundary between them. All ectothermic regulators that live in thermally variable habitats are also poikilotherms part of the time. For example, when there is no sun, warm burrow, or other heat source, a lizard cannot regulate its body temperature. At night, it usually cools off to approximately the air temperature. During this period, it is purely poikilothermic.

Some ectotherms can compensate biochemically for changes in body temperatures

Ectotherms in many habitats are subject to temperature changes that impair metabolism because they cannot behaviorally or physiologically adjust body temperature. The onset of winter and of summer are the most common examples. When it is too cold, a poikilotherm's metabolism may slow down to the point that it cannot obtain any food. Freezing may also kill it. If it is too hot, its membranes, proteins, and nucleic acids may suffer irreversible damage. To avoid problems, many poikilotherms undergo adaptive physiological or biochemical changes when exposed to temperature changes. Some of these changes occur on a daily basis, whereas others are seasonally induced. Some involve dormancy, whereas other changes allow for continued activity even with no mechanism for regulating body temperature.

In some cases, acclimatization to temperature changes allows an animal to maintain a useful level activity in a process called **metabolic compensation**. In this form of homeostasis, an animal's metabolic reactions in cold temperatures are increased to a level that is closer to that of warm-acclimated animals *even though their body temperatures are that of the environment's*. The reverse occurs with warm acclimatization. How is metabolic compensation achieved? In many cases, the mechanisms are not known, but several have been revealed in various animals, all involving specific biochemical changes:

1. **Enzyme concentration changes.** In cold acclimation and acclimatization (see definitions, p. 17), many ectotherms such as some fishes, frogs, and reptiles will increase their levels of metabolic enzymes, particularly those involved in aerobic pathways. An example is shown in Figure 15-15 for alligators, comparing animals acclimatized to winter and summer seasons. This particular study examined the activity levels of key enzymes in muscle tissue. Note that for LDH (structure in Figure 15-10), measured in the laboratory at 15, 22.5, and 30°C, the winter-acclimated animals have considerably higher enzyme activities at all measurement temperatures. This biochemical adjustment allows the cold-acclimated alligator to move better in the cold. Note also that the LDH level of the winter animals at 15°C is about the same as the level of the summer animals at 30°C, so this is a form of homeostasis. However, a cold-acclimated alligator will die of heat-related problems at warm temperatures at which the warm-acclimated animals will thrive. Thus, there appears to be a trade-off between metabolic rate and heat tolerance. Moreover, it takes energy to produce more enzymes, and because energy input is usually reduced in the cold, this strategy has limits.
2. **Homeoviscous membrane adaptation.** As we discussed previously, restructuring of membranes to maintain proper fluidity is a common strategy. The common carp, for example, uses this adaptation.
3. **pH regulation.** Most ectotherms in the cold have higher internal pH values than do warmer animals; that is, warmer animals are more acidic. To some extent, pH changes with temperature automatically because the neutral pH of water and the acid constants (pK_a) of protein buffers (p. 641) decrease with heating and increase with cooling. However, some buffer systems such as phosphate and bicarbonate do not have this property, so apparently animals must actively regulate pH to some extent. The primary hypothesis to explain this observation focuses on the amino acid *histidine*. Of the 20 amino acids used to build proteins, histidine is the most important in acting as a buffer (p. 641), because its pK_a is close to physiological pH, so it is nearly ideal for releasing or binding hydrogen ions over the normal physiological pH range. Binding and release of hydrogen ions by histidines are also crucial in many enzyme active sites for catalyzing reactions, as seen in LDH in Figure 15-10, where histidine with a bound H^+ binds to pyruvate, then donates that H^+ to pyruvate. Importantly, histidine's affinity for H^+ decreases with increasing temperature, so it binds H^+ too weakly to serve effectively as a buffer or catalyst if fluid pH is constant:

Indeed, studies on LDHs from a variety of animals show that binding of pyruvate weakens greatly as temperature rises. The converse is also true: Binding becomes too tight in the cold. This problem can be offset if $[H^+]$ in body fluids is regulated. Take the case of increasing heat. If an animal regulates its body fluids to become more acidic, the higher $[H^+]$ via mass action increases the concentration of histidines in the charged

FIGURE 15-15 Activity of lactate dehydrogenase in muscle from alligators acclimatized to winter and summer conditions. Activity increases in the winter to make up for lower thermal energy. The x-axis indicates temperatures at which the activities were measured in the laboratory.

Source: From F. Seebacher, H. Guderley, R. M. Elsey, & P. L. Trosclair III. (2003). Seasonal acclimatization of muscle metabolic enzymes in a reptile (*Alligator mississippiensis*). *Journal of Experimental Biology* 206:1193–1200.

- form (histidine- H^+) to the level found at colder temperatures, and so restores binding affinity.
4. **Isoform regulation.** A final strategy requires that different forms of the same protein—called *isoforms*—be used at different temperatures. That is, there may be a set of winter proteins and another set of summer proteins, with the genes for these being activated only under appropriate environmental conditions. For example, the common carp expresses distinctly different forms of its myosin and myosin light-chain protein (MLC) in the summer and in the winter. Myosin is the main contractile protein of muscle (p. 337), whereas MLC binds to myosin and modifies its activity. Together, the isoforms expressed in the cold give the fish greater speed and force in the cold. However, the cold-adapted muscle then does not work well at higher temperatures.

Isoform regulation appears to be uncommon, and many of the mechanisms of metabolic compensation are still unknown. Currently, DNA microarrays (p. 35) are being used to look for major changes in gene expression that occur during acclimation. A study by Andrew Gracey and colleagues of the common carp, which acclimatizes annually to winter temperatures, found that about 252 genes (out of 13,400 measured on a microarray) exhibit significantly upregulated expression in all tissues during cold exposure. The genes are involved in RNA processing and translation, mitochondrial metabolism, proteasome function, and restructuring of lipid membranes. Such studies are revealing previously unsuspected mechanisms of temperature acclimatization.

Ectotherms survive extreme cold by metabolic dormancy and by either freeze avoidance or freeze tolerance

Ectotherms generally cannot stay active in extreme cold. Many can survive low temperatures by dramatically lowering their metabolic rates, thereby reducing the rate at which ATP is consumed. Although they may be technically starving, they have sufficient reserves to survive the season. Frequently, metabolic rate can be reduced to as low as 1 to 10% of the normal resting rate: A 10-fold reduction in energy expenditure gains the animal a 10-fold extension of the time that fuel reserves will last. For example, in the Crucian carp the glycogen level that supports brain function for 16 hours in the anoxic winter ponds when energy demand is low, would support the fish for only eight minutes in the summer with the same amount of oxygen. Some species of insects completely arrest their development in a state of *diapause*. Turtles hibernate at depths below the frost line along the banks of streams and at the bottom of ponds. These reptiles survive the entire winter without breathing (p. 641) and with a heart rate of only one beat per minute.

Special adaptations are needed for ectothermic animals whose body temperatures drop below freezing. There are two broad categories of these adaptations: *freeze tolerance* and *freeze avoidance*.

Freeze Tolerance Some ectotherms actually survive freezing of some body fluids (with up to 80% of body water being frozen in such animals). Woolly bear caterpillars spend up to 10 months frozen in the high Arctic, barnacles and mussels freeze when exposed to subfreezing temperatures at low tide, and even some reptiles and amphibians freeze for variable periods of time. For example, spring peeper frogs (*Pseudacris crucifer*) and wood frogs (*Rana sylvatica*) can revive after having as much as 65% of body water converted to ice. During the frozen state, ATP use virtually ceases and neurological activity is minimally detectable. Energy needs of a tissue are normally supplied by nutrients delivered by the circulatory system. However, in a thawing animal the tissues are completely reliant on immediately available energy sources.

What happens to the tissues that actually freeze? Consider a key problem of freezing—the osmotic stress placed on an animal cell as it enters the frozen state. Formation of ice crystals in the ECF (extracellular fluid) immediately changes the osmotic balance with the ICF (intracellular fluid). Because ice excludes solutes from its structure, during the freezing process the composition of the ECF becomes progressively more concentrated as the concentration of water declines. In response, water moves out of the cell. Only when the concentration of solute is great enough can the transformation of water into ice be retarded. The majority of freeze-tolerant animals reach the critical minimum cell volume when approximately 65% of the total body water is converted into the frozen state.

To understand how some animals survive the stresses of freezing on metabolism and cell volume, let's look at what happens to a peeper or wood frog, starting when it is initially exposed to freezing temperatures. When water freezes on the frog's outer skin, a signal sent to the liver

triggers a massive breakdown of glycogen in the liver. Consequently, a flood of *glucose* molecules enters the circulatory system, raising blood sugar concentrations over 450-fold (over 10-fold greater than a diabetic human with moderately uncontrolled blood-sugar concentrations). This serves as an *antifreeze* by lowering the freezing point through simple colligative properties (p. 79). In less than eight hours, the frog's organs become loaded with this nutrient, which has now assumed an additional role as a **compatible cryoprotectant**. The cryoprotectant acts as an *osmolyte* (p. 617) to help keep the cells in osmotic balance with the increasing osmotic pressure in the ECF. Cryoprotectants must also be *compatible* with macromolecules (p. 617). Thus, inorganic ions cannot be used: They are just as effective in lowering freezing points by colligative mechanisms (and that is why humans dump salt on icy roads in many wintry locales), but unlike the compatible solutes such as glucose, they disrupt macromolecules. (Compatibility is the reason humans use small carbohydrates such as ethylene glycol rather than corrosion-promoting salts in automobile radiators.) Wood frogs, at least, also accumulate *urea*, which at modest levels appears to reduce freezing damage to cells and may also help suppress metabolism. In addition, during thawing—the time when cells have no delivery of oxygen—glucose is immediately available as a fuel to generate ATP. Studies have shown that a frozen frog ventricle regains its ability to contract if it is thawed in the presence of glucose but not in the presence of other cryoprotectants such as glycerol. Using this strategy, the frog is ready to resume its active life.

Other animals are also freeze tolerant. For example, Arctic earthworms accumulate glucose in the winter, which serves as both a cellular antifreeze and fuel source. Many insects employ similar mechanisms, often using other carbohydrates such as *trehalose* (p. 614) as compatible cryoprotectants and antifreezes. In addition, many of these animals actually enhance the freezing of their ECFs with **ice-nucleating agents**, small proteins that trigger the formation of small ice crystals. Apparently these agents ensure that ice only forms in the ECF and that ice forms in an ordered fashion rather than in the “normal” way, which would create large crystals that could rupture membranes.

Freeze Avoidance Most overwintering animals are considered intolerant of internal freezing yet may still have body temperatures well below the freezing point. Again, many such animals have antifreeze compounds, but they are used somewhat differently. First, some overwintering animals use compatible cryoprotectants such as sorbitol and glycerol, but throughout the ECF and ICF rather than just the latter. Thus, the ECF is also protected from freezing. Examples include many insects, arachnids, and some Arctic fishes such as the rainbow smelt. However, other insects and polar fishes have special **antifreeze proteins**, which do not work by classic colligative mechanisms. These proteins are effective at much lower concentrations than the compatible cryoprotectants. They generally contain very hydrophilic amino acids and sugar side chains that are thought to bind to growing ice crystals and thus prevent their growth.

In addition to, or instead of using antifreezes, some overwintering animals appear to use the phenomenon of **supercooling**. This is a state of water in which the temperature is well below the freezing point but there is no

trigger or nucleation site to begin ice formation. Some polar fishes and arachnids, such as the Antarctic mite, employ this strategy. Painted turtles (*Chrysemys picta*, common in wetlands across eastern North America) also supercool in the winter, as does at least one mammal, the Arctic ground squirrel (see p. 751). Supercooling is a dangerous strategy, however, because any encounter with external ice can trigger a catastrophically rapid crystallization of body fluids.

Finally, some polar animals such as the Arctic springtail (*Megaphorura arctica*) avoid freezing through *cryoprotective dehydration*. While supercooling, these small insects lose water from their bodies to the point that they cannot freeze. At the same time, they build up *trehalose*, the protective solute we described in Chapter 13 (p. 614) that builds up in many dehydrated organisms in nonfreezing situations.

Ectotherms may survive temporary extreme heat with the heat shock response

Finally, let's examine what ectotherms do when exposed to excess heat. Given enough time, ectotherms may evolve (over many generations) thermostable proteins and membranes. These adaptations appear to have a thermal limit in eukaryotes well below that for prokaryotes; see *Challenges and Controversies: What Is the Maximum Temperature for Life?*

But what happens in the short term? If an organism is exposed to a sudden jump of about 5°C or more in cell temperature, an ancient mechanism is induced: the *heat shock response*. This occurs in all types of organisms from archaea to humans, and involves the activation of genes for **heat shock proteins (HSPs)**, also known as **stress proteins** because other stresses (such as osmotic and chemical shocks) can induce them as well. As shown in Figure 15-16a, these small, thermostable, hydrophobic proteins bind to larger, unfolded proteins and assist their folding into functional conformations. They are attracted to hydrophobic amino acids that are normally in the interior of folded proteins but become exposed on denaturation (unfolding). Some HSPs are always present in cells, where they assist in the folding of newly formed polypeptides coming off ribosomes (hence HSPs are also called *molecular chaperones*). But during heat shock, other HSPs are rapidly induced at the gene transcription level, protecting the cell from heat death. This occurs as follows: In an unstressed cell, there are small amounts of HSPs such as **hsp70**, the most common form (whose weight is about 70,000 daltons). The hsp70s are bound in an inactive state to a protein called **HSF-1** (heat-shock factor 1). Under a sudden heat stress, the hsp70s detach from HSF-1 and bind to and stabilize unfolded proteins. The release also activates HSF-1, which is a *transcription factor* (p. 31). When active, HSF-1 binds to two other HSF-1 proteins to form a trimer (protein complex made of three separate proteins). The trimer enters the nucleus and binds to a *response element* in the DNA (p. 31) called **HSE (heat shock element)**; this action in turn activates the transcription of genes for heat shock proteins. (This mechanism of transcription factors and response elements is a typical process of gene regulation in eukaryotes, as we discussed in Chapter 2.)

As noted, HSPs have been found in all forms of life. Mammals, for example, make them during a fever. An example for a poikilotherm is shown in Figure 15-16b, focusing on hsp70. Two different species of limpets (*Collisella* spp.) live at different levels on a rocky intertidal habitat. The species that lives higher up—and thus is more exposed to excessive heat from the sun when the tide is out—has higher levels of hsp70 and can make more hsp70 than can species living lower in the intertidal zone.

Although HSPs are thought to be universal, heat shock induction can apparently be lost in some species over evolutionary time. Nototheniid fishes, for example, appear to have no heat shock response whatsoever. These Antarctic fish live in a nearly constant temperature environment, about -2°C year-round. In the laboratory, they begin to die of heat stress at 5°C and above! Yet even at 12°C, they cannot make additional HSPs above the basal levels.

Describe the different responses in pure poikilothermy and ectothermic regulation.

Discuss the biochemical adjustments that account for metabolic compensation in ectotherms.

Discuss the differences in freeze tolerance and avoidance, with examples.

Discuss how heat shock proteins aid survival at extreme temperatures.

15.6 Endothermy and Homeothermy

Endothermy has several benefits. The ectotherm's problem of either finding external heat sources or suffering a slowing of metabolism from cooling, can be avoided. Since endotherms usually have body temperatures warmer than their habitats, they have consistently faster biochemical processes than do most ectotherms in the same habitat. This can provide a competitive advantage: expansion of daily activity into nighttime, higher digestion rates, sustained locomotion, habitat expansion, and regulated incubation temperature. Moreover, some endotherms achieve homeothermy—a consistently warm body temperature that allows proteins and membranes to always be at their optima.

But there is a large metabolic cost: Endotherms must generate heat internally to raise body temperature and must do so continuously if they are homeothermic. Heat production ultimately depends on the oxidation of metabolic fuel derived from food, and thus endotherms consume much more energy (5 to 20 times) than do ectotherms of the same mass. Conversely, a high metabolism increases the risk of overheating. So endotherms must also have mechanisms to remove excess heat that are more effective than those of ectotherms. In light of these advantages and disadvantages, we still do not fully understand the evolution of endothermy (see *Unanswered Questions: How, when, and why did endothermy evolve?*).

Challenges and Controversies

What Is the Maximum Temperature for Life?

Although hydrothermal vents can reach 400°C, no life has been found that can tolerate anything close to that level. In 2003, the highest temperature for life yet recorded was demonstrated to be 130°C (266°F), achieved by a hydrothermal vent archaeon. What about animals at the vents? A polychaete annelid, *Alvinella*, which lives at deep-sea hydrothermal vents, has been reported to live at temperatures as high as 80°C. However, many researchers believe the body temperature measurements were flawed (they are difficult to make using a submersible vehicle on an animal that retreats inside a small hard calcium-carbonate tube). Nevertheless, one worm wrapped around the submersible's temperature probe reportedly survived a brief exposure to 105°C! In the laboratory, however, *Alvinella*'s proteins do not work above about the 40 to 45°C range and its collagen (a major connective-tissue protein; p. 65) is stable up to 65°C, suggesting the field data are mis-

leading. In work on a related species, *Paralvinella sulfincola*, Peter Girguis and Raymond Lee placed worms in high-pressure chambers with a regulated temperature gradient ranging from 20°C at one end to 61°C at the other. When kept at their natural habitat pressure, the worms crawled about and settled around the area at 50°C, where they appeared to behave normally. In other experiments, Lee and Christian Rinke found that some individuals could survive short periods at 60°C, and that the species has key enzymes stable up to 50 to 60°C.

On land, two animals rival the vent worm. Saharan desert ants (*Cataglyphis*) and Namibian desert pseudoscorpions (*Eremogarypus perfectus*) have been found to tolerate 55°C body temperatures for a few minutes, and the pseudoscorpion can tolerate up to 65°C in the laboratory! The ant experiences 55°C while running across hot sand to forage at midday. (This behavior gives them a competitive advantage because other animals

Paul Yancey

Paralvinella sulfincola.

are hiding in burrows to avoid the midday heat.) The ants survive in part by loading up on heat shock proteins before foraging. What actually sets the upper limit for these African ants, hydrothermal vent worms, arthropods, and other eukaryotes is not known, but it is suspected to be fundamental features of mitochondrial respiration and membrane stability, gene transcription, and/or translation that cannot be stabilized beyond a certain temperature.

unanswered Questions | How, when, and why did endothermy evolve?

Despite the common view that endothermy and homeothermy have great advantages, scientists are not certain how, when, or even why they evolved. Consider the “when” question: While birds are endothermic, we are still not sure if their dinosaur ancestors were also. Because of their enormous sizes, some dinosaur species would have exhibited gigantothermy (p. 736) but not necessarily true endothermy. But what about smaller dinosaurs? Some fossil evidence suggests that at least some were endothermic—for example, some dinosaur bones have capillary densities similar to those of mammals and higher than in modern (non-avian) reptiles. Recent fossil discoveries of *theropod* dinosaurs (the direct ancestors of birds) have found remnants of feathers and birdlike air sacs (p. 513), consistent with endothermy, as are the birdlike bipedal stances of theropods like *Velociraptor*. Moreover, some fossil embryos and juveniles reveal a rapid growth rate as found in today's endotherms but not ectotherms. However, no dinosaur fossils show evidence of maxilloturbinals, the nasal heat exchangers (p. 745) found in living endotherms. Such exchangers do appear in the late Permian era in some fossils of therapsids, advanced reptiles that are the ancestors of mammals.

The “how” and “why” questions are also perplexing. In shivering mammals, flying insects, and swimming tunas, aerobic loco-

motory muscles are a major or sole source of extra heat. Thus, some biologists have proposed that enhanced aerobic locomotion evolved first and that only later was the heat output used for thermoregulation. Others propose the converse: that heat generation evolved first and that later benefited locomotory ability. Another hypothesis is that high body temperature initially arose because it greatly restricts infections by fungi. Yet other researchers suggest that the ability to keep embryos at an optimal developmental temperature was the first selective advantage of endothermy in land animals. Finally, the latest hypothesis is that endothermy began in herbivores. Eating plant matter yields a lot of carbon but very little nitrogen. Endothermy allows not only a way to eat more food to obtain that nitrogen but also the ability to “burn off” the excess carbon. Definitive evidence to distinguish among these competing ideas is still lacking. <<

Birds and mammals maintain a consistent internal core temperature (homeothermy)

Many organisms have evolved endothermy: birds, mammals, some fishes and non-avian reptiles, some insects, and even some plants! In all cases, these organisms rely on high levels of *aerobic metabolism* for sustainable heat production. High aerobic ability has another function: Most endotherms rely on aerobic metabolism for locomotion more than do ectotherms (with few exceptions) (see *Unanswered*

(a)

(b)

FIGURE 15-16 Role and regulation of heat shock proteins.

(a) Model for regulation of hsp70, a major heat shock protein whose activity is activated by sudden temperature increases and other stresses. Under nonstress conditions, hsp70 (along with hsp40 and 90) is bound in an inactive state to heat-shock factor 1 (HSF-1) in the cytoplasm. Under temperature stress, this complex dissociates, and the hsp proteins bind to other, unfolded cell proteins, preventing aggregations and assisting in their refolding. The unbound HSF-1 moves to the nucleus, forms a trimer (three HSF-1 proteins), and binds to a promoter element in the DNA called the heat shock enhancer (HSE). This in turn activates the gene for hsp70, leading to synthesis of hsp70 mRNA and thus more hsp70 proteins to aid in the stress response. (b) *Collisella* limpets and their production of hsp70 at various temperatures. *C. scabra* lives higher in the rocky intertidal zone than *C. pelta*, and thus is exposed to higher temperatures more often. Hsp70 production is quantified by the incorporation of radioactive amino acids, determined by radioactive counts per minute (cpm).

Questions: How, when, and why did endothermy evolve? Thus, a lizard (ectotherm) may have tremendous burst (anaerobic) capacity that allows it to outrun a mammal of the same size over short distances. However, in a long-distance chase the mammal's aerobic capacity allows it to outrun the lizard, which fatigues quickly.

Among all the different groups of endotherms, only birds and mammals exhibit homeothermy in all of their core organs. We consider these first. The other animals, which are more variable, are discussed later as *heterotherms*.

It is important to recognize that core body temperatures vary among species of birds and mammals (Table 15-3).

Monotreme mammals (platypuses, echidnas), have lower set points than most placental mammals, which in turn have lower set points than most birds. Why these different set points have evolved is not clear. However, one consideration is that it is physiologically easier to warm up than to cool off. Heat is produced by metabolism (following the Second Law of Thermodynamics). But cooling off in an environment hotter than an animal's body requires evaporation of water—often a precious resource, and one that works poorly or not at all at high humidity (p. 735). Thus, it has been proposed that endotherms have evolved optima that are slightly above the average high environmental temperature of their ancestral habitats.

TABLE 15-3 Core Body Temperatures (T_b) Characteristic of Endothermic Vertebrates

Taxon	Common Names	T _b (°C)
Mammals		
Monotremes	Echidna, platypus	30
Edentates	Anteaters, etc.	33–34
Marsupials	Possums, kangaroos, etc.	36
Insectivores	Hedgehogs, moles, etc. Shrews	36 37–38
Chiropterans	Bats	37
Cetaceans	Whales, etc.	37–38
Pinnipeds	Seals, etc.	
Rodents	Mice, rats, etc.	
Perissodactyls	Tapir, rhinoceros, horses	
Primates	Monkeys, humans, etc.	38–39
Carnivora	Dogs, cats, etc.	
Artiodactyls	Cows, camels, pigs, etc.	
Lagomorphs	Rabbits	
Birds		
	Penguins	38
	Ostrich, petrels, etc.	39–40
	Pelicans, parrots, ducks, gamebirds	41–42
	Passerine songbirds	42

Body temperatures also vary among individuals, and vary throughout the day within individuals. For diurnal mammals (including humans), body temperatures typically fall 1 to 2° C at night in response to a biological clock (p. 276). (This is one reason why most humans feel particularly sluggish if awakened before dawn.) The camel, which we described earlier (p. 733), varies even more. Furthermore, there is no one body temperature, because temperature can vary from organ to organ, even in the core; for example, active skeletal muscles are warmer than most other organs.

To maintain a stable core temperature, heat gains must balance heat loss, with mechanisms to gain, retain, generate, and lose excess heat

To maintain a constant total heat content and thus a stable core temperature, an animal body must balance heat input and output (Figure 15-11). We now elaborate on the means by which birds and mammals can adjust heat gains and losses to regulate core body temperature. Recall that the mechanisms fall into broad categories of *gain*, *retain*, *generate*, and *lose* (p. 736).

A roadrunner ruffles its feathers to expose its dark skin, which absorbs sunlight to help heat the animal's blood.

Gaining External Heat/Avoiding Loss to Cold Environs Birds and mammals evolved from ectothermic ancestors and thus have inherited many of the thermoregulatory behaviors and physiology of ectotherms. These include the following:

1. **Ectothermic behavior.** A cold bird or mammal may seek out sunshine or a warm surface, whereas a warm endotherm avoids excessive environmental cold, just as a lizard does. Thus, basking behaviors (serving as effectors) are common in many birds and mammals, especially smaller ones with their high ratios of surface area to volume, and especially in cold weather. House cats, for example, are well known to bask in patches of sunlight. Larger mammals may also exhibit such behaviors: A human basking on the beach or soaking in a hot tub is behaving like a lizard! Long-distance migrations may also serve in part as a thermoregulatory adaptation. For example, one reason why humpback and gray whales migrate from polar feeding waters in the summer to tropical birthing areas in the winter may be to provide a warm habitat for newborns.
2. **Anatomic features such as dark skin that help absorb solar radiation.** Insulation, such as feathers, actually interferes with this absorption. For this reason hummingbirds and roadrunners, which undergo *torpor* (reduced metabolism and body temperatures, p. 750) at night and bask in the sun in the morning to warm up, erect the feathers of their upper backs. Unlike other skin (which is pink), their skin here is black, to more efficiently absorb the solar radiation.

Retaining Internal Heat Retaining internal heat is accomplished by several mechanisms. Some of these also occur in some ectotherms, but in general these mechanisms are more prominent in endotherms:

1. **Vasoconstriction.** The insulative capacity of skin can be varied by controlling the amount of blood flowing through it. Blood flow to the skin serves two functions. First, it provides a nutritive blood supply to the skin. Second, because blood has been heated in the central core, it carries this heat to the skin. But an animal

FIGURE 15-17 Changes in blood flow to the skin for thermoregulation. (a) In a cold environment, blood can be diverted through shunts (anastomoses) deep under the skin to reduce heat loss. (b) If body heat needs to be released to the environment, or if external heat needs to be absorbed from a warm environment, vessels just under the skin surface can be opened.

Source: Willmer, P., G. Stone and I. Johnston, (2000), "Environmental Physiology of Animals", p. 226, Fig. 8.36. Copyright © 2000 Blackwell Publishing. Reproduced with permission of Blackwell Publishing Ltd.

suffering excessive heat loss can vasoconstrict the skin vessels (Figure 15-17a). This reduces blood flow through the skin, decreasing heat loss by keeping the warm blood closer to the core and thus more insulated from the external environment. As you will see later, the hypothalamus regulates this blood flow in vertebrates. Some ectotherms, such as lizards, can use this process to some extent.

2. **Anatomic insulation.** Birds and mammals have evolved integumentary structures that help trap heat in their bodies. These *insulating* (low-heat-conducting) structures include feathers, hair, and subcutaneous adipose layers (including blubber). Such insulation may appear to be static anatomy, but there are some forms of regulation. Many mammals grow more hair and/or adipose tissue in the autumn. For example, the fur of white-tailed deer is thin in the summer and thick and long in the winter. Furthermore, the winter hairs are hollow, allowing them to trap heat inside the shaft. Birds such as goldfinches increase their feather masses up to 50% by wintertime. In animals with dense fur or feathers, contracting the tiny muscles at the base of the hair or feather shafts lifts the hair or feathers off the skin surface (the *piloerection* reflex, which humans retain vestigially). This puffing up traps a layer of poorly conductive air between the skin surface and the environment, increasing the insulating barrier between the core and the cold air and thus reducing heat loss.
3. **Behavioral insulation.** Additional insulation may result from behaviors such as nest building, postural changes, burrowing, and huddling. Certain postural changes, such as a cat curling up in a ball, reduce the exposed

surface area from which heat can escape. Emperor penguins on the Antarctic ice often huddle in the thousands, a behavior estimated to save 25 to 50% energy. Another thermoregulatory behavior in many birds is perching on one leg, tucking the other leg against the body feathers (the leg is a major site of heat loss in birds.) Consider also the sea otter, which grooms its hair and coats it with an oily secretion to help trap a layer of insulating air.

4. **Larger body size in colder climates.** A trend in avian and mammalian species is the evolution of larger average body sizes (such as penguins) in cold-climate species compared to warm-climate relatives. This trend, known as *Bergman's rule*, is predictable based on the properties of ratios between surface area and volume that we discussed earlier (p. 720).
5. **Countercurrent exchangers.** Blood flow can be used to retain core heat in another way known as a **countercurrent exchanger**, found between the core body and many exposed peripheral organs that could lose heat rapidly. (Recall examples of countercurrent flow in fish gills, fish swimbladder systems, and mammalian nephrons.) The exchanger consists of a set of veins and arteries (or venules and arterioles) placed closely together in a dense array known as a **rete mirabile** (Figure 15-18a). Because the vessels are so closely packed, they are nearly in thermal equilibrium. Crucial to the rete's function is that blood flows in opposite directions (countercurrent) in the two types of vessels. Heat moves in the following way: Warm core blood moves out the arteries toward the cold peripheral tissue. In the rete, it encounters cold blood from that periphery. By conduction, the heat moves into

the cold vein and thus returns to the core. The venous blood leaving the rete is thus nearly at the temperature of the periphery so that little core heat is lost.

Retes are found in many endotherms and heterotherms (Figures 15-18b, c, and d). In mammals, they are often in the limbs, such as a dolphin's fluke and flippers. In birds, they are often in the legs to limit heat loss from the feet. You will see later how heterotherms such as tunas use retes.

A different type of countercurrent exchange is found in the nasal passages of birds and mammals. One drawback of endothermy is the potential for high water loss, and not just from thermoregulatory evaporation. Because the lungs must be kept moist for respiratory gases to dissolve into the cells lining the capillaries, lung air in endotherms is always warm and at 100% relative humidity. There is a danger of losing this body water and its heat content to the external environment. Instead, some of the moisture contained in the air from the lungs condenses onto the comparatively cool surface of the **maxilloturbinals** (folds in the nasal cavity; see p. 508), which can be very elaborate. For example, the camel's nose has an enormous surface area in these folds. The subsequent inhalation of drier air from the external environment evaporates this water and cools the surface of the maxilloturbinals in preparation for the next cycle. This type of countercurrent process is called a *temporal counter-current exchanger*, where the opposing flows of a fluid are separated in time (using one tube) rather than in space (using two separate tubes). Mammals on average reclaim as much as 45% of the water (and its heat content) from the exhaled air, whereas kangaroo rats recycle up to 88% of their body water in this fashion. Birds also have such structures. However, ectothermic vertebrates, including non-avian reptiles, do not.

FIGURE 15-19 Brown adipose tissue (BAT) in endotherms. (a) BAT deposits in bats and other mammals are found between the shoulder blades and other locations not shown. (b) Schematic diagram illustrating how BAT generates heat. When activated by cold or diet via a nerve that releases norepinephrine, the uncoupling protein (UCP) called thermogenin in the BAT cells opens and allows protons (H^+) to pass through the inner mitochondrial membrane. This dissipates the proton gradient as heat without making ATP.

Generating More Internal Heat The hallmark of endotherms is their ability to produce internal heat for the purpose of thermoregulation, as follows:

1. **BMR.** One key adaptation was a large increase in birds' and mammals' overall BMR ("idling speed"). Indeed, the BMR of a bird or mammal is typically 5 to 20 times

greater than the SMR of an ectotherm of the same mass. This appears to be due to "leaky" cell membranes. In one study comparing the liver, kidney, and brain of a mammal (laboratory rat) and a reptile (bearded dragon) of the same mass and body temperature, the endotherm (rat) tissues consumed O_2 two to four times faster, in part because the rat Na^+/K^+ ATPase pump used ATP three to six times faster. The pump runs faster because the rat's membranes are leakier to these ions, so the pump must work harder to restore the gradients.

Thyroid hormones (p. 301) regulate the number of active Na^+/K^+ ATPase pump units in vertebrate cell membranes, with basal levels of these hormones being considerably higher in endothermic than in ectothermic vertebrates. In a resting mammal, most body heat is produced by the thoracic and abdominal organs.

2. **Shivering and other muscular activity.** The rate of heat production can be variably increased above the "idling" BMR level in the cold through skeletal muscle activity. Muscles constitute the largest organ system in the avian and mammalian body and are a ready source of heat from the contractile process. Any type of increased muscular activity (such as exercise and NEAT, p. 729) will increase heat production, but there are also specific thermoregulatory mechanisms. In response to a fall in core temperature caused by exposure to cold, skeletal muscle *tone* gradually increases. (Muscle tone is the constant level of tension within the muscles.) This produces some heat. Soon shivering begins. **Shivering** consists of rhythmic, oscillating skeletal-muscle contractions that occur at a rapid rate of 10 to 20 per second. This mechanism is very effective in increasing heat production; all the energy liberated during these muscle tremors is converted to heat because no external work is accomplished. Within a matter of seconds to minutes, internal heat production may increase two- to fivefold as a result of shivering.

3. **Nonshivering (chemical) thermogenesis.** There is one other way to boost heat production above the BMR level. In most experimental mammals, chronic cold exposure brings about an increase in metabolic heat production that is independent of muscle contraction, appearing instead to involve changes in heat-generating chemical activity. This **nonshivering thermogenesis** is mediated by the hormones epinephrine and thyroid hormone and by sympathetic nerves (which use the neurotransmitter norepinephrine). The cellular mechanisms triggered to produce heat are still not fully understood. One mechanism that has been delineated is found in newborn mammals and most small mammals (especially hibernators). These have deposits of *brown adipose tissue* (BAT) (Figure 15-19a), which (as you saw earlier) is especially capable of converting chemical energy into heat. BAT cells, which are devel-

opmentally derived from muscle rather than adipose cells, contain deposits of triglycerides packed with specialized mitochondria (the combination of fat and mitochondria gives this tissue its color). In their inner membranes, these mitochondria contain the *uncoupling protein* UCP-1 (p. 729), a gated proton (H^+) channel also called **thermogenin** (Figure 15-19b). Recall that normal mitochondria generate ATP by using a proton gradient (see Figure 2-20, p. 52). Normally, the protons move down their gradient through an ATP-synthesizing enzyme complex. But when thermogenin channels open, the two processes (H^+ flow and ATP synthesis) become uncoupled and the protons simply flow down their gradient (through thermogenin) without generating ATP, with the energy from this H^+ flow being completely dissipated as heat.

BAT is particularly important in newborn mammals, which have a higher ratio of surface area to volume than do adults, and in hibernators, where it is used to warm the mammal up rapidly as hibernation ends. Also, as we mentioned earlier (p. 729), there is some evidence that BAT may help lean animals “burn off” excess calories.

Losing Excess Heat/Avoiding Gains from Hot Environs A rise in core body temperature is potentially more dangerous than a decline, because of irreversible denaturation of proteins. Thus, several mechanisms exist to remove excess body heat, which can occur not only from hot weather but also from high muscular activity. These mechanisms are as follows:

1. **Reduced insulation.** Desert endotherms may have inherently low insulation; for example, the camel has virtually no subcutaneous fat, storing its adipose instead in its characteristic hump. As we noted earlier, layers of insulation may be regulated. The shedding of hair by a house cat or dog in the springtime is a familiar example. A bird in hot weather may loosely ruffle its feathers to convect heat from the skin.
2. **Enhanced radiation and vasodilation.** In the process of thermoregulation, skin blood flow can vary tremendously. The more blood that reaches the skin from the warm core, the closer the skin's temperature is to the core temperature. The skin's blood vessels diminish the effectiveness of the skin as an insulator by carrying heat to the surface, where it can be lost from the body by radiation, conduction, and convection. Accordingly, vasodilation of the skin vessels (Figure 15-17b), which permits increased flow of heated blood through the skin, increases heat loss. Some external structures with large surface areas help with heat removal from the blood, such as elephant ears and the large beak of the toucan.
3. **Enhanced evaporation.** As you saw earlier, evaporation is the only way to cool off if the environment is hotter than the skin. Recall the importance of the relative humidity (RH, p. 735) of the surrounding air. When the RH is high, the air is nearly or fully saturated with H_2O , so it has limited or no ability to take up additional moisture from the animal. Thus, little or no heat loss can occur on hot, humid days.
4. **Countercurrent exchange.** The rete mechanism discussed earlier for heat retention can also be used to prevent overheating of certain organs. In particular, some fast-running animals such as gazelles have a rete between their brains and the core body, in which warm blood in the carotid artery passes by cool venous blood from the nose, sinuses, and facial skin. This protects the brain from the high heat produced from the skeletal muscles when the animal is running from, say, an attacking cheetah (which also has a similar rete). Horses may protect their brains from overheating in a different way: In addition to cooling sinuses, they have unusual **guttural pouches** (sacs extending from the auditory tubes) surrounding the carotid arteries, which may also help cool the blood.
5. **Avoidance behavior.** Again, like their ectothermic ancestors, birds and mammals seek cooler environs when overheating. This can be a local change, such as moving under a shady tree, or a long-distance process, such as a seasonal migration.
6. **Anatomic reduction of heat gain.** Light-colored surfaces, such as skin, fur, or feathers, reflect sunlight. Camels, for example, have wool in the winter and shiny, reflecting hair in the summer (tropical camels maintain this reflecting hair year-round).

As we noted earlier, evaporative cooling must be balanced with the body's need for water; the camel is an excellent example of this trade-off in a hot climate (p. 733). Some desert birds use the same strategy; that is, they let their body temperatures rise during the day to reduce evaporative cooling, thus saving up to 50% of body water. Another

mechanism involves physiological regulation of the skin barrier. For example, zebra finches deprived of water add layers of lipids to their skin, reducing cutaneous water loss by 75% or more.

The hypothalamus and/or spine integrates a multitude of thermosensory inputs from both the core and the surface of the body

In vertebrates, the hypothalamus controls most mechanisms of thermoregulation. In birds, the hypothalamus appears to control metabolic rate, panting, vasodilation, and shivering, but a reflex integrator in the spine has also been identified that regulates vasodilation and constriction, panting, shivering, and erection of plumage. The hypothalamus (plus the spinal integrator in birds) acts like a “thermostat” in negative-feedback fashion. As we discussed in Chapter 1 (Figure 1-8), a house thermostat keeps track of the temperature in a room and triggers a heating mechanism (the furnace) or a cooling mechanism (the air conditioner) as necessary to maintain the room temperature at the indicated setting. Similarly, the hypothalamus receives afferent information about body temperature from various regions of the body and (particularly in mammals) initiates coordinated adjustments in heat gain and heat loss mechanisms as necessary to correct any deviations in core temperature from the set point. The hypothalamic thermostat is far more sensitive than your house thermostat. The hypothalamus in endotherms can respond to changes in blood temperature as small as 0.01°C.

To make the appropriate adjustments in the delicate balance between the heat loss mechanisms and the opposing heat-producing and heat-conserving mechanisms, the hypothalamus must be continuously appraised of both the skin temperature and the core temperature by means of specialized temperature-sensitive *thermoreceptors*. The core temperature is monitored by *central thermoreceptors*, which are located in the hypothalamus itself as well as elsewhere in the central nervous system and the abdominal organs. These sensors monitor the core temperature that is actually being defended homeostatically. *Peripheral thermoreceptors* monitor skin temperature throughout the body and transmit information about changes in surface temperature to the hypothalamus. To some extent, these sensors serve in *anticipation* fashion. That is, changes in skin temperature give advance warning of potential environmental threats to the core temperature, allowing corrections to be initiated before the core temperature is actually disturbed.

Two centers for temperature regulation are in the hypothalamus. The *posterior region*, activated by cold, triggers reflexes that mediate heat production and heat conservation. The *anterior region*, activated by warmth, initiates reflexes that mediate heat loss. Together, these work to maintain a remarkably consistent core temperature (which, however, oscillates slightly because of feedback delays; see p. 16). Let’s see how.

To regulate core temperature homeostatically, the hypothalamus simultaneously coordinates heat production, heat loss, and heat conservation mechanisms

Let’s now pull together the coordinated adjustments in heat production as well as heat loss and heat conservation in response to exposure to either a cold or a hot environment for

a mammal (Figure 15-20). In response to cold exposure, the posterior region of the hypothalamus directs increased heat production, such as increased muscle tone and shivering and BAT activity, while simultaneously decreasing heat loss (that is, conserving heat) by skin vasoconstriction and other measures. Because there is a limit to the ability to reduce skin temperature through vasoconstriction, when the external temperature falls too low, even maximum vasoconstriction is not sufficient to prevent excessive heat loss. Accordingly, other measures must be instituted to further reduce heat loss, such as puffing up of hair. After maximum skin adjustments have been achieved physiologically, further heat loss can be prevented only by behavioral adaptations (as we described on p. 736).

Under the opposite circumstance—heat exposure—the anterior part of the hypothalamus reduces heat production by decreasing skeletal muscle activity and promoting increased heat loss by inducing skin vasodilation. When even maximal skin vasodilation is inadequate to rid the body of excess heat, sweating or panting is brought into play to accomplish further heat loss through evaporation.

Thermal Neutral Zone The consequences of thermoregulatory actions on metabolism are illustrated in Figure 15-21, which shows the metabolic rate as a function of environmental temperature. In the middle of this diagram lies the **thermal neutral zone (TNZ)**, a range of environmental temperatures in which the animal does not need to expend significant energy for thermoregulation. In this zone, mechanisms involving insulation, blood vessels, and low-energy behaviors are sufficient. Below the neutral zone, at a point called the **lower critical temperature**, metabolic rate increases as the special heat-generating mechanisms are activated. If these mechanisms are insufficient, the animal may suffer from **hypothermia** (dangerously low body temperature). Above the neutral zone, at a point called the **upper critical temperature**, metabolism increases because of panting (which uses rapid muscle activity) or heavy sweating (which uses ion transport processes). These activities counterproductively but unavoidably generate even more heat to deal with, leading to the potential for **hyperthermia** (dangerously high body temperatures).

The width of the TNZ and the critical temperatures depend on the effectiveness of the thermoregulatory adaptations that do not require significant energy. Insulation is often the major factor. For example, the lower critical temperature for the lightly insulated cardinal (*Cardinal cardinalis*) is 18°C, whereas for the heavily insulated emperor penguin (*Aptenodytes forsteri*) it is –10°C. In tropical hummingbirds (such as *Colibri delphinae*), there are no critical temperatures; metabolic rate decreases linearly with environmental temperature as the latter is increased from 4 to 40°C. Seasonal acclimatization can alter the TNZ. For example, with a summer hair coat the critical lower temperature for a beef cow averages 15°C (59°F), whereas with a heavy winter coat wind chills of –8°C (18°F) are comfortably tolerated. Fermentation in ruminants also produces heat as a by-product, contributing to the comparatively low critical lower temperatures observed in ruminants.

During a fever, the hypothalamic thermostat is “reset” to an elevated temperature, which can be beneficial

Fever is an elevation in body temperature as a result of infection or inflammation. In mammals, in response to microbial invasion, certain white blood cells release a **pyrogen** (especially *interleukin-1*, *IL-1*), which among its many infection-fighting effects, acts on the hypothalamic thermoregulatory center to raise the setting of the thermostat (see p. 469). The hypothalamus now maintains the temperature at the new set level instead of maintaining normal body temperature. Shivering is initiated to rapidly increase heat production, while skin vasoconstriction is brought about to reduce heat loss, both of which drive the temperature upward. Thus, fever production in response to an infection is a “deliberate” mechanism, not a pathological one.

Although the overall physiological significance of a fever is still unclear, many medical and veterinary experts believe that a rise in body temperature has a beneficial role in fighting infection in mammals, including humans. A fever augments the inflammatory response and may interfere with bacterial multiplication (see p. 469). Experiments with ectotherms have demonstrated that this is an ancient defense mechanism. Infected lizards and fish seek out warmer habitat areas to raise their body temperatures above their normal optimum. This aids survival because ectotherms prevented from elevating their body temperatures in this way do not survive the infection as well. Medical experiments with humans also show that subjects treated with antifever drugs suffer more than untreated subjects from diseases like pneumonia.

Describe mechanisms of “gain, retain, generate, lose” heat in achieving homeothermy in birds and mammals.

Discuss how the hypothalamus maintains homeothermy with respect to temperatures out of the thermal neutral zone, and when and why it elevates temperature to create a fever.

15.7 Heterothermy

In addition to birds and mammals, many other animals (and even some fungi and plants) exhibit some form of endothermy, but unlike birds and mammals, they do not heat all their cores. Furthermore, some animals including many small birds and mammals cannot maintain high core temperatures continuously, because of their high ratios of surface area to volume, coupled with insufficient food supply. Such animals are called **heterotherms**, falling into two broad categories: *regional* and *temporal*.

Regional heterotherms heat only some parts of their bodies

Regional heterothermy occurs in endothermic animals that heat only certain organs or body regions, not their entire bodies. For example, flying insects such as bees and moths heat their thoraxes by the activity of flight muscles. As a

preflight warm-up, some species shiver their flight muscles before takeoff. During flight they can keep their thoraxes at relatively constant and high temperatures by controlling hemolymph flow between the thorax and abdomen, which are connected by countercurrent flow channels (Figure 15-22a). The abdomen has a thin ventral surface, the *thermal window*, through which excessive heat can be lost.

In the marine realm, two groups of fishes—the *lamnid sharks* (such as the great white) and many *scombroid teleosts* (tunas and billfishes)—have evolved endothermy, primarily in their red or aerobic swimming muscles. These animals migrate over long distances, swimming continuously with these muscles and generating constant heat output. But it is not enough to heat the entire body, because too much heat is lost at the gills. A countercurrent rete system between the aerobic muscle and the gills prevents most of the loss (Figure 15-22b). Presumably, these warm, thermally regulated muscles give these fishes the ability to move between warm and cold waters more easily than ectotherms can. Remarkably, some of these fishes such as the swordfish have special heater organs behind their eyes to heat their retinas and brains. These organs evolved out of eye muscles and have become dedicated to heat production only! Presumably, this allows the fish to see prey better in cold, dark waters.

Temporal heterotherms maintain high body temperatures only for certain time periods

Temporal heterothermy is manifested in endotherms that regularly shift from a regulated high body temperature to a low body temperature, most commonly in daily *torpor* and seasonal *hibernation*.

Torpor Many small endotherms with high metabolic demands, such as shrews and birds, enter a short-term dormant state called **torpor** on a daily basis. At night, for example, a deer mouse’s body temperature (Figure 15-23a) drops from around 35°C to as low as 15 to 20°C (depending on environmental temperatures), saving a large amount of energy. (Note that these animals usually do not let body temperatures drop close to freezing, possibly because the energy cost of rewarming on a daily basis would be prohibitive). This is important because this mouse needs almost constant food input to sustain its metabolism in the active state. Of particular interest is the Australian marsupial called the fat-tailed antechinus. This small mammal goes through nightly torpor, with core body temperatures dropping to 16 to 27°C, and it basks in the sun each morning to reheat its body to 33 to 37°C. Unlike other mammals, however, it does not simultaneously use endothermic mechanisms in the initial phases of rewarming. Thus, it uses lizard-like behavior in a fashion that suggests how thermoregulation first started in mammalian ancestors.

In addition, animals that employ daily torpor tend to have longer life spans. Hummingbirds, for example, typically undergo daily torpor and can live up to 10 years. In contrast, Norwegian shrews (six species, all about the same size as hummingbirds) live only 16 to 20 months and do not undergo regular torpor. The so-called southern African elephant shrew (*Elephantus myurus*), which is not a true shrew but is of similar size, does undergo torpor, and it lives four to six years. Thus, reductions in metabolism on a regular

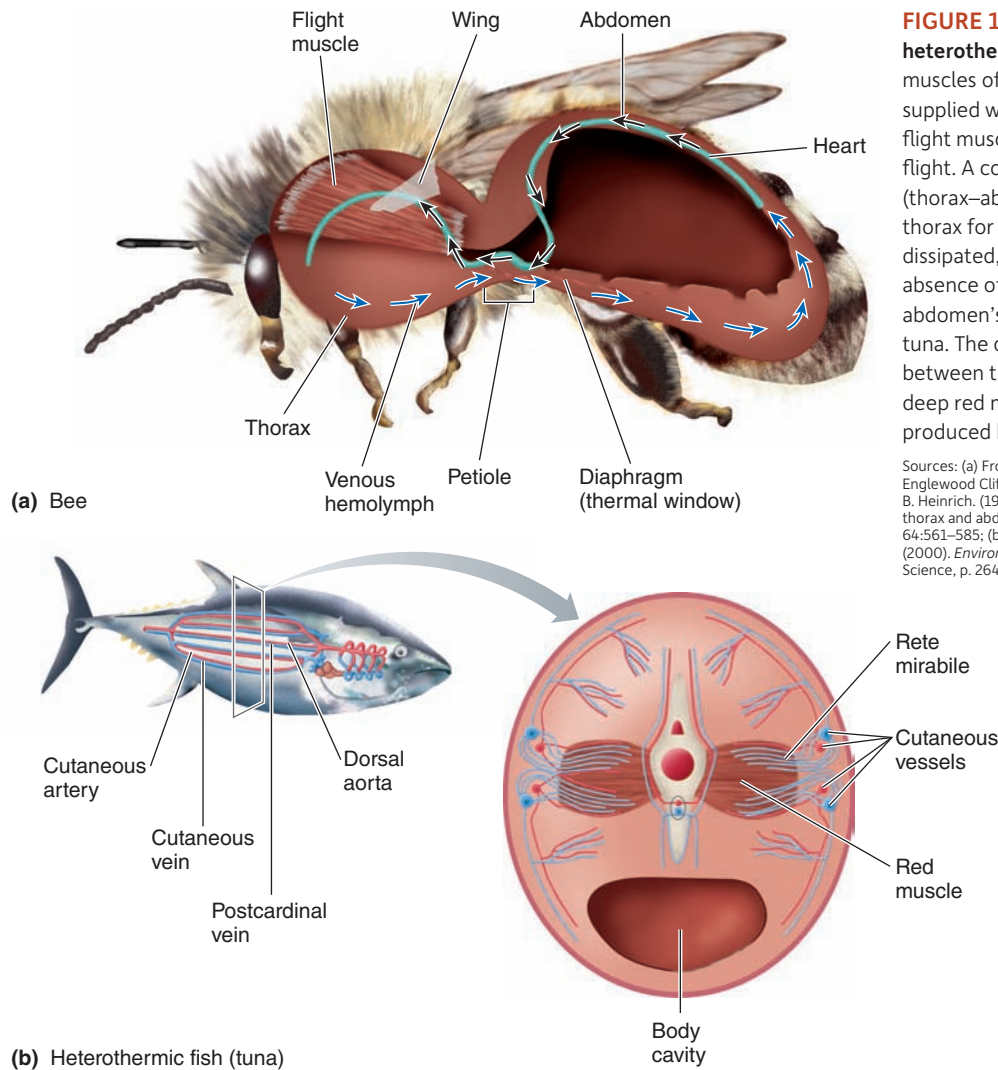

FIGURE 15-22 Countercurrent exchangers in heterotherms. (a) A bumblebee. The flight muscles of honeybees and bumblebees are supplied with blood from the heart, while the flight muscles produce heat at a high rate during flight. A countercurrent flow in the petiole (thorax–abdomen junction) retains heat in the thorax for the flight muscles. If heat needs to be dissipated, venous blood can be pumped in the absence of arterial flow, taking heat to the abdomen's thermal window for removal. (b) A tuna. The diagram shows the rete located between the outer (cutaneous) vessels and the deep red muscle. The rete traps the heat produced by those muscles.

basis may slow the manifestation of aging, much of which is thought to be caused by reactive oxygen species (ROS, p. 53) generated in proportion to metabolic rate.

Hibernation Many small endotherms become nearly or fully poikilothermic as winter approaches, entering a long-term dormant state called **hibernation**, in which body temperatures may drop to near ambient (Figure 15-23b). Remarkably, the Arctic ground squirrel even supercools slightly, with body temperatures of -3°C . Hibernators must store up large amounts of unsaturated fats (which do not turn hard like butter at cold body temperatures) to serve as energy reserves. However, these animals are usually not fully ectothermic. Mammalian hibernators still have a functioning hypothalamic thermostat, but with a greatly lowered set point. The hypothalamus has been shown to regulate a lowering of body temperature and also to regulate heating tissues such as BAT to prevent internal freezing. Many also go through periodic “bouts” of rewarming (Figure 15-23b) and then recooling every few days or weeks. It is not known why they do this, but one hypothesis is that they must warm up in order to void wastes and sometimes to eat cached food, with the latter serving in particular to restore glycogen

stores in their brains. Another hypothesis is that they do this periodic awakening to reactivate their immune systems temporarily in case they have been infected.

Contrary to popular belief, only mammals about marmot size (3 kg) or smaller can truly hibernate, because of the principles of ratios between surface area and volume, discussed earlier. A bear is simply too large to cool off greatly and then reheat in a reasonable time in the springtime, so it essentially sleeps through much of the winter with a body temperature only about 5°C lower than normal. This may be more properly called *winter sleep*, although the term *hibernation* is still often used.

Though hibernation is usually associated with high latitudes, at least one tropical mammal, the Madagascan fat-tailed dwarf lemur (*Cheirogaleus medius*), hibernates. Its body temperature can be purely ectothermic at times, fluctuating by up to 20°C in a day.

Regulation of hibernation is still incompletely understood. In a startling discovery, Mark Roth and colleagues reported in 2005 that mice breathing moderate concentrations of H_2S (the “rotten-egg” gas that is toxic at high levels) went into a reversible, deep hibernation-like state. This is remarkable since mice do not hibernate naturally. How H_2S does

Michener. (1998). Sexual differences in reproductive effort of Richardson's ground squirrels. *Journal of Mammalogy*, 79:1–19.

this, and whether natural hibernators use this gas, is not certain. Some evidence shows that the gas inhibits mitochondrial respiration, but it is also known to be a body regulatory signal (much like NO; p. 93) at minute concentrations.

Some colonial heterotherms create homeothermic “superorganisms”

Finally, spectacular examples of homeothermy can be found in certain animal colonies in which the individual animals are heterothermic or poikilothermic. Several social insects form large colonies that are thermoregulated by the collective behavior of the group. These “superorganisms” include many beehives and termite mounds, in which groups of animals construct ventilation tubes and use their wing beats to heat up or convectively cool the colony. Honeybees also carry water into their hives for evaporative cooling. Thus, beehives can maintain temperatures that are much less variable than the environment. In tropical habitats where the environmental temperature does not vary extensively, some termite mounds are homeothermic all year round.

Thermoregulated hives have recently been shown to be crucial to larval bee development. Pupated larvae were raised at 32, 34, and 36°C in the laboratory. Those raised at the lower temperatures had abnormal neural development. Amazingly, when the colony is infected with a pathogenic fungus, the bees can even create a feverlike state. The fungus, which can kill bee larvae, is greatly inhibited by the elevated temperature. Swarms of honeybees have also been documented using rapid wing beats to create heat intense enough (over 50°C) to kill parasitic wasps attempting to invade the hive.

One amazing group of mammals, the naked mole rats, has evolved a hivelike system that resembles these insect colonies. See *A Closer Look at Adaptation: The Naked Mole Rat—Mammalian Hive Ectotherm*.

15.8 Thermal Physiology and Climate Change

By the first decade of the 21st century, science had firmly established that the atmosphere and oceans are warming up. Indeed, the years 2005 and 2010 were the hottest years on record. Average ocean surface temperature in July 2009 was the warmest ever recorded. This **global warming** is clearly due, at least in part, to anthropogenic (man-made) “greenhouse” gases, mainly CO₂ from fossil-fuel burning and methane from cattle (p. 669), rice paddies, and other sources. (Recall from Chapter 13 that CO₂ is also acidifying the oceans.) These gases, which prevent infrared (heat) radiation from leaving the Earth, have increased dramatically in the last century or so in parallel with temperature increases.

Arctic regions have warmed the most, and climate is becoming more extreme

The warming trend is not by any means uniform. In particular, in the last 30 years, southern temperate regions have not experienced net warming, while the Arctic has experienced

A Closer Look at Adaptation

The Naked Mole Rat—Mammalian Hive Ectotherm

Although traditional physiology states that all mammals are endotherms, there is at least one remarkable exception: the naked mole rat. Twelve known species of naked mole rats live in underground tunnel complexes underneath savanna and grasslands of equatorial Africa. *Heterocephalus glaber* has been the most studied species. These mole rats have almost no body fur (although they do have fine hairs) and no subcutaneous fat, and thus have no effective insulation. Most amazingly, they cannot individually regulate their body temperatures via endothermy. Thus, their body temperatures do fluctuate somewhat. But a degree of homeothermy around 31°C is still achieved using mechanisms like those of social insects. First, they occasionally bask in the sun at their tunnel entrances. Second, the animals do produce some heat, and by huddling together while sleeping (along with some insulation provided by the soil around the tunnel), they can trap much of this heat. Altogether, their thermoregulatory mechanisms are very similar to those of termites in their mounds.

Thermoregulatory physiology of these mammals is not the only parallel to insect physiology. Both species have a social

structure (termed *eusocial*) that is very much like the hive societies of social insects. There is a single queen mole rat, for example, that mates with a few dominant males; there are many workers that dig the tunnels and gather food; and there are a few soldiers that do not work but protect the colony from predators such as snakes. Thus, cooperation within the colony is essential to survival because a pair of mole rats on their own would not be able to perform all the functions needed to cope with environmental challenges.

A naked mole rat.

These animals are becoming laboratory models for medical research because they have other amazing physiological features relating to many other chapters in this book. For example, they have no functional nociceptors for noxious chemicals (Chapter 6, p. 260), allowing them to tolerate the buildup of ammonia in their burrows. They are incredibly tolerant of hypoxia (their brains surviving after 30 minutes without O₂), an obvious adaptation to burrow life (Chapter 11, p. 542). Their two large teeth evolved from fixed chewing structures (Chapter 14, p. 663) into independently moveable digging and manipulating devices, with about 30% of the animal's somatosensory cortex (Chapter 5, p. 192) devoted to those teeth. Perhaps most remarkably, their lifespan is about 30 years, compared to 3 years or less for a similar sized rat (lifespan normally scales inversely with body size; Chapter 1, p. 10). They do not get osteoporosis (Chapter 7, p. 328) and appear to avoid cancer as well, perhaps due to better immune-surveillance mechanisms (Chapter 10, p. 486), and they have proteins highly resistant to reactive oxygen species (ROS; Chapter 2, p. 53).

the greatest warming (Figure 15-24a) including increasing loss of the Arctic ice cap. Climate appears to be getting more chaotic, and the term **climate change** is increasingly used more often than global warming. Earth's climate has many (poorly understood) feedback components ("geophysiology," p. 14) and may exhibit the "flaws" inherent in feedback systems (p. 16) such as oscillating under- and overshoots (e.g., hotter summers but colder winters). Uncertain is whether climate change is subject to negative or positive feedbacks or both. For example, warmer oceans lead to more evaporation, which has increased rainfall and (in winter) snowfall in some areas; likewise, evaporation along with more DMS (p. 14) may also trigger more cloud formation that would block sunlight, thus cooling the planet (negative feedback). Conversely, increased melting of sea ice and snow (which reflect sunlight) exposes more water and dark land to the rays of the sun. The water and land in turn absorb more solar energy, which could accelerate global warming and melting, and so on (positive feedback).

Animal physiology, behavior, and genes are already being affected by warming trends

As you might expect, due to the pervasive importance of temperature, habitat temperature changes are expected to impact all types of organisms. Animal physiologists are increasingly studying such impacts, at the theoretical level using physiological principles, in the laboratory to test potential effects, and in the natural world to test for effects already occurring. At the theoretical level, a study by Michael Dillon, George Wang, and Raymond Huey in 2010 yielded a perhaps unexpected prediction. While the Arctic is warming faster than the tropics (Figure 15-24a), metabolic rates (MR) of tropical ectotherms will likely rise faster than those of Arctic ectotherms (Figure 15-24b). This is because of the Q_{10} effect we described earlier (p. 730), in which MR doubles (or more) with each 10°C rise in temperature. This is an exponentially rather than linear effect. For example, an MR of 1 kJ/hr at 0°C might rise to 2 at 10°C, but an MR of 6 kJ/hr at 25°C could rise to 12 at 35°C. Thus, the absolute change is much greater in the tropics.

Laboratory studies are also revealing. For example, Hans Pörtner and colleagues have shown that, in fish at least, both cooling and warming reduce an animal's *aerobic scope* (p. 720) and that this might be the first major effect of climate change.

What about real-world effects? Considerable evidence has accumulated showing they are already occurring. Let's look at some of the studies.

Heat Shock Although global averages have risen only a few degrees, temporary but severe heat waves have greatly increased. For example, 30,000 flying foxes died of heat stress in Australia between 1994 and 2010 during unprecedented heat waves reaching 43°C or more. Tropical species are predicted to be hardest hit, not only because of the Q_{10} effect, but also because their physiologies are adapted to fairly consistent temperatures rather than seasonally changing ones.

Energy Balance Effects Habitat warming is affecting the “animal energy equation” for many animals, such as the following:

- *Tropical corals* that build reefs rely heavily on symbiotic algae for sugars and amino acids. Under heat stress, corals will “bleach”—that is, they expel their symbionts (with their photosynthetic pigments). Unless the coral can obtain more symbionts, they eventually die. Indeed, large-scale deaths of bleached coral have occurred during unprecedented temperatures. For example, in 2010, 50% of coral colonies died in many reefs of Southeast Asian and Indian Ocean after water temperature increased by 4°C above normal.
- *Tropical lizards* of Mexico are suffering: 12% of 200 populations of *Sceloporus serrifer* (blue spiny lizards) have died out in recent decades. Studies show that those lost populations were in areas where springtime temperatures have increased to the point that the animals probably had to reduce foraging time, staying in burrows to avoid overheating.
- *Yellow-bellied marmots* in Europe are getting fatter (and perhaps more successful) with warming due to longer foraging seasons, but *Arctic foxes* in Iceland have shrunk in size, perhaps as an adaptive way to cool off more easily, or due to decreased food supply.

Habitat Change Some animals have shifted habitats; for example, in 2003 Terry Root and colleagues gathered data from 143 studies and showed that hundreds of Northern Hemisphere species including mollusks, amphibians, birds, and mammals, as well as plants, have shifted north in correlation with warming. Other shifts include these:

- The two *limpet* species we discussed earlier (p. 733) have shifted ranges, with the southern species displacing the northern species in Monterey Bay, which has warmed up.
- The number of continental *butterfly* species in Britain has increased as they are now migrating north, presumably to find cooler temperatures.
- *Birds* in the University of California's Deep Canyon Reserve have moved upslope by 117 m in the last 30 years, correlating with an increase of 5°C in average temperature in the breeding season and a decline in rainfall by 44%.

Reproduction Finally, reproductive effects are also occurring, some of them genetic.

- The *grapevine moth* of Spain now breeds 12 days earlier than a century ago. The change correlates with a 3°C rise in springtime temperatures between 1984 and 2006. This pest, which eats grapevines, may increase its damage to vineyards.
- *Red squirrels* of the Yukon are breeding 18 days earlier than in the past, as springtime temperatures and food supply are increasing. This appears to be a genetic, evolved change.
- *Pitcher-plant mosquitoes* go into winter dormancy based on photoperiod, with northern populations entering dormancy earlier than southern ones. Now, in concert with warming, the northern groups are entering dormancy later, a change that is genetic (evolved).

As you can see, some species may be adapting to warming effects (some behaviorally, some by evolutionary genetic changes), while some are affected negatively and others positively. The long-term effects on ecological interactions are still uncertain. Only time will tell.

How Energy Balance and Thermal Adaptations Contribute to the Body as a Whole

Because energy can be neither created nor destroyed, for body mass and body temperature, respectively, to remain constant, input must equal output in both an endotherm's total energy balance and its heat-energy balance. If total energy input exceeds total energy output, the extra energy is stored in the body, and body mass increases. Similarly, if the input of heat energy exceeds its output, body temperature increases. Conversely, if output exceeds input, body mass decreases or body temperature falls. The hypothalamus is

the major integrating center in mammals for maintaining both a constant total energy balance (and thus a constant body mass) and a constant heat–energy balance (and thus a constant body temperature). However, the effectors for temperature and energy regulation include components of many other systems covered in previous chapters. Energy balance, for example, obviously requires the digestive system and endocrine as well as hormonal regulation (such as insulin) and neural regulation (including behaviors such as eating). Temperature regulation involves (among other things) the skin and its blood vessels (and sweat glands in some mam-

mals), respiration (panting), and skeletal muscles (shivering, or behavioral avoidance or seeking).

Body temperature is one of the most pervasive influences on body functions, which slow down if too cold, and suffer from denaturing macromolecules if too warm. Some ectotherms achieve partial homeostasis by controlling external heat exchanges (mainly through behavior), whereas others are not homeostatic but must adapt through dormancy or internal biochemical adjustments. Endotherms achieve homeostasis (homeothermy) much more consistently with physiological mechanisms.

Chapter Summary

- Life follows the laws of thermodynamics. Energy cannot be created or destroyed (First Law), and useful energy is continually lost to entropy (Second Law). To compensate for entropy, animals require input of food energy, most of which is converted to heat output.
- Energy input must equal energy output, which is measured as metabolic rates in the form of basal metabolism, activity, diet-induced thermogenesis (DIT), and production. Indirect calorimetry through respirometry of O_2 consumption is a common measurement method.
- Energy of production determines net energy balance, which can be positive, negative, or neutral. Basal and standard metabolic rates (BMR, SMR) are the “idling costs” for life, regulated in part by thyroid hormones. BMR and SMR are scaled to body mass: Smaller animals need more energy per unit mass than larger ones, for unclear reasons. Increased muscle activity is the factor that can most increase metabolic rate, as indicated by metabolic scope (ratio of maximal activity to BMR or SMR). DIT occurs after eating in most animals, and involves the costs of processing food.
- Some adult animals maintain long-term neutral energy balance, while others undergo regulated periods of positive or negative energy balance. Food intake in mammals is controlled primarily by the hypothalamus in response to numerous inputs, with internal signals such as orexins. Leptin from adipose and insulin from the pancreas are signals of long-term energy balance, while others such as ghrelin from the stomach and CCK from the intestine signal short-term energy deficiency or sufficiency. Effectors for energy balance are mechanisms to regulate eating and expenditures via regulated changes in BMR, DIT, activity, and production. Brown adipose tissue (BAT), for example, can burn off excess food energy.
- Different energy-balance set points among species result from evolutionary adaptations to different food supplies. Plentiful food favors “lean” set points to maintain agility, while intermittent food favors “heavy” set points for storing up reserves for famine periods.
- Temperature alters rates of chemical reactions and denatures macromolecules. Biomolecules can be altered to work optimally at different temperatures: Membrane fluidity is kept optimal by changes in saturation (homeoviscous adaptation), while proteins evolve to balance thermostability with flexibility needed for activity.
- The thermal adaptation strategies of animals depend on their primary source of heat: Endotherms rely on internal heat, ectotherms on external heat; poikilotherms have variable body temperatures, homeotherms have nearly constant body temperatures.
- Heat exchange between the body and the environment takes place by radiation, conduction, convection, and evaporation. Heat gain versus heat loss determines core body temperature. Animals gain heat from the environment while avoiding losses, retain body heat, generate more body heat, and lose excess heat.
- Body temperatures of ectotherms may follow the environment (poikilothermy), or may be regulated by external exchanges such as solar basking, shade seeking (ectothermic regulation via gain, retain, lose). Some ectotherms can compensate biochemically for changes in body temperatures with internal adjustments in enzyme concentration, pH, membrane saturation, and protein isoforms.
- Ectotherms survive extreme cold by metabolic dormancy and by either freeze tolerance (often with antifreeze carbohydrates in cells to prevent ICF but not ECF freezing), or freeze avoidance with antifreeze proteins, supercooling, or dehydration. Ectotherms may survive temporary extreme heat with heat shock proteins that protect other proteins.
- Birds and mammals maintain a consistent internal core temperature (homeothermy). To do so, heat gain must balance heat loss, using numerous mechanisms to gain (e.g., ectothermic behavior), retain (e.g., insulation, vasoconstriction, countercurrent exchangers), generate (e.g., high BMR, shivering, BAT), and lose excess (e.g., sweating, panting, vasodilation) heat.
- The hypothalamus and/or spine integrates a multitude of thermosensory inputs from both the core and the surface of the body. To regulate core temperature homeostatically, the hypothalamus simultaneously coordinates heat production, heat loss, and heat conservation mechanisms. During a fever, the hypothalamic thermostat is “reset” to an elevated temperature, which can be beneficial.
- Regional heterotherms heat only some parts of their bodies. Temporal heterotherms maintain high body temperatures only for certain time periods. Some colonial heterotherms create homeothermic “superorganisms” such as termite mounds and beehives.
- Climate change, particularly warming, is having documented effects on animal migration, metabolism, habitat location, and reproduction.

Review, Synthesize, and Analyze

1. If more food energy is consumed than is expended, explain the possible fates of the excess energy.
2. Explain how drugs that selectively block key appetite signals would affect feeding behavior.

3. The basal metabolic rate (BMR) is about 72 kcal/hr (301 kJ/hr) in an average human, with nearly all the energy converted to heat. If we could not lose this heat, our temperature would rise until we boiled (although we would die long before reaching that temperature). How long would that take? If an amount of energy ΔU is put into a liquid of mass m , the temperature change ΔT (in °C) is given by the following formula:

$$\Delta T = \Delta U / m \times C$$

Here, C is the specific heat of the liquid. For water, $C = 1.0 \text{ kcal/kg} \cdot ^\circ\text{C}$. Calculate how long it would take for BMR heat to boil your body fluids (assume 42 liters of water in your body and a starting body temperature at 37°C).

4. Why is it dangerous to engage in heavy exercise on a hot, humid day?

5. Discuss the advantages and disadvantages of ectothermy and endothermy, and why the latter might have evolved in some groups.
6. Different groups of homeotherms have different body temperatures. Why might that be?
7. Do you think fish run a fever when they have a systemic infection? Why or why not?
8. Compare the role of BAT in body-mass regulation and body-temperature regulation.
9. Small endotherms such as hummingbirds are temporal heterotherms, saving energy at night by undergoing torpor. Why don't large animals such as humans do this as well?
10. The discovery that H_2S triggers hibernation in a nonhibernating rodent has led to proposals for human applications. What might those be, and why?

Reproductive Systems

16.1 Introduction: Reproductive Processes

The central theme of this book has been the physiological processes aimed at maintaining homeostasis to ensure survival of the individual animal. However, as we noted in Chapter 1 and in several subsequent chapters, some processes, such as growth and development, are not aimed toward homeostasis, but rather constitute regulated changes. We end this book with a discussion of reproductive systems, which also are not aimed toward homeostasis and, moreover, are not necessary for survival of an individual. Instead, they are essential for perpetuation of species. Ever since the first life on Earth evolved, only cells give rise to new cells; that is, each species survives beyond the lives of its individual members only through reproduction using a complex genotypic “recipe.” Our understanding of the origin of self-reproducing life is highly incomplete, but progress is continuing. Craig Venter in 2010 created the first synthetic genome: a putative “Frankenstein” microbe (*Mycoplasma laboratorum*). His team synthesized a DNA molecule and placed it in a bacterial

cell, which had its DNA removed, thus instructing the cell to operate and reproduce with an entirely new blueprint. Theoretically, this feat may yield important insight into the initial evolution of life; it may also open the door to the creation of novel genomes, which could be designed to perform specific reactions, leading to advances in environmental and energy applications.

Animals may reproduce asexually or sexually

Those first cells on Earth, and indeed all extant prokaryotes, reproduce by mitosis: a *cloning* process in which one cell divides to give rise to two genetically identical cells. Eukaryotic cells also reproduce this way, but eukaryotes also evolved an innovation called *sex*. Let’s look at animal reproduction, which can occur in three ways (with more than one occurring in some species):

1. **Budding or fission**, in which an animal produces a “copy” of itself without embryonic development; for example, some sea anemones split in half to produce two adults from one.

2. **Parthenogenesis**, in which an unfertilized egg develops into an embryo (see p. 767).
3. **Sexual reproduction**, which depends on the union of male and female **gametes** (reproductive, or **germ**, cells), each with a single set of chromosomes (*haploid*), to form a new individual with a unique *diploid* (that is, twice haploid) set of chromosomes (Figure 16-1).

Perhaps surprisingly, biologists since Darwin have struggled to understand why sexual reproduction is so widespread among eukaryotes but not prokaryotes. The first two methods above are called *asexual* cloning, a much faster way to reproduce that seemingly should allow rapid takeover of a habitat. However, even sea anemones regularly switch from cloning to sex. Why? Three hypotheses have found experimental support in recent years. (1) Sex allows different beneficial mutations arising in different individuals to come together, enhancing adaptation to changing environments. (2) Cloning passes on all harmful mutations,

FIGURE 16-1 Chromosomal distribution in sexual reproduction.

© Cengage Learning, 2013

whereas sex allows an individual to pick up a healthy gene from a mate for its offspring. Indeed, water fleas (*Daphnia*) that reproduce asexually have more harmful mutations than sexually reproducing populations. (3) By increasing genetic diversity, sex reduces the effectiveness of parasites that have evolved to attack a specific genome. In support of this, Curt Lively and colleagues have found that a group of asexual New Zealand snails died off due to evolving parasites (and were eventually replaced by a rare, different strain of asexual snails); however, a nearby group of sexual snails have had much more steady population levels.

In this chapter we will focus primarily on sexual reproduction. Let's begin with major variations of that process.

Animals may reproduce by *r*-selected, *K*-selected, or intermediate ecological strategies

Animals employ a variety of strategies to ensure that gamete union occurs successfully and sufficient offspring are produced. Conventionally, sexual reproductive processes are classified according to their ecological and physiological adaptations. The ecological approach considers parents to have limited energy resources for producing offspring. Use of parental energy is classified according to two opposite strategies termed *r*-selected and *K*-selected reproduction (*r* is the rate of population growth, and *K* is the carrying capacity of the environment). A highly *r*-selected species places virtu-

ally all its reproductive resources into producing thousands (or more) of offspring, with no parental care and minimal nourishment. Most of the offspring do not survive, but the overwhelming numbers usually ensure that a few survive to perpetuate the species. *K*-selected species, in contrast, produce relatively few offspring, with most of the parental reproductive energy being used for nourishing and/or protecting the offspring. With this strategy, a much greater percentage of offspring survive. Any given species may be fully *r*-selected, such as a seastar that releases millions of eggs with very little yolk (nutritional stores) into the ocean; fully *K*-selected, such as a gorilla that gives birth to a few live offspring that are subsequently nourished and protected; or intermediate, such as a female garibaldi fish that produces hundreds of eggs with yolk for nutrition while the male provides some parental protection of developing eggs.

Animals may reproduce physiologically by oviparity, ovoviviparity, or viviparity

Physiological classification of sexual reproduction uses three categories (Figure 16-2):

- **Oviparous**, meaning that young develop in (and hatch from) eggs after expulsion from the mother's body (*ovi*-, "egg"; *parous*, "produce") (most nonvertebrates, fishes, amphibians, nonavian reptiles).
- **Ovoviviparous**, the production of eggs (not necessarily with shells) that use *yolk* to develop partly or fully *within* the body of the parent and may also hatch there to emerge "live" (*vivi*, "live") (some marine nonvertebrates, a few insects, some fishes and nonavian reptiles, all birds, and many pelagic sharks such as sand tiger and great white sharks).
- **Viviparous**, the production of young within the parent's body that use maternal blood nutrients (usually via a *placenta*) to develop and that emerge "live" (almost all mammals and some pelagic sharks such as the hammerhead).

Note the differences in nourishment for developing young: yolk or other forms of nutrients within the egg in the case of oviparous and ovoviviparous and placenta in the case of viviparous.

Rattlesnakes, some sharks, and guppies are examples of ovoviviparity: The female develops eggs in utero, but because no nutrients are taken from the female during development, these animals are not considered viviparous. As exemplified in the sand tiger shark (*Carcharias taurus*) the yolk is rapidly absorbed and the embryos then feed on unfertilized eggs or other embryos in the uterus. In such species only a single pup may be born from each uterus.

Similarly, because copulation does not occur in true oviparous species (insemination as well as fertilization is external to the genital tract), birds are also classified as ovoviviparous. This classification illuminates some of the reproductive similarities between birds and mammals as well as distinguishing birds from true oviparous species. For example, in true oviparous species the membranes surrounding the egg must be penetrable by the sperm. Some fish and arthropods have **micropiles**, small pores in the shell to allow sperm entrance. Further, in oviparous species embryonic development is external to the maternal genital tract, and thus the maternal contribution to the offspring arises solely

FIGURE 16-2 Reproductive strategies in animals. (a) Snails are oviparous, meaning they release eggs from which the young later hatch. (b) Many snakes and lizards, and some fishes, are ovoviviparous. Their fertilized eggs develop inside the mother, and then offspring are born alive. Yolk reserves sustain development in the egg. In this figure, the live born copperhead offspring are still encased in their egg sacs. (c) Birds are ovoviviparous because there is some internal development in the female. Their fertilized eggs contain large yolk reserves, and they develop and hatch outside the mother's body. (d) Most mammals are viviparous; their young are born live. The young of the opossum complete development in a pouch on the mother's ventral surface. The juvenile stages continue to draw nourishment from mammary glands in the mother's pouch.

from the nucleus and (typically yolky) cytoplasm of the egg. In contrast, insemination and fertilization are inside the maternal genital tract of ovoviviparous animals, including birds, before addition of the shell membrane. Thus, with the earliest embryonic development occurring within the genital tract, the maternal parent has some opportunity to affect embryonic development in addition to providing the nucleus and cytoplasm of the egg.

Viviparous animals have internal insemination and fertilization, with embryonic development occurring entirely within the maternal genital tract using maternal blood nutrients rather than yolk. Offspring from viviparous species are comparatively fully developed, and are to some extent free-

living animals, although there are some variations. For example, rat pups are born **altricial**, meaning they are absolutely dependent on continued parental care, whereas guinea pig piglets are born **precocial** and so require minimal parental care. However, gestation is 64 days in guinea pigs and only 21 in the rat. Rat pups are born blind, hairless, and immobile, whereas the guinea pig piglets are fully furred; the eyes are open, and the young begin foraging soon after birth. The maternal parent may thus affect the developing offspring by providing the egg itself, that is, the nucleus and cytoplasm, the environment for fertilization, and subsequently the environment (including nutrients) for gestation of the developing fetus.

Unlike most reptiles, viviparous plesiosaurs, giant sea creatures living about 75 million years ago, gave birth to their young in the water rather than laying eggs on land. All mammals are viviparous except monotremes, the egg-laying duck-billed platypus (*Ornithorhynchus*) and the spiny anteater (*Echidna*; p. 423). These mammals represent the evolutionary transition between ovoviviparity and viviparity: The porous egg remains developing in the female tract for a considerable time, receiving nutrients from the mother's fluids without a placenta, before being laid with a small amount of yolk (p. 801). The transition is further seen in yolk genes: Whereas birds have three or more copies of a gene for a major yolk protein, *vitellogenin* (p. 795), platypuses have only one (which became a pseudogene in other mammals). Marsupials (*marsupium*, “pouch”), in contrast, are viviparous with a placenta, but their newborn young are highly altricial: They leave the uterus at a comparatively undeveloped stage and climb (using limbs that develop more rapidly than in any other vertebrate) into the pouch of the female, where they attach to a *teat* (p. 810).

Animals use various strategies to ensure breeding at the appropriate time

To optimize the number of offspring that can be raised to maturity, animals need to reproduce at an appropriate time. Let's examine the factors and adaptations involved.

Seasonal Breeding One major strategy for reproductive success is to breed seasonally. Seasonal **anestrus** (reproductive quiescence) evolved as a means of preventing females from giving birth during periods of the year when survival of the offspring is unlikely. Most nontropical seasonal breeders give birth in spring, when environmental and nutritional conditions support growth of the offspring. In birds, for example, seasonal breeding is particularly highly evolved, in part because the young depend on fresh food from the day of hatching. The energy requirements of the parent increase between 20 and 70% above normal because of the requirements associated with yolk synthesis and deposition of yolk in the maturing oocytes; thus, food availability is crucial for the laying female as well as for the hatchling. **Circannual** (biological) clocks in the brain (Chapter 7, p. 277) are partly in control of this seasonal reproduction, but the clocks are set or **entrained** by environmental signals (see Figure 7-8). Photoperiod, the amount of time during the day when there is light, is by far the most important factor determining the onset of the breeding season. The unique regularity of the annual change in day length makes it ideal for regulating seasonal breeding, with the result that most groups of organisms have evolved the ability to use photoperiod as the primary factor regulating reproduction. Thus, in temperate latitudes, virtually all bird species breed in the spring. However, seasonal conditions for all photoperiodic species are not identical each year, so other environmental cues are used for fine-tuning the reproductive processes set in motion by changes in day length. These modifying factors can, within specified limits, accelerate or retard photoperiod-induced gonadal growth. These factors include but are not limited to temperature, presence of the male, and the availability of a particular food source. The great tit, for example, is completely dependent on the availability of caterpillars and thus on the ambient temperature, which affects caterpillar popu-

lations in the spring and alters the onset of their breeding cycle. Similarly, the crossbill reproduces very early in the spring when pine seeds become available.

Photoperiod is not the deciding factor for many tropical and desert species, and breeding cycles may correlate with rainy seasons or may be irregular. In these species, changes in temperature or rainfall determine the timing of gonadal development. For example, the zebra finch (*Poephila gutta*) is an “opportunistic” breeder that lives in the desert and ovulates within a day of rainfall, the increase in humidity apparently triggering the reproductive cycle. If favorable conditions persist, the zebra finch lays a succession of clutches. The fact that the zebra finch remains in a state of readiness is somewhat comparable to the strategy used by *induced ovulators* (see p. 786). Within tropical regions, where there are pronounced wet and dry seasons, reproduction tends to occur in association with the decrease in light intensity associated with the rainy season. However, the environmental triggers are not clear in all cases. Recent studies on tropical (Panamanian) antbirds have shown that even slight changes in photoperiod (from 12 hours to 13 hours daylight) can trigger gonadal growth leading to breeding (only at the equator is daylight time 12 hours year round). In Panama, the longer daylight months are the rainy season.

The time of egg hatching in some species such as reptiles (for example, snapping turtles), arachnids, and insects also normally depends on environmental conditions. For example, eggs that have overwintered or **diapaused** (entered dormancy) rely on seasonal increases in temperature to initiate the hatching process. Normally, a cumulative period above a critical temperature, rather than a simple temperature threshold, is required. Alternatively, the eggs of species such as mosquitoes and dragonflies rely on decreasing oxygen concentrations in water, as well as on increasing temperatures, to cue the time of hatch.

Synchronization and Mating Behaviors A final set of reproductive strategies ensures that both sexes are ready to breed at the same time. Optimal conditions include both environmental (such as springtime) and internal (such as when eggs are ripe and ready for fertilization). Reproduction, especially for females, is energetically costly, and success of a species can depend on efficient use of this energy. We have already discussed seasonal cues that trigger reproduction at an optimal time, but these cues are not very precise, and could, for example, result in some individuals being ready to breed a few days ahead of others. Thus, a variety of other cues and triggers have evolved to synchronize reproduction between the sexes.

For animals with external fertilization and without complex behavior, other environmental cues and pheromones or other biologically produced agents (such as light in fireflies, p. 96) serve as synchronizing signals. A spectacular example is found in the annelid palolo worm (*Leodice viridis*) of South Pacific coral reefs. In the springtime (September to November in the southern hemisphere), the posterior segments of these worms become ripe with gametes. During the last quarter moon of October and November, typically at low tide, this part of the worm detaches (becoming an *epitoke*) and floats to the surface, where it releases its gametes. Because all mature worms in the vicinity do this at the same time, external fertilization has a high probability of success. Female epitokes also emit a pheromone that attracts wriggling male epitokes and stimulates release of sperm.

Palolo worms, *Palola siciliensis* (entire worm with palolo or epitoke attached).

(Many marine annelids reproduce with epitokes.) Similarly, many reef corals spawn synchronously just after full moon in summertime. Although corals lack eyes, recent studies show they have genes for *cryptochrome* proteins, which react to blue light (in this case in moonlight) and were first discovered in biological clocks of more advanced animals (pp. 264 and 276).

Animals with complex behavioral capacities may use pheromones, typically produced by females when they are ready for fertilization, but they often perform elaborate reproductive behaviors called **courtship displays**. These are most commonly ritualistic patterns of movement and/or songs that allow males and females of the same species to recognize and attract each other and to signal and synchronize mating readiness. Courtship behaviors are thought to advertise the genetic fitness of the potential mate, as another way to ensure efficient use of reproductive resources. These behaviors occur in the greatest complexity in vertebrates. It usually (but not always) the male that displays to the female. The most elaborate vertebrate courtships are among the bowerbirds of New Guinea and nearby islands. The male bowerbirds of many species construct elaborate *bowers*, a patch of ground partly enclosed with woven twigs, decorated with small objects such as leaves, shells, dead insects, flowers, paper, and glass, creating a splash of color that stands out in the forest (see Figure 6-1c, p. 211). Females that are ready to mate begin visiting bowers and appear to be attracted to the more elaborate and colorful ones. But that is not enough. The male, on a female's arrival, also performs a ritualistic strutting dance (with sound and puffing of feathers) that needs to be pleasing to the female, or she leaves for another bower. Recent studies using electronic robots made to mimic female bowerbirds show that the males adjust the intensity of their displays according to whether the female appears to be gaining or losing interest. Thus, feedback synchronization occurs between the sexes.

Many arthropods also have complex courtship displays. For many male spiders, these displays are a matter of life or death. A female spider is almost always ready to eat any small animal; thus, the male (who is generally smaller than the female) must signal her in such a manner that suppresses her appetite and increases her readiness to mate. For example, a male wolf spider waves his distinctly marked front legs and **pedipalps** (limbs modified to carry sperm) in ritualistic

patterns in front of the female prior to inserting his pedipalp with sperm into her vaginal opening.

Reproductive capability ultimately depends on intricate relationships among the environment, the nervous and endocrine systems, reproductive organs, and target cells of sex hormones. In this chapter, we focus primarily on the basic sexual and reproductive functions that are under nervous and hormonal control.

List specific differences between oviparous, ovoviviparous, and viviparous as reproductive strategies.

What strategies are employed to ensure that both sexes are ready to breed at the same time?

16.2 Reproductive Systems and Genetics

Unlike the other body systems, which are essentially identical in the two sexes, the reproductive systems of males and females are remarkably sexually dimorphic, befitting their different roles in the reproductive process.

The reproductive system of vertebrates includes the hypothalamus, gonads, and reproductive tract

The primary reproductive organs, or **gonads**, of most vertebrates consist of *testes* in the male and *ovaries* in the female. In both sexes in vertebrates, the mature gonads are found in pairs and perform the dual function of (1) producing gametes (**gametogenesis**), that is, **spermatozoa (sperm)** in the male and **ova (eggs)** in the female, and (2) secreting sex hormones, primarily *testosterone* in males and *estrogens* (the major form being *estradiol*) and *progesterone* in females (see Figure 7-3, p. 272). However, as discussed later, males also make estrogens and females make testosterone with crucial roles—for example, males need estrogens for bone maintenance and sperm production; females need testosterone for *libido*.

In addition to the gonads, the reproductive system in each sex includes a **reproductive tract** encompassing a system of ducts that are specialized to transport or house the gametes after they are released, plus **accessory sex glands** that empty their supportive secretions into these passageways. The accessory glands of insects are paired tubular secretory structures that release their secretions into the genital tract. *Mammary glands* (from Latin *mamma* for “breast,” the origin of the term “mammal”) in mammalian females and *prostate glands* in mammalian males also are considered accessory reproductive organs. The externally visible portions of the reproductive system are known as **external genitalia** as opposed to those internally housed portions, termed the **internal genitalia**.

The anatomy of the reproductive organs is related to the reproductive strategies characteristic for a particular species. Female reproductive organs differ considerably between those animals that require internal fertilization and those that use external fertilization. In addition, female anatomy differs

between those species that store large volumes of yolk in the egg and species that store a relatively small volume.

In some species, evolution of **secondary sexual characteristics**, the many external characteristics of vertebrates that are not directly involved in reproduction itself, can be used to distinguish between males and females. These features include body configuration, hair distribution, feather coloration, and sexual weaponry. Often the secondary sexual characteristics are of great importance in courting and mating behavior: The rooster's comb attracts the hen's attention, and the stag's antlers are useful to ward off other stags and establish dominance in the herd. For the most part, testosterone in the male and estrogens in the female govern the development and maintenance of these characteristics. While the evolution of weaponry in females is infrequently observed, the available examples support their importance. For example, in the African gemsbok antelope (*Oryx gazella*) defense against predators likely drove the evolution of female horns. And the female dung beetle (*Onthophagus sagittaris*) with the heftier horns controls more dung and is able to lay more dung-encased eggs.

Overview of Male Reproductive Functions and Organs The essential reproductive functions of the male are as follows:

1. Production of sperm (*spermatogenesis*) continuously in huge numbers, since only a small percentage survive the hazardous journey to the site of fertilization, and many spermatozoa may be needed to break down the barriers surrounding the female gamete (oocyte).
2. Delivery of sperm to the female.

In most mammals the sperm-producing organs, the **testes**, are suspended outside the abdominal cavity in a skin-covered sac, the **scrotum**, which lies within the angle between the posterior (inferior) appendages. In fishes the paired testes are suspended by membranes from the dorsal part of the body cavity. Mammals have a testicular cooling mechanism, which we consider later in this chapter.

The male reproductive system is designed to deliver sperm to the female reproductive tract in a liquid vehicle, **semen**, which is conducive to sperm viability. In mammals, secretions from the major male accessory sex glands, the **seminal vesicles**, **prostate gland**, and **bulbourethral glands** (Figure 16-3) provide the bulk of the seminal fluid. The **penis**, or **hemipenis** (in avian drakes), is the organ used to deposit semen in the female. Sperm exit the mammalian testes through the **vasa efferentia**, **epididymis**, **ductus (vas) deferens**, **ejaculatory duct**, and **urethra**, the latter being a canal that runs the length of the penis. Instead of an epididymis, in birds the *vasa efferentia* conduct sperm from the testis to a short epididymal duct that is continued as the vas deferens, where it eventually opens into an enlarged area prior to entering the cloaca. Both the vas deferens and enlarged region serve as sperm storage sites. Lacking the accessory glands of

mammals, birds derive seminal fluids from the *seminiferous tubules* and the *vasa efferentia*.

Overview of Female Reproductive Functions and Organs The female's role in reproduction is often more complicated than the male's, especially if internal fertilization is involved. The major structures of the female reproductive tract in reptiles including birds and mammals include the **vagina**, **cervix**, **uterus**, **oviducts**, and external genitalia with internal extensions. These and the **ovaries** lie within the pelvic and abdominal cavity (Figure 16-4a). The essential female reproductive functions include:

1. Production of ova (*oogenesis*) and ovulation in the **ovaries** (although management of the ovulated oocyte depends on species).
2. Reception of sperm.
3. Transport of the sperm and ovum to a common site for *fertilization* (or *conception*).
4. Giving birth to the young (**parturition**) in a viviparous animal, or laying eggs in an oviparous animal.

5. Nourishing the offspring by milk production (**lactation**) in mammals. Placental and marsupial mammals have an additional role: nourishment of the developing fetus internally until it can survive in the outside world (**gestation**, or **pregnancy**) via a **placenta** (structurally different in the two mammalian groups; see p. 803), a vascular structure that supplies the fetus with nutrients in exchange for waste products generated by the fetus.

The mammalian female **oviducts** (**Fallopian tubes** in mammals) capture ova on ovulation (Figures 16-4a and 16-4c) and serve as the site of fertilization if fertilization occurs internally. In some vertebrates, the oviduct is lined with secretory and ciliated cells, which provide a suitable environment for the ova and help transport the spermatozoa. The portion of each mammalian tube adjacent to its respective ovary expands to form the **infundibulum**, a thin, funnel-shaped structure that

captures the egg after release from the ovary. The “catching” of the egg involves active participation on the part of the infundibulum and is not simply a passive process by which the egg is funneled into the oviduct. The infundibulum is covered in fingerlike projections called **fimbriae** (Figure 16-4c), which function to cause the infundibulum to slip over the ovarian surface at ovulation, increasing the probability of “catching” the oocyte.

The product of fertilization is known as an **embryo** (**zygote** before cell division) during early development when tissue differentiation is taking place. The best demarcation is the establishment of organ systems and a functioning placenta in placental mammals. Beyond this time, features of the developing mammal are discernible and the embryo, now termed a **fetus**, is connected to the mother through the placenta for the duration of gestation.

Also in mammals, the thick-walled, hollow **uterus** serves as a protective and nutritive structure for maintaining the fetus. Considerable variation exists among species with regard to the anatomic organization of oviducts and uterus. Among mammals there are three distinct anatomical uterine structures: the **simplex uterus** (primates) with a single uterine body, the **bicornuate uterus** (dog, mare, cow) with a small uterine body and two uterine horns or **cornua**, and the **duplex uterus** (marsupials, rabbits), with two cervical canals that separate each uterine horn into distinct compartments. The corpus is comparatively large in the mare, less extensive in the cow and sheep, and small in the dog and pig while in some species, such as the rat and rabbit, no uterine body is present.

In oviparous and ovoviviparous vertebrates, the oviducts are the site for deposition of nonembryonic egg materials (albumin). In birds and reptiles, the uterus serves as a **shell gland** for calcification of the egg’s outer layer.

The caudal portion of the uterus is the **cervix**, which projects into the vagina. The **cervical canal**, a single small opening, serves as the site of semen deposition in some species or as a pathway for sperm deposited in the anterior vagina to pass into the uterus in others. During mammalian pregnancy the cervix effectively closes the external opening of the uterus, producing a viscous mucus that prevents the entry of foreign material into the uterus. The cervix becomes greatly dilated during parturition, as it serves as the passageway for delivery of the fetus from the uterus to the vagina.

The **vagina**, a muscular, expandable tube connecting the uterus to the external environment (Figure 16-4), is primarily an organ of copulation and serves as a receptacle for sperm. The female external genitalia are collectively referred to as the **vulva** in mammals. In humans and Old World monkeys, two pairs of skin folds, the **labia minora** and **labia majora**, surround the vaginal and urethral openings laterally. The minora are homologous to the male prepuce, whereas the majora are a homolog of the male scrotum (see Figure 16-7 later). In mammals, the **clitoris**, an erectile structure composed of tissue comparable to the glans penis, lies at the anterior end of the folds of the labia minora. Recent work by Helen O’Connell and colleagues has shown that the human clitoris is much larger than is traditionally shown, because much of its mass remains hidden internally, consisting of large, highly vascular internal bulbs that surround the urethra and vagina (Figure 16-4b). These bulbs engorge during intercourse, perhaps to squeeze the urethra closed to prevent infections, to support the vaginal wall during penile penetration, and/or to increase pleasure signaling. These

structures were missed by the prudish Victorian anatomists who, until very recently, provided the diagrams widely used. Interestingly, this situation becomes exaggerated in the female hyena, because the external size of her clitoris is similar to the penis of the male, and she has a false scrotum, making it particularly difficult to distinguish between the two sexes.

The ventral portion of the cloaca of birds is comparable to the mammalian vulva. The cloaca serves as a common pathway for urinary, fecal, and reproductive products.

Reproductive systems in insects include the neuroendocrine organs, gonads, and reproductive tract

The reproductive system of male insects consists of a pair of testes, seminal vesicles, and accessory glands (Figure 16-5a). Most insects have one pair of accessory glands but the desert locust can have up to 15 pairs. Secretions from the accessory glands may include a supply of nutrients to the female and seminal fluid that serves as a carrier for the spermatozoa or that hardens about them to form a sperm-containing capsule, the **spermatophore**. The vas efferens and vas deferens connect the **sperm tube** (site of spermatogenesis) to the ejaculatory duct. As you will soon see, the process of spermatogenesis in each sperm tube is comparable to that in other animals.

In many species such as bumblebees, the formation of a temporary **mating** or **copulatory plug** (also found in some vertebrates, p. 779) after fertilization prevents both loss of semen from the female tract and entry of sperm into the vagina (genital chamber) from a competing male. Contraction of the female ducts then transports the spermatozoa to the **spermatheca**, the organ that stores the sperm prior to entry into the vagina (Figure 16-5b).

The reproductive system of a female insect consists of a pair of ovaries, a system of ducts through which the eggs navigate to the outside, the accessory glands, and the spermatheca (Figure 16-5b). There are three types of insect ovaries: the ancestral form, or **panoistic**, those without nurse cells (cells that provide nutrients to the oocyte in the early stages of development by cytoplasmic processes called **nutritive chords**); and **meroistic**, those ovaries with nurse cells. There are two subdivisions of meroistic ovaries: **telotrophic**, in which the nurse cells are found in the germarium, and **polytrophic**, where the nurse cells are enclosed in the follicle. The **germarium** forms the anterior portion of the ovariole and it is in this egg-producing portion of the ovary that cystocyte divisions occur and the clusters of cystocytes become enveloped by follicle cells. Externally, female insects have an **ovipositor**, an extension of the abdomen, used to lay eggs, for example, by insertion into the ground or into a host animal (as is done by parasitic wasps; see Figure 10-2c, p. 462). The ovipositor is modified in many species for other functions. Considered one of the most feared defenses among animals, the hymenopteran *stinger* is a modified ovipositor. In some species such as infertile honey bees, this sexual structure has completely lost its reproductive function. In such a bee, an entire section of the animal’s abdomen is torn off when it stings its victim, killing the bee in the process.

Recall that in insects it is the *quantity of juvenile hormone (JH)* released at each molt that determines the *quality* of the molt, that is, the time to maturity (p. 281). As the concentration of JH falls, each molting episode triggered by *ecdysone*

FIGURE 16-5 Reproductive systems of insects. (a) Male reproductive system. (b) Female reproductive system.

Source: C. A. Triplehorn, D. J. Borror, & N. F. Johnson. (1989). *Introduction to the Study of Insects*, 6th ed. Belmont, CA: Thomson/Brooks/Cole, p. 57, Figure 3-31.

results in a progressively less juvenile morphology until finally the adult genes are completely expressed and the adult form emerges. The gonads and their accessory glands either develop slowly during the molting cycles or not until the final molt to the adult stage, when the inhibitory effects of JH are absent. Most adult male insects emerge with fully formed reproductive systems, including a supply of mature spermatozoa.

JH plays a role in oogenesis in some species, primarily to initiate **vitellogenesis** (deposition of yolk in an oocyte, including the protein *vitellogenin* made in the fat body; see p. 281), which leads to egg development in the ovarioles (tubular structures forming the ovary). In other species, egg development is delayed until the adult stage, when the release of another brain hormone stimulates ecdysone release from the prothoracic gland in response to environmental cues such as temperature, photoperiod, or even specific in-

put such as ingestion of a blood meal in mosquitoes. Ecdysone, in turn, initiates vitellogenesis and egg maturation in concert with secretions from the ovarioles. Ovulation is believed to be a hormonally controlled event involving the release of a brain peptide, whereas **oviposition** (egg lay) also requires the contribution of the nervous system because the female can carefully select the time and the site for oviposition. Secretions from the accessory glands are species dependent and include such functions as encasing the eggs in frothy or gelatinous secretions, storing them in protective casings (**oothecae**) or simply gluing them to a particular surface, normally the food plant consumed during juvenile stage of development.

Reproductive cells each contain a half set of chromosomes

The DNA molecules that carry the cell's genetic code are not randomly crammed into the nucleus but are precisely organized into **chromosomes**. Each chromosome consists of a different DNA molecule that contains a unique set of genes. Somatic (body) cells contain matching pairs of chromosomes (the **diploid number**), which can be sorted on the basis of various distinguishing features. Chromosomes composing a matched pair are termed **homologous chromosomes**, one member of each pair having been derived from the individual's maternal parent and the other from the paternal parent. Gametes (that is, sperm and eggs) contain only one member of each homologous pair (the **haploid number**).

Gametogenesis occurs by meiosis, resulting in genetically unique sperm and ova

Most cells in an animal's body can reproduce themselves, a process important in growth, replacement, and repair of tissues. Cell division in somatic cells is accomplished by **mitosis**. In mitosis, the chromosomes (which contain the DNA) replicate (make duplicate copies of themselves), then the identical chromosomes are separated so that a complete set of genotypic information (that is, a diploid number of chromosomes) is distributed to each of the two new daughter cells. Nuclear division in the specialized case of gametes is accomplished by **meiosis**, in which only one of the two sets of homologous chromosomes (that is, a haploid number of chromosomes) is distributed to each of four new daughter cells. Importantly, not all the maternally derived chromosomes go to one daughter cell and the paternally derived chromosomes to the other cell. Because of this process, each sperm and oocyte has a unique complement of chromosomes (Table 16-1). When fertilization takes place, a sperm and ovum fuse to form a new individual with one member of each chromosomal pair having been inherited from the maternal parent and the other member from the paternal parent (see Figure 16-1).

The sex of an individual is determined by the combination of sex chromosomes or by environmental stimuli

In some vertebrates, including all mammals and birds, individuals are destined to become males or females by **genetic sex determination (GSD)**, in which a sex is determined by the *sex chromosomes* they inherit. Recall that, as the chromosome pairs are separated during meiosis, each sperm or ovum receives only one member of each chromosome pair. Of the chromosome pairs, **autosomal chromosomes** include all the chromosomes that are shared by the males and females of a species. The remaining pair of chromosomes are the **sex chromosomes** and represent the single pair of chromosomes whose makeup is different for males and females, of which there are two genotypically different types. In contrast, many other vertebrates exhibit **environmental sex determination (ESD)**, in which external factors like temperature determine an embryo’s sex. Let’s look at the details in major groups.

Mammals: XX/XY Mammals have GSD using a larger **X chromosome** and a smaller **Y chromosome**. Sex depends on the combination of these: **Genotypic males** have both an X and a Y chromosome and are called **heterogametic**; **genotypic females** have two X chromosomes and are called **homogametic**. Thus, in mammals, the genotypic difference responsible for all the anatomic and functional distinctions between normal males and females is the single Y chromosome. Males have it; females do not. When the XY homologs separate during sperm formation, half the sperm receive an X chromosome and the other half a Y chromosome. In contrast, during oogenesis every ovum receives an X chromosome because separation of the XX sex chromosome pair yields only X chromosomes. During fertilization, combination of an X-bearing sperm with an X-bearing ovum produces a genotypic female, XX, whereas union of a Y-bearing sperm with an X-bearing ovum results in a genotypic male, XY. Thus, genotypic sex is determined at the time of conception and depends on which type of sex chromosome is contained within the fertilizing sperm.

Amazingly, the duck-billed platypus (a monotreme) has five Y and five X chromosomes in males and ten X chromosomes in females! One of the X chromosomes has the *DMRT1* gene found in the bird Z chromosome, to which we now turn.

Birds: ZZ/ZW Birds use the ZZ/ZW GSD system, with the heterozygote ZW being the female and the homozygote ZZ being the male. The Z and W terms are used to avoid confusion with species in which the female is homogametic. After meiosis, all the sperm cells carry a large Z chromosome, whereas only half of the egg cells carry a Z chromosome and the other half carry a small W chromosome. The mechanism of sex determination is not fully understood but involves differential steroidogenesis under the control of the Z-chromosome *DMRT1* gene, which activates male development. Later you will see how a sex-regulating gene works in mammals.

Reptiles (Nonavian) Many other vertebrates exhibit ESD. In all crocodilians, many turtles and lizards, and a few snakes, sex determination depends on the temperature at which eggs are incubated. In some turtles, embryos become males when

they are incubated at low temperatures and into females when incubated at high temperatures. In crocodillians, females develop at high and low temperatures, and males at intermediate ones. In many species, the female can control the sex ratio of her offspring by choosing a particular thermal habitat for her eggs. In species that exhibit ESD, the mechanism is still genetic (a result of the particular genes inherited). For example, researchers have recently cloned a gene, *Sf1* (*stereodogenesis factor 1*) that is key to sexual development in turtles. Although this gene is present in all turtles of that species, its expression changes with environmental temperature.

Other Vertebrates Most urodele amphibians (newts, salamanders) have a ZZ/ZW system, whereas anurans (frogs) have an XX/XY system. Fish are even more complex, exhibiting one of the most diverse collections of reproductive strategies in the animal kingdom. Some have diffuse, indiscernible chromosomes, making sex determination cytologically difficult. Some exhibit the XX/XY system, others have the ZZ/ZW system, others have ESD based on temperature or social interactions, and some rely on complex combinations of genes; moreover, some are **hermaphroditic** (having both sexes in one individual). The latter come in two forms: **simultaneous** hermaphroditism, in which both sets of reproductive systems are active at the same time, and **sequential** hermaphroditism, in which an individual fish changes gender during its life cycle. The simultaneous form is rare; an example is the mangrove killifish *Rivulus marmoratus*. To complicate things even more, the sequential form can be protandry, protogyny, or both ways. **Protandry**, in which a male becomes a female, is less common; an example is the anemone (clown) fish *Amphiprion*. **Protogyny**, in which a female becomes a male, is common in many coral-reef fishes such as wrasses. Both-ways switching, in which a fish can change between genders in both directions, is rare, but has been seen in some reef gobies. The triggers for switching sexes are not known for all species, but for some the trigger is age (body size), whereas in others it is social interactions such as male–male interactions. In anemone fish, if a female is lost, a male changes into a female. Occasionally some species of fish express multiple forms of one sex. Some mature parrot fish, for example, come in one female and two distinct male forms: a small one (nonmating) and a large “supermale” form (which controls a harem of females and has exclusive mating rights).

Insects In most insects the male has one X (sex) chromosome, whereas the female has two. Males are referred to as XO (if

only one chromosome in the pair is present) or XY (heterogametic with the Y chromosome being different in size from the X chromosome), whereas the female is XX (homogametic). One exception to this pattern is found in the Lepidoptera (butterflies and so forth), where the female is heterogametic.

An unfertilized egg can develop into a male or female in parthenogenesis

Parthenogenesis (p. 757) also occurs in many species including water fleas, some insects, a few reptiles (such as whiptail lizards), and some fishes (including occasionally in hammerhead sharks). Parthenogenetic development that produces females implies that either the eggs failed to undergo meiosis or that the two cleavage nuclei fused to restore the diploid condition, whereas production of a male involves the loss of an X chromosome. Depending on the time of year, gall wasps and aphids produce either males or females parthenogenetically.

At least one group, the bdelloid rotifers, living in an all-female world, reproduce only parthenogenetically (spawn- ing cloned daughters instead of using sex). Recently it has been found that they may avoid the low genetic diversity of asexual reproduction by promiscuous gene transfer: Their genomes are riddled with genes of other animals, fungi, plants, and even bacteria!

Sex differentiation in mammals depends on the presence or absence of Y-chromosome masculinizing determinants during critical periods of embryonic development

Differences between mammalian males and females exist at three levels: genotypic, gonadal, and phenotypic (anatomic and/or physiologic) sex (Figure 16-6).

Genotypic and Gonadal Sex **Genotypic sex**, which depends on the combination of sex chromosomes at the time of conception, in turn determines **gonadal sex**, that is, whether testes or ovaries develop. The presence or absence of a Y chromosome determines gonadal differentiation in mammals. All mammalian embryos have the potential to differentiate along either male or female lines because the developing reproductive tissues include the precursors of both sexes. Gonadal specificity in the human appears during the seventh week of intrauterine life, when the indifferent gonadal tissue of a genotypic male begins to differentiate into testes under the influence of the **sex-determining region** of the Y chromosome (SRY), the single gene that is responsible for sex determination. This gene triggers a chain of reactions that leads to physical development of a male. The sex-determining region of the Y chromosome “masculinizes” the gonads (induces their development into testes) by stimulating production of **testis-determining factor** (TDF) by primordial gonadal cells. TDF, which is a specific plasma membrane protein found only in males, directs differentiation of the gonads into testes. Because genotypic females lack the SRY gene and so do not produce TDF, their gonadal cells never receive a signal for testicular formation, so the undifferentiated gonadal tissue starts developing during the ninth week into ovaries instead.

Because of this pattern, female sex development has been called the “default” state: If the SRY region of the Y chromosome is present, the embryo becomes a male; if not,

it “automatically” becomes a female. This must involve regulatory genes, but while the SRY/TDF “master regulator” for male development has been known for some time, genes for female development are not fully known. One gene, *Wnt-4*, was discovered first as a key regulator of kidney development. Yet it also orchestrates female sexual development: It suppresses the production of testosterone and triggers the development of the *Müllerian duct*, the embryonic duct that develops into the female reproductive tract (see below). In mice with a mutant *Wnt-4* gene, the female does not develop a normal oviduct, uterus, or vagina; instead, she develops internal male structures. Other candidate genes such as a transcription factor called *FoxL2* are being analyzed; mice with nonfunctioning *FoxL2* do not develop ovarian granulosa cells. How *Wnt-4*, *FoxL2*, and other regulatory genes exert their effects is not yet known.

Phenotypic Sex **Phenotypic sex**, the apparent anatomic sex of an individual, depends on the genotypically determined gonadal sex. **Sexual differentiation** concerns the embryonic development of the external genitalia and reproductive tract along either male or female lines. As with the undifferentiated gonads, embryos of both sexes have the potential to develop either male or female reproductive tracts and external genitalia. Differentiation into a male-type reproductive system is induced by **androgens**, which are masculinizing hormones secreted by the developing testes. Testosterone is the most potent androgen. The absence of these testicular hormones in female fetuses results in the development of a female-type reproductive system. Let’s examine the internal tract and external genitalia separately.

- **Reproductive tract:** Two primitive duct systems—the **mesonephric ducts**, or **Wolffian ducts**, and the **paramesonephric**, or **Müllerian ducts**—develop in all mammalian embryos. In males, the reproductive tract develops from the Wolffian ducts and the Müllerian ducts degenerate, whereas in females the Müllerian ducts differentiate into the reproductive tract and the Wolffian ducts regress (Figure 16-6). Because both duct systems are present before sexual differentiation occurs, the early embryo has the potential to develop either a male or a female reproductive tract. Differentiation into a male-type reproductive system is induced by (1) androgens from the newly developed Leydig cells, with **dihydrotestosterone (DHT)**, the reduced form of testosterone, being the most potent one; and (2) **anti-Müllerian hormone (AMH)** from the early Sertoli cells, which trigger the destruction of the precursor of the female genital reproductive tract (Figure 16-6). A hormone from the placenta, **chorionic gonadotropin** (p. 805), activates this early testicular secretion. Testosterone induces development of the Wolffian ducts into the male tract (epididymis, ductus deferens, ejaculatory duct, and seminal vesicles). This hormone, after being converted into DHT, is also responsible for differentiating the external genitalia into the penis and scrotum. Meanwhile, AMH causes regression of the Müllerian ducts. In the absence of testosterone and AMH in females, the Wolffian ducts regress, the Müllerian ducts develop into the female tract (oviducts, uterus, and vagina), and the genitalia differentiate into the clitoris and labia.
- **External genitalia:** Unlike the tract, male and female external genitalia develop from the same embryonic

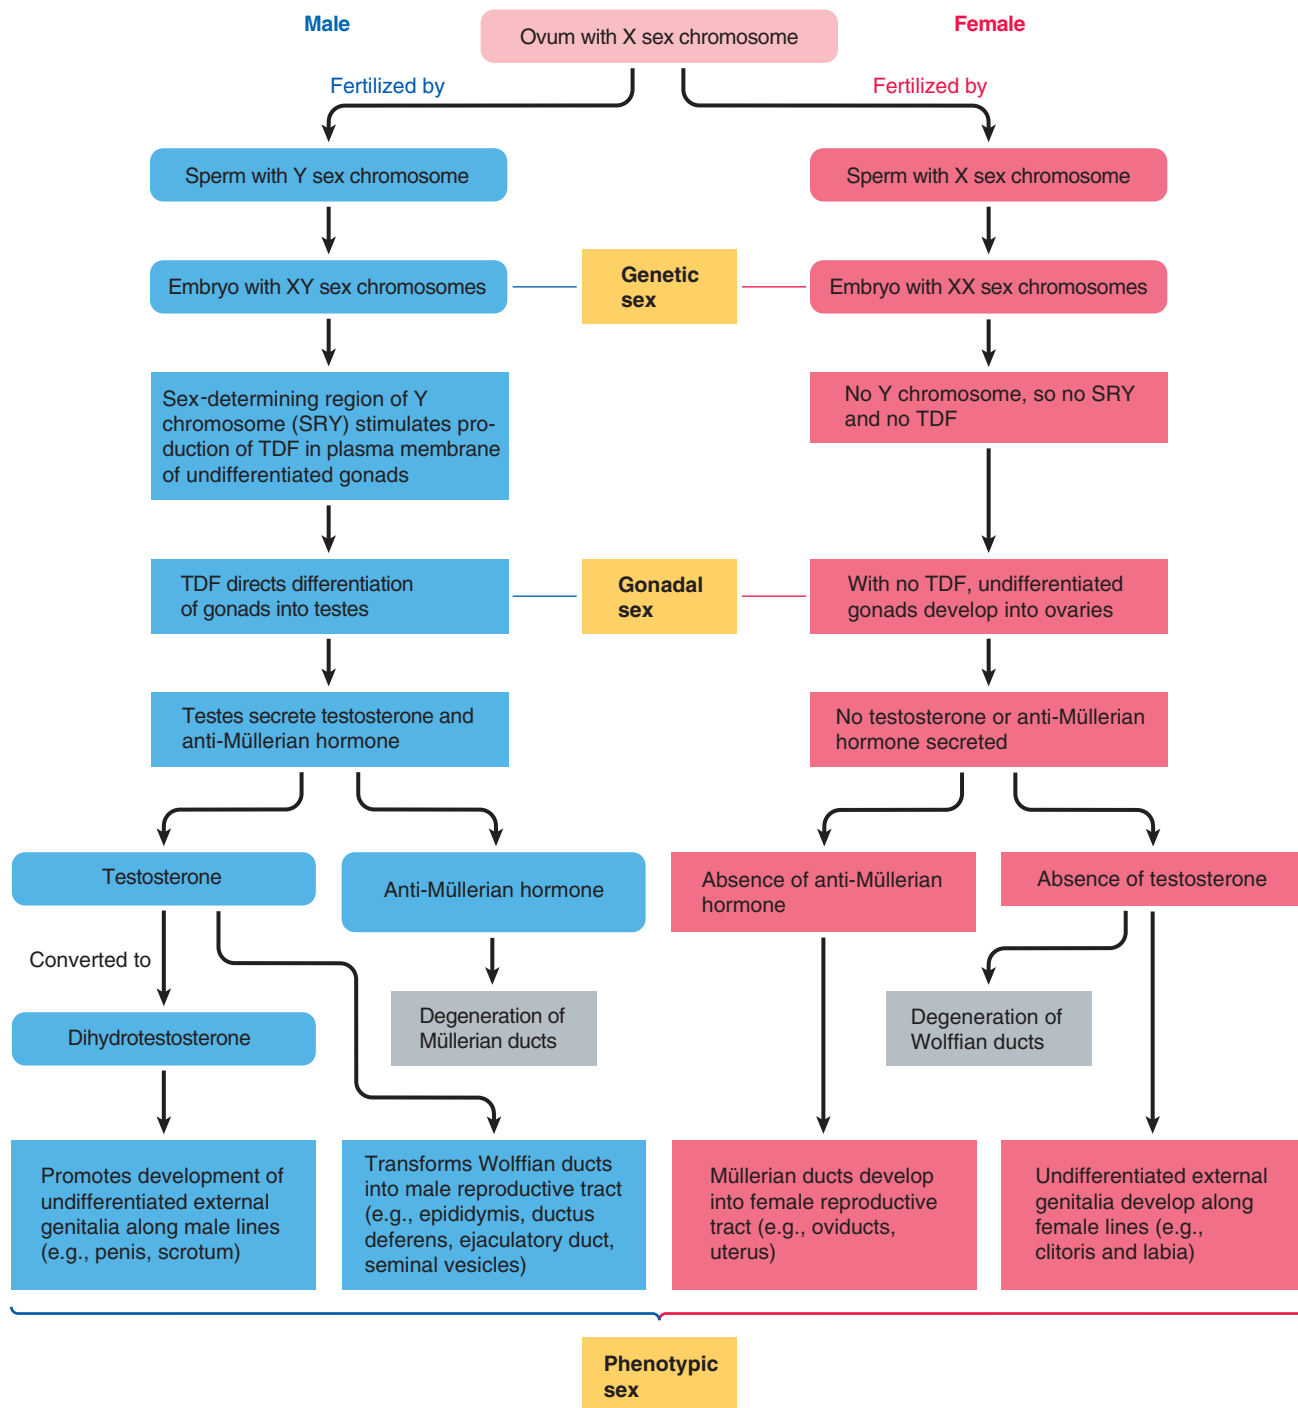

FIGURE 16-6 Sexual differentiation in mammals.

tissue in mammals. In both sexes in mammals, the undifferentiated external genitals consist of a *genital tubercle*, paired *urethral folds* surrounding a urethral groove, and, more laterally, *genital (labioscrotal) swellings* (Figure 16-7). The **genital tubercle** gives rise to highly sensitive tissue—in males the *glans penis* (the distal end of the penis) and in females the *clitoris*. The major distinctions between the glans penis and clitoris are the smaller size of the external parts of the clitoris, the lack of spongy tissue, and the urethral opening at the end of the glans

penis. The urethra is the tube through which urine is transported from the bladder to the outside and also serves in males as a passageway for exit of semen through the penis to the outside. In males, the **urethral folds** fuse around the urethral groove to form the penis, which encircles the urethra. The **genital swellings** similarly fuse to form the scrotum and **prepuce**, a fold of skin (a double fold in the stallion) that extends over the end of the penis and more or less completely covers the glans penis.

Note that the indifferent embryonic reproductive tissue develops into a female structure unless *actively* suppressed by masculinizing factors. Although considered a “default” process, in fact female differentiation requires an equally well-orchestrated (though poorly understood) developmental program. However it is *not due to estrogens* from ovaries. In the absence of male testicular hormones, a female reproductive tract and external genitalia develop regardless of the genotypic sex of the individual. Ovaries do not need to be present for feminization of the fetal genital tissue. Such a control pattern for determining sex differentiation is appropriate, considering that fetuses of both sexes are exposed to high concentrations of female sex hormones throughout gestation. If female sex hormones exerted influence over the development of the reproductive tract and external genitalia, all fetuses would be feminized. It is worth noting that masculinization of the brain at least in part is the result of “female” estrogens, which are generated by an enzyme located in the neural tissue, *P450 aromatase* (see p. 772).

Errors in Sexual Differentiation In the usual case, genotypic sex and phenotypic sex are compatible; that is, a genotypic male appears to be a male anatomically and functions as a male, and the same compatibility holds true for females. Occasionally, however, discrepancies occur between genotypic and phenotypic sexes because of errors in sexual differentiation, as the following examples illustrate:

- In cattle carrying twin fetuses, one of each sex with co-circulation of blood between the two, exposure of the female co-twin to anti-Müllerian hormone regresses the genital reproductive tract (that is, Müllerian duct derivatives), but not the urogenital (that is, posterior vagina and external genitalia), with the consequence that these animals are infertile. Such heifers are termed **freemartins**.
- If testes in a genotypic male fail to properly differentiate and secrete hormones, the result is the development of an apparent anatomic female in a genotypic male, which, of course, will be sterile.

- Because testosterone acts on the Wolffian ducts to convert them into a male reproductive tract but the testosterone derivative DHT masculinizes the external genitalia, a genotypic deficiency of the enzyme that converts testosterone into DHT results in a genotype with male abdominal (that is, undescended) testes and a male reproductive tract but with female external genitalia.
- The adrenal gland normally secretes a weak androgen, *dehydroepiandrosterone*, in insufficient quantities to masculinize females. However, pathologically excessive secretion of this hormone in a genotypically female fetus during critical developmental stages imposes differentiation of the genitalia along male lines.

Ultimately current research studies suggest that a cell's genetic identity "trumps" any hormonal instructions. Studies in **gynandormorphs**, an animal with both male and female characteristics resulting from early-stage anomalies, reveal that individual cells maintain their individual male or female identities during development regardless of their hormonal environment.

Discuss the differences between males and females with regard to genetic, gonadal, and phenotypic sex.

What parts of the male and female reproductive systems develop from the Wolffian and Müllerian ducts? What regulates these developments?

16.3 Male Reproductive Physiology

Testes in most mammals descend into the scrotum to become external

In the mammalian embryo, the testes develop from the gonadal ridge located at the rear of the abdominal cavity. In the last phase of fetal life (dependent on the species), they begin a slow descent, passing out of the abdominal cavity through an opening in the abdominal wall called the **inguinal canal** into the scrotum, one testis dropping into each pocket of the scrotal sac. Testosterone from the fetal testes is responsible for inducing descent of the testes into the scrotum. In most instances in which the testes are retained within the inguinal canal at birth, descent occurs naturally before sexual maturity or can be encouraged with administration of testosterone. Rarely, a testis remains undescended into adulthood, a condition known as **cryptorchidism** ("hidden testis"). Subnormal amounts of androgen are synthesized in the cryptorchid testes, and the elevated core body temperature interferes with mitosis of spermatogonia, so spermatozoa are not normally produced (see next section). This condition is more prevalent in humans, horses, and pigs. In a bull with a **short scrotum**, the testes can be artificially forced into the dorsal region of the scrotum by

placing a large rubber band around the lower portion of the scrotum. Within four weeks the lower scrotum sloughs off at the juncture of the rubber band because of the impaired circulation. Although such a bull is infertile, the marked reduction in scrotal size does not affect testosterone concentrations, with the result that animals maintain a high rate of growth and at slaughter have leaner (reduced fat content) carcasses.

Following descent of the testes into the scrotum through the inguinal canal, the abdominal opening closes snugly around the vas deferens, cremaster muscle, blood vessels, and nerves that traverse between each testis and the abdominal cavity. Incomplete closure or rupture of this opening permits abdominal viscera to slip through, resulting in an **inguinal hernia**, a condition most frequently observed in humans, horses, and swine.

The scrotal location of the testes provides a cooler environment essential for temperature-sensitive spermatogenesis in mammals

The temperature within the scrotum averages several degrees Celsius less than normal body (core) temperature. Descent of the testes into this cooler environment is essential because spermatogenesis in most mammals is temperature sensitive and cannot occur at normal body temperature. This is why a cryptorchid is unable to produce viable sperm.

In those mammals without a scrotum, alternative mechanisms associated with temperature regulation are found. For example, whales and elephants have countercurrent exchange mechanisms (retes; see Figure 15-18a, p. 745) for cooling the testes despite their abdominal location. In some mammals, including the rat and rabbit, the testes move into and out of the body cavity seemingly at will through an opening in the inguinal canal.

unanswered Questions | Why can't sperm develop at core body temperatures?

On the face of it, that mammalian sperm cannot develop at core body temperatures (37 to 39°C) makes no sense. After all, other tissues in mammals have membranes and macromolecules adapted to work at normal body temperatures. Moreover, measurements in domestic chicken's testes (which are internal) show that this bird, at least, has normal spermatogenesis at core temperatures of 40–41°C. (It was once thought that air sacs cooled the testes in birds, but evidence is lacking.) Why mammalian sperm require temperatures of 33 to 35°C is not known. One suggestion is that mutation rate increases with temperature, something that might be detrimental to cells that reproduce so rapidly and in such high numbers. Another idea is that testicles first became external as a sexual display in some mammals, and sperm later lost their tolerance for normal body temperatures. However, we do not know the answer. <<

The position of an external scrotum in relation to the abdominal cavity can be varied by a spinal reflex mechanism that plays an important role in regulating testicular temperature. Reflex contraction of the *external cremaster muscle* on

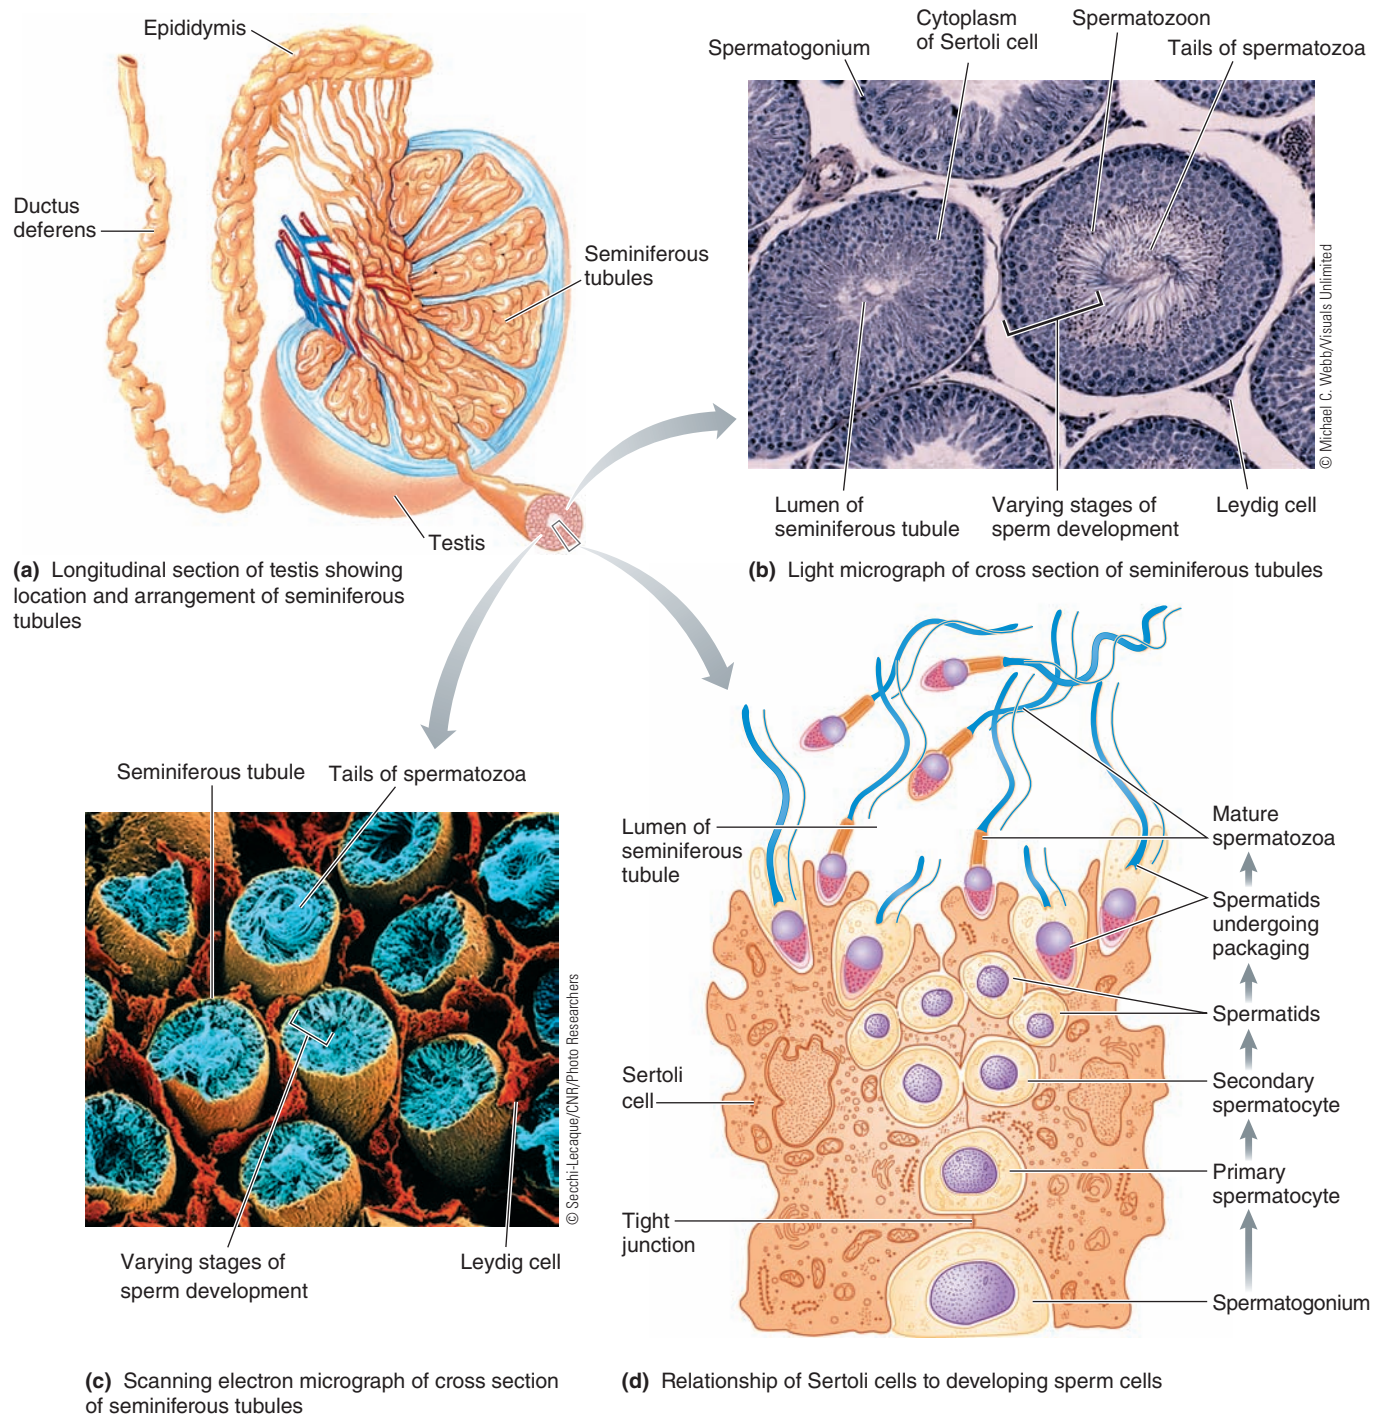

FIGURE 16-8 Anatomy of testis depicting the site of spermatogenesis. (a) The seminiferous tubules are the sperm-producing portion of the testis. (b) The undifferentiated germ cells (the spermatogonia) lie in the periphery of the tubule, and the differentiated spermatozoa are in the lumen, with the various stages of sperm development in between. (c) Note the presence of the highly differentiated spermatozoa (recognizable by their tails) in the lumen of the seminiferous tubules. (d) Relationship of the Sertoli cells to the developing sperm cell.

exposure to a cold environment raises the testicles and the contraction of the *tunica dartos muscle* decreases the scrotal surface area to bring the testes closer to the warmer abdomen. Conversely, on exposure to heat, muscle relaxation permits the scrotal sac to become more pendulous, moving the testes farther from the warm core of the body.

The testicular Leydig cells secrete masculinizing testosterone during the breeding season

The majority of vertebrate testicular mass consists of highly coiled **seminiferous tubules** within which spermatogenesis takes place (Figure 16-8). The endocrine cells that

produce testosterone—the **Leydig**, or **interstitial**, cells—are located in the connective tissue (interstitial tissue) between the seminiferous tubules. Thus, the portions of the testes that produce sperm and secrete testosterone are structurally and functionally distinct. During the breeding season, the testes perform the dual function of producing sperm and secreting testosterone.

Testosterone is a steroid hormone derived from cholesterol, as are the female sex hormones, estrogen and progesterone (see Figure 7-3, p. 272). The Leydig cells contain a high concentration of the enzymes required to direct cholesterol through the testosterone-yielding pathway. Once produced, some of the testosterone is secreted into the blood and transported, primarily bound to plasma proteins, to its target sites of action. A substantial portion of the newly synthesized testosterone is bound by androgen-binding protein in the lumen of the Sertoli cells, where it plays an important role in sperm production by locally increasing androgen concentrations.

To exert its effects, testosterone (and other androgens) bind with androgen receptors in the cytoplasm of target cells. The androgen-receptor complex moves to the nucleus, where it binds with the androgen response element on DNA, leading to transcription of genes that direct synthesis of new proteins that carry out the desired cellular response (see Figure 7-4, p. 274).

Most but not all of testosterone’s actions ultimately are directed toward ensuring delivery of sperm to the female. The effects of testosterone can be grouped into five categories: (1) effects on the reproductive system before birth, (2) effects on sex-specific tissues after birth, (3) other reproduction-related effects, (4) effects on secondary sexual characteristics, and (5) nonreproductive actions (Table 16-2).

Effects on the Reproductive System before Birth Before birth of a mammal, testosterone secretion by the fetal testes masculinizes the reproductive tract and external genitalia and promotes descent of the testes into the scrotum, as already described. Testosterone can cross the blood–brain barrier and does so in the male; in the brain, it is then converted to the estrogen *estradiol* by the enzyme **P450 aromatase**, which defeminizes the hypothalamus by eliminating the GnRH surge center so that a male pattern of hormone secretion occurs. In order to prevent the estradiol produced from the fetal ovaries from defeminizing the female hypothalamus, **alpha-fetoprotein**, a glycoprotein synthesized in the embryonic yolk sac and later the fetal liver, binds estradiol and prevents it from crossing the blood–brain barrier.

After birth, testosterone secretion is markedly reduced, and then slowly increases as the individual animal reaches sexual maturity or *puberty*, supporting the slow, but timely development of the testes and remainder of the reproductive system so it is ready to function at puberty. For example, in the colt, FSH and LH concentrations both peak at around 40 weeks of age. FSH remains elevated until the time of puberty (~83 weeks), whereas LH concentrations return to baseline. Interestingly, testosterone concentrations prior to puberty remain low and do not increase at 40 weeks of age in conjunction with the increase in FSH and LH, but rapidly peak at the time of puberty.

Effects on Sex-Specific Tissues after Birth Puberty is considered a gradual process, not a single event, and is recognized as the attainment of sexual maturity with the ability to

reproduce. Puberty is denoted by the first ovulation in females or the presence of active sperm in the ejaculate in males. At puberty in males, the secretion of GnRH is at the appropriate frequency and quantity to stimulate gonadotropin (LH, FSH; p. 290) release by the anterior pituitary (adenohypophysis). In turn, the gonadotropins promote the Leydig cells to secrete sufficient testosterone as a result of the decreasing sensitivity of the hypothalamus to the negative-feedback effects of testosterone, which initiates spermatogenesis. Testosterone, usually acting in the dihydro form, governs the growth and maturation of the entire male reproductive system. Ongoing testosterone secretion is essential for spermatogenesis and for maintaining a mature male reproductive tract throughout adulthood. Studies using a knock-out mouse with the androgen receptor gene deleted demonstrate an alteration in the expression of several key steroidogenic enzymes in Leydig cells, indicating that testosterone is also an autocrine factor regulating its own production. In this same model there was also observed an arrest of spermatogenesis at the spermatid stage of development. Following castration (surgical removal of the testes) or testicular failure caused by disease, the sex organs regress in size and function.

In contrast, it is believed that female mammals must develop a minimum body fat content before reproductive cycles can be initiated. The link between metabolic status and gonadotropin release, which may involve the peptide signals *leptin* and *kisspeptin*, is not fully understood, as we will discuss later (p. 798).

TABLE 16-3 Average Age (Range) of Puberty in the Male and Female of Various Mammals

Species	Male	Female
Cat	9 months (8–10)	8 months (4–12)
Cow	11 months (7–18)	11 months (9–24)
Camel	3–5 years	3 years
Dog	9 months (5–12)	12 months (6–24)

The onset of puberty varies considerably among and within species (Table 16-3). For example, most birds reproduce in the year after hatch, but some, notably seabirds, hawks, and ratites, exhibit deferred sexual maturity and breed only when three or more years of age. Large albatrosses and condors reach sexual maturity only between the ages of 9 and 11 years. Even within a particular species there is considerable diversity in the age at which an animal first breeds.

Other Reproduction-Related Effects Testosterone governs development of sexual **libido** (drive or desire for sexual activity) in advance of puberty and helps maintain that drive in the adult male. That drive stimulated by testosterone is important for facilitating mating. Once libido has developed, testosterone is no longer absolutely required for its maintenance. Castrated animals sometimes remain sexually active but at a reduced level.

The testes of the boar secrete large quantities of compounds known as C-16 unsaturated androgens. These androgens function as pheromones when secreted in the **preputial glands** of the boar. The prepuce surrounds the penis and contains a diverticulum (pouch). Release of the pheromone stimulates a sow in heat to assume the immobile mating stance.

Effects on Secondary Sexual Characteristics: Antlers and Their Regeneration All male secondary sexual characteristics depend on testosterone for their development and maintenance (see the box, *A Closer Look at Adaption: A Rut for One Season*, p. 795). These male characteristics induced by testosterone are important for mate acquisition and/or retention and include (1) the male pattern of hair, antler, or feather growth; (2) thick skin; and (3) the male body configuration (for example, the heavy musculature associated with the necks of deer in rut) as a result of protein deposition. In human males, (4) a deep voice is caused by enlargement of the larynx and thickening of the vocal cords. A male castrated before puberty (human: eunuch; sheep: wether; pig: barrow; cattle: steer; and so forth) does not mature sexually or develop secondary sexual characteristics.

Antlers are a characteristic feature of male deer and function as weapons and status symbols when rival males compete over females, food, and territory. Antlers are com-

posed of skin, bone, nerves, blood vessels, fibrous tissue, and cartilage and should not be confused with horns, which are a keratinized tissue that grow from their base under the control of underlying mesenchymal cells and remain a permanent fixture for the duration of the animals' life. Testosterone controls the initial development of the antlers at puberty, normally in the spring of the animal's second year of life, as well as the seasonal cycle of casting and regrowth of the antlers in the adult. Antlers are actually bony structures that develop from pedicles (bony protuberances) on the frontal bones of the skull. They are cast and regrown each year in association with the breeding season. The high blood concentrations of testosterone in the autumn (1) trigger a growth phase, during which the antlers are covered in a velvety hair that is endowed with an exceptionally rich blood supply, and (2) prevent the process of rejection of this tissue for the duration of the breeding season.

Once the antlers become fully calcified, the overlying skin peels off; the mature antlers are now dead, insensitive structures that function as weapons for the rutting season. At the end of the breeding season, as the testes regress and concentrations of testosterone decline, the dead antlers are cast, and new ones are regenerated from the living pedicles.

Nonreproductive Actions Testosterone exerts several important effects not directly related to reproduction: induction of aggressive behavior and a general protein anabolic (synthesis) effect that promotes greater muscling and bone growth. These effects play an indirect role in reproduction by enhancing the ability of males to compete for females. Ironically, testosterone not only stimulates bone growth but eventually prevents further growth by sealing the growing ends of the long bones (that is, ossifying, or "closing," the epiphyseal plates—see p. 293).

Spermatogenesis yields an abundance of highly specialized, mobile sperm

The basic pattern of spermatogenesis is functionally similar among all animals. In fact, many of the original descriptions of spermatogenesis were obtained from insect models. Two functionally important cell types are present in the mammalian sperm-producing seminiferous tubules (Figure 16-8a): **germ cells**, progenitors that are mostly in various stages of sperm development, and **Sertoli cells**, which provide crucial support for spermatogenesis (Figure 16-8b, c, and d). **Spermatogenesis** is a complex process by which relatively undifferentiated germ cells, the **A-type spermatogonia** (each of which contains a diploid complement of 2N chromosomes), proliferate and are converted into extremely specialized, motile spermatozoa (sperm), each bearing a randomly distributed haploid set of 1N chromosomes.

Microscopic examination of a seminiferous tubule reveals layers of germ cells in an anatomic progression of sperm development, starting with the least differentiated in the outer layer and moving inward through various stages of division to the lumen, where the highly differentiated sperm are ready for exit from the seminiferous epithelium (*spermiation*) (Figure 16-8b, c, and d). In bulls, spermatogenesis takes 64 days for development from a spermatogonium to a mature sperm. In normal male animals, a large number of spermatozoa are produced each day: approximately 6.0×10^9 in the bull and 16.5×10^9 in the boar.

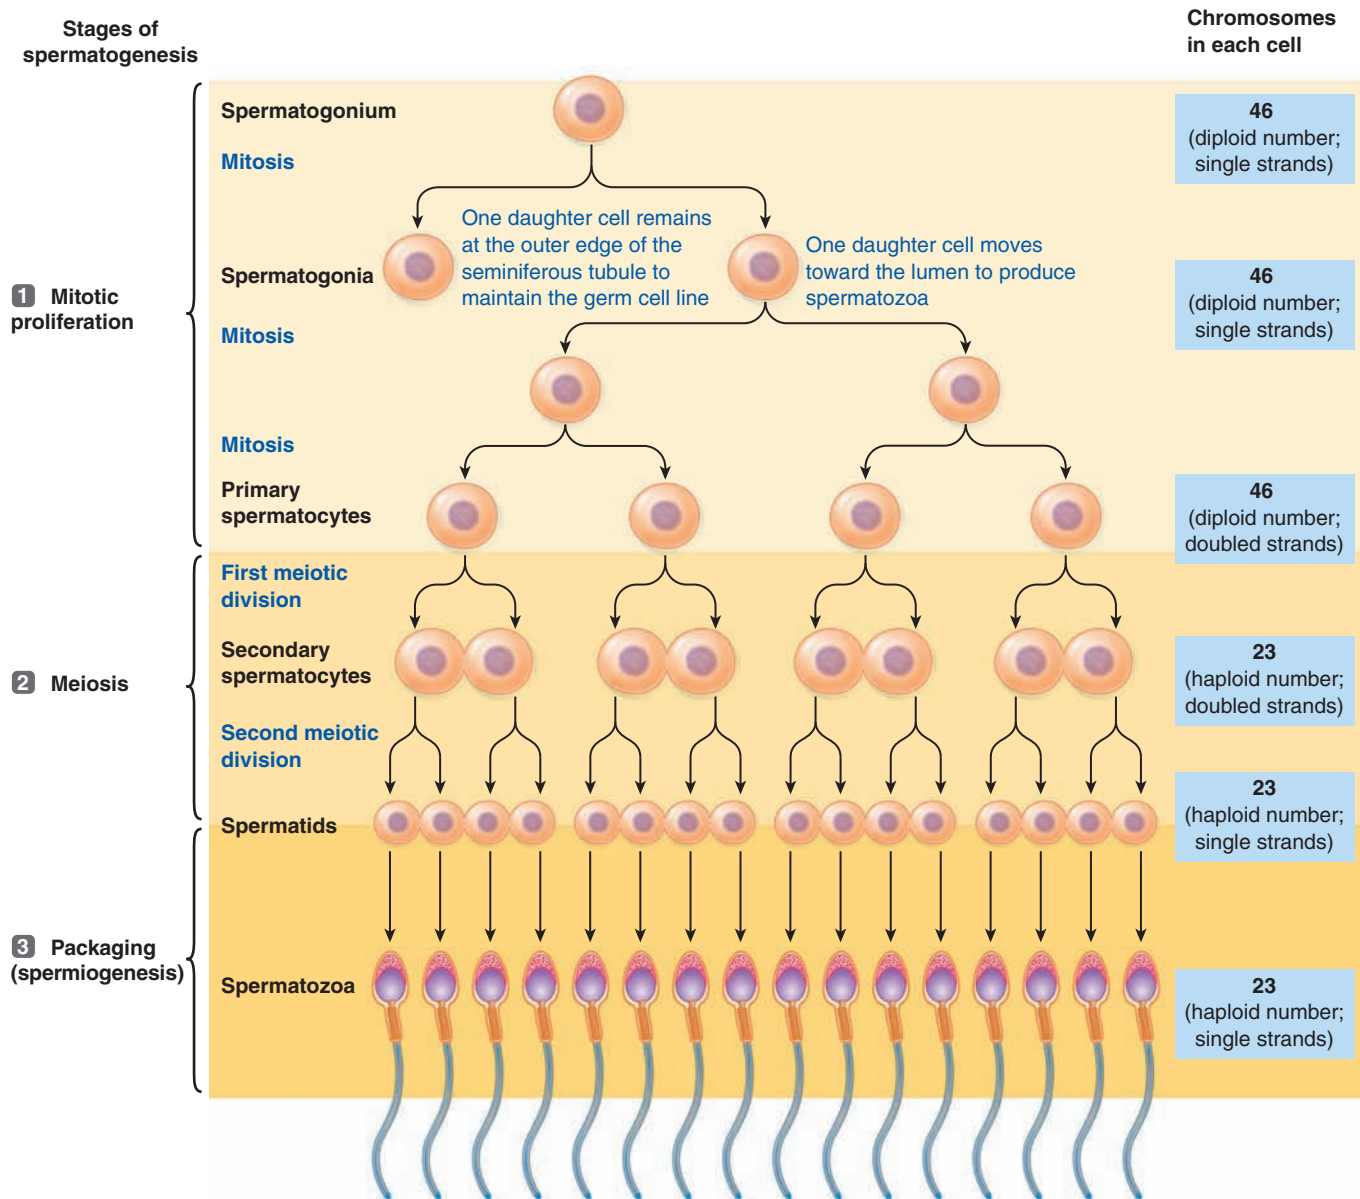

FIGURE 16-9 Spermatogenesis.

© Cengage Learning, 2013

Comparably, recall from Figure 16-5a the sperm tube of a male insect: Each tube has a **germarium** (site where spermatogenesis is initiated) and three zones. Zone 1, or the region of growth at the periphery of the sperm tube, is associated with the maturation of spermatogonia to spermatocytes. Zone 2 is the site of maturation and reduction, and Zone 3 is the site of the transformation of spermatids into spermatozoa.

Spermatogenesis encompasses three major stages: *mitotic proliferation* (*spermatocytogenesis*), *meiosis*, and *packaging* (*spermiogenesis*) (Figure 16-9).

Mitotic Proliferation Spermatogonia located in the basal (outermost) layer of the tubule continuously divide mitotically, with all new cells bearing the full complement of $2n$ chromosomes that are identical to those of the parent cell. Such proliferation provides a continual supply of new germ

cells. Following mitotic division of a spermatogonium, one of the daughter cells remains at the outer edge of the tubule as an undifferentiated spermatogonium, thus maintaining the germ cell line. The other daughter cell starts moving toward the lumen while undergoing the various steps required to form sperm, which are released into the lumen. The sperm-forming daughter cell divides mitotically several times more to form four identical **primary spermatocytes**. After the last mitotic division, the primary spermatocytes enter a resting phase during which the chromosomes are duplicated and the doubled strands remain together in preparation for the first meiotic division.

Meiosis During meiosis, each primary spermatocyte (with a diploid number of $2N$, $4n$ doubled chromosomes with pairing of the homologous chromosomes) forms two **secondary sper-**

matocytes (each with a haploid number of $1N$, $2n$ doubled chromosomes), referred to as the *reductional division* because the number of sets of homologous chromosomes has been reduced, even though there are still two copies of each. The secondary spermatocytes then divide during the second meiotic division separating the two copies of each chromosome into daughter cells during the first meiotic division, yielding four **spermatids** (each with $1N$, $1n$ haploid complement).

No further division takes place beyond this stage of spermatogenesis. Each spermatid is remodeled into a single spermatozoon. Because each sperm-producing spermatogonium mitotically produces four primary spermatocytes and each primary spermatocyte meiotically yields four spermatids (spermatozoa-to-be), the spermatogenic sequence in mammals can theoretically produce 16 spermatozoa each time a spermatogonium initiates this process. Usually, however, some cells are lost at various stages, so the efficiency of spermatogenesis is rarely this high.

Packaging After meiosis, spermatids still resemble undifferentiated spermatogonia structurally, except for their $1N$ complement of chromosomes. Production of extremely specialized, motile spermatozoa from spermatids requires extensive remodeling of cellular elements, a process known as **spermiogenesis**. Sperm are essentially “stripped down” cells in which most of the cytosol and any organelles not needed for the task of delivering the sperm’s genotypic information to an ovum have been extruded. Thus, sperm travel lightly, taking only the bare essentials to accomplish fertilization with them.

A **spermatozoon** has three parts (Figure 16-10): a head capped with an acrosome, a midpiece, and a tail. The **head** consists primarily of the nucleus, which contains the sperm’s complement of genotypic information. The **acrosome**, an enzyme-filled vesicle that caps the tip of the head, is used as an “enzymatic drill” for penetrating the ovum. It is formed by aggregation of vesicles comprising the endoplasmic reticulum–Golgi complex before these organelles are discarded. The acrosomal enzymes remain inactive until the sperm contacts an egg, at which time the enzymes are released. A long, whiplike tail that grows out of one of the centrioles provides motility for the spermatozoon. Motility is powered by energy generated by the mitochondria concentrated within the **midpiece** of the sperm. (Insect sperm lack a midpiece, and the mitochondria are in the tail.)

Until sperm maturation is complete, the developing germ cells arising from a single primary spermatocyte remain joined by cytoplasmic bridges. These connections, which result from incomplete cytoplasmic division, permit cytoplasm to be exchanged among the four developing sperm. This linkage is important in mammals because the X chromosome, but not the Y chromosome, contains genes that code for cellular products essential for development of the sperm. (Whereas the large X chromosome contains several thousand genes, the small Y chromosome has only a few dozen, the most important of which are the *SRY* gene and others that play critical roles in male fertility.) Recall that half the sperm receive an X and the other half a Y chromosome. If it were not for the sharing of cytoplasm so that all the haploid cells are provided with the products coded for by X chromosomes until sperm development is complete, the Y-bearing, male-producing sperm would not be able to develop and survive.

Throughout their development, vertebrate sperm remain intimately associated with Sertoli cells

The seminiferous tubules house the **Sertoli cells** in addition to the spermatogonia and developing sperm cells. The Sertoli cells, which are epithelial cells, lie side by side and form a ring that extends from the outer basement membrane to the lumen of the tubule. Each Sertoli cell spans the entire distance from the outer membrane to the fluid-filled lumen (Figure 16-8b

and d). Adjacent Sertoli cells are joined by tight junctions (p. 66) at a point slightly beneath the outer membrane. Developing sperm cells are tucked between adjacent Sertoli cells, with spermatogonia lying at the outer perimeter of the tubule, outside the tight junction. During spermatogenesis, developing sperm cells arising from spermatogonial mitotic activity pass through the tight junctions, which transiently separate to make a path for them, then migrate toward the lumen in intimate association with the adjacent Sertoli cells, undergoing their further divisions during this migration. The cytoplasm of the Sertoli cells envelops the migrating germ cells, which remain buried within these cytoplasmic recesses throughout their development. Sertoli cells form tight junctions and gap junctions with the developing sperm cells. Recall that gap junctions allow for small molecules to pass directly from one cell's cytoplasm to another's (p. 67). At all stages of spermatogenic maturation, the developing sperm and Sertoli cells exchange small molecules and communicate with one another by means of this direct cell-to-cell binding. Final release of a mature spermatozoa from the Sertoli cell, a process called **spermiation**, requires the breakdown of the tight junctions and gap junctions between the Sertoli cell and spermatozoa.

The supportive Sertoli cells perform the following functions essential for spermatogenesis:

- The tight junctions between adjacent Sertoli cells form a **blood–testis barrier** that prevents bloodborne substances from passing between the cells to gain entry to the lumen of the seminiferous tubule. Because of this barrier, only selected molecules that can pass through the Sertoli cells (such as FSH, the gonadotropin that stimulates the Sertoli cells) reach the intratubular fluid. As a result, the composition of the intratubular fluid varies considerably from that of the blood. The unique composition of this fluid that bathes the germ cells is critical for later stages of sperm development. The blood–testis barrier also prevents the antibody-producing cells in the extracellular fluid entering the seminiferous tubule, thus preventing the formation of antibodies against the highly differentiated spermatozoa.
- Because the secluded developing sperm cells do not have direct access to bloodborne nutrients, the “nurse” Sertoli cells provide nourishment for them. Developing sperm cells cannot efficiently use glucose. The Sertoli cells take up glucose via a GLUT-1 symporter, metabolize the glucose to lactate, then transfer the lactate to the sperm cells, which can use lactate as an energy source.
- The Sertoli cells have an important phagocytic function. They engulf the cytoplasm extruded from the spermatids during their remodeling and destroy defective germ cells that fail to successfully complete all stages of spermatogenesis.
- The Sertoli cells secrete into the lumen **seminiferous tubule fluid**, which “flushes” the released sperm from the tubule into the epididymis for storage and further processing.
- An important component of Sertoli secretion is **androgen-binding protein**. As the name implies, this protein binds androgens (that is, testosterone), thus maintaining a very high level of this hormone within the lumen of the seminiferous tubules. This high local concentration of testosterone is essential for sustaining sperm production. Androgen-binding protein is necessary to retain testoster-

one within the lumen because this steroid hormone is lipid soluble and could easily diffuse across the plasma membranes and leave the lumen. Testosterone itself stimulates production of androgen-binding protein.

- The Sertoli cells are the site of action for control of spermatogenesis by both testosterone and follicle-stimulating hormone (FSH). IGF-1 also stimulates the proliferation of Sertoli cells and spermatogenesis. The Sertoli cells themselves release another hormone, the peptide *inhibin*, which negatively regulates FSH secretion.
- During fetal development, Sertoli cells also secrete anti-Müllerian factor (AMH).

LH and FSH from the anterior pituitary control testosterone secretion and spermatogenesis

The vertebrate testes are controlled by the two gonadotropic hormones secreted by the anterior pituitary, **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, both of which are produced by the same cell type, the gonadotrope. Each hormone in each sex acts on the gonads by activating cAMP.

Feedback Regulation of Testicular Function LH and FSH act on separate components of the testes (Figure 16-11). Luteinizing hormone acts on the Leydig (interstitial) cells and regulates testosterone secretion. Follicle-stimulating hormone acts on the Sertoli cells to enhance spermatogenesis. Secretion of both LH and FSH from the anterior pituitary is stimulated in turn by a single hypothalamic hormone, **gonadotropin-releasing hormone (GnRH)** or inhibited by a **gonadotropin-inhibiting hormone (GnIH)**. GnIH was first localized in the hypothalamic paraventricular nucleus of birds, while in mammals, GnIH cell bodies were found clustered in the mediobasal hypothalamus with pronounced projections and terminals throughout the central nervous system.

Recent studies have shown that GnIH also has direct inhibitory actions on GnRH neurons. GnIH reduces rates of firing and induces hyperpolarization in substantial portions of the total population of GnRH neurons. Moreover, since GnIH neurons are not neurosecretory, it appears that GnIH may have largely a hypothalamic site of action on gonadotropin secretion. It is well known that stress inhibits reproduction, in part due to an increase in GnIH production during exposure to acute stressors. Studies in male rats reveal that GnIH production also reduces the expression of sexual behaviors.

GnRH is released from the hypothalamus in secretory bursts (pulses). In seasonally breeding vertebrates, the rate at which GnRH is secreted decreases during the nonbreeding season, as does the amount associated with each burst (see Figure 7-8). Because GnRH stimulates the gonadotropic hormone secretory cells in the anterior pituitary, this pulsatile pattern of hypothalamic secretion results in similar episodic bursts in LH and FSH secretion. Unexpectedly it was determined that GnRH neurons do not contain steroid receptors and so would not be directly responsive to seasonal changes in day length. These being the case, gonadal steroids were suggested to regulate GnRH release through an alternative mechanism. The answer was eventually found in neurons that express steroid receptors, specifically those located in the *periventricular nucleus* and the *arcuate nucleus* (pp. 282 and 724) among others. Projections from these cell bodies are sent to the preoptic area of the hypothalamus, where there

FIGURE 16-11 Control of testicular function.

© Cengage Learning, 2013

is an abundance of GnRH cell bodies. The stimulatory peptide released from these neurons was named **kisspeptin**, a reference to its discovery in Hershey, Pennsylvania, the home of the American chocolate “Hershey’s kisses.”

Even though GnRH controls the relative secretion of both LH and FSH, the blood concentrations of these two gonadotropic hormones do not always parallel each other for two reasons. (1) LH is removed from the blood more rapidly between the secretory bursts than is the more slowly metabolized FSH, so the pulsatile variations in blood concentrations of LH are much more pronounced than are those of FSH. (2) Two other regulatory factors besides GnRH—**testosterone** and **inhibin**—differentially influence the release of LH and FSH.

Testosterone, the product of LH stimulation of the Leydig cells, acts in negative-feedback fashion to inhibit LH secretion in two ways. The predominant negative-feedback effect of testosterone is to decrease the episodes of GnRH release by acting on the hypothalamus, thus indirectly decreasing both LH and FSH release by the anterior pituitary. In addition, testosterone acts directly on the anterior pituitary to reduce the

responsiveness of the LH secretory cells to GnRH. The latter action explains why testosterone exerts a greater inhibitory effect on LH secretion than on FSH secretion. The testicular inhibitory signal specifically directed at controlling FSH secretion is **inhibin** from the Sertoli cells. **Inhibin** acts directly on the anterior pituitary to inhibit FSH secretion. This feedback inhibition of FSH by a Sertoli cell product is appropriate because FSH stimulates spermatogenesis by acting on the Sertoli cells.

Roles of Testosterone and FSH in Spermatogenesis

Both testosterone and FSH play critical roles in controlling spermatogenesis, each exerting its effect by acting on the Sertoli cells. Testosterone is essential for both mitosis and meiosis of the germ cells, whereas FSH is required to initiate spermatogenesis before puberty as well as for spermatid remodeling. Testosterone concentration is much higher in the testes than in the blood because a substantial portion of this hormone produced locally by the Leydig cells is retained in the intratubular fluid, complexed with androgen-binding protein secreted by the Sertoli cells. Only this high concentration of testicular testosterone is adequate to sustain sperm production.

Conversion of Testosterone to Estrogen in Males

Although testosterone is classically considered to be the male sex hormone and estrogens to be female sex hormones, the distinctions are not as clear-cut as once thought. In addition to the small amount of estrogens produced by the adrenal cortex (see p. 305), a portion of the testosterone secreted by the testes is converted to estradiol outside of the testes by the enzyme *aromatase* which is widely distributed (e.g., the brain, p. 772) but most abundant in adipose tissue. The boar and the stallion testicle both have significant aromatase activity in the Sertoli cells

and as a result secrete substantial quantities of estradiol. Because of this conversion, it is sometimes difficult to distinguish effects of testosterone itself and testosterone-turned-estradiol inside cells. For example, scientists recently learned that closure of the epiphyseal plates in males is induced not by testosterone per se but by testosterone converted into estradiol by aromatization. Estrogen receptors have been identified in the mammalian male brain, testes, prostate, bone, and elsewhere. Recent findings indicate that estrogens play an essential role in male reproductive health, including being important in spermatogenesis and contributing to normal sexuality. Also, it probably contributes to bone homeostasis. The depth, breadth, and mechanisms of action of estrogens in males are only beginning to be explored. (Likewise, in addition to the weak androgenic hormone DHEA produced by the adrenal cortex in both sexes, the ovaries in females also secrete a small amount of testosterone, which is important to libido but may have other functions that remain unclear.)

Gonadotropin-releasing hormone activity increases at puberty

Even though the fetal testes secrete testosterone, which directs masculine development of the reproductive system, after birth the testes become quiescent. Subsequently, in

response to the increasing secretion of gonadotropins, there is a gradual increase in the secretion of testosterone until puberty. The prepubertal delay in the onset of reproductive capability allows time for the animal to mature physically enough to handle offspring, for example, mastering the skills necessary to obtain sufficient food items.

Early in the prepubertal period, GnRH secretory pulses occur (at about four-hour intervals in humans), causing brief increases in LH secretion and accordingly, testosterone secretion. The frequency of episodic GnRH secretion gradually increases until the adult pattern of GnRH, FSH, LH, and testosterone secretion is established. Under the influence of the rising testosterone concentrations, particularly in the peripubertal period, the physical changes that encompass the secondary sexual characteristics and reproductive maturation become evident.

The low frequency of GnRH activity during the prepubertal period appears due to active inhibition of GnRH release by both hormonal and neural mechanisms. Before puberty, the hypothalamus is extremely sensitive to the negative-feedback actions of testosterone, so the very small amounts of testosterone produced by the prepubertal testes can inhibit GnRH release. During the prepubertal period the hypothalamus becomes less sensitive to feedback inhibition by testosterone. Because the low concentrations of testosterone no longer suppress the hypothalamus, GnRH and gonadotropic hormone concentrations rise until sufficient to induce spermatogenesis and therefore puberty.

The ducts of the reproductive tract store and concentrate sperm and increase their fertility

The remainder of the male reproductive system (besides the testes) is designed to deliver sperm to the female reproductive tract. Essentially, it consists of (1) a tortuous pathway of tubes that transport sperm from the testes to the outside of the body; (2) several glands, which contribute secretions that are important to the viability and motility of the sperm; and (3) the penis or its equivalent, which is designed to penetrate and deposit the sperm within the vagina (or in the uterus, as in the stallion and boar). We next examine each of these duct parts in greater detail, beginning with the reproductive tract.

Functions of the Epididymis and Ductus Deferens The epididymis and ductus deferens perform several important functions. They serve as the sperm's exit route from the testis. As they leave the testis, the sperm can neither move nor fertilize. They gain both capabilities during their passage through the epididymis. This maturational process is stimulated by the testosterone retained within the tubular fluid bound to androgen-binding protein. Sperm's capacity to fertilize is enhanced even further by exposure to secretions of the female reproductive tract, which remove seminal plasma proteins from the surface of the sperm cell. This enhancement of sperm's capacity as a result of the removal of seminal plasma proteins in the female reproductive tracts is known as **capacitation**. Scientists believe that a type of *defensin* (p. 463), a protein secreted by the epididymis that defends sperm from microorganisms, may serve a second role by boosting sperm's motility. The epididymis concentrates the sperm 100-fold by absorbing most of the fluid that

enters from the seminiferous tubules. The maturing sperm are slowly moved through the epididymis into the ductus deferens by rhythmic contractions of the smooth muscle in the walls of these tubes.

The ductus deferens serves as an important site for sperm storage. Because the tightly packed sperm are relatively inactive and their metabolic needs are accordingly low, they can be stored in the epididymis tail for prolonged periods, even though they have no nutrient blood supply and are nourished only by simple sugars present in the tubular secretions.

The epididymis, because of its folded arrangement, is comma-shaped and loosely attached to the caudal surface of each testis (Figures 16-3 and 16-8a) and ranges in length from 30 to 60 mm depending on the species. During the breeding season the cells within the epididymis undergo hypertrophy and secrete seminal fluid. Once sperm are produced in the seminiferous tubules, they are swept into the epididymis as a result of the pressure created by the continual secretion of tubular fluid by the Sertoli cells. As a result of coalescence of the efferent ductules leaving the rete testis tubules, the epididymal ducts from each testis converge to form a large, thick-walled, muscular duct—the **ductus (vas) deferens**. The ductus deferens from each testis passes up out of the scrotum and through the inguinal canal into the pelvic cavity, where it eventually empties into the urethra at the neck of the bladder (Figure 16-3). The **ampulla** is an enlarged portion of the ductus deferens located immediately before the entrance into the urethra or the cloaca. An enlarged muscle layer characterizes it, in association with an increase in the size of the lumen. The ampulla is present in the primate, bull, ram, stallion, and cock, but is reduced or absent in the boar, dog, and fox. Subsequently, the urethra carries sperm out of the penis during **ejaculation**, the forceful expulsion of semen from the body.

The accessory sex glands contribute the bulk of the semen

Several accessory sex glands—especially the seminal vesicles and prostate—empty their secretions into the duct system before it joins the urethra (Figure 16-3). A pair of saclike *seminal vesicles* empty into the last portion of the two ductus deferens, one on each side. The short segment of duct that passes beyond the entry point of the seminal vesicle to join the urethra constitutes the *ejaculatory duct*. The *prostate* is a large single gland that completely surrounds the ejaculatory ducts and urethra (some species have only a small *bulb*, as in humans, whereas others have both a bulb and a longer *disseminate* prostate that surrounds a longer portion of the pelvic urethra). Another pair of accessory sex glands, the *bulbourethral glands*, drains into the urethra after it has passed through the prostate, just before it enters the penis. Numerous mucus-secreting glands are located along the length of the urethra.

Semen During ejaculation, the accessory sex glands contribute secretions that provide support for the continuing viability of the sperm inside the female reproductive tract (in animals with internal fertilization) or in water (such as fish semen). These secretions constitute the bulk of the **semen**, which consists of a mixture of accessory sex-gland secretions, sperm, and mucus. Sperm make up only a small percentage of the total ejaculated fluid. In some mammals, such

as rodents and the boar and stallion, the seminal fluid has special coagulation properties that plug the female reproductive tract (as in some insects; p. 764) and minimize loss of spermatozoa after ejaculation. In rodents, this solidified *copulatory plug* is later lost from the vagina, signaling that successful copulation has occurred.

The Male Accessory Glands Although the accessory sex gland secretions are not absolutely essential for fertilization, they do make species-specific contributions that greatly facilitate the fertilization process in mammals:

- The **seminal vesicles** or **vesicular glands** are paired glands that empty into the pelvic urethra and (1) supply fructose, which serves as the primary energy source for ejaculated sperm; (2) secrete *prostaglandins*, which stimulate contractions of the smooth muscle in both the male and female reproductive tracts, helping to transport sperm from their storage site in the male to the site of fertilization in the female oviduct; (3) provide more than half the semen volume, which helps wash the sperm into the urethra and also dilutes the thick mass of sperm, thus enabling them to develop motility; and (4) secrete fibrinogen, a precursor of fibrin, which forms the meshwork of a clot (see Figure 9-11, p. 397). Seminal vesicles vary significantly between species but are absent in the dog, fox, and birds.
- The **prostate gland** (1) secretes an alkaline fluid that neutralizes the acidic vaginal secretions, an important function because sperm are more viable in a slightly alkaline environment; (2) provides clotting enzymes; and (3) releases **prostate-specific antigen (PSA)**. The prostate clotting enzymes act on fibrinogen from the seminal vesicles to produce fibrin, which “clots” the semen, thus helping to keep the ejaculated sperm in the female reproductive tract during withdrawal of the penis. Shortly thereafter, the seminal clot is broken down by prostate-specific antigen, a fibrin-degrading enzyme from the prostate, releasing motile sperm within the female tract. The prostate varies in structure from branched tubular to tubuloalveolar. The prostate gland is large in the boar, comparatively smaller in the bull, and absent in the smaller ruminants. It is absent in the cock, but is extremely well developed in the dog and fox.
- During sexual arousal, the **bulbourethral glands** secrete a mucuslike substance that neutralizes the acidic pH in the urethra, provides lubrication, and causes the seminal plasma to coagulate following ejaculation. These glands are particularly enlarged in the boar, but are absent in the fox, dog, and birds.

Before turning our attention to the act of delivering sperm to the female, we are briefly going to digress and discuss the diverse roles of *prostaglandins*, which were first discovered in semen but are abundant throughout the body.

Prostaglandins are ubiquitous, locally acting chemical messengers

Although **prostaglandins** were first identified in the semen and were believed to be of prostate gland origin (hence their name, even though the seminal vesicles are now known to produce more prostaglandins than the prostate), their production and actions are by no means limited to the repro-

ductive system. These 20-carbon fatty acid derivatives are among the most ubiquitous and physiologically active substances in vertebrates. They are produced in virtually all tissues from arachidonic acid, a fatty-acid constituent of the phospholipids within the plasma membrane. Prostaglandins and other closely related arachidonic-acid derivatives, namely, *prostaglandins*, *thromboxanes*, and *leukotrienes*, are collectively known as **eicosanoids**, and are among the most biologically active compounds known. On appropriate stimulation, arachidonic acid is split from the plasma membrane by a cytosolic enzyme and then is converted into the appropriate eicosanoid, which acts as a paracrine locally within or near its site of production. After eicosanoids act, they are inactivated rapidly by local enzymes before they gain access to the blood, or if they do reach the circulatory system, they are swiftly degraded on their first pass through the lungs so that large quantities are not dispersed through the systemic arterial system.

Prostaglandins are designated as belonging to one of nine groups—PGA, PGB, PGC, PGD, PGE, PGF, PGG, PGH, or PGI (prostaglandin)—according to structural variations in the five-carbon ring that they contain at one end (Figure 16-12). Within each group, prostaglandins are further identified by the number of double bonds present in the two side chains that project from the ring structure (for example, PGE₁ has one double bond and PGE₂ has two double bonds).

Prostaglandins exert a bewildering variety of effects. Not only are slight variations in prostaglandin structure accompanied by profound differences in biological action, but the same prostaglandin molecule may even exert opposite effects in different tissues. Besides enhancing sperm transport in semen, these abundant chemical messengers are known or suspected to exert other actions in the female reproductive system and in the respiratory, urinary, digestive, nervous, and endocrine systems, in addition to affecting platelet aggregation, fat metabolism, and inflammation and fever (p. 469). Salicylate drugs such as aspirin and other nonsteroidal anti-inflammatory drugs inhibit the production of prostaglandins (see p. 461).

Next, before considering the female in greater detail, we examine the means by which males and females come together to accomplish reproduction.

The penis in many vertebrates is both erectile and extendible

The mammalian penis consists of three parts, the **root**, **body** or **shaft**, and **glans**. The body normally constitutes the major portion of the organ. In some mammals (such as mink, raccoons, bats, and moles, but not humans, horses, bulls, rams, boars, bucks, and most primates) the penis contains a penile bone called the **os penis** or **baculum** (Figure 16-13). The free end of the penis, the glans, is richly supplied with nerves. In some species the penis is highly erectile. In the boar the penis has the unique feature of existing as a left-handed corkscrew, which actually penetrates, with rotary motion, into the cervix and locks in place, providing the pressure needed for the stimulation of ejaculation.

Some mammals (boars, bulls, and rams) have a penis containing an increased quantity of connective tissue relative to the amount of erectile tissue. The penis of these animals contains a **sigmoid flexure**, an S-shaped configuration along the shaft of the penis (Figure 16-13). The straightening of

(b)

the curve of the penis results in extension of the penis from the sheath. Consequently, during erection there is little change in the diameter of the penis. The **retractor penis muscle** is a paired muscle located on the ventral face of the penis. It originates at the root of the penis and shunts across the S-shaped curve. These muscles control the degree of extension of the penis by their action on the sigmoid flexure and retract the penis into the sheath after extension.

In lizards and snakes, the penis is paired and represents an extension of the cloaca. During copulation this **hemipenis** is everted into the cloaca of the female. To sustain intromission in the female, the hemipenis contains spiny ridges. The body of the normally flaccid penis can become erect as a consequence of testicular vasocongestion (engorgement with blood). In birds the pelvic urethra ends in either a cloaca or a hemipenis. In some species of sharks, skates, and other chondrichthyan fishes, males transfer sperm to females through a groove in their **claspers**, a pair of modified pectoral fins.

16.4 Mating

Ultimately, union of male and female gametes often requires *mating* behavior to accomplish delivery of sperm-laden semen to mature ova. In species with internal fertilization, sperm enter the female vagina through the **sex act**, also called **sexual intercourse**, **coitus**, or **copulation**. Extinct fish called placoderms (armored or “plated skin”) that lived approximately 375 million years ago were likely the first backboned creatures to copulate and give birth to live young. In most vertebrates, mating occurs at the peak of female fertility, which is *estrus* in most mammals (see p. 784). A few species, including humans, bonobos, chimpanzees, and dolphins, engage in sex acts (including same-sex interactions) for pleasure in addition to reproduction, in part as a means of reinforcing social bonds and status.

The male sex act is characterized by erection and ejaculation

After a suitable partner has been located, species-specific courtship behavior (p. 761) is initiated in many species. In many mammals, a mating posture assumed by the female (**lordosis**) serves as a powerful trigger for sexual stimulation in the male. Arousal of the male stimulates the erection and protrusion of the penis. The *male sex act* involves two components: (1) **erection**, the straightening or hardening of the penis to permit its entry into the vagina, and (2) **ejaculation**,

FIGURE 16-13 Classification of penile structures. (a) The penises of rams, goats, and boars are fibroelastic. Erection results in a straightening of the sigmoid flexure. Engorgement of the corpus cavernosum with blood distends and elongates this class of penis. (b) The penis of cats and horses is musculocavernous. Erection results in a more complex change in the position, length, and stiffness of the penis compared to fibroelastic forms. (c) The musculocavernous penis of dogs contains a central bony portion (*os penis*) that aids in intromission into the female's vagina with only a partial erection. Erection is completed in the female's vagina. The local engorgement of the *bulbus glandis* is prolonged by occlusion of the penile venous return by the vaginal constrictor muscles. This contraction maintains and lengthens the duration of the intravaginal erection. Intravaginal engorgement associated with dilation of the penile bulb prevents withdrawal of the penis from the vagina, leading to the so-called tie between the two.

or forceful expulsion of semen into the urethra and out of the penis. In addition to these strictly reproduction-related components, the **sexual response cycle** also encompasses broader physiological responses that can be divided into four phases:

1. The *excitement phase*, which includes erection (and heightened sexual awareness in humans, at least).
2. The *plateau phase*, which is characterized by intensification of these responses, plus more generalized body responses, such as steadily increasing heart rate, blood pressure, respiratory rate, and muscle tension.
3. The *orgasmic phase*, which includes ejaculation as well as other responses that culminate in a burst of stimulating neural signals in pleasure centers of the brain.
4. The *resolution phase*, which returns genitalia and body systems to their prearousal state.

Erection is accomplished by penis vasocongestion

In those species in which the penis consists almost entirely of **erectile tissue**, the body consists of three columns of spongelike vascular spaces extending the length of the organ. In the absence of sexual excitation, the erectile tissues contain little blood, because the arterioles that supply these vascular chambers are constricted and venous drainage is maximal. As a result, the penis remains small and flaccid. During sexual arousal, these arterioles reflexly dilate and the erectile tissue fills with blood, causing the penis to enlarge both in length and width and to become more rigid. In the stallion, for example, these vascular spaces are particularly enlarged such that, during erection, considerable increases in the penial size are achieved as a result of accumulation of blood in

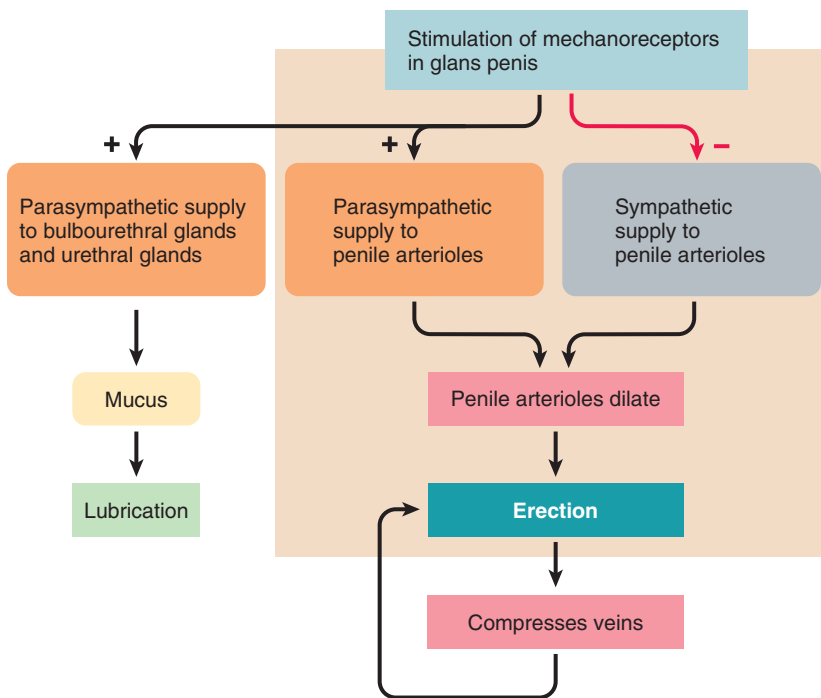

FIGURE 16-14 Erection reflex in a male mammal.

© Cengage Learning, 2013

these spaces. In contrast, the vascular spaces in the bull, ram, and boar are comparatively small except in the distal bend of the sigmoid flexure. Additional buildup of blood and further enhancement of erection are achieved by a reduction in venous outflow. The veins that drain the erectile tissue are compressed as a result of engorgement and expansion of the vascular spaces brought about by increased arterial inflow.

Erection Reflex The erection reflex is a spinal reflex triggered by stimulation of highly sensitive mechanoreceptors located in the glans penis. The actual **erection-generating center** lies in the sacral segments of the spinal cord. Tactile stimulation of the glans reflexly triggers, by means of this center, increased parasympathetic vasodilator activity and decreased sympathetic vasoconstrictor activity to the penile arterioles. The result is rapid, pronounced vasodilation of these arterioles and an ensuing erection (Figure 16-14).

This parasympathetically induced vasodilation is the major instance of direct parasympathetic control over blood vessel caliber (internal diameter) in the body. Parasympathetic stimulation brings about relaxation of penile arteriolar smooth muscle by means of *nitric oxide* (NO), which causes arteriolar vasodilation in response to local tissue changes elsewhere in the body (see p. 392). Specifically, NO activates a membrane-bound enzyme, guanylate cyclase, within nearby arteriolar smooth muscle cells. This enzyme activates cyclic guanosine monophosphate (cGMP), an intracellular second messenger similar to cAMP (see p. 435). Cyclic GMP in turn leads to relaxation of the penile arteriolar smooth muscle, bringing about a pronounced local vasodilation. Arterioles are typically supplied only by sympathetic nerves, with increased sympathetic activity producing vasoconstriction and decreased sympathetic activity resulting in

vasodilation. Concurrent parasympathetic stimulation and sympathetic inhibition of penile arterioles accomplish vasodilation more rapidly and in greater magnitude than is possible in other arterioles supplied only by sympathetic nerves. At the same time, parasympathetic impulses promote secretion of lubricating mucus from the bulbourethral glands and the urethral glands in preparation for coitus.

Recent research has led to the discovery of numerous regions throughout the brain that can influence the male sexual response. The erection-influencing brain sites appear extensively interconnected and function as a unified network to either facilitate or inhibit the basic spinal erection reflex, depending on the momentary circumstances. Failure to achieve an erection may occur despite appropriate stimulation as a result of inhibition of the erection reflex by higher brain centers. Treatment of erectile dysfunction in human males by drugs that stimulate NO production has become a major application of knowledge gained from physiological research.

Ejaculation includes emission and expulsion

The second component of the male sex act is ejaculation. Like erection, ejaculation is accomplished by a spinal reflex. The same types of tactile and psychic stimuli that induce erection cause ejaculation when the level of excitation intensifies to a critical peak. The ejaculatory response occurs in two phases: emission and expulsion. First, sympathetic impulses cause sequential contraction of smooth muscles in the prostate, reproductive ducts, and seminal vesicles. This contractile activity delivers prostatic fluid, then sperm, and finally seminal vesicle fluid (collectively, *semen*) into the urethra. This phase of the ejaculatory reflex is known as **emission**. During this time, the sphincter at the neck of the bladder is tightly closed to prevent semen from entering the bladder and urine from being expelled along with the ejaculate through the urethra. Second, the filling of the urethra with semen triggers nerve impulses that activate a series of skeletal muscles at the penis base. Rhythmic contractions of these muscles increase the pressure within the penis, forcibly expelling the semen through the urethra to the exterior. This is the **expulsion** phase of ejaculation.

Orgasm in turn, refers to the pelvic and overall systemic responses that culminate the sex act. These include the rhythmic contractions that occur during semen expulsion and the involuntary rhythmic throbbing of pelvic muscles associated with the peak intensity of the overall body responses that were manifested during the earlier phases. While only humans can report the intense pleasure associated with orgasm, observations of chimpanzees and bonobos suggest that they also experience this reinforcing phenomenon.

During the resolution phase following orgasm, sympathetic vasoconstrictor impulses slow the inflow of blood into the penis, causing the erection to subside. Muscle tone returns to normal while the cardiovascular and respiratory systems return to their prearousal level of activity. Once

ejaculation has occurred, a temporary refractory period of variable duration ensues before sexual stimulation can trigger another erection.

Volume and Sperm Content of the Ejaculate The volume and sperm content of the ejaculate depend on the length of time between ejaculations. Production of spermatozoa in mammals ranges from <1 to 25 billion spermatozoa per day for both testes. In humans, an average ejaculate contains about 180 million sperm (66 million/mL), but some ejaculates contain as many as 400 million sperm. In birds, the volume of the ejaculate is comparatively small (200–800 μ L in a turkey), but the density of spermatozoa (4,000–7,000 per μ L) is usually higher. Because the increased body size of domesticated male turkeys (toms) relative to the hens makes normal mating extremely difficult, the poultry industry uses artificial insemination extensively in turkeys.

Even though only one spermatozoon actually fertilizes the ovum, large numbers of accompanying sperm are often needed to provide sufficient acrosomal enzymes (the acrosome is the membrane-bound organelle of the spermatozoon that contains proteolytic enzymes) to break down the barriers surrounding the ovum (zona pellucida) until the fertilizing sperm is engulfed into the ovum's cytoplasm. The quality of sperm must be taken into account when assessing the fertility potential of a semen sample. The presence of substantial numbers of sperm with abnormal motility or structure, such as sperm with distorted tails, reduces the chances of fertilization.

The female sex act is similar to the male sex act

In humans at least, both sexes experience the same four phases of the sexual cycle—excitement, plateau, orgasm, and resolution. Furthermore, the physiologic mechanisms responsible for orgasm are fundamentally the same in males and females. The excitement phase in human females can be initiated by either physical or psychological stimuli. Tactile stimulation of the externally exposed portion of the glans clitoris and surrounding perineal area is an especially powerful sexual stimulus. These stimuli trigger spinal reflexes that bring about parasympathetically induced vasodilation of arterioles throughout the vagina and external genitalia, especially the clitoris. The latter—like its male homolog, the penis—is composed largely of erectile tissue (recall that it is much larger than traditionally reported; Figure 16-4b).

Vasocongestion of the vaginal capillaries forces fluid out of the vessels into the vaginal lumen. This fluid, which is the first positive indication of sexual arousal, serves as the primary lubricant for intercourse. Additional lubrication is provided by the mucus secretions from the male and by mucus released during sexual arousal from glands located at the outer opening of the vagina.

During the plateau phase, the changes initiated during the excitement phase intensify, while systemic responses similar to those in the male (such as increased heart rate, blood pressure, respiratory rate, and muscle tension) occur. If erotic stimulation continues, the sexual response culminates in orgasm as sympathetic impulses trigger rhythmic contractions of the pelvic musculature as in males. Systemic responses identical to those of the male orgasm also occur. Again, observations of chimpanzee and bonobo females suggest that they experience intense pleasure as do human fe-

males. During resolution, pelvic vasocongestion and the systemic manifestations gradually subside.

Oxytocin has several roles in mating and other social interactions

Oxytocin is a pituitary hormone most closely associated with labor, lactation, and other female reproductive processes that you will see in detail later. But it is also found in males. Why? Oxytocin appears to play roles in mating-related behaviors in both sexes. It is released during arousal and orgasm, and may stimulate orgasmic muscle contractions in both sexes. Oxytocin has been localized in the testes and semen of several mammalian species and may be a paracrine factor inducing contraction of the seminiferous tubules during ejaculation. Most notably, oxytocin in females, as well as vasopressin in males (as in the prairie vole, p. 286), reinforce pair-bonding between mates. Oxytocin's actions go beyond mating: Human males who sniffed an experimental oxytocin spray were much more likely to trust other males in their own group, while simultaneously becoming more antagonistic toward strangers. Though oxytocin is popularly dubbed the “trust hormone,” its affects are thus more complex.

16.5 Female Reproductive Physiology

In some vertebrates, female reproductive physiology is more complex than the male's.

Complex cycling characterizes female reproductive physiology in many vertebrates, including estrous cycles in most mammals

As in the vertebrates male, female reproduction involves interactions of internal and environmental factors mediated by the hypothalamic–pituitary–gonadal axis. However, unlike the continuous sperm production and relatively constant testosterone secretion in males, the release of ova or deposition of eggs is intermittent, and secretion of female sex hormones displays wide cyclical swings. In mammals, there are two separate but coordinated cycles:

1. The **ovarian cycle**, in which an oocyte matures in the ovary and is *ovulated* to travel to the uterus. As the primary female reproductive organs, ovaries perform the dual function of producing ova (*oogenesis*) and secreting the female sex hormones estrogens and progesterone.
2. The **uterine cycle**, in which the uterine lining is prepared for a fertilized egg to implant (primarily due to the ovarian hormones).

TABLE 16-4 Reproductive Cycles of Various Mammals

Genus species ^a	Cycle Type ^b	Cycle Length ^c	Duration of Estrus	Ovulation Type ^d	Time	Luteal Phase in Absence of Coitus
<i>Felis domesticus</i> (cat)	S, P	14	4 days	I	24–30 hr after coitus	No
<i>Bos taurus</i> (cow)	C, P	17–27	13–14 hr	Sp	12–16 hr after end of estrus	Yes
<i>Canis familiaris</i> (dog)	S, M	60	7–9 days	Sp	1–3 days after onset of estrus	Yes

Source: H. E. Kidder and R. Cochrane, West Virginia University.

If fertilization does not occur, the cycles repeat. If fertilization does occur, the cycles are interrupted, while the female system adapts to nurture and protect the newly conceived embryo until it has developed the ability to live outside the maternal environment. Furthermore, the mammalian female continues her reproductive duties after birth by producing milk (lactation) for the young's nourishment. Thus, the female reproductive system is characterized by complex cycles that are interrupted only by more complex changes should pregnancy ensue.

The ovarian and uterine cycles together constitute an **estrous cycle** in most mammals, defined as the time from one period of sexual receptivity to the next. Sexual receptivity is called **estrus** (a noun, not to be confused with the adjective *estrous*) or **heat**, which occurs periodically under certain specified conditions (often at the time of ovulation).

Ovarian cycles are very similar among mammals, but uterine cycles differ in two versions. In the *estrous* type, if there is not a pregnancy, the uterine lining that has been prepared for an embryo is reabsorbed. In contrast, some primates, including humans, have a **menstrual cycle**, in which uterine lining is sloughed off periodically (*menstruation*). The cycle begins at the end of each menstruation and occurs uniformly throughout the year. These primates also usually have distinct *estrus* (receptivity) periods, although human females are considered to be continuously receptive.

The duration of estrous and menstrual cycles is species specific but variable within a species (Table 16-4). In general, the principles governing reproduction are the same for the different species, but there are notable differences. For example, the frequency of estrous cycles differs between

Concepts and Controversies

Environmental Estrogens: Bad News for Reproduction

For the past 60 years, humans have been polluting the environment with synthetic endocrine-disrupting chemicals (**EDCs**, p. 275) as an unintended side effect of industrialization. As you saw in Chapter 7, these hormonelike pollutants bind with the receptor sites normally reserved for the naturally occurring hormones, either mimicking or blocking normal hormonal activity. Many EDCs have been found to alter sex steroid functions. Some are *estrogenic* and exert feminizing effects as estrogen agonists. Others (androgen antagonists) block a male's own androgens from accomplishing their intended masculinizing effects. For example, studies suggest that bacteria in wastewater from pulp mills can convert the sterols in pine pulp into androgens. By contrast, anti-androgen compounds have been found in the fungicides commonly sprayed on vegetable and fruit crops. Anti-androgenic action demasculinizes males, producing an outcome similar to that brought about by estrogenic EDCs. Yet another cause for concern are the androgens used by the livestock industry to enhance the production of muscle (that is, meat) in feedlot cattle. (Androgens have a protein anabolic effect.) These drugs do not end up in the meat, but they can get into drinking water and other food as hormone-laden feces contaminate rivers and streams.

Estrogenic pollutants are everywhere in our environment. They contaminate food, drinking water, and air. Proven feminizing synthetic compounds include (1) certain weed killers and insecticides, (2) some detergent breakdown products, (3) petro-

leum by-products found in car exhaust, (4) common food preservatives used to retard rancidity, and (5) softeners that make plastics flexible. These plastic softeners are commonly found in food packaging and can readily leach into food with which they come in contact, especially during heating. Plastic softeners are among the most plentiful industrial contaminants in our environment. An estimated 87,000 synthetic chemicals are already in our environment. Scientists suspect that the estrogen-mimicking chemicals among these may underlie a spectrum of reproductive disorders that have been rising in the past 60 years—the same time period during which large amounts of these pollutants have been introduced into the environment.

Evidence of Gender Bending in Animals

Some fish and wild animal populations that have been severely exposed to environmental EDCs—such as those living in or near water heavily polluted with chemical wastes—display a high rate of grossly impaired reproductive systems. Examples include male fish that are hermaphrodites (having both male and female reproductive parts) and male alligators with abnormally small penises. Similar reproductive abnormalities have been identified in land mammals. Presumably, excessive exposure to estrogen agonists is emasculating these populations.

Environmental estrogens are implicated in the rising incidence of breast cancer in female humans. Breast gland cancer is 25 to

30% more prevalent now than in the 1940s. Many of the established risk factors for mammary gland cancer, such as starting to menstruate earlier than usual and undergoing menopause later than usual, are associated with an elevation in the total lifetime exposure to estrogen. Because increased exposure to natural estrogens bumps up the risk for mammary gland cancer, prolonged exposure to environmental estrogens may be contributing to the rising prevalence of this malignancy among women (and men as well).

Some environment-disrupting chemicals are the natural estrogen-like compounds called **phytoestrogens**, synthesized by some plant species. Usually the ingestion of these compounds is disadvantageous to the reproductive success of an animal, but in some situations can be of benefit. The California quail (*Lophortyx californicus*) is a photoperiodic species that relies on day length to regulate the time of the breeding season. In the more arid regions of its range, it breeds irregularly, depending on the amount of rainfall in the previous winter. During dry years, high concentrations of phytoestrogens are produced in the desert plants on which the quail feed. As with endocrine-disrupting chemicals, these phytoestrogens suppress reproductive development, in this situation by feeding back onto the hypothalamic–pituitary axis. By suppressing reproductive activity in these lean years, the animal does not use scarce body reserves on a clutch of eggs that will not likely reach sexual maturity.

species: Cattle, swine, and rodents are **continuously polyestrous** (cycles occurring uniformly throughout the year), while others are **seasonally polyestrous** (estrous cycles are restricted to a particular time of year). Deer, sheep, and goats are examples of **short-day breeders** because they exhibit estrous cycles as day length decreases, whereas bears, hamsters, and horses are **long-day breeders**; that is, they come into estrous as day length increases. **Seasonally monoestrous** females (most carnivores, including bears, dogs, foxes, and wolves) are characterized as having a single estrous event followed by a long period of **anestrus** (period of time without regular cyclic activity). For example, most female dogs have about two estrus periods in a year. In these animals the period of estrus is prolonged and lasts for several days, thus increasing the probability of securing a mate.

Reproductive capability begins at puberty in mammalian females, but reproductive potential of many primates, some rodents, whales, dogs, rabbits, elephants, and domestic livestock, ceases gradually during middle age (unlike males, who typically have reproductive potential through the remainder of life, although it gradually declines). In primates with menstrual cycles, this cessation is called **menopause** due to the complete cessation of **menses** (the outflow of uterine materials during menstruation).

An understanding of the hormonal interactions governing follicular development and ovulation has permitted the manipulation of ovulation of some domestic species for management purposes. Thus, domesticated animals may have regular, repeated cycles during the year, whereas animals in the wild may have more sporadic estrous cycles

because they are either pregnant or lactating. For this reason, it may be more appropriate to consider **calving intervals**, literally from one birth to the next. Considering the juvenile period and the times of gestation and lactation, plus any decline in reproductive capacity with age, *anestrus* may constitute the more common condition of a normal female animal.

Although ovarian cycles are similar in many ways among vertebrates, differences can be found in the type of ovulation. Most animals are **spontaneous ovulators** that ovulate with a regular frequency and do not require copulation. Some species of birds, for example, ovulate daily for extended periods of time without any contact with the male. **Reflex (induced) ovulation** has been described for a large number of mammals including the cat, mink, ferret, rabbit, and camel. In this strategy ovulation is induced by stimulation of sensory receptors in the vagina and cervix during coitus, either mechanically or by semen components (camelids). Although the strategy is considered a more primitive condition than spontaneous ovulation, very few examples have been described in any taxa other than mammals. Exceptions include some reptiles including the whiptail lizard (*Cnemidophorus inornatus*), red-sided garter snake (*Thamnophis sirtalis parietalis*), and loggerhead sea turtle (*Caretta caretta*).

Functions of Estrogens and Progesterone As we noted earlier, the ovaries synthesize estrogens and progesterone. These sex hormones act together to promote the opportunity for fertilization of the ovum and, in mammals, to prepare the female reproductive system for pregnancy. Estrogens in the female govern many functions similar to those carried out by testosterone in the male, such as maturation and maintenance of the entire female reproductive system and establishment of female secondary sexual characteristics. In general, the actions of estrogens are important to pre-conception events. Estrogens are essential for the female to become sexually receptive and permit copulation, ova maturation and release, and transport of sperm from the vagina to the site of fertilization in the oviduct. Two different nuclear estrogen receptors can be identified in estrogen-responsive tissues—*ER α* and *ER β* . These receptors differ in their distribution among estrogens target cells and in the responses they trigger when bound with an estrogen. Some target cells have only *ER α* receptors, some only *ER β* receptors, and some both. For example, both ER receptors are localized in Leydig cells, whereas *ER β* is mostly confined to Sertoli cells and developing germ cells. These findings may help explain the complex effects of *environmental estrogens* (see *Concepts and Controversies: Environmental Estrogens: Bad News for Reproduction*).

Estrogens in mammals contribute to mammary gland development in anticipation of lactation. The other ovarian steroid, progesterone, is important in preparing a suitable environment for nourishing a developing embryo/fetus and for contributing to the mammary glands ability to produce milk (see p. 810).

The steps of gametogenesis are the same in both sexes, but the timing and outcome differ sharply

Oogenesis contrasts sharply with spermatogenesis in several important aspects, even though the identical steps of chromosome replication and division take place during gamete production in both sexes. The undifferentiated primordial

germ cells in the fetal ovaries, the **oogonia** (comparable to the spermatogonia), divide mitotically during gestation and/or neonatally, after which time mitotic proliferation ceases.

Formation of Primary Oocytes and Primary Follicles During the last part of fetal life, the oogonia begin the early steps of the first meiotic division but do not complete it. Known now as **primary oocytes**, they contain the diploid number of $2N$ replicated chromosomes, which are gathered into homologous pairs but do not separate. The primary oocytes remain in this state of meiotic arrest until they are prepared for ovulation. A presumed purpose of this nuclear arrest is to inactivate the DNA in the female gamete in order to reduce the possibility of biochemical insult during the lifetime of the female.

Before birth, each primary oocyte is surrounded by a single layer of flattened **granulosa cells**. Together, an oocyte and surrounding granulosa cells make up a **primordial follicle**. Oocytes that fail to be incorporated into follicles self-destruct by apoptosis (cell suicide). At birth only a fraction of the original primordial follicles remain, each containing a single primary oocyte capable of producing a single ovum. In most mammals, no new oocytes or follicles appear after birth; the follicles already present in the ovaries at birth serve as a reservoir from which all ova throughout the reproductive life of a female must be drawn. Of these follicles, only a small percentage (about 400 in humans) mature and release ova.

The pool of primary follicles present at birth gives rise to an ongoing trickle of developing follicles. Once it starts to develop, a follicle is destined for one of two fates: It reaches maturity and ovulates, or it degenerates, a process known as **atresia**. Until puberty, all the follicles that start to develop undergo atresia in the early stages without ever ovulating. Even after puberty, many of the follicles are **anovulatory** (that is, no ovum is released). Of the initial pool of follicles, most (for example, 99.98% in humans) never ovulate but instead undergo atresia at some stage in development. At the end of the female's reproductive life, only a few follicles remain in the ovaries, and soon even these succumb to atresia.

This limited gamete potential, which is thought to be determined at birth in mammalian females, is in sharp contrast to the continual process of spermatogenesis in males. (Although in rabbits at least, there is evidence of some new oocytes forming after puberty.) Furthermore, there is considerable chromosome wastage in oogenesis compared with spermatogenesis. Let's see how.

Formation of Secondary Oocytes and Secondary Follicles

The primary oocyte within a primary follicle is still a diploid cell that contains $2N$ doubled chromosomes. A portion of the resting pool of follicles starts developing into **secondary (antral) follicles**. The number of developing follicles at any time is roughly proportional to the size of the pool, but the mechanisms that determine which follicles in the pool develop during a given cycle are unknown. Development of a secondary follicle is characterized by growth of the primary oocyte and by expansion (proliferation) and differentiation of the surrounding cell layers. The extent of oocyte enlargement is species dependent. Oocyte enlargement is due to a buildup of cytoplasmic and/or yolk materials that will be needed by the early embryo. The follicle next acquires a dependence on gonadotropins, in part as a result of the dif-

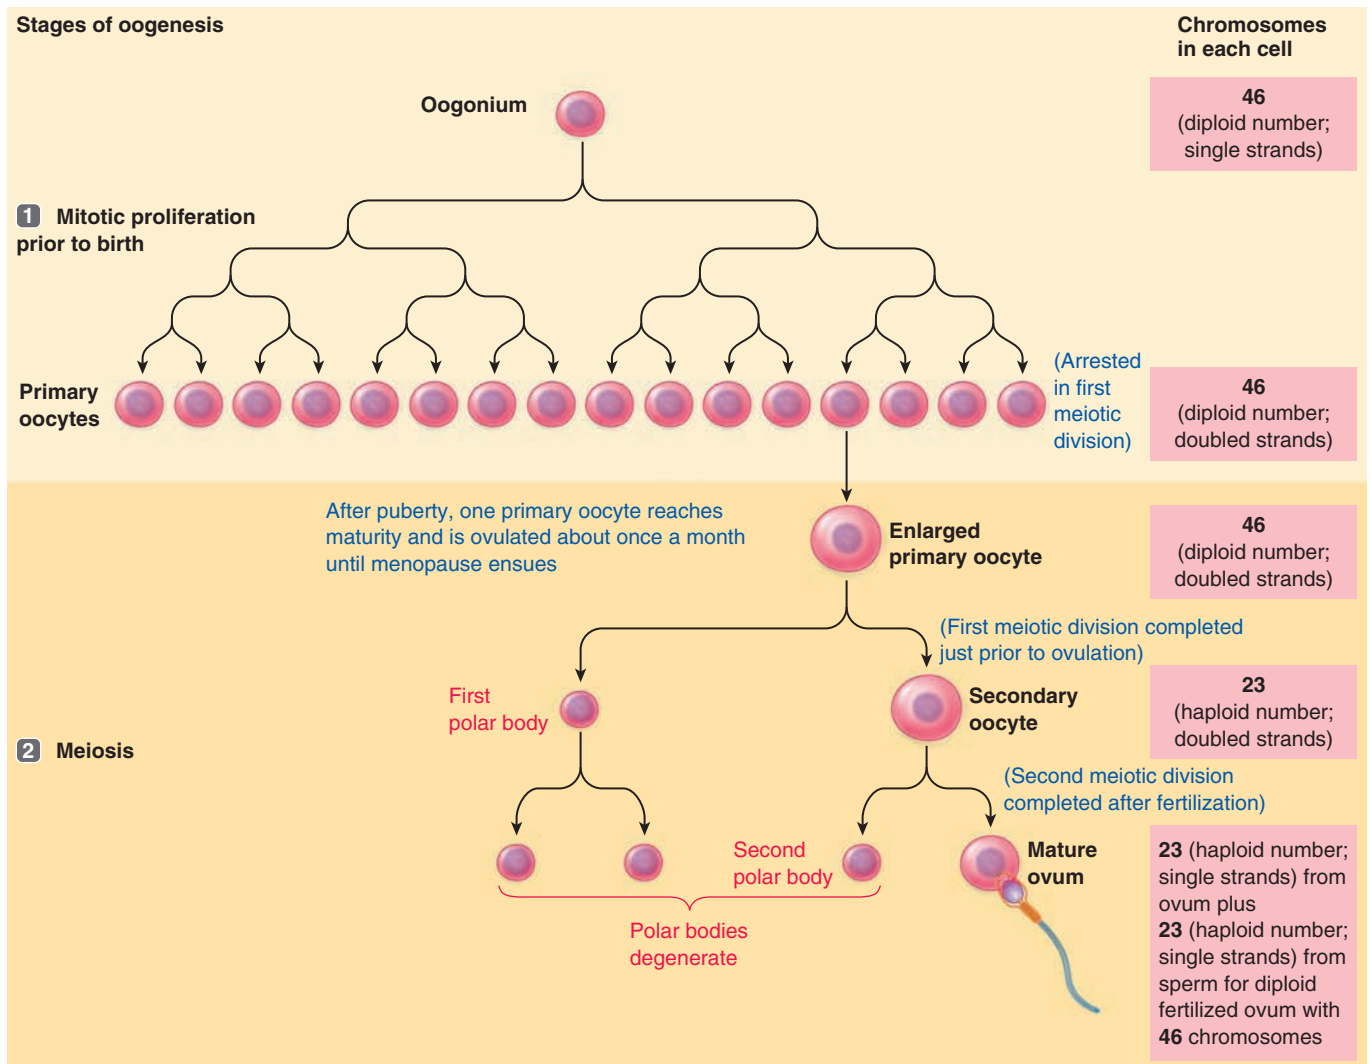

FIGURE 16-15 Oogenesis. Compare with Figure 16-9, p. 774, spermatogenesis.

© Cengage Learning, 2013

ferentiation of the cells surrounding the granulosa into theca cells, which markedly increases estrogen production by the follicular cells.

Just before ovulation, the primary oocyte, whose nucleus has been in meiotic arrest, often for years, completes its first meiotic division, except in the horse and the carnivores, which ovulate a primary oocyte in association with the extended period of estrus. This division yields two daughter cells, each receiving a haploid set of n doubled chromosomes, analogous to the formation of secondary spermatocytes (Figure 16-15). However, almost all the cytoplasm remains with one of the daughter cells, now called the **secondary oocyte**, which is destined to become the ovum. The chromosomes of the other daughter cell together with a small share of cytoplasm form the **first polar body**. In this way, the ovum-to-be loses half of its chromosomes to form a haploid gamete but retains all its nutrient-rich cytoplasm. The nutrient-poor polar body soon degenerates.

Formation of a Mature Ovum Actually, the secondary oocyte, and not the mature ovum, is ovulated and fertilized, but common usage refers to the developing female gamete as

an *ovum* even in its primary and secondary oocyte stages. Sperm entry into the secondary oocyte is needed to trigger the second meiotic division. Secondary oocytes that are not fertilized never complete this final division. During this division, a half set of chromosomes along with a thin layer of cytoplasm is extruded as the **second polar body**. The other half set of n unpaired chromosomes remains behind in what is now the **mature ovum** (sometimes called the *ootid*, comparable to the spermatid, until the polar bodies disintegrate and the mature ovum alone remains). These $1N$ maternal chromosomes unite with the $1N$ paternal chromosomes of the penetrating sperm to complete fertilization. If the first polar body has not already degenerated, it too undergoes the second meiotic division at the same time the fertilized secondary oocyte is dividing its chromosomes.

Comparison of Steps in Oogenesis and Spermatogenesis

The steps involved in chromosome distribution during oogenesis parallel those of spermatogenesis, except that the cytoplasmic distribution and time span for completion sharply differ. Just as four haploid spermatids are produced by each primary spermatocyte, four haploid daughter cells

are produced by each primary oocyte (if the first polar body did not degenerate before it completes the second meiotic division). In spermatogenesis, each daughter cell develops into a highly specialized, motile spermatozoon unencumbered by unessential cytoplasm and organelles, its only destiny being to supply half of the genes for a new individual. In oogenesis, however, of the four daughter cells, only the one destined to become the ovum receives cytoplasm. This uneven distribution of cytoplasm is important because the ovum, in addition to providing half the genes, provides all the cytoplasmic components needed to support early development of the fertilized ovum. The large, relatively undifferentiated ovum contains numerous nutrients, organelles, and structural and enzymatic proteins. The three other cytoplasm-deficient daughter cells, the polar bodies, rapidly degenerate, their chromosomes being deliberately wasted.

The ovarian cycle of mammals consists of alternating follicular and luteal phases

Recall that the ovaries (and their regulators) orchestrate the events of the ovarian cycle (as well as producing hormones to regulate the uterine cycle, as we will see later). The shape, size and functionality of the ovaries vary both with the species of animal as well as with the stage of the estrous cycle. For example, in cattle and sheep it is almond shaped, in the horse the ovary is bean shaped, and in the sow and bird the ovary resembles a cluster of grapes. The ovaries of the cow and horse are easily examined by rectal palpation. In some species ovaries can be visualized by *transrectal ultrasonography*. In chickens, only the left ovary and oviduct normally mature. The right ovary remains vestigial, although it develops if the left ovary is removed or becomes diseased.

After the onset of puberty, the mammalian ovary alternates between two phases:

1. The **follicular phase**, which is dominated by the presence of maturing follicles, which produce a mature egg ready for ovulation and the steroids responsible for maturing the oocyte. The follicular hormones also govern the development of the reproductive tract and facilitate sexual receptivity.
2. The **luteal phase**, which is characterized by the presence of the *corpus luteum* (to be described shortly), the dominant ovarian structure during this phase. It secretes progesterone and, in so doing, prepares the female reproductive tract for pregnancy if the released egg is fertilized.

In estrous mammals, the follicular phase is comparatively reduced, usually encompassing no more than 20% of the estrous cycle, with the luteal phase encompassing the remaining 80%. In primates with menstrual cycles, the phases are more equal. We will now examine each of these phases in detail.

The follicular phase is characterized by the development of maturing follicles

At any given time throughout an estrous or menstrual cycle, portions of the primary follicles are starting to develop. In monovulators the follicle that will become the ovulatory follicle leaves the resting pool many cycles prior to the one in which it will become the ovulatory follicle. Estradiol and in-

hibin (as in males, p. 777) from that follicle reduce secretion of FSH by negative feedback. The others, lacking hormonal support, undergo atresia. During follicular development, as the primary oocyte is synthesizing and storing materials for future use if fertilized, important changes are taking place in the cells surrounding the reactivated oocyte in preparation for the egg's release from the ovary (Figure 16-16).

Proliferation of Granulosa Cells and Formation of the Zona Pellucida First, the single layer of *granulosa cells* in a primary follicle proliferates to form several layers that surround the oocyte termed the secondary follicle. The granulosa secretes a thick, gel-like material that covers the oocyte and separates it from the surrounding granulosa cells. This intervening membrane is known as the **zona pellucida** in mammals (most animal ova have a similar coating). Tendrils from the granulosa cells penetrate the zona pellucida and surround the oocyte's surface membrane.

As with sperm and Sertoli cells, gap junctions penetrate the zona pellucida and extend between the oocyte and surrounding granulosa cells in a developing follicle. Ions and small molecules can travel through these connecting tunnels. Recall that gap junctions between excitable cells permit the spread of action potentials from one cell to the next as charge-carrying ions pass through these connecting tunnels (see p. 66). The cells in a developing follicle are not excitable, so gap junctions here serve a role other than transfer of electrical activity. Glucose, amino acids, and other important molecules are delivered to the oocyte from the granulosa cells through these tunnels, enabling the egg to stockpile these critical nutrients. Also, signaling molecules pass through the gap junctions in both directions, helping to coordinate the changes that take place in the oocyte and surrounding cells as both mature and prepare for ovulation. The nurturing relationship between granulosa cells and a developing egg is similar in many ways to the relationship between Sertoli cells and developing sperm.

Proliferation of Thecal Cells; Estrogen Secretion At the same time the oocyte is enlarging and the granulosa cells are proliferating, specialized ovarian connective tissue cells in contact with the expanding granulosa proliferate and differentiate to form an outer layer of **thecal cells** in response to paracrine secreted by the granulosa cells. The thecal and granulosa cells, collectively known as **follicular cells**, function as a unit to secrete estrogen. Of the three physiologically important estrogens—estradiol, estrone, and estriol (the last being important only in the human)—the principal ovarian estrogen is usually estradiol (although in the sow it is estrone).

Formation of the Antrum The early stages of follicular development that occur without gonadotropin influence are not part of the follicular phase of the ovarian cycle. Only preantral follicles that have developed sufficiently to respond to FSH stimulation are “recruited” at the beginning of the follicular phase when FSH levels rise. The hormonal environment that exists during the follicular phase promotes enlargement and development of the follicular cells' secretory capacity, converting the primary follicle into a tertiary, or **antral, follicle** capable of estrogen secretion. This stage of follicular development is characterized by the formation of a fluid-filled **antrum** surrounded by the granulosa cells (Fig-

FIGURE 16-16 Development of the follicle, ovulation, and formation of the corpus luteum in a mammal.

ure 16-16). The follicular fluid originates partially from transudation (passage through capillary pores) of plasma and partially from follicular cell secretions. As the follicular cells start producing estrogen, some of this hormone is secreted into the blood for distribution throughout the body. However, a portion of the estrogen collects in the hormone-rich antral fluid.

The oocyte has nearly reached full size by the time the antrum begins to form. The shift to an antral follicle initiates a period of rapid follicular growth. During this time, the follicle increases in size from a diameter of less than 1 mm to 12 to 16 mm, depending on the species of mammal (30 to 50 mm in equids). In contrast, in the chicken there is not an antrum but an oocyte of nearly 3 to 4 cm. Part of the

follicular growth is due to continued proliferation of the granulosa and thecal cells, but most is due to a dramatic expansion of the antrum. As the follicle grows, estrogens are produced in increasing quantities.

Formation of a Mature Follicle One or more of the follicles usually grows more rapidly than the others, developing into **dominant** (or **preovulatory**) follicle(s). (The term **Graafian** follicle is often used for this in humans only.) In polyovular species (that is, most mammals) more than one follicle becomes part of the cohort of preovulatory follicles. A dominant follicle that develops into a mature follicle generally has the most FSH receptors and therefore is most responsive to hormonal stimulation. The antrum occupies most of the space in a mature follicle. The oocyte, surrounded by the zona pellucida and a single layer of granulosa cells, is displaced asymmetrically at one side of the growing follicle in a little mound of cells that protrudes into the antrum, the **cumulus oophorus**.

Ovulation The greatly expanded mature follicle bulges on the ovarian surface, and ultimately develops a thinned area that ruptures to release the oocyte at **ovulation**. Rupture of the follicle is facilitated by the release from the follicular cells of enzymes that digest the connective tissue in the follicular wall. The bulging wall is thus weakened so that it balloons out even further, to the point that it can no longer contain the rapidly expanding follicular contents.

Just before ovulation, the oocyte completes its first meiotic division. The ovum (secondary oocyte), still surrounded by its zona pellucida and granulosa cells, is swept out of the ruptured follicle into the infundibulum (which, in most species, surrounds the ovary) by the leaking antral fluid (Figure 16-16b). The layer of granulosa cells surrounding the oocyte is called the **corona radiata** (“radiating crown”) from the time of the secretion of the zona and the establishment of the cytoplasmic extensions of these cells to feed the oocyte. The cumulus oocyte complex that is ovulated consists of the oocyte, corona radiata, and a mass of additional granulosa (nonmural). The released ovum is quickly drawn into the oviduct, where fertilization may or may not take place. The other developing follicles that failed to reach maturity and ovulate undergo degeneration, never to be reactivated.

Rupture of the follicle at ovulation signals the end of the follicular phase and ushers in the luteal phase.

The luteal phase is characterized by the presence of a corpus luteum and secretion of progesterone

The ruptured follicle that is left behind in the ovary following release of the ovum undergoes a rapid change. The granulosa and thecal cells remaining in the remnant follicle first collapse into the emptied antral space that has been partially filled by clotted blood.

Formation of the Corpus Luteum; Estrogen and Progesterone Secretion These old follicular cells soon undergo a dramatic structural transformation to form the **corpus luteum** in a process called **luteinization** (Figure 16-16c). The follicular-turned-luteal cells hypertrophy and are converted into very active steroidogenic (steroid hormone-producing)

tissue. Beta-carotene, stored in lipid droplets within the corpus luteum, gives this tissue a yellowish appearance, particularly in the cow, hence its name (*corpus*, “body”; *luteum*, “yellow”), although in some species, such as sheep, pigs, and rats, it is a reddish pink. The corpus luteum becomes highly vascularized as blood vessels from the theca invade the luteinizing granulosa. These changes are appropriate for the luteal function, which is to secrete abundant quantities of progesterone along with lesser amounts of estrogens into the blood. Estrogen secretion in the follicular phase followed by progesterone secretion in the luteal phase is essential for preparing the uterus to be a suitable site for attachment or implantation of a fertilized ovum.

Degeneration of the Corpus Luteum If the released ovum is not fertilized and does not implant, lysis of the corpus luteum is initiated by $\text{PGF}_{2\alpha}$ from the endometrium (Figure 16-16d). The luteal cells degenerate and are phagocytized, the vascular supply is withdrawn, and connective tissue rapidly fills in to form a fibrous tissue mass known as the **corpus albicans** (“white body”). The luteal phase is now over, and one ovarian cycle is complete.

Corpus Luteum of Pregnancy If fertilization and implantation/attachment does take place, the corpus luteum continues to grow and produces increasing quantities of progesterone instead of degenerating. Now called the **corpus luteum of pregnancy**, this ovarian structure persists until the end of pregnancy. It provides the hormones essential for maintaining pregnancy in women, mares, and ewes until the developing placenta can take over this crucial function. However, in the sow, cow, doe, goat, and rat the corpus luteum is the source of progesterone for the duration of gestation.

The estrous cycle is regulated by complex hormonal interactions among the hypothalamus, anterior pituitary, and ovarian endocrine units

The estrous cycle can be divided into four phases: *proestrus* and *estrus*, which correspond with the ovarian follicular phase and are dominated by estrogens, and *metestrus* and *diestrus*, which correspond with the luteal phase and are dominated by progesterone. **Proestrus** begins with the regression of the corpus luteum and ends with the onset of estrus and is associated with development and ripening of the follicles. **Estrus** is the time of sexual receptivity and usually terminates with ovulation. **Metestrus**, the early postovulatory period, is associated with the development of the corpus luteum. **Diestrus** is associated with a functioning corpus luteum and begins after ovulation and ends with regression of the corpus luteum. If conception occurs, the female enters a period of *anestrus* during pregnancy, which ultimately ends with the positive-feedback cycle of *parturition* or the process of giving birth to the offspring.

As you have seen, the ovary has two related endocrine units: the estrogen-secreting follicle and the corpus luteum, which secretes progesterone. These units are sequentially triggered by complex cyclical hormonal relationships among the hypothalamus, anterior pituitary, and these two ovarian endocrine units. As in the male, gonadal function in the female is controlled directly by the anterior-pituitary gonadotropic hormones, follicle-stimulating hormone (FSH), and

FIGURE 16-17 Correlation between hormonal levels and the follicular and luteal phases of the bovine estrous cycle. The cycle begins with a surge in LH (day 0) in mid-follicular phase, which initiates the transition to the luteal phase. The upper grey arrows indicate the luteal phase only.

luteinizing hormone (LH). These hormones, in turn, are regulated by pulsatile episodes of hypothalamic gonadotropin-releasing hormone (GnRH) and feedback actions of gonadal hormones.

Differing from the male, however, control of the female gonads is complicated by the cyclical nature of ovarian function. For example, the effects of FSH and LH on the ovaries depend on the stage of the estrous cycle. Also in contrast to the male, FSH is not strictly responsible for gametogenesis, nor is LH solely responsible for gonadal hormone secretion. Using the bovine (cow) estrous cycle as an example, we consider control of follicular function, ovulation, and the corpus luteum, noting that the processes described are similar to those in other mammals (Table 16-4). We will follow Figures 16-17 and 16-18 to integrate the various concurrent and sequential activities that take place throughout the cycle. The cycle length is marked by behavioral estrus, which occurs, on the average, at intervals of 21 to 22 days, although estrous cycles of 17 to 24 days are considered normal.

Ovulation by Positive Feedback After regression of the corpus luteum in the cow, the rapidly increasing secretion of estradiol by the dominant follicle initiates a **luteinizing hormone (LH) surge** (day 0; Figures 16-17 and 16-18a). Ovulation of the dominant follicle occurs 24 to 27 hours after the LH surge. In the primate menstrual cycle, the LH surge occurs in midcycle, but in estrous mammals, the LH surge occurs at or very close to the onset of estrus at the beginning of the cycle, as shown in Figure 16-17. (Note that Figure 16-18 also applies to the menstrual cycle, which however begins with part c.) The surge brings about four major changes in the follicle:

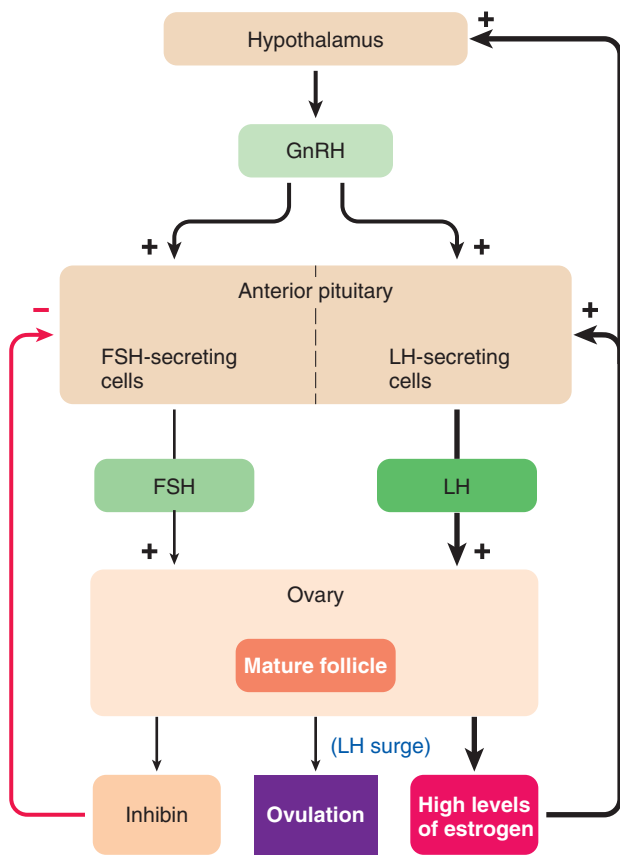

- It halts estrogen synthesis by the follicular cell.
- It reinitiates meiosis in the oocyte of the developing follicle by blocking secretion of an *oocyte maturation-inhibiting substance* produced by the granulosa cells. This substance is believed to be responsible for arresting meiosis in the primary oocytes once they are wrapped within granulosa cells in the fetal ovary.

- It triggers production of locally acting prostaglandin E₂, which supports ovulation by promoting vascular changes that cause rapid swelling of the follicle while inducing enzymatic digestion of the follicular wall, the latter aided by a preovulatory increase in the intrafollicular secretion of progesterone. Prostaglandin F_{2α} (PGF_{2α}) then stimulates contractions of myoepithelial or smooth-muscle-type cells in the theca externa at the base of the follicle. Together these actions lead to rupture of the weakened wall that covers the bulging follicle.
- It causes *differentiation of follicular cells into luteal cells*. Because the LH surge triggers both ovulation and luteinization, formation of the corpus luteum automatically follows ovulation.

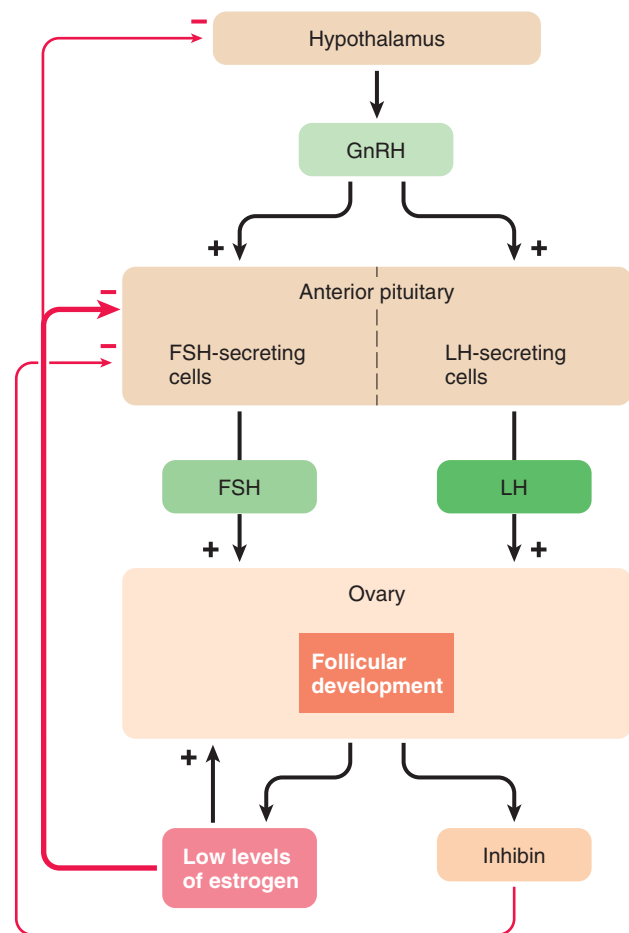

Thus, the surge in LH secretion is a dramatic point in the cycle; it terminates the follicular phase and initiates the luteal phase.

Two different modes of LH secretion—tonic secretion of LH responsible for promoting follicular development and hormone secretion and the LH surge that causes ovulation—not only occur at different times and produce different effects on the ovaries, but also are controlled by different mechanisms. Tonic LH secretion is reduced to low frequency by the increasing concentrations of progesterone during the luteal phase (Figure 16-18b) and is briefly suppressed by the inhibitory action of the low concentrations of estrogen during the follicular phase (Figure 16-18c). Because tonic LH secretion stimulates both estrogens and progesterone secretion, this is a typical negative-feedback control system.

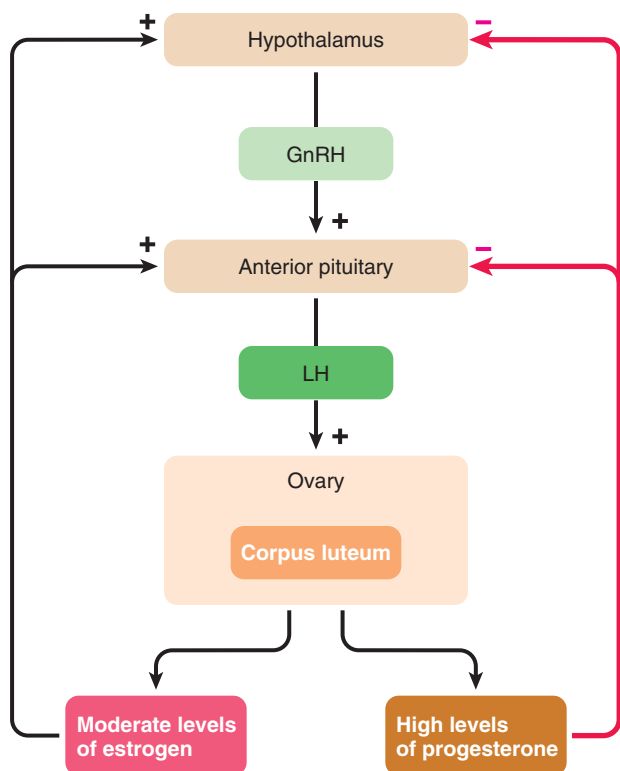

In contrast, the LH surge is triggered by a *positive-feedback* effect of estrogen. Whereas the low, rising concentrations of estrogens early in the follicular phase *inhibit* LH secretion, the high concentration of estrogens that occur during peak estrogen secretion late in the follicular phase *stimulates* LH secretion and initiates the LH surge (Figure 16-18a). Thus, LH enhances estrogen production by the follicle, and the resultant peak estrogen concentration stimulates LH secretion. The high plasma concentration of estrogens acts

(a)

(c)

(b)

© Cengage Learning, 2013

directly on the hypothalamus to increase the frequency of GnRH pulses, thereby increasing both LH and FSH secretion. It also acts directly on the anterior pituitary to specifically increase the sensitivity of LH-secreting cells to GnRH. The latter effect accounts in large part for the much greater surge in LH secretion compared to FSH secretion at estrus. Also, continued inhibin secretion by the follicular cells preferentially inhibits the FSH-secreting cells, keeping the FSH concentrations from rising as high as the LH concentrations. There is no known requirement for the modest surge in FSH that accompanies the pronounced and pivotal LH surge; however, low doses of FSH injected directly into sheep follicles cause ovulation. Because only a mature, preovulatory follicle (not follicles in earlier stages of development) can secrete sufficient amounts of estrogens to trigger the LH surge, ovulation is not induced until a follicle has reached the proper size and degree of maturation. In a way, then, the follicle lets the hypothalamus know when it is ready to be stimulated to ovulate. The LH surge lasts for only one to two days (prior to ovulation in both the horse and pig), although the surge duration is shorter in the cow and ewe, while in the mare the surge continues after ovulation.

Luteal Phase The luteal phase (Figure 16-18b), dominated by the corpus luteum (as you have seen), is measured from the time of ovulation until regression of the corpus luteum (luteolysis). It is the longest portion of the estrous cycle. Following ovulation, the corpus luteum begins to form at the site of ovulation and can be seen from ovulation until day 3 as a **corpus hemorrhagicum**. At about day 3 to 5, the corpus luteum loses its bloody appearance and begins to increase in size and to produce sufficient progesterone such that the increase in hormone secretion is detectable in the peripheral circulation. By approximately midcycle, the corpus luteum reaches its maximum size and production of progesterone (Figure 16-17).

LH “maintains” the corpus luteum (hence its name); that is, after triggering development of the corpus luteum, LH stimulates ongoing steroid hormone secretion by this ovarian structure, with progesterone being its most abundant hormonal product (estrogen is not produced by the corpus luteum of cows and ewes). Progesterone has two major regulatory roles:

1. It inhibits the release of LH. High concentrations of progesterone reduce the frequency of secretion of pulses of gonadotropin-releasing hormone (GnRH) from the hypothalamus and thus the frequency of secretion of pulses of LH from the anterior pituitary gland, and prevent the surge of LH and subsequent ovulation (Figure 16-18b).
2. It directs the endometrial secretion of prostaglandin $F_{2\alpha}$ and controls the timing of secretion of $PGF_{2\alpha}$ for luteolysis by regulating the timing of the initial increase in secretion of $PGF_{2\alpha}$, which usually occurs around day 12 of the estrous cycle in the pig and sheep and day 14 in the cow (Figure 16-17). In ruminants, progesterone modulates the secretion of $PGF_{2\alpha}$, keeping it at midrange episodic values until luteal regression has begun. As concentrations of progesterone decline, greater peaks of secretion of $PGF_{2\alpha}$, produced by the uterus and the corpus luteum, complete luteal regression and end the luteal phase. Notice in Figure 16-17 that the maximal secretion of $PGF_{2\alpha}$ occurs after luteal function (secretion of progesterone) has already ceased.

Follicular Phase The follicular phase is initiated only after luteolysis is under way. As luteolysis proceeds, the decreasing concentrations of progesterone reduce the negative feedback on pulsatile secretion of LH by the anterior pituitary. The increased frequency of pulses of LH promotes the final maturation of the large antral follicle. During the follicular phase, LH reaches higher concentrations than in the luteal phase, because negative feedback from progesterone on the hypothalamus is removed (Figure 16-18c).

Dominant follicles, as they continue to grow, secrete increasing concentrations of estradiol and inhibin so that FSH declines during the follicular phase but estradiol does not limit pulse frequency of LH. When the dominant follicle reaches adequate size (10 mm in diameter is approximately the minimum required for ovulation in the cow, as compared to 7 mm in a pig) and secretion of estradiol from the follicles reaches threshold, a preovulatory surge of LH and FSH occurs (Figure 16-17). Immediately after the preovulatory surge of LH, concentrations of estradiol abruptly decline and a secondary smaller pulse of FSH occurs on the day of ovulation.

While early stages of ovarian follicular development are not dependent on gonadotropins, pulses of FSH recruit a cohort of secondary follicles and is required for their growth from approximately 4 to 9 mm in diameter. Thus, the process of follicular growth and degeneration occurs continuously throughout the entire estrous cycle. However, more frequent pulses of LH are necessary for development of the follicle beyond about 9 mm. FSH induces antrum formation, further follicular development, and estrogen secretion. As the follicles grow, they secrete increasing amounts of estradiol and inhibin. Each of these hormones exerts negative-feedback effects on the secretion of FSH (estradiol limits secretion of GnRH by the hypothalamus, and inhibin reduces responsiveness of the anterior pituitary to GnRH; Figure 16-18c). In the pig, in which concentrations of progesterone are an order of magnitude greater than in the cow and ewe, no large antral follicles develop during the luteal phase.

FSH and estrogens stimulate proliferation of the granulosa cells, whereas LH and FSH are required for synthesis and secretion of estrogens by the follicle, although these hormones act on different cells and at different steps in the estrogen production pathway. Both granulosa and thecal cells participate in estrogen production. The conversion of cholesterol into an estrogen requires a number of sequential steps, the last of which is conversion of androgens into estrogens (see Figure 7-3). Thecal cells readily produce androgens but have limited capacity to convert them into estrogens except in the pig, whose thecal cells have copious aromatase activity. Granulosa cells, in contrast, can readily convert androgens into estrogens but cannot produce androgens in the first place. Luteinizing hormone acts on the thecal cells to stimulate androgen production, whereas FSH acts on the granulosa cells to promote the conversion of thecal androgens (which diffuse into the granulosa cells from the thecal cells) into estrogens. Because low basal concentrations of FSH are sufficient to promote this final conversion to estrogen, the rate of estrogen secretion by the follicle primarily depends on the circulating concentration of LH, which continues to rise. Furthermore, as the follicle continues to grow, more estrogen is produced simply because more estrogen-producing follicular cells are present.

This differential sensitivity of FSH- and LH-producing cells to negative feedback by estrogens is at least in part responsible for the fact that the serum FSH concentration, unlike the serum LH concentration, declines as the estrogen concentrations rise. Another contributing factor to the fall in FSH is the secretion of inhibin by the follicular cells, which preferentially inhibits FSH secretion at the anterior pituitary, just as it does in the male. The decline in FSH secretion brings about atresia of all but the single most mature of the developing follicles. As FSH concentrations decline, the dominant follicle becomes more dependent on LH. Continued pulses of LH maintain the growth of the dominant follicle until it is either ovulated or becomes **atresic** (degenerated and reabsorbed).

In contrast to FSH, LH secretion continues to rise slowly despite inhibition of GnRH (and thus indirectly, LH) secretion. This seeming paradox is due to the fact that estrogens alone cannot completely suppress tonic (low-level, ongoing) LH secretion; progesterone is required to more fully curtail the frequency of tonic LH secretion. Because progesterone does not appear until the luteal phase of the cycle, the

basal level of circulating LH slowly increases during the follicular phase under incomplete inhibition by estrogens alone.

Subnormal Luteal Phase A subnormal luteal phase is defined by low secretion of progesterone or can occur during treatment with other *progestogens* (progesterone-related steroids) for synchronization of estrus. Lower circulating concentrations of progestogen lead to an *increased* frequency of release of pulses of LH from the anterior pituitary gland. Increased LH stimulates continued growth of the largest ovarian follicle, which is followed by increased secretion of estradiol by the **persistent largest follicle**; that is, the largest dominant follicle continues to increase in size and becomes *persistent*. Low dosages of administered progestogens, native or synthetic, result in reduced fertility in association with follicular persistence. In contrast, a low frequency of pulses of LH fails to support continued follicular growth and allows earlier degeneration or more frequent replacement of the largest follicle. Treatment with higher dosages of progesterone or a progestogen can be used to cause atresia of the largest follicle and initiation of growth of a new cohort of follicles.

The uterine changes that occur during the estrous cycle reflect hormonal changes during the ovarian cycle

The fluctuations in circulating levels of estrogens and progesterone that occur during the ovarian cycle induce profound cyclic changes in the uterus in the *uterine cycle*. In estrous mammals, the complete removal of the uterus, **hysterectomy**, after ovulation results in the persistence of the corpus luteum as if the female were pregnant. Because it reflects hormonal changes that occur during the ovarian cycle, the uterine cycle averages 17 to 24 days (in cattle), as does the ovarian cycle, although there is considerable variation from this mean even in normal animals. This variability is primarily a reflection of differing lengths of the follicular phase; the duration of the luteal phase is fairly constant within a species. However, across species the duration of the luteal phase varies considerably. Consistent changes that take place throughout the cycle include the preparation of the uterus for implantation should a released ovum be fertilized, which involves a thickening of the uterine lining (*endometrium*) that is reduced at the end of the luteal phase in the absence of conception (recall that it is reabsorbed in estrous species and sloughed off in menstrual species).

We briefly examine the influences of estrogens and progesterone on the uterus and then consider the effects of cyclic fluctuations of these hormones on uterine structure and function.

Influence of Estrogen and Progesterone on the Uterus The uterus consists of two main layers: the **myometrium**, the outer smooth-muscle layer; and the **endometrium**, the inner lining that contains numerous blood vessels and glands. Estrogens stimulate growth of both the myometrium and the endometrium. It also induces the synthesis of progesterone receptors in the endometrium. Thus, progesterone can exert an effect on the endometrium only after it has been “primed” by estrogen. Progesterone acts on the estrogen-primed endometrium to convert it into a hospitable and nutritious lining

suitable for implantation of a fertilized ovum. Under the influence of progesterone, the endometrial connective tissue becomes loose and edematous as a result of an accumulation of electrolytes and water, which facilitates implantation of the fertilized ovum. Progesterone further prepares the endometrium to sustain an early-developing embryo by inducing the endometrial glands to secrete and store large quantities of glycogen and by causing tremendous growth of the endometrial blood vessels. Progesterone also reduces the contractility of the uterus to provide a “quiet” environment for implantation and embryonic growth in the cow, pig, and ewe but not in the mare. In this species, contractions of the myometrium serve to transport the embryo throughout the uterine lumen so as to reduce secretion of $\text{PGF}_{2\alpha}$ and prevent luteolysis.

Fluctuating concentrations of estrogens and progesterone produce cyclic changes in cervical mucus

Hormonally induced changes in the cervix occur during the ovarian cycle as well. Under the influence of estrogens during the follicular phase, the mucus secreted by the cervix becomes abundant, clear, and thin. This change, which is most pronounced when estrogens are at their peak and ovulation is approaching, facilitates passage of sperm through the cervical canal. After ovulation, under the influence of progesterone from the corpus luteum, the mucus becomes thick and sticky, essentially forming a plug across the cervical opening. This plug constitutes an important defense mechanism by preventing bacteria that might threaten a pregnancy (should conception have occurred) from entering the uterus from the vagina. Sperm cannot penetrate this thick mucus barrier.

The reproductive cycles of nonviviparous vertebrates are fundamentally similar but have some unique differences

The details of female reproductive features we have been discussing are primarily those of mammals. How does the reproductive cycle of a viviparous cow compare to the ovulatory cycle of an ovoviviparous bird or oviparous fish? Each reproductive strategy represents separate evolutionary trends, with the result that there are as many similarities between these strategies as there are differences. For example, as in mammalian species, the hormonal pathway of reproduction in birds and fishes revolves around the hypothalamic–pituitary–gonadal axis. The hypothalamus is activated by specific environmental cues: day length in some species of birds and pheromones in some species of fish. Following this activation, kisspeptin stimulates GnRH synthesis and release into the hypothalamic–hypophyseal portal vasculature. However, different bird and fish species have two to three forms of GnRH, the number depending on the species, although it is believed that only one form of GnRH governs the release of LH. We initially focus on the ovulatory cycle of the domestic chicken.

Ovarian Follicular Growth and the Ovulatory Cycle in the Domestic Hen At the time of hatching, the chick embryo contains approximately a million oocytes, many of which

A Closer Look at Adaptation

A Rut for One Season

As day length declines in the fall, thick-necked bucks start shredding trees, making “scrapes” (areas scraped by the bucks’ front hooves), focusing on does, and fighting other bucks. Basically the culmination of the rut, which translates to successfully breeding as many does as possible, involves all the activity that leads to this event. During this period, deer release various pheromones as they primarily use scent for communication at this time. Studies suggest that each reproductively active deer exudes a unique odor that communicates its identity as well as its sexual status.

Glands that are used for communication purposes include:

- *Tarsal gland*: Early in the rut, this gland on the inside of the back knee joint of dominant bucks turns dark brown in color. Urine deposited on the gland reacts with bacteria that live on the surface, which then steadily darkens with time. As the time nears to when the fe-

males ovulate, these glands are almost black in color. Scent is subsequently released onto the surrounding vegetation as the buck moves through his territory. Females also urinate over the tarsal gland (rub urination), and when it eventually turns black, they are in estrus, meaning that they are about to ovulate.

- *Metatarsal gland*: Approximately two-thirds of the way down the leg between the knee joint and the hoof is the metatarsal gland, one whose function has not been elucidated, although it has been suggested to produce an “alarm scent.”
- *Forehead gland*: Located between the base of the antlers and the eyes, this gland is easily identified in adult bucks because the hair in this region is particularly dark and brown. Prior to the rut, the bucks rub trees and overhanging branches with the base of their antlers, thus exposing the moist undersurface of the trees to the secretions from the fore-

head gland. In this fashion, bucks are advertising their territory and relative dominance, for the most dominant bucks have the most active forehead glands.

- *Preorbital gland*: Located on the inside corner of the eye, this gland advertises the presence of the buck and warns off potential intruders. Scents from the pre-orbital gland generally are positioned on branches that overhang the scrape.
- *Interdigital gland*: Located between the hooves, this gland enables the deer to follow other deer by smell.
- *Vomer nasal gland*: This gland is located in the nasal cavity (p. 238). When a doe is close to estrus, bucks will approach her when she urinates, occasionally licking the urine and curling their lip in the Flehman response. The VNO detects when the does are beginning to go into estrus. Secretions from the uterus in association with behavioral changes in the doe signal she is ready to mate.

become atresic in the first weeks. However, the remaining follicles enter a stage of slow growth to 1 to 2 mm in size that continues for months or even years. During this time, neutral lipids are deposited as yolk in the oocyte. In the weeks before the onset of lay (egg production), which in the domestic hen begins at approximately 18 weeks of age, a small proportion of these oocytes begins to enlarge. This stage of follicular development lasts for approximately eight to nine weeks, with recruitment of oocytes continuing throughout the female’s reproductive life. As a consequence of the deposition of a white, proteinaceous, primordial yolk, these oocytes increase in size to about 2 to 6 mm in diameter. When the follicles reach 5 to 8 mm in diameter, they enter the final rapid-growth phase, which is characterized by the rapid deposition of yellow yolk. During this stage, the follicles grow to more than 35 mm in diameter in as few as 7 to 11 days.

One of the most obvious differences in follicular development between birds and mammals now becomes evident, because in the bird’s ovary the follicles do not mature synchronously. The yellow yolky follicles form an orderly hierarchy of different sizes so that at the peak of egg production, the largest (F1 follicle) of about 40 to 45 mm in diameter is the one destined to be ovulated next, the second largest follicle (F2) the following day, the third largest (F3) two days later, and so on. Normally, the ovary of the hen contains up to 10 yellow yolky follicles, together with a greater number of small yellow follicles and numerous small white follicles awaiting recruitment or atresia (Figure 16-19). The actual number of rapidly growing follicles generally remains stable in an individual hen, with just one

follicle from the intermediate phase recruited into the final growth phase once the largest follicle is ovulated. However, it is not known how new follicles are recruited into the intermediate phase.

In response to the increase in estrogen concentrations prior to the onset of lay, very-low-density lipoprotein (VLDL, p. 389) and vitellogenin (similar forms of which are found in most yolk-producing animals; see pp. 765 and 798) are synthesized in the liver. These are the major precursors of yellow yolk and are transported to the ovary, where they are deposited in the yolk. Researchers have studied the growth of yellow yolky follicles by feeding the hen differently colored lipid-soluble dyes (Figure 16-19a). The dye is laid down in the yolk as concentric rings marking the day of feeding. Using this technique, researchers showed that follicles require from 11 to 13 days to mature from an intermediate follicle to one of ovulable size.

Because yolk is an energy-expensive material to produce, the number of follicles in the hierarchy, their size relative to body weight, and the interval between successive ovulations differ greatly among different species of birds. Most birds lay an egg each day until the clutch is complete. A longer interval between egg lay has energy advantages but creates difficulties in synchronizing the timing of hatch and increases the likelihood of predation. Normally clutch size is smaller, and the interval between eggs is longer, in species producing larger eggs. Many species of birds are **determinate** layers; that is, they lay a fixed number of eggs in a clutch, whereas others are **indeterminate** layers and can continue to lay eggs for extended periods of time, particularly if the eggs are removed from the nest as they are laid. With the onset

FIGURE 16-19 Ovary of a laying hen. (a) Midsagittal section through the follicle of an egg. Xanthophylls (yellow to orange carotenoid pigments) from the diet are transported rapidly from the bloodstream to the developing yolk; consequently, more pigment is deposited when the hen is eating. This process gives rise to 7 to 11 dark (xanthophyll-rich) and light concentric yolk layers. (b) Ovary, follicles, and reproductive tract of a laying hen. (c) Follicular hierarchy. Follicles are arranged in order from the largest (F1) to the smallest. F1 also denotes the follicle next in line to be ovulated. The F1 follicle is the principal source of progesterone, the steroid hormone that induces the preovulatory surge of LH from the anterior pituitary.

of agriculture and domestication of species over 4,000 years ago, humans have exploited this property of indeterminate layers and developed strains of chickens, ducks, and quail that can lay over 300 eggs each year.

Eggs laid on successive days are known as a **sequence**, whereas days on which no eggs are laid are termed **pause** days. The first egg of a long sequence may be laid earlier in the day than the first egg of a hen producing a short sequence. The general rule is that ovulation occurs 6 to 8 hours after the ovulatory surge of LH, with the egg spending about 24 hours in the oviduct before it is laid (**oviposited**). There is a close relationship between ovulation and oviposition, with ovulation occurring 15 to 75 minutes after oviposition, except if it is the last egg of a sequence. Because of this relationship, the time of lay becomes a practical guide to the time of ovulation in a bird. To achieve sequences of 50 to 100 eggs, ovulation occurs every day at approximately

the same time, and the egg from that ovulation is subsequently laid 24 hours later. Between sequences, there are one or more pause days. Chickens held under normal light–dark cycles of 14L:10D lay their eggs in the first half of the light period, whereas under the same lighting conditions, quail lay their eggs late in the day and early into the dark period. In both situations, an ovulatory surge of LH occurs six hours before oviposition, which means that the ovulatory surge in chickens occurred during the night, whereas in quail, it occurred during the morning. Egg laying is thus *entrained* by the light–dark cycle and can readily be affected by any changes in the photoperiod.

Two additional features pertinent to the ovulatory cycle need to be pointed out. The first is that each ovulation in a hen occurs slightly later on subsequent days. The second is that the preovulatory release of LH is restricted to a 10- to 11-hour period each day, the so-called **open period**. The

FIGURE 16-20 Expression of the LH receptor (LHR) gene in the channel catfish ovary. Cyclic changes in the LH receptor gene through a complete spawning cycle reveal an increase in expression associated with ovulation. The LHR binds to the LH-like gonadotropin (GTH-2) of fish.

Cloning of a functional, luteinizing hormone receptor and preovulatory induction of gene expression. 'Biology of Reproduction', 64:1016. Reproduced with permission via Copyright Clearance Center.

preovulatory release of LH can be initiated only from the onset of darkness to about one hour after the onset of the light period.

With age there is a decline in the rate of recruitment of follicles into the hierarchy and in the maturation of these follicles, and an increase in the rate of atresia of small follicles. If we induce a cessation in lay (**forced molt**), older hens lay eggs more frequently and of a greater quality (thicker shells) when production is resumed.

Unlike the situation in female mammals, ovulation of the F1 (largest) follicle in birds is preceded by an increase in the concentrations of progesterone and LH. The preovulatory surge of LH is caused by a positive-feedback interaction, comparable to the effect of estrogens at the hypothalamus in mammals, but it is progesterone that stimulates the release of GnRH and hence LH. LH, in turn, stimulates the secretion of more progesterone from the granulosa of the mature preovulatory follicle. Thus, in birds, it is the granulosa that produce progesterone, most of which diffuses to the thecal cells, where it is converted to estrogen. As the follicles mature, the enzyme activity diminishes within the theca but increases in the granulosa, resulting in the enhanced production of progesterone at the time of ovulation. There are two possible reasons for this switch in the pattern of steroid synthesis by the maturing follicle. First, birds require estrogens for synthesis of Ca^{2+} -ATPase in the shell gland as well as for yolk synthesis by the liver, and estrogens must be available in sufficient concentrations well before ovulation. Secondly, progesterone is the hormone responsible for the positive-feedback cycle, generating both the surge in LH and ovulation of the F1 follicle, and so the synthesis of this steroid needs to be restricted to the few mature follicles. The preovulatory releases of progesterone and LH are initiated 10 to 12 hours before ovulation, with LH peaking 6 to 8 hours before ovulation and progesterone peaking 2 to 4 hours before ovulation.

Ultimately, the expulsion of the egg from the uterus (shell gland) into the vagina is mediated by an increase in the release of arginine vasotocin (AVT), a neurohypophyseal hormone (p. 285). Once the egg enters the vagina, rhythmic

contractions of abdominal and vaginal muscles force expulsion of the egg. This event, termed **bearing down**, results from a nervous reflex generated by the egg stretching the vaginal lumen. Vaginal muscles contract in response to the increased concentrations of AVT.

Spawning Cycles of Fish Most information on the spawning cycles of viviparous species of fish has been obtained from studies in teleosts. Three modes of oocyte development are recognized, based on the recruitment of new oocytes: **synchronous**, **group synchronous**, and **asynchronous**. In those species showing synchronous development, all the oocytes mature and ovulate at the same time. This strategy is used by some species of salmon and eels that spawn once and die. In species employing group synchronous development, oocytes are partitioned into groups that mature at different rates and are then ovulated periodically throughout the breeding season. This group is categorized as being multiple spawners with comparatively short spawning seasons. The third strategy is the most complex, because oocytes are found at all stages of development throughout the spawning cycle. Oocytes are recruited continuously into the pool of maturing oocytes. As with group synchronous fish, asynchronous fish are multiple spawners but they have a prolonged spawning season.

In the hypothalamic-pituitary-gonadal axis in fishes, the pituitary gonadotropins *GTH-1* has FSH-like activity and *GTH-2* has LH-like activity, and each functions comparably to their mammalian counterparts. However, neuroendocrine regulation of *GTH-2* in teleost fish is under dual hypothalamic control. *GTH-2* release is inhibited by dopamine, which functions as a gonadotropin release-inhibiting hormone. Dopamine acts directly at the pituitary to modulate the actions of GnRH as well as the release of *GTH-2*.

GTH-1 is important for vitellogenesis and early gonadal development, and is secreted for an extended period of time. For example, concentrations of LH receptor gene and *GTH-1* in coho salmon and catfish steadily increase from early in May until they reach peak concentrations in September and then decline through December (Figure 16-20).

In response to GTH-1, the ovarian granulosa cells synthesize estradiol, which stimulates the production of *vitellogenin* in the liver. GTH-1 is responsible for generating GTH-2 in the pituitary gland. Once vitellogenesis is completed, a preovulatory surge of GTH-2 is generated, which initiates final oocyte maturation and ovulation of the mature oocytes. The surge in GTH-2 is comparatively rapid (several days), although the actual profile is species dependent.

Normally the surge in GTH-2 is initiated by external environmental cues such as photoperiod, water temperature, and adequate water velocities along with conditions suitable for the survival of the larvae. Other factors that can elicit the GTH-2 surge include pheromones, sound production by male fishes, and the courtship behavior of males, factors that reliably ensure that the eggs are fertilized once ovulated. A dopamine antagonist can artificially induce ovulation; in cobia (*Rachycentron canadum*), a migratory pelagic species of fish, human chorionic gonadotropin (p. 806) can induce ovulation.

In addition to GTH-2, final oocyte maturation and ovulation in fish require an additional factor produced by the follicular cells. *Maturation-inducing hormone* (MIH) is a progestogen synthesized via a two-cell mechanism comparable to that by which estradiol is synthesized. In this model, there are receptors for GTH-2 on both the thecal and granulosa cells, unlike the mechanism for estradiol synthesis.

Among the various fish groups the path that sperm and eggs take to get to the outside differs considerably. Oocytes can be ovulated either into the coelom of the fish and moved into the oviduct and the cloaca by ciliated epithelium lining the peritoneal cavity or into an ovarian cavity and moved down the oviduct to the cloaca without entering the peritoneal cavity itself.

Sexual maturity events in mammalian females are similar to those in males

As with males, sexual maturation (puberty) in mammalian females is not a binary switch but rather a long progression of greater and greater function of the hypothalamic-hypophyseal-gonadal axis until the time when the hypothalamus has become sufficiently mature that it allows the next follicle to produce enough estrogens to elicit the first LH surge. Unlike the fetal testes, the fetal ovaries do not need to be functional, because feminization of the female reproductive system automatically takes place in the absence of fetal testosterone secretion without the presence of female sex hormones. As the prepubertal female matures, an increase in the frequency of GnRH pulses is associated with a decrease in the sensitivity of the hypothalamus to estrogen. Puberty occurs at about three to four months of age in rabbits. However, it can vary from 6 to 16 months in sheep, and goats depending on the season of birth (spring or fall). Puberty is from 6 to 7 months in pigs, 10 to 15 months in cattle, and 15 to 18 months in horses. Domestication of the wolf, ancestor of dogs, has reduced the age of puberty from 2 years to between 6 and 12 months in modern dog breeds.

Puberty can be best considered as the age at which a female can support pregnancy. In most female mammals, a requisite body size is required before the onset of puberty can occur, and there is evidence that metabolic signals can affect the development of the hypothalamic neurons and the rate of GnRH release. Reproductive function is influenced

by body weight and nutritional status, for gonadotropin secretion is reduced in animals and humans that are nutritionally restricted. GnRH begins stimulating the release of the anterior-pituitary gonadotropic hormones, which in turn stimulate ovarian activity. The resultant secretion of estrogens by the activated ovaries induces growth and maturation of the female reproductive tract as well as development of the female secondary sexual characteristics. Estrogen's prominent action in the latter regard is to promote fat deposition. Enlargement of the mammary glands at puberty is due primarily to fat deposition in the mammary gland tissue and not to functional development of the mammary glands. The pubertal rise in estrogens does close the epiphyseal plates, however, halting further growth in height, similar to the effect of testosterone in males.

Leptin, a peptide produced by adipocytes and a potent satiety factor (see p. 725), may be a signal that informs the hypothalamus that metabolic stores are sufficient for initiating reproductive function. In this model, leptin-responsive neurons in the arcuate nucleus synthesize kisspeptin, whose release is influenced by nutritional status. Food deprivation in prepubertal rats decreased the expression of kisspeptin mRNA, while administration of kisspeptin to chronically undernourished prepubertal rats increased the suppressed levels of LH and estrogen. In some species leptin may play only a permissive function, functioning as a “barometer” of body function, and not necessarily an initiator of puberty, because leptin concentrations in monkeys do not change around the onset of puberty. The feeding of high-protein feedstuffs (flushing) to animals causes an acute response in terms of gonadotropin release to improve ovulation rates; this method has long been practiced in agriculture. Whether leptin is involved in these effects has not been determined. Other factors can modulate the onset of puberty, including the photoperiod during the peripubertal period (sheep), season of birth (sheep), as well as the presence or absence of siblings during the peripubertal period (cattle and swine).

Seasonal Regression and Recrudescence of Ovarian Function After puberty in most seasonally breeding animals, other factors, in turn, influence the timing of GnRH release and the recrudescence (reawakening) of ovarian function (see Figure 7-8). As we have discussed previously, photoperiod at temperate latitudes is the most important factor determining the onset and termination of the breeding cycle. Light is initially perceived in the retina (although in birds the eyes are not required for the stimulation of reproduction) and transferred by the optic nerve to a specific area of the hypothalamus known as the *suprachiasmatic* (SCN) *nucleus* (*mediobasal hypothalamus* in birds; see p. 282). From the SCN, a nerve tract travels to the *superior cervical ganglion* (SCG). From here, a synapse is made with cells in the pineal gland. **Pinealocytes** in turn cease the secretion of the hormone *melatonin*, which is secreted during the period of dark (**scotophase**). During the daylight hours (**photophase**), the light detected by the retinal cells of the eye, through the SCG, activates neurons that limit the release of melatonin from the pineal gland (again, in birds, a definitive role for the pineal has not been conclusively established). However, during the dark period, this inhibitory pathway is shut down by a reduction in the firing rate of nerves in the light-sensitive areas of the retina. The amount of melatonin released from the pinealocytes is a function of the duration of the

period of darkness, although data in experimental animals indicate that receiving only brief flashes of light, separated by a given number of hours of dark (skeleton photoperiod), results in similar quantities of melatonin released. Under normal conditions in short-day breeders, sufficient quantities of melatonin are released only when a critical length of the dark period is reached, which then triggers an increase in GnRH release from the hypothalamus. In seasonal long-day breeders, termination of the breeding season is associated with the development of **photorefractoriness**, the inability of the long day lengths to sustain the breeding cycle. In birds this is believed to be the result of an increase in GnIH associated with a decline in the release of GnRH. GnIH is also elevated in birds incubating an egg and is believed to be responsible for suppressing gonadotropic function at this time.

16.6 Fertilization and Implantation

You have now learned about the events that take place if fertilization does not occur in a mammal. Because the primary function of the reproductive system is, of course, reproduction, we next turn our attention to the sequence of events that ensue when this function is accomplished.

The oviduct is the site of fertilization

Fertilization, the union of male and female gametes, in most mammals occurs in the **ampullary–isthmic junction**, the midpoint of the oviduct. Thus, both the ovum and the sperm must be transported from their gonadal sites of production to the ampullary–isthmic junction in the female.

Ovum Transport to the Oviduct At ovulation the ovum is released into the abdominal cavity, but the oviduct picks it up quickly. The fimbriae (Figure 16-4c) contract in a sweeping motion to guide the released ovum into the oviduct. Furthermore, the fimbriae are lined by cilia that beat in waves toward the ostium (interior) of the oviduct, further assuring the ovum's passage into the oviduct. Within the oviduct, the ovum is propelled rapidly by peristaltic contractions and ciliary action to the ampullary–isthmic junction.

Conception can take place during a limited time span in each cycle, the **fertile period**. If not fertilized, the ovum begins to disintegrate within 4 hours in the rabbit and 24 hours in the guinea pig and human. In most mammalian species studied, the survival of the egg is so short as to preclude fertilization in the uterus. Cells that line the reproductive tract are responsible for phagocytizing the ovum.

Fertilization must therefore occur in the brief time when the ovum is still viable. In contrast, the ability of sperm to survive in the female reproductive tract is highly variable among species. For example, in some species of bats sperm survive from the time of mating in the fall until the time of ovulation in the spring because of the presence of specific anatomic features involved in sperm storage. In farm and laboratory animals the survivability of sperm is considerably shorter and ranges from 30 to 35 days in the hen (which also has a sperm storage organ), 5 days in the mare and human, and 26 to 30 hours in the rabbit. (Contrast these values with those in a queen bee, who, after a single insemination, can continue to lay fertilized eggs for as long as four years.)

Sperm Transport to the Oviduct In some mammals sperm are deposited in the vagina at ejaculation (primates, cows, sheep, rabbits), whereas in others the sperm are delivered to the cervix or are deposited in the uterus (horses and pigs). These sperm must travel through the uterus and then up to the egg into the upper third of the oviduct. The first sperm arrive in the oviduct within a half hour after ejaculation, but these may not be capacitated. To accomplish this formidable journey, sperm need the help of the female reproductive tract. The first hurdle is passage through the cervical canal. Throughout most of the cycle, because of high progesterone or low estrogen, the cervical mucus is too thick to permit sperm penetration. The cervical mucus become thin and watery enough to permit sperm to penetrate only when estrogen is high, as occurs in the presence of a mature follicle about to ovulate. Sperm migrate up the cervical canal under their own power. The canal remains penetrable for only two or three days during each cycle, around the time of ovulation. In species in which the sperm are deposited in the vagina, the process of capacitation (p. 778) is initiated as they pass through the cervix. However, in those species where the sperm are deposited directly in the uterus, capacitation is initiated here and is completed in the oviduct.

Once the sperm have entered the uterus, contractions of the myometrium churn them around in “washing-machine” fashion. This action quickly disperses the sperm throughout the uterine cavity. When sperm reach the uterotubal junction, they are moved up the oviduct toward the site of fertilization with the help of smooth muscle contractions and cilia that move in the direction of the ampullary–isthmic junction (region of the oviduct where the isthmus makes an anatomic transition into the ampulla) under the influence of high concentrations of estrogens present near ovulation. Furthermore, new research indicates that ova are not passive partners in conception. Mature eggs have been shown to release **allurin**, a recently identified chemical that attracts sperm and causes them to propel themselves toward the waiting female gamete, although this likely only influences cells that are very close (<1 cm) to the oocyte. Interestingly, the allurin receptor, called *hOR17-4*, is an olfactory receptor (OR) similar to those found in the nose for smell perception (see p. 237). Therefore, sperm are believed to “smell” the egg. According to current thinking, activation of the *hOR17-4* receptor on binding with a chemottractant from the egg triggers a second-messenger pathway in sperm that brings about intracellular Ca^{2+} release. This Ca^{2+} turns on the microtubule sliding that brings about tail movement and sperm swimming in the direction of the chemical signal.

FIGURE 16-21 Process of fertilization (mammal).

Even around ovulation time, when sperm can penetrate the cervical canal, of the several hundred million sperm deposited in a single ejaculate only a few thousand make it to the oviduct. The fact that only a very small percentage of the deposited sperm ever reach their destination is one reason why sperm concentration must be so high. Sperm, like ova, have limited life spans. Another reason so many sperm are needed is that the acrosomal enzymes assist in digesting the zona pellucida, allowing sperm to penetrate the zona and arrive in the perivitelline space (Figure 16-21). In addition, in some species a high percentage of sperm have nonfertilizing roles, as you will see shortly.

Fertilization Although the tail of the sperm is used to maneuver for final penetration of the ovum, motility ceases once contact with the ovum is made. To fertilize an ovum, a sperm must pass through the corona radiata and zona pellucida surrounding it (or equivalent jelly coating in nonmammalian animals). Contact of the sperm with the cumulus-oocyte complex results in hyperactivation of the sperm cell, which is responsible in part for denuding the oocyte of the cumulus cells. Sperm can penetrate the zona pellucida only after binding with specific receptor sites on the surface of this layer. The binding partners between the sperm and ovum have recently been identified. **Fertilin**, a protein found on the plasma

membrane of the sperm, binds with glycoproteins known as **ZP3** in the outer layer of the zona pellucida. Only sperm of the same species can bind to these zona pellucida sites and pass through. Binding of sperm triggers the **acrosome reaction**, in which the acrosomal membrane disrupts and the acrosomal enzymes are released. The acrosomal enzymes digest the zona pellucida, enabling the sperm, with its tail still beating, to tunnel a path through this protective barrier.

The first sperm to reach the ovum itself fuses with the plasma membrane of the ovum (actually a secondary oocyte), and its head enters the ovum's cytoplasm. The sperm's tail is frequently lost in this process, but the head carries the crucial genetic information. Sperm-egg fusion triggers a chemical change in the ovum's surrounding membrane that makes this outer layer impenetrable to the entry of any more sperm. This phenomenon is known as **block to polyspermy** ("many sperm"). Specifically, fertilization-induced release of intracellular Ca^{2+} into the cytosol triggers the exocytosis of enzyme-filled **cortical granules** that are located in the outermost, or cortical, region of the egg into the space between the egg membrane and the zona pellucida. These enzymes diffuse into the zona pellucida, where they inactivate the ZP3 receptors so that other sperm reaching the zona pellucida cannot bind with it. The enzymes also crosslink molecules in the zona pellucida, hardening it and sealing off

FIGURE 16-22 Early stages of development from fertilization to implantation (mammal; shown for a human). Note that the fertilized ovum progressively divides and differentiates into a blastocyst as it moves from the site of fertilization in the upper oviduct to the site of implantation in the uterus.

tunnels in progress to keep other penetrating sperm from advancing. Furthermore, the released Ca^{2+} triggers the second meiotic division of the egg, which is now ready to unite with the sperm to complete the fertilization process.

Within an hour, the sperm and egg pronuclei fuse, thanks to a centrosome (microtubule organizing center) provided by the sperm that forms microtubules to bring the male and female chromosome sets together for uniting. In addition to contributing its half of the chromosomes to the fertilized ovum, now called a **zygote**, the fertilizing sperm also activates ovum enzymes that are essential for the early embryonic developmental program.

We have been describing these events for mammals, but they are broadly similar in many phyla. Indeed, many of the steps of fertilization—penetration of the egg jelly coat, block to polyspermy, role of calcium—were first delineated in sea urchins (echinoderms).

Sperm may compete among males

In mammals with females that routinely copulate with many males (including many primates such as chimpanzees), males are said to engage in **sperm competition**. They typically have testes much larger than the average mammalian species in order to produce large quantities of sperm to outcompete, and possibly to block and kill, rival sperm in the female tract. (In contrast, primates such as the gorilla in which one dominant male mates exclusively with females, the testes are comparatively smaller in size.) Recent work on honey bees and leafcutter ants by Den Boer and Boris Baer has shown that seminal fluid contains chemicals that enhance survival of a male's own sperm but which damage sperm from other males.

The mammalian blastocyst implants in the endometrium through the action of its trophoblastic enzymes

During the first few days following fertilization, the zygote usually remains within the ampulla because the high, decreasing concentrations of estrogens are still directing contractions and ciliary motion toward the site of fertilization. As the concentration of estrogens continues to decline, contractions and ciliary movement in the isthmic portion of the oviduct reverse, transporting the zygote to the uterus.

The Beginning Steps in the Ampulla The zygote is not idle during this time, however. It rapidly undergoes a number of mitotic cell divisions to form a solid ball of cells called the **morula** (Figure 16-22). Meanwhile, the rising concentrations of progesterone from the newly developing corpus luteum that formed after ovulation has a quieting influence on the uterus and stimulates the release of a nutrient medium (glycogen) from the endometrium into the reproductive tract lumen for use as energy by the early embryo. The nutrients stored in the cytoplasm of the mammalian ovum can sustain the product of conception for less than a day. The concentration of secreted nutrients increases more rapidly in the small confines of the ampulla than in the uterine lumen.

Descent of the Morula to the Uterus Several days after ovulation, progesterone is being produced in sufficient quantities to relax the oviduct constriction, thus permitting the morula to be propelled into the uterus by oviductal

peristaltic contractions and ciliary activity. The temporary delay before the developing embryo passes into the uterus allows sufficient nutrients to accumulate in the uterine lumen to support the embryo until implantation can take place. If the morula arrives prematurely, it dies.

When the morula descends into the uterus, it floats freely within the uterine cavity for another three to four days, living on the endometrial secretions and continuing to divide. During the first six to seven days after ovulation, whereas the developing embryo is in transit in the oviduct and floating in the uterine lumen, the uterine lining is simultaneously being prepared for implantation or attachment under the influence of luteal-phase progesterone. During this time, the uterus is in its secretory, or progesterational phase, storing up glycogen and becoming richly vascularized.

Implantation of the Blastocyst in the Prepared Endometrium In the usual case, by the time the endometrium is suitable for implantation (about a week after ovulation), the morula has descended to the uterus and continued to proliferate and differentiate into a blastocyst capable of implantation. The week's delay after fertilization and before implantation allows time for both the endometrium and the developing embryo to prepare for implantation.

A **blastocyst** is a single-layered sphere of cells encircling a fluid-filled cavity, with a dense mass of cells grouped together at one side (Figure 16-22). This dense mass, called the **inner cell mass**, is destined to become the embryo itself. The remainder of the blastocyst will never be incorporated into the fetus but serves a supportive role during intrauterine life. The thin outermost layer, the **trophoblast**, is responsible for accomplishing implantation, after which it develops into the fetal portion of the placenta. The **amnion** forms either by cavitation, or opening up of a cavity (in rodents and humans), or folding (in noninvasive species).

When the blastocyst is ready to implant, its surface becomes sticky. By this time the endometrium is ready to accept the early embryo and it too has become more adhesive through increased formation of cell adhesion molecules (CAMs, p. 65) that help “Velcro” the blastocyst when it first contacts the uterine lining. Implantation occurs within two to five weeks after fertilization, the interval as short as two weeks in the cat and as long as five weeks in cattle and horses. The blastocyst adheres to the uterine lining on the side of its inner-cell mass (Figure 16-23).

During the preattachment phase, the blastocyst experiences phenomenal growth. For example, blastocysts of the pig increase from 2 mm in size on day 10 to 200 mm on day 12 and 1,000 mm by day 16, mainly due to development of the extraembryonic membranes, or **placentation**.

Placentation is the vascularization of the chorionic epithelium and is not the same thing as elongation. Elongation in noninvasive species allows for maximum interaction with as much uterine surface as possible to ensure **maternal recognition of pregnancy** is accomplished and that surface area for attachment is sufficient to provide nutrients to the developing conceptus in a situation where intimate interaction with the maternal vasculature does not exist.

Preventing Rejection of the Embryo/Fetus What prevents the mother from immunologically rejecting the embryo/fetus, which is actually a “foreigner” to the mother’s immune system, being half-derived from genetically different

1 When the free-floating blastocyst adheres to the endometrial lining, cords of trophoblastic cells begin to penetrate the endometrium.

2 Advancing cords of trophoblastic cells tunnel deeper into the endometrium, carving out a hole for the blastocyst. The boundaries between the cells in the advancing trophoblastic tissue disintegrate.

3 When implantation is finished, the blastocyst is completely buried in the endometrium.

FIGURE 16-24 Schematic representation of interlocking maternal and fetal structures that form the placenta in a human. Fingerlike projections of chorionic (fetal) tissue form the placental villi, which protrude into a pool of maternal blood. Decidual (maternal) capillary walls are broken down by the expanding chorion so that maternal blood oozes through the spaces between the placental villi. Fetal placental capillaries branch off of the umbilical artery and project into the placental villi. Fetal blood flowing through these vessels is separated from the maternal blood by only the thin chorionic layer that forms the placental villi. Maternal blood enters through the maternal arterioles, then percolates through the pool of blood in the intervillous spaces. Here, exchanges are made between the fetal and maternal blood before the fetal blood leaves through the umbilical vein and maternal blood exits through the maternal venules.

paternal chromosomes? Following are several proposals under investigation. New evidence indicates that the trophoblasts produce **Fas ligand**, which binds with **Fas**, a specialized receptor on the surface of approaching activated maternal cytotoxic T cells. Cytotoxic T cells are the immune cells that carry out the job of destroying foreign cells (see p. 480). This binding triggers the immune cells that are targeted to destroy the developing foreigner to undergo apoptosis, sparing the embryo/fetus from immune rejection. Other researchers have found that the fetal portion of the placenta, which is derived from trophoblasts, produces an enzyme, **indoleamine 2,3-dioxygenase (IDO)**, which destroys tryptophan. Tryptophan, an amino acid, is a critical factor in the activation of maternal cytotoxic T cells. Thus, the embryo/fetus, through its trophoblast connection, is believed to defend itself against rejection by shutting down the activity of the mother's cytotoxic T cells within the placenta that would otherwise attack the developing foreign tissues. Furthermore, recent studies demonstrate that production of **regulatory T cells** is doubled or tripled in pregnant experimental animals. Regulatory T cells suppress maternal cytotoxic T cells that might target the fetus (see p. 480).

The placenta is the organ of exchange between maternal and fetal blood

The glycogen stores (in rats and humans) in the endometrium are sufficient to nourish the embryo only during its first few weeks. To sustain the growing embryo for the duration of its intrauterine life, the *placenta*, a specialized organ of exchange between the maternal and fetal blood, is rapidly developed (Figure 16-24). The placenta is derived from both trophoblastic and decidual tissue. In noninvasive species, **histotroph**, which consists of proteins (some of which are growth factors), prostaglandins, ions, carbohydrates, and so on, is produced by the endometrium and subsequently absorbed by the embryo and digested in the yolk sac.

Modes of placentation differ among species

By the time the embryo has attached to the uterine luminal epithelium, the trophoblastic layer is two cell layers thick and is called the **chorion**. As the chorion continues to expand, it fuses (in placental mammals) with a structure called the **allantois** (an outgrowth of the hindgut) forming the vascularized **chorioallantoic** membrane. (In marsupials, the placenta is *choriovitelline*, forming from the chorion and yolk-sac or vitelline lining.) Placentas can be classified according to their degree of invasiveness and the anatomy of those regions of greatest maternal–fetal interaction (Figure 16-24). If we describe the potential placental layers available and then begin to remove layers as we describe progressively more invasive placentation, you will be able to see the interrelationship of the different modes of placentation. On the maternal side the maximum number of layers could include endothelial cells lining the blood vessels, a basement membrane, endometrial stromal tissue, another basement membrane, and the uterine luminal epithelium. On the fetal side we could potentially have chorionic epithelium, a basement membrane, chorioallantoic stromal tissue, another basement membrane, and endothelial cells lining the blood vessels. Thus, six potential tissue layers separate maternal and fetal blood.

- In the pig, cow, and ewe, all six tissue layers are present, and the type of placentation is referred to as **epithelial-** (the maternal component) **chorial-** (the fetal component). In the pig, chorion is in contact with the uterine luminal epithelium throughout the surface of the placenta, so this arrangement is called **diffuse**.
- In ruminants, the greatest contact of the chorion with the uterine luminal epithelium occurs at discreet sites at which fetal membranes interact with maternal **caruncles** (round thickenings) such that chorionic villi project into the caruncles forming **placentomes**, and so we call this **placentomal**.
- In the carnivores, the conceptus erodes the uterine luminal epithelium and underlying stroma at sites of greatest

- attachment such that chorion is in contact with maternal endothelium, an arrangement called **endothelial-chorial** (four tissue layers). The erosion of maternal tissue occurs only in regions around a band in the central portion of the placenta, or zone, and is referred to as **zonary attachment**.
- In the human and higher primates, the conceptus erodes maternal uterine luminal epithelium, stroma, and the underlying endothelial cells, allowing the chorionic epithelium to have direct access to maternal blood, a type of placentation referred to as **hemo-chorial**. Because this is a very invasive placentation, only a small site on the placental surface is involved, and the shape of placentation is referred to as **discoid**.
 - In the most invasive placentation, found in rodents, not only are all three tissue layers on the maternal side eroded, but the chorioallantoic epithelium and underlying stroma are eroded and the conceptus endothelial cells are in direct contact with maternal blood; we refer to this as **hemo-endothelial placentation**. It is found in the shape of a disk of interaction between the conceptus and maternal system.

Throughout gestation, fetal blood continuously travels between the placental villi and the fetal circulatory system via the **umbilical artery** and **umbilical vein**, which are wrapped within the **umbilical cord**, a lifeline between the primate fetus and the placenta (Figure 16-24). The maternal blood within the placenta is continuously replaced as fresh blood enters through the uterine arterioles; percolates through the intervillous spaces, where it exchanges substances with fetal blood in the surrounding villi; then exits through the uterine vein.

During intrauterine life, the placenta performs the functions of the digestive system and the respiratory system for the “parasitic” fetus. This is not to say that the fetus does not have these organ systems, but rather that they cannot (and do not need to) function within the uterine environment. Intra-uterine urination is common and contributes to the volume of amniotic fluid. Nutrients and O₂ diffuse from the maternal blood across the thin placental barrier into the fetal blood, whereas CO₂ and other metabolic wastes simultaneously diffuse from the fetal blood into the maternal blood. The nutrients and O₂ brought to the fetus in the maternal blood are acquired by the maternal digestive and respiratory systems, and the maternal lungs and kidneys eliminate the CO₂ and wastes transferred into the maternal blood, respectively. Thus, the maternal digestive tract, respiratory system, and kidneys serve the fetus’s needs as well as the mother’s.

Transport of Substances across the Placental Barrier The means by which materials move across the placenta depends on the substance. Some substances that can permeate the placental membrane, such as O₂, CO₂, water, and electrolytes, cross by simple diffusion. Some traverse the placental barrier by special mediated-transport systems in the placental membranes, such as glucose by facilitated diffusion and amino acids by secondary active transport. Other substances such as cholesterol in the form of LDL move across by receptor-mediated endocytosis. Unfortunately, many drugs, environmental pollutants, other chemical agents, and microorganisms in the female’s bloodstream can cross the placental barrier, some of which are harmful to the developing fetus.

TABLE 16-5 Placental Hormones

Hormone	Function
Chorionic Gonadotropin	Maintains corpus luteum of pregnancy Stimulates secretion of testosterone by developing testes in XY embryos
Estrogen (also secreted by corpus luteum of pregnancy)	Stimulates growth of myometrium, increasing uterine strength for parturition Helps prepare mammary glands for lactation
Progesterone (also secreted by corpus luteum of pregnancy)	Suppresses uterine contractions to provide quiet environment for fetus Promotes formation of cervical mucus plug to prevent uterine contamination Helps prepare mammary glands for lactation
Chorionic Somatomammotropin (also called placental lactogen; has a structure similar to both prolactin and growth hormone)	Helps prepare mammary glands for lactation (similar to prolactin) Believed to reduce maternal use of glucose and to promote breakdown of stored fat (similar to growth hormone) so that greater quantities of glucose and free fatty acids can be shunted to the fetus
Relaxin (also secreted by corpus luteum of pregnancy)	Softens the cervix in preparation for cervical dilation at parturition Loosens connective tissue between pelvic bones in preparation for parturition
Placental PTHrp (parathyroid hormone-related peptide)	Increases maternal plasma Ca ²⁺ levels for use in calcifying fetal bones; if necessary, promotes localized dissolution of maternal bone, mobilizing mother’s Ca ²⁺ stores for use by developing fetus

The placenta assumes yet another important responsibility—it becomes a temporary endocrine organ during pregnancy, a topic to which we now turn.

Hormones secreted by the corpus luteum and placenta play a critical role in maintaining pregnancy

The placenta has the remarkable capacity to secrete a number of peptide and steroid hormones essential for maintaining pregnancy. The most important are *chorionic gonadotropin*, *estrogen*, and *progesterone* (Table 16-5). Serving as the major endocrine organ of pregnancy, the placenta is unique among endocrine tissues in two regards. First, it is a transient tissue. Second, secretion of its hormones is not subject to extrinsic control, in contrast to the stringent, often-complex mechanisms that regulate the secretion of other hormones. Instead, the type and rate of placen-

tal hormone secretion depend primarily on the species of animal and stage of pregnancy.

In all mammals, the corpus luteum is important in the early stages of pregnancy for secreting progesterone, but, as exemplified in the human, ewe, and mare, its contribution declines with time as the placental contribution of progesterone increases. For example, the corpus luteum is not required in women and ewes after approximately 50 days and in the mare after 100 days of pregnancy, whereas the corpus luteum is required for the duration of pregnancy in the pig, cow, goat, and deer.

One of the first events in primates is the secretion by the developing chorion of *chorionic gonadotropin* (CG), a polypeptide hormone that prolongs the life span of the corpus luteum. In the mare, *equine chorionic gonadotropin* (eCG) is also called *pregnant mare's serum gonadotropin* (PMSG). The placenta of the mare is notable for unique structures termed **endometrial cups**, temporary endocrine units ranging in size from millimeters to several centimeters that produce eCG. After approximately 60 days of gestation, these cups are sloughed into the uterine lumen. Recall that during the menstrual cycle in humans (and some other primates), the corpus luteum degenerates and the highly prepared, luteal-dependent uterine lining sloughs if fertilization and implantation have not occurred. When fertilization does occur, the implanted human blastocyst saves itself by producing human CG (*hCG*). This hormone, which is functionally similar to LH, stimulates and maintains the corpus luteum so that it does not degenerate. Now called the *corpus luteum of pregnancy*, this ovarian endocrine unit grows even larger and produces increasingly greater amounts of progesterone until the placenta takes over secretion of these steroid hormones (see p. 790). Because of the persistence of circulating estrogens and progesterone, the thickened endometrial tissue of the human is maintained instead of sloughing. In menstrual primates, accordingly, menstruation ceases during pregnancy. The eCG of the mare is produced around 60 days of gestation, and like the hCG, eCG primarily exhibits LH-like activity, although if administered to other species eCG exhibits FSH-like activity. This is important for the mare because the corpora lutea do not persist beyond about day 70 of gestation and are supplemented by the growth and luteinization of new follicles under the influence of eCG to save the pregnancy. These accessory corpora lutea only maintain pregnancy for another short period until the placenta finally takes over progesterone production at around 100 days of gestation.

Maternal body systems respond to the increased demands of gestation

The period of gestation (pregnancy) is about 1 month in the rabbit, 3.8 months in the sow, 5 months in the ewe and goat, 9 months in the cow and woman, 15 to 16 months in the sperm whale, and 1.8 years in African forest and savanna elephants. During gestation, the fetus continues to grow and develop to the point of being able to leave its maternal life support system. Meanwhile, a number of changes take place within the female to accommodate the demands of the pregnancy. The most obvious is uterine enlargement. The uterus expands and increases in weight more than 16 times in women, exclusive of its contents. The mammary glands enlarge and develop the capability to produce milk.

Body systems other than the reproductive system make needed adjustments. The volume of blood increases by 30%, and the cardiovascular system responds to the increasing demands of the growing placental mass. The weight gain experienced during pregnancy is due only in part to the weight of the fetus. The remainder is primarily caused by the growth of the uterus, including the placenta, and the increased blood volume. Respiratory activity is increased by about 16% to handle the additional fetal requirements for O₂ use and CO₂ removal. Urinary output increases, and the kidneys excrete the additional wastes from the fetus.

The increased metabolic demands of the growing fetus increase nutritional requirements for the female. In general, the fetus takes what it needs from the female, even if this leaves the female with a nutritional deficit. For example, the placental hormone *chorionic somatomammotropin* (CS), also known as *placental lactogen* (PL), is thought to be responsible for the decreased use of glucose by the female and the mobilization of free fatty acids from maternal adipose stores, similar to the actions of growth hormone (see p. 292). (In fact, CS has a structure similar to both growth hormone and prolactin. In the mammary gland, CS helps prepare these glands for lactation, similar to prolactin's effect, although much weaker.) As a result of the CS-induced metabolic changes in the female, greater quantities of glucose and fatty acids are available for shunting to the fetus. The extent to which CS exerts somatotrophic versus lactogenic effects is ultimately species dependent. For example, in the ewe CS is more effective in promoting lactation. Also, if the female does not consume sufficient Ca²⁺ in her diet, placental *parathyroid-hormone-related peptide* mobilizes Ca²⁺ from the maternal bones to ensure adequate calcification of the fetal bones.

16.7 Parturition and Lactation

Parturition (labor, delivery, or birth) is the process by which the uterus expels the fetus and placenta from the female. Parturition is divided into three stages: (1) dilation of the cervical canal to accommodate passage of the fetus from the uterus through the vagina and to the outside, (2) contractions of the uterine myometrium that are sufficiently strong to expel the fetus, and (3) expulsion of the placenta.

Changes during late gestation prepare for parturition

Several events take place near the end of pregnancy in preparation for parturition. Throughout gestation, the cervix remains sealed. As parturition approaches, the cervix begins to

soften (or “ripen”) as a result of the dissociation of its tough connective tissue (collagen) fibers. This softening is believed to be caused by **relaxin**, a peptide hormone produced in most mammals by the corpus luteum of pregnancy and by the placenta. However, in species such as the rabbit, relaxin is produced entirely in the placenta. Relaxin also “relaxes” the pelvic bones. Furthermore, $\text{PGF}_{2\alpha}$ released by the placental membranes overlying the cervix stimulates the synthesis of relaxin and promotes the production of cervical enzymes that degrade the collagen fibers and help soften the cervix. $\text{PGF}_{2\alpha}$ initiates regular, nondirectional uterine contractions and regression of the CL. These small contractions (sometimes called *contractures*) help orient the fetus(es) so that the head and front appendages are in contact with the cervix in preparation for exiting through the birth canal. If the fetus is not positioned correctly, a difficult birth (*dystocia*), results.

Rhythmic, coordinated contractions, usually painless at first, begin at the onset of true labor in response to pituitary *oxytocin* (see p. 286). As labor progresses, the contractions occur with increasing frequency and intensity and are accompanied by increasing discomfort. These strong, rhythmic, and directional contractions force the fetus against the cervix, resulting in dilation of the cervix. Then, after having dilated the cervix sufficiently for passage of the fetus, these contractions force the fetus out through the birth canal.

The factors that trigger the onset of parturition are only partially understood

The exact factors responsible for triggering this change in uterine contractility and thus initiating parturition are not fully established, although considerable progress has been made in recent years in unraveling the sequence of events. During early gestation, maternal estrogen levels are relatively low, but, as gestation proceeds, placental estrogen secretion continues to rise, associated with the increase in concentrations of $\text{PGF}_{2\alpha}$. However, the timing and magnitude of the increase in estrogens vary among species. In the immediate days before the onset of parturition, soaring levels of estrogens bring about changes in the uterus and cervix to prepare them for labor and delivery (Figure 16-25). First, high levels of estrogens promote the synthesis of connexons within the uterine smooth-muscle cells. These myometrial cells are not functionally linked to any extent throughout most of gestation. The newly manufactured connexons are inserted in the myometrial plasma membranes to form gap junctions (see p. 66) that electrically link the uterine smooth-muscle cells so that they become able to contract as a coordinated unit.

Simultaneously, the high levels of estrogens cause a dramatic, progressive increase in the concentration of myometrial receptors for oxytocin. Together, these myometrial changes collectively bring about the increased uterine responsiveness to oxytocin that ultimately initiates labor. In addition to preparing the uterus for labor, the increasing levels of estrogen promote production of local prostaglandins that contribute to cervical ripening by stimulating cervical enzymes that locally degrade collagen fibers. Furthermore, these prostaglandins themselves increase uterine responsiveness to oxytocin.

Role of Oxytocin Oxytocin is a peptide hormone that is produced by the hypothalamus, stored in the posterior pituitary, and released into the blood from the posterior pituitary.

FIGURE 16-25 Secretion rates of human placental hormones.

© Cengage Learning, 2013

itary on nervous stimulation by the hypothalamus (see p. 286). Oxytocin exerts its effects via the $\text{IP}_3/\text{Ca}^{2+}/\text{DAG}$ pathway. A powerful uterine muscle stimulant, oxytocin plays the key role in the progression of labor. However, this hormone was discounted as serving as the trigger to parturition because the circulating concentrations of oxytocin remain constant prior to the onset of labor. The discovery that uterine responsiveness to oxytocin is greater at term than in nonpregnant females (because of the increased concentration of myometrial oxytocin receptors) led to the now widely accepted conclusion that labor begins when the oxytocin receptor concentration reaches a critical threshold that permits the onset of strong, coordinated contractions in response to ordinary concentrations of circulating oxytocin.

In addition to preparing the uterus for labor, the increasing levels of estrogens promote production of the local prostaglandins that contribute to cervical ripening. Oxytocin has other roles, including the triggering of uterine contractions during orgasm, milk ejection during lactation, and maternal behavior related to bonding with the father and the offspring (see p. 286). *Pitocin* is the synthetic form of oxytocin used to induce labor if it is not progressing well in humans and many domestic mammals (it is also used to treat birds and reptiles suffering from egg binding, in which eggs have become trapped in the reproductive tract).

Role of Corticotropin-Releasing Hormone Until recently, scientists were baffled by the factors responsible for the rising levels of placental estrogen secretion. Recent research has shed new light on the probable mechanism. Evidence suggests that *corticotropin-releasing hormone* (CRH) secreted by the fetal portion of the placenta into both the maternal and fetal circulation not only drives the synthesis of placental estrogen, thus ultimately dictating the timing of the onset of labor, but also promotes changes in the fetal lungs needed for breathing air; see Figure 16-27. Recall that

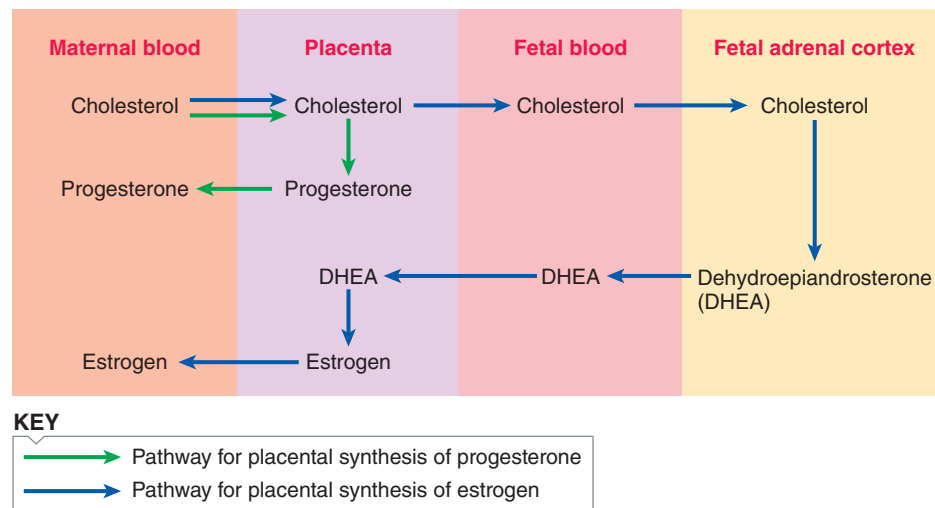

FIGURE 16-26 Secretion of estrogen and progesterone by the human placenta. The placenta secretes increasing quantities of progesterone and estrogen into the maternal blood after the first trimester. The placenta itself can convert cholesterol into progesterone (green pathway) but lacks some of the enzymes necessary to convert cholesterol into estrogen. However, the placenta can convert DHEA derived from cholesterol in the fetal adrenal cortex into estrogen when DHEA reaches the placenta by means of the fetal blood (blue pathway).

© Cengage Learning, 2013

CRH is normally secreted by the hypothalamus and regulates the output of ACTH by the anterior pituitary. In turn, ACTH stimulates production of both cortisol and DHEA by the adrenal cortex. In the fetus, much of the CRH comes from the placenta rather than solely from the fetal hypothalamus. The additional cortisol secretion summoned by the extra CRH promotes fetal lung maturation. Specifically, cortisol stimulates the synthesis of pulmonary surfactant, which facilitates lung expansion and reduces the work of breathing (see p. 521).

The bumped-up rate of DHEA secretion by the adrenal cortex in response to placental CRH leads to the rising concentrations of placental estrogen secretion. Recall that the human placenta converts DHEA from the fetal adrenal gland into estrogen, which enters the maternal bloodstream (Figure 16-26). In most other species, the placenta has the ability to synthesize estrogens *de novo*.

When sufficiently high, this estrogen combined with lowered progesterone sets in motion the events that initiate labor. Thus, pregnancy duration and delivery timing are determined largely by the placenta's rate of CRH production. That is, a "placental clock" ticks out a predetermined length of time until parturition. The timing of parturition is established early in pregnancy, with delivery at the end point of a maturational process that extends throughout the entire gestation. The ticking of the placental clock is measured by the rate of placental secretion. As the pregnancy progresses, CRH concentrations in maternal plasma rise. Researchers can accurately predict the timing of parturition by measuring the maternal plasma concentrations of CRH. Higher-than-normal concentrations are associated with premature deliveries, whereas lower-than-normal concentrations indicate late deliveries. These and other data suggest that a critical level of maternal CRH of placental origin may directly trigger parturition. Placental CRH ensures that when labor

begins, the infant is ready for life outside the womb. It does so by concurrently increasing the fetal cortisol needed for lung maturation and the estrogens needed for the uterine changes that bring on labor. The remaining unanswered question regarding the placental clock is: What controls placental secretion of CRH?

Role of Inflammation and Lung Maturation Surprisingly, recent research suggests that *inflammation* plays a central role in the labor process, in the onset of both full-term labor and premature labor. Less surprisingly, recent research also indicates that the maturing *lungs* are involved. The inflammatory mechanism begins with activation of *nuclear factor κB* (NF-κB) in the uterus. NF-κB boosts production of inflammatory cytokines such as *interleukin-8* (IL-8) (see p. 469) and prostaglandins that increase the sensitivity of the uterus to contraction-inducing chemical messengers and help soften the cervix. What activates NF-κB, setting off an inflammatory cascade that helps prompt labor? Various factors associated with the onset of full-term labor and premature labor can cause an upsurge in NF-κB. These include stretching of the uterine muscle and the presence of the pulmonary *surfactant protein SP-A* (stimulated by the action of CRH on the fetal lungs) in the amniotic fluid from the fetus. SP-A promotes the migration of fetal macrophages to the uterus (Figure 16-27). These macrophages, in turn, produce the inflammatory cytokine *interleukin-1β* (IL-1β) that activates NF-κB. In this way, fetal lung maturation contributes to the onset of labor, just the time at which the lungs are ready for the transition to air breathing.

Bacterial infections and allergic reactions can lead to premature labor by activating NF-κB. Also, multiple-fetus pregnancies are at risk for premature labor, likely because the increased uterine stretching triggers earlier activation of NF-κB.

Parturition is accomplished by a positive-feedback cycle

Once the high concentrations of estrogens have increased uterine responsiveness to oxytocin to a critical level and regular uterine contractions have begun, myometrial contractions progressively increase in frequency, strength, and duration throughout labor until the uterine contents are expelled. This progressive increase in contractions is a classical example of a positive-feedback cycle, which in this case involves *cervical stretch*, *oxytocin*, and *prostaglandin* (Figure 16-27; see also Figure 1-10, p. 18). Each uterine contraction begins at the oviductal end of the uterus and sweeps downward, forcing the fetus(es) toward the cervix. Pressure of the fetus against the cervix accomplishes two things. First, the fetal head pushing against the softened cervix acts as a wedge to dilate the cervical canal. Second, cervical stretch in response to fetal pressure stimulates stretch receptors that produce a reflex neural signal, which travels up the spinal cord to the hypothalamus. This in turn triggers oxytocin release from the posterior pituitary. Additional oxytocin promotes more powerful uterine contractions. As a result, the fetus is pushed more forcefully against the cervix, increasing stretch and so stimulating the release of even more oxytocin, and so on. This cycle is reinforced as oxytocin stimulates prostaglandin production by the decidua. As a powerful myometrial stimulant, prostaglandin further enhances uterine contractions. Oxytocin secretion, $\text{PGF}_{2\alpha}$ production, and uterine contractions continue to increase in this positive-feedback fashion throughout labor until the pressure on the cervix is relieved by delivery.

Stages of Labor Recall that labor has three stages: (1) cervical dilation, (2) delivery of the young, and (3) delivery of the placenta. At the onset of labor or sometime during the first stage, the membranes surrounding the amniotic sac rupture. The fluid surrounding the amnion is *chorioallantoic fluid*. The amnion does not rupture until much later during parturition, so it can protect the fetus from physical damage during the early stages of parturition. As the chorioallantoic fluid escapes out of the vagina, it helps lubricate the birth canal. During the first stage, the cervix of ungulates (hoofed mammals) is forced to dilate to accommodate the diameter of the young's head and front feet. This stage is the longest, lasting from 1 to 12 hours in the sow, 2 to 6 hours in the ewe and cow, and several hours to as long as 24 hours in humans. If another part of the fetus's body other than the head is oriented against the cervix, it is generally less effective than the head as a wedge, although in the sow, half of the fetuses come headfirst and half rear-end first. (Also, whales are born at sea tail first to prevent drowning.) The head has the largest diameter of the fetus's body. In some species, if the fetus approaches the birth canal feet first, the cervix may not be dilated sufficiently by the feet to permit passage of the head. Without medical intervention in such a case, the fetus's head would remain stuck behind the too-narrow cervical opening.

The second stage of labor, the actual birth, begins once cervical dilation is complete. When the offspring begins to move through the cervix and vagina, stretch receptors in the vagina activate a neural reflex that triggers contractions of the abdominal wall in synchrony with the uterine contractions. These abdominal contractions greatly increase the

force pushing the fetus through the birth canal. Stage 2 is usually much shorter than the first stage and lasts 30 to 90 minutes. The fetus is still attached to the placenta by the umbilical cord at birth, and this cord breaks as the newborn animal begins to move about following delivery, with the stump shriveling up in a few days to form the umbilicus (navel).

Shortly after delivery of the fetus, a second series of uterine contractions causes the placenta to separate from the endometrium and be expelled through the vagina. Delivery of the placenta, or **afterbirth**, constitutes the third stage of labor, which is typically the shortest stage, being completed within 15 to 30 minutes in humans, 1 hour in the mare, 5 to 8 hours in the ewe, and as long as 12 hours in the cow, after the young is born. After the placenta is expelled, continued contractions of the myometrium constrict the uterine blood vessels supplying the site of placental attachment to prevent hemorrhage. In sows, cows, ewes, mares, and so on, there is no erosion of maternal tissue and therefore no danger of hemorrhage. Most female terrestrial mammals then eat the placenta (**placentophagy**), which contain high levels of prostaglandins that may foster *involution* (see next section). The placenta also contains **placental opioid-enhancing factor (POEF)**, which is thought to trigger pain-inhibiting opioids (p. 310) in the mother's brain.

Uterine Involution After delivery, the uterus shrinks to its pregestational size, a process known as **involution**, which requires 4 weeks in the ewe and sow, 12 weeks in the dog, and 4 to 6 weeks in the human. During involution, the remaining endometrial tissue not expelled with the placenta gradually disintegrates and sloughs off, producing a vaginal discharge called **lochia** that continues for three to six weeks following parturition. After this period, the endometrium is restored to its nonpregnant state. Involution occurs largely because of the precipitous fall in circulating estrogens and progesterone when the placental source of these steroids is lost at delivery. The process is facilitated by suckling the infant(s) because of the oxytocin released in response to mammary gland stimulation. In addition to playing an important role in lactation, this periodic nursing-induced postpartum release of oxytocin promotes myometrial contractions that stimulate uterine muscle tone, thus enhancing involution.

Lactation requires multiple hormonal inputs

The female reproductive system of mammals supports the new being from the moment of its conception through gestation and continues to nourish it during its early life outside the supportive uterine environment. However, only two species of mammals, whales and bears, can fast during the energetically challenging period of lactation. This strategy permits baleen whales to feed in the seasonally productive polar regions of the world's oceans and retain the advantage of breeding in the warmer, tropical regions of the world.

Because the evolution of the mammary gland preceded that of placental gestation, even egg-laying mammals (monotremes) produce milk for their young (hence the name "mammal"). **Lactogenesis** is the process by which mammary alveolar cells acquire the ability to secrete milk (or its equivalent), for milk is essential for survival of the newborn, and, interestingly, the basic structure of the mammary gland is

remarkably consistent across the class Mammalia. Accordingly, development begun during puberty is completed during gestation as the mammary glands are prepared for lactation (milk production).

The mammary gland is a modified sweat gland, the basic structure and location established during embryonic development. The glands develop from the so-called mammary or **milk line**, two rows that extend from the thoracic region, parallel to the midline of the abdomen that appears in the early embryo. Subsequently, the milk lines differentiate into mammary buds, the number and location dependent on the species of mammal. For example, the mammary glands of some mammals (deer, cattle, goats, camels, horses, and sheep) have an inguinal (located near the groin) location and in nonpregnant females consist mostly of adipose tissue and a rudimentary duct system. In primates and elephants, the mammary glands develop in the pectoral region, whereas in litter-bearing species, such as rabbits, dogs, cats, and pigs, mammary glands develop along the entire length of the milk line. Pigs normally have seven pairs of mammary glands, whereas dogs and cats usually have five pairs of glands. The sea mammals (whales, dolphins, seals, and manatees) develop mammary buds in either the pectoral or inguinal region. Structures associated with the mammary gland include the **teat** or **nipple**, the part of the mammary gland from which the young suckle milk (Figure 16-28). At its distal end, the teat has fine openings that permit expulsion of the milk. The number of openings can be as few as one, such as in cattle, which have a collecting **cistern**, which permits pooling of milk from several ducts before exiting the gland, as compared to the nipple, which has multiple lactiferous ducts.

The mammary gland (udder) of the cow has distinct right and left halves, and each has a front and hindquarter. Each half of the mammary gland is independent with regard to its blood supply, innervation, and lymphatic drainage. Under the hormonal environment present during pregnancy, the mammary glands develop the internal glandular structure and function necessary for milk production. A mammary gland capable of lactating consists of a network of progressively smaller ducts that branch out from the teat and terminate in lobules (Figure 16-28). Each lobule is made up of a cluster of saclike epithelial-lined, milk-producing glands known as **alveoli** that constitute the milk-producing glands. Milk is synthesized by the epithelial cells and then secreted into the alveolar lumen, which is drained by a milk-collecting duct that transports the milk to the teat cistern. Ejection of milk from the teat occurs via the teat canal, which is normally kept closed by a muscle sphincter (circular muscle whose contraction closes the canal). **Mastitis**, infection of the mammary gland by microorganisms, can occur if the sphincter is not kept tightly closed.

Prevention of Lactation during Gestation Most mammary gland growth occurs during pregnancy, when the high concentration of estrogens promotes extensive duct development and the high level of progesterone stimulates abundant alveolar-lobular formation. The adipose tissue is steadily consumed and replaced by ducts, lobular alveoli, blood and lymph vessels, and the necessary connective tissue structures associated with the suspensory apparatus. Elevated concentrations of **prolactin** (an anterior pituitary hormone stimulated by the rising levels of estrogen) and **chorionic somato-**

mamotropin (a peptide hormone produced by the placenta that has a structure similar to both prolactin and growth hormone) contribute to mammary gland development by inducing the synthesis of enzymes needed for milk production.

By the middle of pregnancy, the mammary glands are fully capable of producing milk; however, milk secretion does not occur until parturition, even though prolactin—the primary stimulant of milk secretion—is present. The high estrogen and progesterone concentrations during the last half of pregnancy prevent lactation by blocking prolactin's stimulatory action on milk secretion. Thus, even though the high levels of placental steroids induce the development of the milk-producing machinery in the mammary glands, they prevent these glands from becoming operational until the young is born and milk is needed. The abrupt decline in estrogens and progesterone that occurs with loss of the placenta at parturition initiates lactation. (The functions of estrogens and progesterone during gestation and lactation as well as throughout the reproductive life of females are summarized in Table 16-6.)

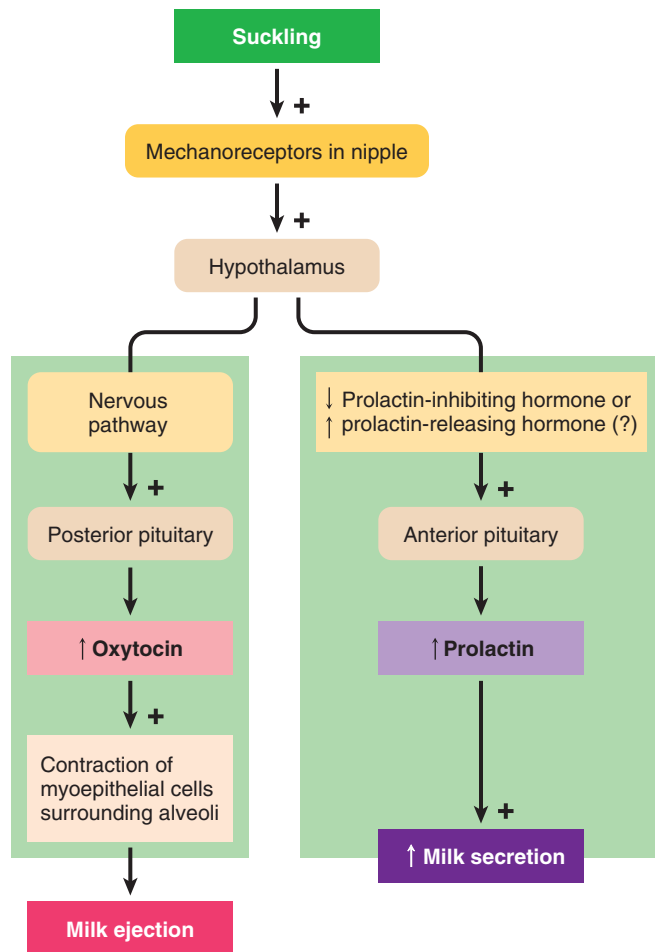

FIGURE 16-29 Suckling reflexes (mammal).

© Cengage Learning, 2013

Once milk production begins after delivery, two hormones maintain lactation: (1) prolactin, which acts on the alveolar epithelium to promote secretion of milk, and (2) oxytocin, which produces **milk ejection**. The latter refers to the forced expulsion of milk from the lumen of the alveoli out through the ducts. Release of both of these hormones is stimulated by a neuroendocrine reflex triggered by suckling (Figure 16-29). Let's examine each of these hormones and their roles in detail.

Oxytocin Release and Milk Ejection The neonate cannot directly suck milk out of the alveolar lumen. Instead, milk must be actively squeezed out of the alveoli into the ducts and hence toward the nipple by contraction of specialized myoepithelial cells (musclelike epithelial cells) that surround each alveolus. Suckling of the mammary gland by the neonate stimulates sensory nerve endings in the nipple, initiating action potentials that travel up the spinal cord to the hypothalamus. Thus activated, the hypothalamus triggers a burst of oxytocin release from the posterior pituitary. Oxytocin in turn stimulates contraction of the myoepithelial cells in the mammary glands to bring about milk ejection, or “milk letdown.” Cetacean (whale) young lack proper lips, so gripping the nipple is difficult at best. For this reason the female actually squirts the milk into the mouth of the young, using

TABLE 16-6 Actions of Estrogens and Progesterone (in Mammals)

ESTROGENS

Effects on Sex-Specific Tissues

Essential for egg maturation and release

Stimulates growth and maintenance of entire female reproductive tract

Stimulates granulosa cell proliferation, which leads to follicle maturation

Thins cervical mucus to permit sperm penetration

Enhances transport of sperm to oviduct by stimulating upward contractions of uterus and oviduct

Stimulates growth of endometrium and myometrium

Induces synthesis of progesterone receptors in endometrium

Triggers onset of parturition by increasing uterine responsiveness to oxytocin during late gestation through a twofold effect: by inducing synthesis of myometrial oxytocin receptors and by increasing myometrial gap junctions so that the uterus can contract as a coordinated unit in response to oxytocin

Other Reproductive Effects

Promotes development of secondary sexual characteristics

Controls GnRH and gonadotropin secretion

Low levels inhibit secretion

High levels responsible for triggering LH surge

Stimulates duct development in mammary glands during gestation

Inhibits milk-secreting actions of prolactin during gestation

Nonreproductive Effects

Promotes fat deposition

Increases bone density; closes epiphyseal plates

Promotes vasodilation by increasing nitric oxide production in arterioles (cardioprotective)

PROGESTERONE

Prepares a suitable environment for nourishment of a developing embryo/fetus

Promotes formation of a thick mucus plug in the cervical canal

Inhibits hypothalamic GnRH and gonadotropin secretion

Stimulates alveolar development in the mammary gland during gestation

Inhibits the milk-secreting actions of prolactin during gestation

Inhibits uterine contractions during gestation

© Cengage Learning, 2013

contractions of both the myoepithelial cells as well as surrounding cutaneous muscles. Milk letdown continues only as long as the infant continues to nurse. In this way, the milk ejection reflex ensures that milk exits the mammary glands only in the amount needed by the young. Even though the alveoli may be full of milk, the milk cannot be released

without oxytocin. Often the presence of the calf or other conditioned reflexes can generate a release of oxytocin, whereas milk letdown is inhibited in situations in which the female is stressed.

Prolactin Release and Milk Ejection Suckling not only triggers oxytocin release but also stimulates prolactin secretion. Prolactin output by the anterior pituitary is controlled by two hypothalamic secretions: *prolactin-inhibiting hormone* (PIH) and *prolactin-releasing hormone* (PRH). PIH has been shown to be dopamine, which also serves as a neurotransmitter in the brain. The chemical nature of PRH has not been identified with certainty, but scientists suspect that in most mammals (though not in the cow) PRH is oxytocin secreted by the hypothalamus into the hypothalamic-hypophyseal portal system to stimulate prolactin secretion by the anterior pituitary (see p. 288). This role of oxytocin is distinct from the roles of oxytocin produced by the hypothalamus and stored in the posterior pituitary. The oxytocin released by the posterior pituitary plays a key role in parturition by causing powerful uterine muscle contractions and also brings about milk ejection by stimulating contraction of the myoepithelial cells of lactating mammary glands.

Throughout most of the female's life, PIH is the dominant influence, so prolactin concentrations normally remain low. During lactation, a burst in prolactin secretion occurs each time the infant stimulates the udder and/or teats. Afferent impulses initiated in the nipple on suckling are carried by the spinal cord to the hypothalamus. This reflex ultimately leads to prolactin release by the anterior pituitary, although it is unclear whether this outcome is accomplished by inhibition of PIH or stimulation of PRH secretion or both. Prolactin then acts on the alveolar epithelium to promote secretion of milk to replenish that lost from the alveoli by milk ejection. In some species of mammals (cows and goats) once lactation has been established, the basal concentration of prolactin as well as the induced release of prolactin at milking decline without affecting milk yield.

Suckling concurrently stimulates milk ejection and milk production, therefore ensuring that the rate of milk synthesis keeps pace with the young's needs for milk. The more the infant nurses, the more milk is removed by letdown and the more milk is produced for the next suckling. Thus, twins elicit more milk production than do single offspring. In addition to prolactin, which is the most important factor controlling synthesis of milk, at least four other hormones are essential for their permissive role in milk production: cortisol, insulin, parathyroid hormone, and growth hormone (see Chapter 7). Among its actions, growth hormone enhances milk production by increasing the mammary gland's uptake from the blood of nutrients needed for the synthesis of milk (see p. 292).

Prolactin fittingly appears to facilitate bonding, or attachment, between a mother and the newborn in birds and mammals. Prolactin (as well as oxytocin, p. 296) is thought to trigger maternal behaviors such as denning in wolves, incubation behavior in birds, bonding of mothers to offspring, and suppression of sex drive during nursing periods. For more on prolactin, see the box, *Molecular Biology and Genomics: Prolactin: A Key with Many Locks in Females and Males*.

Broody behavior in commercial turkeys involves in a pause or cessation in egg lay correlating with a surge in prolactin. Because of the decreased production, research efforts

have investigated means to lower concentrations of prolactin in affected birds. Seasonal increases in the concentrations of plasma prolactin are believed to play a role in determining the end of the breeding season for birds breeding at temperate latitudes.

Mammary gland feeding is advantageous to both the infant and the parent

Milk consists of variable amounts of water, triglyceride fat, the carbohydrate lactose (milk sugar), a number of proteins, vitamins, and the minerals calcium and phosphate. For example, because the period of lactation is so short in the Weddell seal, the percentage of energy-rich fat in milk can be as high as 42%, whereas in the mare, which has a prolonged period of lactation, it can be as low as 1.3%. Human milk contains significant amounts of *omega-3* fatty acids (p. 72), which may promote brain development. Protein content of milk is high in the Weddell seal (15.8%) and low in primates (0.8% in humans and 1.5% in other primates). Remarkably, given the differing ages of the neonates undergoing development in the brood patch of marsupials, each of four mammary glands can produce a milk of differing composition!

In addition to supplying nutrients, milk contains a host of immune cells, antibodies, and other chemicals that help protect the infant against infection until it can mount an effective immune response on its own a few months after birth. **Colostrum**, the milk produced for the first five days postpartum, contains lower concentrations of fat and lactose but higher concentrations of protein and immunoprotective components. In many mammals some passive immunity is transferred from the female to the fetus during gestation through the passage of antibodies across the placenta (see p. 480). These antibodies are short-lived, however, and often do not persist until the infant can fend for itself immunologically. Mammary-gland-fed young gain additional protection during this vulnerable period through a variety of mechanisms:

- Mammary gland milk—especially in colostrum—contains an abundance of immune cells—both B and T lymphocytes, macrophages, and neutrophils (see p. 480)—that produce antibodies and destroy pathogenic microorganisms outright.
- **Secretory IgA**, a special type of antibody, is present in great amounts in mammary gland milk. Secretory IgA consists of two IgA antibody molecules joined together with a so-called secretory component that helps protect the antibodies from destruction by the infant's acidic gastric juice and digestive enzymes. The collection of IgA antibodies ingested by a mammary-gland-fed young is specifically targeted against the particular pathogens in the environment of the female—and, accordingly, of the infant as well.
- Some components in milk, such as mucus, adhere to potentially harmful microorganisms, thus preventing them from attaching to and crossing the intestinal mucosa.
- **Lactoferrin** is a mammary-gland milk constituent that thwarts growth of harmful bacteria by decreasing the availability of iron, a mineral needed for multiplication of these pathogens (see p. 469).
- **Bifidus factor** in mammary gland milk, in contrast, promotes multiplication of the nonpathogenic microorgan-

Molecular Biology and Genomics

Prolactin: A Key with Many Locks in Females and Males

As you have seen, prolactin is classically known for its role in milk production (hence its name). But it has many other roles, some only recently discovered. Recall that a particular chemical messenger can have multiple, sometimes unrelated roles because of different receptor systems on different target cells (“same key, different locks,” p. 93). Prolactin is a prime example because its roles have diversified during vertebrate evolution. First, it is an ancient hormone found in all vertebrates, and its genetic codes show that it probably evolved along with growth hormone (GH) from an even more ancient ancestral gene. In fishes and amphibians, prolactin is involved in regulating osmotic balance, particularly in retaining salt in these animals’ adaptation to freshwater (p. 627). This is a function that some physiologists suspect occurs in mammals: It reduces Na^+ and K^+ output in the urine and content in sweat, and increases uptake of these ions from the intestines.

As you have seen for birds and mammals in this chapter, prolactin signaling evolved another set of functions involved in reproduction. These functions are not only those for milk and parental behavior but also are for early stages of reproduction. Female knock-out mice lacking prolactin receptors cannot reproduce, because the uterus does not allow embryonic implantation. The reason is that the corpus luteum undergoes

apoptosis (programmed death) in the absence of prolactin stimulation; in turn, the corpus luteum does not make enough progesterone to prepare the uterus.

Males also use prolactin in reproduction. It may trigger paternal behavior: For example, prolactin is high during brooding in male birds that help care for eggs and hatchlings; and California mice (*Peromyscus californicus*), unusual rodents because males help care for the young, have high prolactin levels and more prolactin receptors in their hypothalamus than do other rodents. Also, Tillmann Krüger and colleagues have found that prolactin levels surge during orgasms in both human sexes and that prolactin is associated with feelings of relaxation and satisfaction. In males, it inhibits erection in postcoitus recovery.

Prolactin also has developmental roles in all vertebrates. Its relation to GH is seen in fishes and amphibians that undergo metamorphoses: Prolactin appears to oppose metamorphosis and enhance growth of the larval stage. Yet another developmental role is found in fishes, adult amphibians, reptiles, birds, and some mammals: Prolactin stimulates various aspects of skin development (e.g., molting in reptiles and the defeathering of bird brood patches). Furthermore, prolactin receptors have been found in numerous other nonrepro-

ductive cells in mammals, where their role is often uncertain. One example is the mammalian lymphocyte system: T and B cells (p. 374) have prolactin receptors and can also produce prolactin. Mice in which prolactin binding is blocked have weak immune responses and are thus more susceptible to disease.

Prolactin also violates the dogma for peptide-hormone signal transduction. Like all peptide hormones, prolactin binds to target cell receptors on the plasma membrane to exert its effects (a *tyrosine kinase* system; see p. 95). The dogma is that such lipophobic hormones always work this way, whereas lipophilic hormones such as steroids work by binding to internal receptors that directly regulate gene expression (p. 274). But now many exceptions to these “rules” have been found. Progesterone, for example, is a steroid that has been found to bind to both membrane and internal receptors. Prolactin has been found to bind to a protein called *cyclophilin B* (*CypB*) at the membrane of breast cancer cells, but then moves to the nucleus with *CypB* to activate genes. Knock-down of *CYPB* with RNA interference (p. 33) has shown that these genes are involved in cell growth, motility and tumorigenesis. In this way, prolactin may be a major culprit in the spread of breast cancer cells in human females.

ism *Lactobacillus bifidus* in the infant’s digestive tract. Growth of this harmless bacterium helps crowd out potentially harmful bacteria.

- Other components in mammary gland milk promote maturation of the young’s digestive system so that it is less vulnerable to diarrhea-causing bacteria and viruses.
- Still other factors in mammary gland milk hasten the development of the infant’s own immune capabilities.

Toothed whales (*Odontoceti*) wean their young any time from 2 to 13 years, much later than other marine and terrestrial mammals. It has been observed that reproductively senescent pilot whales, whose weaning period lasts four to five years, are still lactating. In many species a resumption of estrus does not occur until after the young are weaned. Suckling suppresses the estrous cycle by inhibiting LH and FSH secretion, probably through inhibition of GnRH, thus permitting all the female’s resources to be directed toward the newborn instead of being shared with a new embryo. This becomes a very important mechanism for spacing births.

Cessation of Milk Production at Weaning After weaning, two mechanisms contribute to the cessation of milk production. First, without suckling, prolactin secretion is not stimulated, thus removing the primary stimulus for continued milk synthesis and secretion. Also because of the lack of suckling, milk letdown does not occur in the absence of oxytocin release. Because milk production does not immediately shut down, milk accumulates in the alveoli, engorging the mammary glands. The resultant pressure buildup acts directly on the alveolar epithelial cells to suppress further milk production. Cessation of lactation at weaning therefore results from a lack of suckling-induced stimulation of both prolactin and oxytocin secretion.

The end is a new beginning

Reproduction is an appropriate way to end our discussion of physiology from genes to organisms. The single cell resulting from the union of male and female gametes divides mitotically and differentiates into a multicellular individual made

How Reproductive Systems Contribute to the Body as a Whole

The reproductive system is unique in that it is not essential for individual homeostasis or for survival of the individual, but it is essential for sustaining the thread of life from generation to generation. Reproduction depends on the union of male and female gametes (reproductive cells), each with a half set of chromosomes, to form a new individual with a full, unique set of chromosomes. Unlike the other body systems, which are essentially identical in the two sexes, the reproductive systems of males and females are remarkably different, befitting their different roles in the reproductive process.

In addition to basic reproduction, sexual recombination appears to be critical to the long-term survival of most eukaryotic species. The reasons are not fully understood, but probably involve purging of harmful mutations, faster adaptation to changing environments, and/or warding off parasites that have evolved to attack a specific genome.

Chapter Summary

- Reproduction depends on the union of male and female gametes (reproductive, or germ, cells), each with a single set of chromosomes (haploid), to form a new individual with a diploid (that is, twice haploid), unique set of chromosomes.
- Physiological classification of reproductive processes uses three categories: oviparous, meaning the parents release eggs from which the young hatch after expulsion from the body; ovoviviparous, the production of eggs (not necessarily with shells) that hatch within the body of the parent; and viviparous, the production of living young within the body.
- The primary reproductive organs, or gonads, of most vertebrates consist of testes in the male and ovaries in the female. In both sexes in vertebrates, the mature gonads are found in pairs and perform the dual function of (1) producing gametes (gametogenesis), that is, spermatozoa (sperm) in the male and ova (eggs) in the female, and (2) secreting sex hormones, primarily testosterone in males and estrogens (the major form being estradiol) and progesterone in females.
- The male reproductive system is designed to deliver sperm to the female reproductive tract in a liquid vehicle, semen, which is conducive to sperm viability. In contrast, the female's role in reproduction is often more complicated, especially if internal fertilization is involved.
- Nuclear division in the specialized case of gametes is accomplished by meiosis, in which only one of the two sets of homologous chromosomes (that is, a haploid number of chromosomes) is distributed to each of four new daughter cells. Each reproductive cell contains a half set of chromosomes.
- Sex differentiation in mammals depends on the presence or absence of masculinizing determinants during critical periods of embryonic development.
- Puberty in both sexes is a gradual process and not a single event and is recognized as the attainment of sexual maturity and the ability to reproduce.
- Testosterone, usually acting in the dihydro form, governs the growth and maturation of the entire male reproductive system. Ongoing testosterone secretion is essential for spermatogenesis and for maintaining a mature male reproductive tract throughout adulthood.
- A spermatozoon has three parts: a head capped with an acrosome, a midpiece, and a tail. Throughout their development, vertebrate sperm remain intimately associated with Sertoli cells.
- Secretion of both LH and FSH from the anterior pituitary is stimulated in turn by gonadotropin-releasing hormone (GnRH) or inhibited by gonadotropin-inhibiting hormone (GnIH).

- The ducts of the reproductive tract store and concentrate sperm and increase their fertility. During ejaculation, the accessory sex glands contribute secretions that provide support for the continuing viability of the sperm inside the female reproductive tract (in animals with internal fertilization) or in water (such as fish semen).
- In those species in which the penis consists almost entirely of erectile tissue, the body consists of three columns of spongelike vascular spaces extending the length of the organ.
- Female mammals have two interlinked cycles: ovarian and uterine. Together, they form an estrous cycle in most mammals, the time from one period of sexual receptivity to the next. Receptivity is called estrus, or heat, occurring under certain specified conditions. Some primates have a menstrual cycle in which the uterine lining is periodically shed rather than reabsorbed as in estrous. Most animals are spontaneous ovulators that ovulate with a regular frequency and do not require copulation.
- Oogenesis contrasts sharply with spermatogenesis in several important aspects, even though the identical steps of chromosome replication and division take place during gamete production in both sexes. The undifferentiated primordial germ cells in the fetal ovaries, the oogonia (comparable to the spermatogonia), divide mitotically during gestation and/or neonatally, after which time mitotic proliferation ceases.
- After the onset of puberty, the ovary alternates between two phases: the follicular phase, which is dominated by the presence of maturing follicles, and the luteal phase, which is characterized by the presence of the corpus luteum.
- Just before ovulation, the oocyte completes its first meiotic division. The ovum (secondary oocyte), still surrounded by its zona pellucida and granulosa cells, is swept out of the ruptured follicle into the infundibulum (which, in most species, surrounds the ovary) by the leaking antral fluid.
- Rupture of the follicle at ovulation signals the end of the follicular phase and ushers in the luteal phase. Old follicular cells soon undergo a dramatic structural transformation to form the corpus luteum, in a process called luteinization. The follicular-turned-luteal cells hypertrophy and are converted into very active steroidogenic tissue.
- As with males, sexual maturation (puberty) in mammalian females is a long progression leading to the time when the hypothalamus is sufficiently mature to allow the next follicle to produce enough estrogens to elicit the first LH surge.
- Fertilization is the union of male and female gametes. Conception can take place during a limited time span in each cycle, the fertile period. In mammals, copulation involves stimulation of erectile tissues (penis, clitoris), delivery of sperm into the vagina by ejaculation, and orgasm in both sexes.
- The mammalian blastocyst implants in the endometrium through trophoblastic enzymes. To sustain the growing embryo for its intra-uterine life, the placenta, a specialized organ of exchange between the maternal and fetal blood, is rapidly developed. The placenta secretes a number of peptide and steroid hormones essential for maintaining pregnancy. The most important are chorionic gonadotropin, estrogen, and progesterone.
- Parturition (labor, delivery, or birth) involves the uterus expelling the fetus and placenta. Pregnancy duration and delivery timing are determined largely by the placenta's rate of CRH production and lung maturation. Labor is divided into three stages: (1) cervical dilation, (2) delivery of the young, and (3) delivery of the placenta.
- The mammalian female continues to nourish the newborn. Suckling concurrently stimulates milk ejection and milk production, therefore ensuring that the rate of milk synthesis keeps pace with the young's needs for milk. Milk consists of variable amounts of water, triglyceride fat, the carbohydrate lactose (milk sugar), a number of proteins, vitamins, and the minerals calcium and phosphate.

Review, Synthesize, and Analyze

1. What feature of the reproductive system makes it unique from each of the other body systems? (*Hint: Consider the survival of an individual versus a species.*)
2. Of what functional significance is the scrotal location of the testes?
3. Occasionally, testicular tumors composed of interstitial cells of Leydig may secrete up to 100 times the normal amount of testosterone. When such a tumor develops in young animals, they grow up much shorter than their genetic potential. Explain why. What other symptoms would be present?
4. The hypothalamus releases GnRH in pulsatile bursts once every two to three hours, with no secretion occurring in between. The blood concentration of GnRH depends on the frequency of these bursts of secretion. A promising line of research for a new method of contraception involves administration of GnRH-like drugs. In what way could such drugs act as contraceptives when GnRH is the hypothalamic hormone that triggers the chain of events leading to ovulation? (*Hint: The anterior pituitary is "programmed" to respond only to the normal pulsatile pattern of GnRH.*)
5. How are the ovum and spermatozoa transported to the site of fertilization? Describe the process of fertilization.
6. Compare oogenesis with spermatogenesis.
7. Describe the events of the follicular and luteal phases of the ovarian cycle. Correlate the phases of the uterine cycle with those of the ovarian cycle.
8. Explain the physiologic basis for administering a posterior pituitary extract to induce or facilitate labor.
9. Discuss why sexual reproduction is more widespread than asexual reproduction among animals.

Answers to Check Your Understanding Questions

check your understanding 1.1

- Proximate explanations in physiology answer the question, “How does it work?” Evolutionary ones answer the question, “How did it get to be this way?” through history. For example, a proximate description is that the human spine is a movable support device for the upper body and a protective conduit for the major nerve cords. The evolutionary explanation addresses our spine’s flaws by analyzing its ancestral origin as a horizontal flexible swimming device in fishes.
- Adaptations are beneficial features that enhance overall survival of the species. They are not always optimal because they are constrained by evolutionary history.
- “For a large number of problems there will be some animal of choice, or a few such animals, on which it can be most conveniently studied.” For example, to study basic neuron functions, John Zachary Young chose the giant squid axon because it was much easier to pierce with electrodes than the much smaller mammalian neurons.

check your understanding 1.2

- (1) Ask a question about nature. (2) Propose alternative hypotheses to explain the phenomenon. (3) Design experiments or observations that test the hypotheses by making testable predictions. (4) Conduct the observations or experiments. (5) Using the outcome of these tests, refine the earlier questions and hypotheses and design new tests.

check your understanding 1.3

- The basic function of life include self-organization, self-regulation, self-support and movement, and self-reproduction (see details on p. 7).
- The four major types of tissue are (1) epithelial—linings and endocrine and exocrine glands; (2) connective tissue—loose, tendons, bone, blood or hemolymph; (3) muscular—skeletal, cardiac, smooth; (4) nervous.
- Organs form from two or more tissues, e.g., an epithelium forming lining with glands, and an underlying connective tissue “glue.” Organs may also have muscles for movement with nerves to control them and the glands.

check your understanding 1.4

- Surface area increases as the square of the radius, whereas volume increases as the cube. Thus, to obtain nutrients and get rid of wastes through the surface, a larger organism is at a disadvantage because of its smaller surface-area-to-volume ratio. But to retain heat, the larger organism has an advantage.

check your understanding 1.5

- *Homeostasis* means “similar state,” the maintenance of relatively consistent internal conditions. This allows internal structures and functions to operate at their optima.

- Negative feedback occurs when a change in a controlled variable triggers a response that opposes the change, driving the variable in the opposite direction of the initial change. A referenced system has a sensor to measure the variable, an integrator to make decisions using a set point for the desired state, and effectors to make corrections. An example is the thermostat system for home heating/cooling. An antagonistic system has opposing effectors, such as a furnace and air conditioner, for better control.
- Anticipation activates corrective responses of negative feedback before a disturbance occurs, so there is no delay in the correction. Acclimatization improves a component of the system so that it works better under new conditions.

check your understanding 1.6

- Reset systems raise or lower the set point of a negative-feedback system to a new level, which can be useful for a new situation such as a fever. Positive-feedback systems rapidly accentuate changes rather than opposing them; this can be useful when a rapid response is needed, such as blood clotting.

check your understanding 1.7

- Intrinsic controls are those regulated by a single tissue or organ on its own; extrinsic controls are regulatory mechanisms initiated outside an organ to alter its activity. For example, a mammalian heart beats regularly due to its own internal pacemaker, but nerves and hormones can speed it up or slow it down to meet demands of the whole body.
- Many simple local needs of organs, such as blood flow, can be more rapidly and precisely adjusted if they do not have to wait for signals to and from distant regulators.
- The functional systems are based on organ contributions to the entire organism, based on specific body needs such as circulation, respiration, etc. Thus, the systems approach allows us to study how the involved organs all work together and what processes they have in common.

check your understanding 2.1

- A eukaryotic cell’s three major subdivisions are the (1) Plasma membrane, (2) cytoplasm, and (3) nucleus.
- Flexibility is necessary for cell shape changes (e.g., passage of a red blood cell through a capillary) and for many transport proteins to move molecules through membranes.

check your understanding 2.2

- In the process of transcription, the gene is transcribed into a pre-messenger RNA molecule by an enzyme called RNA polymerase. This pre-mRNA is a complementary copy of the gene that contains the coding and noncod-

ing sequences. The pre-mRNA, in turn, is processed into a final messenger RNA by removal of the dispersed introns and ligation of the exon. This step is followed by the addition of noncoding signal sequences to the leading and trailing ends of the molecule. The mature mRNA can now exit the nucleus through its membrane pores.

- Different cell types transcribe different sets of genes and thus synthesize different proteins for their specialized roles. In addition, many genes are active only under certain conditions or life stages.
- Differential gene expression is accomplished through two levels of control: (1) regulation of individual genes with promoters and transcription factors and (2) regulation of transcription factors in different tissues and at different stages. See also the discussion on pp. 31–32.

check your understanding 2.3

- Gene therapy could potentially be used to treat a defect arising from a mutated gene by inserting a normal gene.
- The discovery of iPSCs demonstrates the ability to rejuvenate adult cells by the introduction of various genes that are normally active during the embryonic stage of development.
- Cloning refers to the process by which the nucleus of a fertilized egg is removed or destroyed and a carefully selected nucleus from an adult cell is injected in its place. In both approaches, factors synthesized within the egg somehow rewind the internal clock of the adult genetic material and restore it to the pluripotent state, much like the response of an adult cell to the introduction of embryonic genes or gene products.

check your understanding 2.4

- The ER is an elaborate, fluid-filled membranous system distributed extensively throughout the cytosol, where it is primarily a protein-manufacturing factory. The rough ER consists of stacks of relatively flattened interconnected sacs, whereas the smooth ER is a meshwork of tiny interconnected tubules (Figure 2-9). The rough ER and its ribosomes synthesize and release a variety of new proteins into the ER lumen, whereas the smooth ER serves primarily as a central packaging and discharge site for molecules that are to be transported from the ER. Newly synthesized proteins and lipids pass from the rough ER to gather in the smooth ER, where they are packaged for transport out of the cell.

check your understanding 2.5

- Finished proteins are pinched off the Golgi complex to form a membrane-enclosed vesicle. Each distinct type of vesicle takes up a specific product before budding off. Vesicles with their selected cargo destined for different intracellular

sites are wrapped in membranes containing distinctly different surface proteins. For extracellular transport, numerous large secretory vesicles, which contain proteins to be secreted, bud off from the Golgi stacks and, on the appropriate signal, move to the cell's periphery, fuse with the plasma membrane, and empty the contents to the outside.

- Before budding off from the outermost Golgi sac, the portion of the Golgi membrane that will be used to enclose the secretory vesicle becomes "coated" with a layer of specific proteins from the cytosol. Coat proteins, in turn, bind with another specific protein facing the outer surface of the membrane. The linking of these coat proteins causes the surface membrane of the Golgi sac to curve and form a dome-shaped bud around the captured cargo. Eventually, the surface membrane closes and pinches off the vesicle. Golgi vesicles with their selected cargo destined for different sites also contain distinctly different surface proteins or docking markers. These vesicles can then "dock" and "unload" selected cargo only at the appropriate docking-marker acceptor, a protein located only at the proper destination within the cell.

check your understanding 2.6, 2.7

- Lysosomes remove worn out organelles as well as fuse with aged or damaged organelles to remove parts of the cell. This selective self-digestion makes way for new replacement parts. Lysosomes also play an important role in tissue regression, such as during the normal reduction in the uterine lining following pregnancy. Another important intracellular digestive apparatus is the proteasome, which has the job of taking in internal cell proteins and chopping them up into reusable amino acids, notably those proteins that are no longer useful. Peroxisomes are similar to lysosomes in that they are membrane-enclosed sacs containing enzymes, but unlike the lysosomes, which contain hydrolytic enzymes, peroxisomes house several powerful oxidative enzymes and contain most of the cell's catalase.
- Antioxidants inactivate potentially harmful free radicals before they can damage the cell or its functions.

check your understanding 2.8

- The density of mitochondria in muscle fiber varies greatly, depending on energy needs. The greater the energy expenditure, the greater the mitochondrial content. For example, animals that are continually active (e.g., flying animals) contain muscle fibers with high densities of mitochondria, whereas those that are mostly sessile have low mitochondrial content.
- End products from mitochondrial metabolism include H_2O and free radicals (reactive oxygen species). Free radicals react readily with other molecules, either acquiring or giving up an electron to achieve stability.
- Mitochondria are enclosed by a double membrane—a smooth outer membrane that surrounds the mitochondrion itself and an inner membrane that forms a series of infoldings called cristae, which project into an inner cavity filled with a gel-like solution known as the matrix (Figure 2-16). Cristae contain crucial proteins that ultimately are responsible for converting much of the energy in food into a usable form (the electron transport proteins). The folds of the inner membrane greatly increase the surface area available for housing these important proteins. The matrix consists of a concentrated mixture of hundreds of dif-

ferent dissolved enzymes (the citric acid cycle enzymes) that are important in respiration.

- Oxygen deficiency forces cells to rely on glycolysis and other anaerobic reactions. Most animals can rely on anaerobic metabolism for only relatively brief periods. However, some species of organisms—the facultative anaerobes—can adapt to anaerobic conditions for periods ranging from days to months by substituting other electron acceptors for oxygen or by entering dormant states.

check your understanding 2.9, 2.10

- Vaults are noted for their octagonal shape that fit precisely into the nuclear pores. Because they are hollow, it is believed that they transport specific molecules such as mRNA or ribosome subunits synthesized in the nucleus and transport them to other sites in the cell.
- In vertebrate adipose tissue, the stored triglycerides can occupy almost the entire cytosol, coalescing to form one large fat droplet as compared with other cells in which the fat appears as small droplets known as inclusions. Fats and sugars are stored as triglycerides and glycogen, respectively.

check your understanding 2.11, 2.12

- Microtubules are one of the components of the cytoskeleton; they anchor many of the membranous organelles and serve as "highways" along which vesicles are transported within the cell by "molecular motors." They are also essential for maintaining an asymmetric cell shape, such as that of a nerve cell. During cell division, the centrioles form a mitotic spindle out of microtubules to direct movement of chromosomes. Microfilaments serve at least two functions: (1) They play a vital role in various cellular contractile systems, and (2) they act as mechanical stiffeners for several specific cellular projections.
- Microtubules are essential for maintaining an asymmetric cell shape, such as that of a nerve cell, whose elongated axon may extend 1 meter in length or more in a large vertebrate, from the origin of the cell body in the spinal cord to the termination of the axon at a muscle.

check your understanding 2.13

- Cells subjected to considerable stress rely on (1) desmosomes, which are composed of dense, buttonlike cytoplasmic thickenings known as plaque located on the inner surface of each of the two adjacent cells, and (2) strong glycoprotein filaments containing cadherins (a type of CAM) that extend across the space between the two cells and attach to the plaque on both sides.
- Electrical activity in one cell can be transmitted to another through gap junctions: small connecting tunnels known as connexons.

check your understanding 3.1

- Phospholipids have a polar head containing a negatively charged phosphate group and two nonpolar fatty acid tails. When in contact with water (Figure 3-2b), these two-sided molecules self-assemble into a lipid bilayer, a double layer of lipid molecules. The hydrophobic tails of phospholipids bury themselves in the center away from the water, whereas the hydrophilic heads line up on both sides in contact with the water. The membrane's hydrophobic interior limits the passage of polar molecules either from the ECF or the ICF.
- A certain degree of membrane fluidity is required, for example, for the proper action of transport and channel proteins and for cell shape changes. Cholesterol contributes to both

the fluidity and the stability of the membrane. By being tucked in between the phospholipid molecules, cholesterol molecules prevent the fatty acid chains from packing together and crystallizing, a process that would drastically reduce membrane fluidity. Cholesterol provides some rigidity to the membrane and can counter some of the detrimental effects of elevated temperatures. Second, the addition of double bonds into the fatty acid molecule results in chains that do not stack together well and, therefore, do not become too rigid in the cold, thus offsetting the effects of low temperatures on fluidity.

- A variety of different proteins within the plasma membrane serve the following specialized functions: channels, carriers, receptors, docking-marker acceptors, enzymes, CAMs, and self-identity markers.
- The sugar chains on the outer-membrane surface serve as self-identity markers that enable cells to identify and interact with each other in the following ways: (1) The unique combination of sugar chains projecting from the surface membrane serves as the "trademark" of a particular cell type, enabling a cell to recognize others of its own kind; and (2) carbohydrate-containing surface markers are also involved in tissue growth, which is normally held within certain limits of cell density.

check your understanding 3.2

- Diffusion occurs if a substance can move from a region of higher concentration to a region of lower concentration. Diffusion assumes that each molecule moves separately and randomly in any direction. Osmosis is the net movement of water through a membrane down its concentration gradient.
- The movement of ions (electrically charged particles that have either lost or gained an electron) down an electrical gradient is not an example of diffusion because they are not randomly moving in any direction but are rather conducted along an electrical gradient.
- If ECF solute concentrations increase, water moves osmotically down its concentration into the cell, causing it to swell. If ECF solute concentrations decrease, water moves down its concentration out of the cell, causing it to shrink.
- Factors in addition to the concentration gradient influence the rate of net diffusion across a membrane. See Table 3-1 and the discussion on pp. 76–77.

check your understanding 3.3

- Aquaporins are channel proteins evolved specifically for the passage of water molecules. They are found in all membranes where rapid water movement is necessary.
- Facilitated diffusion uses a carrier to facilitate the transfer of a particular substance across the membrane "downhill" from high to low concentration. This process is passive and does not require energy because movement occurs naturally down a concentration gradient. Active transport, in contrast, requires the carrier to expend energy to transfer its passenger "uphill" against a concentration gradient, from an area of lower concentration to an area of higher concentration. Both forms of transport do not directly require energy; although with secondary active transport, energy is required in the entire process but is not directly required to run the pump. See Figures 3-11 and 3-15 and the discussion on p. 84.
- The Na^+/K^+ ATPase pump transports Na^+ out of the cell, concentrating it in the ECF of multicellular organisms, and picks up K^+ from the

outside, concentrating it in the ICF (Figure 3-14). The Na^+/K^+ pump maintains Na^+ and K^+ concentration gradients across the plasma membrane of all cells. It helps regulate cell volume, and the energy used to run the Na^+/K^+ pump also indirectly serves as the energy source for the cotransport of glucose and amino acids across intestinal and kidney cells.

- Vesicular transport requires energy expenditure by the cell, so this is an active method of membrane transport. Energy is needed to accomplish vesicle formation and vesicle movement within the cell.

check your understanding 3.4

- Signal transduction is the process by which instructions from extracellular chemical messengers are conveyed to the target cell's interior for execution. Lipophilic extracellular messengers gain entry into the cell by dissolving in and passing through the lipid bilayer of the target cell's plasma membrane, whereas lipophobic messengers first bind with surface membrane receptors specific for that given messenger. The desired intracellular response is achieved by only three general means: (1) by opening or closing specific channels in the membrane to regulate the movement of particular ions into or out of the cell, (2) by activating an enzyme that phosphorylates a cell protein, or (3) by transferring the signal to an intracellular chemical messenger (the second messenger), which, in turn, triggers a preprogrammed series of biochemical events within the cell. See also Figure 3-17 and the general discussion on pp. 93–95.
- Deliberate programmed cell death is termed *apoptosis*. A cell signaled to commit suicide detaches itself from its neighbors and decreases in size. The suicidal cell activates a cascade of normally inactive intracellular protein-cutting enzymes, the caspases, which destroy the cell from within. Once unleashed, the caspases act like molecular scissors to systematically dismantle the cell. Snipping protein after protein, they chop up the nucleus, disassembling its life-essential DNA, then break down the internal shape-holding cytoskeleton, and finally fragment the cell itself into disposable membrane-enclosed packets.

check your understanding 3.5

- The simultaneous existence of an electrical gradient and concentration (chemical) gradient for a particular ion is called an electrochemical gradient, which contributes to the electrical properties of the plasma membrane as a result of the unequal separation of both ions and charges.
- The force that keeps K^+ high inside the cell is due to the activity of the Na^+/K^+ pump. This active transport mechanism counterbalances the rate of leakage (Figure 3-26). At resting potential, the pump transports K^+ back into the cell, essentially the same number of K^+ ions that leaked out.
- For the same reason, the force that keeps Na^+ low inside the cell is the result of the activity of the Na^+/K^+ pump. The pump effectively transports to the outside the Na^+ ions that leaked in. In addition, although Na^+ continually leaks inward down its electrochemical gradient, it does so only slowly because of its low permeability, that is, because of the scarcity of Na^+ leak channels.

check your understanding 4.1

- Two types of cells, neurons and muscle cells, can undergo transient, rapid changes in their membrane potentials. These fluctuations in potential serve as electrical signals.

- **Polarization:** Charges are separated across the plasma membrane, so the membrane has potential to do work. Any time the value of the membrane potential is not 0 mV, in either the positive or negative direction, the membrane is in a state of polarization. **Depolarization:** A change in potential that makes the membrane less polarized than at resting potential.

Hyperpolarization: A change in potential that makes the membrane more polarized (more negative) than at resting potential.

Repolarization: The membrane returns to resting potential after having been depolarized.

Resting potential: The constant membrane potential present when a cell is electrically at rest, that is, not producing electrical signals.

- Ions responsible for carrying charge can cross the membrane only through channels specific to them. There are two types of channels: (1) leak channels, or nongated channels, which are open all the time, and (2) gated channels, which can be opened or closed in response to specific triggering events.

check your understanding 4.2

- Graded potentials are produced by a triggering event that causes gated Na^+ ion channels to open in a specialized region of the excitable cell membrane. The magnitude of the graded potential decreases the farther it moves away from the initial active area.
- The passive electrotonic flow of current along a membrane does not require the opening of channels and is therefore faster than current flow generated by action potentials, which require the opening of Na^+ voltage-gated channels. The passive movement of the electrical depolarization can be described by Ohm's law, where ΔV_m is the actual voltage change across the membrane; ΔI , the amount of current (amperes); and R , the resistance encountered by the current passing along the membrane (ohms).

check your understanding 4.3

- **Threshold potential:** The critical potential that must be reached before an action potential is initiated in an excitable cell. **Action potential:** A brief, rapid, large change in membrane potential that serves as a long-distance electrical signal in an excitable cell. **Refractory period:** The time period when a recently activated patch of membrane is refractory to further stimulation, which prevents the action potential from spreading backward into the area through which it has just passed and ensures the unidirectional propagation of the action potential away from the initial site of activation. **All-or-none law:** An excitable membrane either responds to a stimulus with a maximal action potential that spreads nondecrementally throughout the membrane or does not respond with an action potential at all.
- A neuron consists of three basic parts: the cell body, dendrites, and axon. The dendrites and cell body are the neuron's input zone, because these components receive and integrate incoming signals. Action potentials are then conducted along the axon from the axon hillock to the typically highly branching endings at the axon terminals. Functionally, therefore, the axon is the conducting zone of the neuron, whereas the axon terminals constitute the output zone.
- Saltatory conduction propagates action potentials more rapidly than does conduction by local current flow, because the action potential leaps over myelinated sections, whereas it must be regenerated within every section of an un-

myelinated axonal membrane from beginning to end. Contiguous conduction thus involves the spread of the action potential along every patch of membrane down the length of the axon. An increase in fiber diameter increases the speed of propagation in both unmyelinated and myelinated fibers.

check your understanding 4.4

- Neurotransmitters are very short-range chemical messengers, which diffuse from their site of release across a narrow extracellular space to act locally on only an adjoining target cell, which is usually another neuron, muscle, or gland. Neurotransmitters come in several chemical classes of signal molecules, but the most common ones are amines.
- Synapses typically operate in one direction only so that false messages do not inadvertently travel from effectors to integrators; that is, the presynaptic neuron brings about changes in membrane potential of the postsynaptic (target) membrane, but the postsynaptic membrane does not influence the potential of the presynaptic neuron.
- Chemical synapses involve the release of neurotransmitters followed by the opening and closing of channels on the postsynaptic membrane, which requires time, whereas action potential waveforms are essentially transmitted across electrical synapses unperturbed, moving along the axon as if the synapse wasn't present.

check your understanding 4.5

- See Figure 4-16 and the discussion on pp. 130–132.
- Neurotransmitters usually function by changing the conformation of chemically gated channels in so-called fast synapses. Another mode of synaptic transmission used by some neurotransmitters, such as serotonin, involves the activation of intracellular second messengers, such as cAMP, within the postsynaptic neuron. Synapses that lead to responses mediated by second messengers are known as slow synapses, because these responses take longer and often persist for longer periods (because of second-messenger cascades) than those accomplished by fast synapses.
- At an excitatory synapse, the response to the neurotransmitter–receptor combination is the opening of nonspecific cation channels within the subsynaptic membrane that permit simultaneous passage of Na^+ and K^+ through them. In contrast, at an inhibitory synapse, the combination of a chemical messenger with its receptor site increases the permeability of the subsynaptic membrane to either K^+ or Cl^- by altering these ions' respective channel conformations.

check your understanding 4.6

- See Figure 4-18 and the discussion on p. 134.
- The muscle cells' electrical response is turned off by an enzyme present in the motor end-plate membrane, acetylcholinesterase, which inactivates ACh. This occurs because ACh binding to the receptor is reversible.
- Unlike most vertebrate neuromuscular systems, neurons that innervate arthropod muscles are both inhibitory as well as excitatory. For example, the neuromuscular systems regulating claw opening and closing in decapod crustaceans (such as crabs) contain both excitatory and inhibitory motor input. Inhibitory motor neurons also have endings on the presynaptic terminals of the excitatory motor neurons.

check your understanding 4.7

- Threshold potential is lowest at the axon hillock because this region has a much greater density of voltage-gated Na^+ channels than anywhere else in the neuron. When summation of EPSPs takes place, the lower threshold of the axon hillock is reached first, so an action potential originating here is propagated to the end of the axon.
- A presynaptic axon terminal may itself be innervated by another axon terminal (Figure 4-21). Neurotransmitter released from a modulatory terminal binds with receptor sites on the axon terminal. This binding alters the amount of transmitter released in response to action potentials. If the amount of transmitter released from the axon terminal is reduced, the phenomenon is known as presynaptic inhibition. If the release of transmitter is enhanced, the effect is presynaptic facilitation.
- A neuron can influence the level of activity in many other cells by divergence of output. The term *divergence* refers to the branching of axon terminals so that a single cell synapses with and influences many other cells. A neuron may also have many other neurons synapsing on it. Such a relationship is known as convergence. Through this converging input, a single cell is influenced by thousands of other cells.

check your understanding 4.8

- Temperature and pressure affect action potential propagation acutely in unadapted animals. Temperature directly affects the rates of all reactions, including channel opening and closing, whereas high pressure inhibits the proper folding of proteins, reduces the movement of proteins during functional shape changes, and reduces membrane fluidity. The consequences of high pressure include a reduction in the activity of the Na^+/K^+ pump, a decrease in the rate at which an action potential is propagated, a decrease in the rate of axonal repolarization, an increase in axon potential duration, and an inhibition of excitatory synaptic transmission because of reduced neurotransmitter release from the presynaptic terminal and a reduced binding of ACh to its receptor on the muscle membrane. High temperature can reverse some of the effects of high pressure; that is, a moderate increase in temperature restores fluidity to the membrane and increases the activity of the Na^+/K^+ pump.
- The mechanisms by which toxins modify synaptic transmission between neurons include (1) altering the synthesis, axonal transport, storage, or release of a neurotransmitter; (2) modifying neurotransmitter interaction with the postsynaptic receptor; (3) influencing neurotransmitter reuptake or destruction; and (4) replacing a deficient neurotransmitter with a substitute transmitter.

check your understanding 5.1

- The minimum components of a reflex arc include a sensory neuron that controls an effector cell directly. Most reflex arcs have two or more neurons involved, with information being transmitted through one or more intermediate synapses (Figure 5-1b, c).
- Over evolutionary time in many animal groups, the interneuronal component progressively expanded and formed more complex interconnections, especially at the head end of the nervous system, forming a brain (cephalization). From the brain, many neural control pathways became routed through the centralized nerve cords (centralization). Associated with this evolution was the acquisition of more specialized

receptors for sensing the external environment and the routing of their information through the nerve cord to the brain for processing.

- Complex ganglionic nervous systems are characteristic of higher nonvertebrates because a centralized brain is not always necessary and may even be detrimental for some kinds of neural regulation. For this reason, ganglia in each segment of an arthropod have become specialized in coordinating the regional function of each body segment, that is, legs, wings, tail or abdomen, and structures on the head.
- The logarithm of brain weight as a function of body weight is typically linear for a variety of vertebrates, with the positive slope indicating that the overall size of an animal is related to its relative brain size (Figure 5-4). A larger brain is required of animals that must use their intellect to locate ripened fruits, compared with those that simply find leaves. Carnivores (who must hunt wary prey) also tend to have larger brains than herbivores.

check your understanding 5.2

- In vertebrates, the CNS consists of the brain and spinal cord, and the PNS consists of nerve fibers that carry information between the CNS and other parts of the body (the periphery) (Figure 5-5). The PNS also includes ganglia (also in a segmented pattern) that contain the cell bodies of most sensory neurons and some nonmotor effector neurons. The PNS is further subdivided into afferent and efferent divisions.
- Because each autonomic neurotransmitter and medullary hormone stimulate activity in some tissues but inhibit activity in others, the particular responses depend on the specific receptor types available for each neurotransmitter. For example, two types of acetylcholine (cholinergic) receptors—nicotinic and muscarinic—have been identified on the basis of their response to particular drugs (Table 5-4). There are also two major classes of adrenergic receptors for norepinephrine and epinephrine.

check your understanding 5.3

- Four major features help protect the vertebrate CNS from injury: (1) It is enclosed by hard, bony structures: the cranium (skull) encases the brain, and the vertebral column surrounds the spinal cord. (2) Three protective and nourishing membranes, the meninges, lie between the bony covering and the nervous tissue. From the outermost to the innermost layer, these are the dura mater, the arachnoid mater, and the pia mater (*mater*, “mother”). (3) The brain “floats” in a special cushioning fluid, the cerebrospinal fluid (CSF). (4) A highly selective blood–brain barrier limits access of bloodborne materials into the vulnerable brain tissue.
- Systemic capillaries are characterized by holes or pores between the cells making up the capillary wall, which permits free exchange of all plasma components, except the large plasma proteins, with the surrounding interstitial fluid. In the brain capillaries, the endothelial cells are joined by tight junctions, which completely seal the capillary wall so that nothing can be exchanged across the wall by passing between the cells (Figure 5-14).
- *Neural plasticity* refers to the ability of the nervous system to generate new synaptic connections, axonal and dendritic branches, and neurons. There are two main sites of neurogenesis in the adult brain. The first is the hippocampus (a key memory center), in addition to the subventricular zone (SVZ) associated with

the lateral ventricles of the brain. Cell division also can occur in the hypothalamus in response to seasonal and other environmental signals.

check your understanding 5.4

- The brainstem is the smallest and least changed region of the vertebrate brain (Table 5-6). It controls many of the life-sustaining processes, such as breathing and circulation—processes that have remained essentially unchanged during vertebrate evolution.
- The forebrain has changed the most over evolutionary time, in parallel with the dramatic increase in the number of interconnections, a reflection of this structure being the highest, most complex integrating area of the brain.

check your understanding 5.5

- A nerve is a bundle of peripheral nerve axons, some afferent and some efferent, enclosed by a connective tissue covering and following the same pathway, whereas a neuron is a nerve cell specialized to initiate, propagate, and transmit electrical signal, typically consisting of a cell body, dendrites, and axon.
- A reflex that is integrated at the spinal cord without involvement of the brain is termed a spinal reflex. Often neuronal connections that produce patterned or stereotyped movements find their origins in the spinal cord (e.g., rudimentary walking or swimming motion). In contrast, a fixed action pattern represents a short sequence of behavior that constitutes a unique part of the behavioral makeup of a species (e.g., courtship or threat display).
- Built into the withdrawal reflex is inhibition of the muscle that antagonizes (opposes) the desired response. This type of neuronal connection, involving stimulation of the nerve supply to one muscle and simultaneous inhibition of the nerves to its antagonistic muscle, is known as reciprocal innervation.

check your understanding 5.6

- Key functions of the brainstem include (1) the receipt and integration of all synaptic input via the reticular formation; (2) sensation input and motor output in the head and neck via cranial nerves; (3) reflex control of the heart, blood vessels, respiration, and digestion; (4) modulation of the sense of pain; and (5) housing of the centers responsible for sleep.
- The cerebellum compares the “intentions” or “orders” of the higher centers (especially the motor cortex) with the “performance” of the muscles and then corrects any “errors” or deviations from the intended movement even in the absence of feedback from sensors (Figure 5-25). The cerebellum even appears able to predict the position of a body part in the next fraction of a second and to make adjustments accordingly. These ongoing anticipatory adjustments are especially important for rapidly changing activities such as climbing, swinging through trees, and running, in which delays in sensory feedback would make the action clumsy.

check your understanding 5.7

- The basal nuclei’s role in motor control include (1) inhibiting muscle tone throughout the body (proper muscle tone is normally maintained by a balance of excitatory and inhibitory inputs to the neurons that innervate skeletal muscles); (2) selecting and maintaining purposeful motor activity while suppressing useless or unwanted patterns of movement; and (3) helping monitor and coordinate slow,

sustained contractions, especially those related to posture and support.

- The hypothalamus is the area of the brain most notably involved in regulating the direct homeostasis of the internal environment. The hypothalamus is an integrating center for many important homeostatic functions, including (1) controlling body temperature (although this ability varies considerably among vertebrates); (2) controlling thirst and urine output; (3) controlling food intake; (4) controlling anterior pituitary hormone secretion; (5) synthesizing posterior pituitary hormones; (6) controlling uterine contractions and milk ejection; (7) serving as a major autonomic nervous system coordinating center, which, in turn, affects all smooth muscle, cardiac muscle, and exocrine glands; (8) playing a role in emotional and behavioral patterns; and (9) participating in the sleep–wake cycle.
- The amygdala of the mammalian limbic system processes inputs that give rise to the sensation of fear, a sense that normally helps animals avoid danger. In this region, a link between an unconditioned stimulus and a conditioned stimulus is formed, which leads to a strengthening of synaptic connections in this region, which, once laid down, are retained for the lifetime of the animal. Basic innate behavioral patterns are also controlled in part by the limbic system and include those directed toward perpetuation of the species (sociosexual behaviors conducive to mating).

check your understanding 5.8

- Functions associated with the four divisions of the mammalian cerebrum are as follows: The occipital lobes are a sensory and association area that carries out the initial perception and processing of visual input in the cortex. Similarly, auditory (sound) sensation is initially received and processed by the temporal lobes. The parietal lobes are primarily responsible for receiving and processing body sensory input (e.g., touch, temperature, pain). The frontal lobes contain motor and higher association areas and are responsible for four main functions: (1) nonreflex motor activity; (2) vocal ability (in mammals with this capability); (3) some types of long-term memory; and (4) higher mental functions, such as planning, involving multiple sensory inputs and memory.
- The sensory cortex deals with sensory perception; the motor cortex initiates nonreflex or learned movements; and the association cortices are the sites of complex memory, integration, and planning, as well as (in some species) self-awareness, language, and personality traits.
- The greater the sensory input density from a specific area of the body, the greater the area of the cortex devoted to processing this information. For each species, the extent of each body part is indicative of the relative proportion and location of the somatosensory cortex devoted to that area (Figure 5-31).

check your understanding 5.9

- *Habituation* represents a decreased responsiveness to repetitive presentations of an indifferent stimulus, that is, one that is neither rewarding nor punishing; *sensitization* refers to increased responsiveness to mild stimuli following a strong or noxious stimulus. Habituation is the most common form of learning; by learning to ignore indifferent stimuli, the animal is free to focus on other more important stimuli.

- Long-term memory storage requires the activation of specific genes that control protein synthesis. These proteins, in turn, are needed for the formation of new synaptic connections. Thus, long-term memory storage involves permanent physical changes in the brain.
- Formation of enduring memories involves not only the activation of positive regulatory factors (CREB-1) that favor memory storage but also the turning off of inhibitory, constraining factors (CREB-2) that prevent memory storage. In life-threatening situations, sufficient MAP kinase molecules are presumably sent to the nucleus rapidly enough to inactivate the CREB-2 molecules so that protein kinase A activates sufficient CREB molecules to ensure that the animal recalls the details of this experience for future reference.

check your understanding 6.1

- Modalities include mechanoreception for physical stimuli, chemoreception for chemicals, thermoreception for hot or cold, photoreception for light, electroreception for electric fields, and magnetoreception for magnetic fields; chemoreceptive and mechanoreceptive nociceptors for pain are sometimes listed separately. Their roles are exteroception for external stimuli, interoception for internal states, or proprioception for motion and position.
- The most ancient, found in all life, were probably mechanically gated channels, which open in response to physical changes, such as swelling, and chemically gated channels and receptors that signal in response to specific chemicals. Light sensing begins with receptors. Animals later evolved voltage-gated channels to transmit long-range signals and thermally gated channels to sense specific temperatures.

check your understanding 6.2

- Tonic receptors fire continuously as long as they are stimulated—for example, joint proprioceptors often do this since continual information on limb position is crucial. Phasic receptors shut off after a while under continuous stimulus—for example, olfactory receptors do this since paying attention to an ongoing unimportant odor diverts brain power.
- For touch, each sensory neuron responds to stimuli only within a circumscribed region of the skin surface surrounding it; this region is its receptive field. Smaller fields increase acuity or discriminating ability, as does lateral inhibition. See Figure 6-7.
- An adequate stimulus is one that a receptor most readily responds to; it alters the receptor's permeability, leading to a local graded voltage change (i.e., one proportional in strength to the stimulus). This is the receptor potential; it may initiate action potentials in an afferent neuron for long-distance signaling, but only if it reaches threshold.

check your understanding 6.3

- Proprioceptors inform the CNS about body and limb position and movement, which are essential for coordinated motions.
- Hair cells have stereocilia, which depending on which way they bend due to external movements such as current or sound waves, open and close ion channels, as shown in Figure 6-11. In the fish lateral line, these sense water pressure and flow changes.
- All are proprioceptors for position and movement. Statocysts (Figure 6-9) are gravity sensors

in many animal phyla, using signals made by mineralized moveable grains called statoliths. The utricle (for vertical motion) and saccule (for horizontal motion) of vertebrate heads (Figure 6-14) work similarly with otoliths. The vertebrate semicircular canals (Figure 6-13) detect rotational acceleration or deceleration of the head in three dimensions due to relative fluid movement within them.

check your understanding 6.4

- Intensity or loudness depends on a sound wave amplitude, in decibels (dB); hearing ranges from a leaf rustling (about 10 dB) to a waterfall roaring (perhaps 100 dB, a 100 million times louder than the leaf rustling) or higher. Pitch is determined by frequency. Infrasound attenuates only slightly in the environment and so can function in long-distance communication (e.g., by whales and elephants). Ultrasound is useful because its numerous small waves can reflect well off very small features, making it ideal for echolocation in bats and toothed whales. Timbre depends on overtones (other frequencies superimposed on the basic pitch); echolocating dolphins use it to discriminate objects, while many birds and mammals use timbre to distinguish voices.
- The pinna is a skin-covered flap of cartilage that collects sound waves and channels them down the external ear canal to the tympanic membrane, a taut drumlike structure that vibrates, pushing on the three ossicle bones, which act as levers to push on the oval window of the cochlea (Figure 6-17). The window vibrates fluid in the cochlea, which then transmits the vibrations to the basilar membrane. This discriminates sounds as shown in Figures 6-19 and 6-20. Figure 6-21 summarizes the events.

check your understanding 6.5

- See Figure 6-23 for (1) salt, which aids in acquiring electrolytes; (2) bitter, which helps avoid plant toxins; (3) sweet, for energy-rich carbohydrates; (4) acid, for avoiding rotting food; and (5) umami, for proteins.
- The bulb for general odor detection in mammals is on the roof of the nasal cavity (Figure 6-24); the VNO for pheromones lies near the nasal entrance. Receptors are activated by binding of specific chemicals, with each receptor binding several types of molecules weakly to strongly. By comparing strengths of binding signals from multiple receptors, the brain can distinguish far more odors than there are receptors.

check your understanding 6.6

- The answer begins with retinal in the opsin protein and should include all steps of Figure 6-36 to the bipolar and ganglion cells, which work as shown in Figure 6-39.
- Rods have rhodopsin, in which retinal can absorb most wavelengths of light and therefore allow animals to see shades of gray. Cones have various scotopsins, which absorb at different wavelengths, and therefore allow animals to see specific colors. L types are for red; M, for green; S, for blue; and UV, for ultraviolet. There are various combinations among animals—for example, shallow fish have L, M, and S, but deep ones have lost L types due to lack of red light. Many birds see UV, which aids locating the sun on cloudy days.
- Vertebrate eyes are camera types as shown in Figure 6-28 with ciliary receptor cells such as rods. Phototransduction was described earlier. Insect eyes are compound types with numerous rhabdomeric receptor cells (Figure 6-44).

Images are made in the brain as if each cell were a pixel in a newspaper photo. Transduction is similar to vertebrates, but the events lead to channel opening rather than closing.

check your understanding 6.7

- In mammalian skin, one receptor responds to increased temperature (warmth sensors) above the skin's temperature, while the other receptor responds to decreasing temperature (cold sensors) below skin temperature. These help the brain anticipate threats to core temperature. Infrared receptors in pit vipers help them detect body heat of prey mammals and perhaps also habitat temperatures for behavioral thermoregulation. All involve TRP-type channel proteins, which appear to be thermally gated.
- This depends on the type of animal and its habitat. In general, increased heat is more likely to be immediately harmful than a comparable decrease in temperature.

check your understanding 6.8

- Fast pain is a quick response to direct mechanical or heat damage (which may subside) that is transmitted over large, myelinated A-delta fibers. It is followed by a slower, prolonged chemical response to inflammation and cell contents released by damage that is transmitted by small, unmyelinated C fibers.
- See Figure 6-46.

check your understanding 6.9

- Passive electroreception serves to detect extraneous electric fields, not an animal's own electrical currents, and is used for electrolocation of other animals, as in prey location by sharks. Sharks and their relatives have ampullary receptors filled with a clear, salty gel (a glycoprotein complex) that readily transmits minute electrical currents. Active electroreception resembles echolocation in that the animal assesses its environment by actively emitting signals with electric organs (Figure 6-47) and receiving the feedback signal. Magnetoreception detects the Earth's magnetic field and is used as a compass sense for migration, as in many birds. The mechanism is unclear, but three hypotheses are given on p. 264.

check your understanding 7.1

- Hormones are chemically classified into three categories: peptides and proteins, amines, and steroids. The peptide and protein hormones consist of specific amino acids arranged in a chain of varying length. Amines are derived from the amino acid tyrosine. Steroids are neutral lipids derived from cholesterol. All peptides and catecholamines are hydrophilic, whereas all steroid and thyroid hormones are lipophilic.
- Hormones produce their effects by altering intracellular proteins through ion fluxes, second messengers, and transcription factors.
- The plasma concentration of a hormone depends on the hormone's rate of secretion into the blood by the endocrine gland; for a few hormones, the rate of metabolic activation; for lipophilic hormones, the extent of binding to plasma proteins; and finally the rate of removal from the circulation by metabolic inactivation and excretion in urine.

check your understanding 7.2

- See Figure 7-7b and the discussion on p. 280. The quantity of JH released from the corpora allata determines whether metamorphosis will occur.

check your understanding 7.3

- Short-day breeders rely on steadily increasing concentrations of melatonin (Figure 7-8), whereas long-day breeders rely on the progressively decreasing concentrations of melatonin to trigger the onset of the breeding season.
- Once synchronized with a regular environmental cycle such as day-night or summer-winter, clocks permit organisms to prepare for these cyclical changes in advance of their actual occurrence. Neural clocks regulate many neuromuscular functions, such as feeding and other behaviors, as well as hormonal secretion. Clock genes interact with each other through both transcription and negative-feedback loops to produce a cycle that lasts approximately a day. The mechanism is detailed in the box, *Molecular Biology and Genomics: Clocks and Genes*, on p. 284.
- Anterior pituitary hormone release is regulated by peptides released from the hypothalamus through a unique vascular link, whereas the posterior pituitary hormones are synthesized in the hypothalamus and transported to the posterior pituitary by a neural pathway.
- MSH plays a vital role in the camouflage of selected species. α -MSH controls skin coloration via the dispersion of storage granules containing the pigment melanin.

check your understanding 7.4

- GH's indirect growth-promoting actions are mediated by IGFs, which act on the target cells to cause growth of both soft tissues and bones, whereas GH can directly bind with receptors on its target organs, namely adipose tissue, skeletal muscles, and liver, to exert its metabolic effects.
- Administering GH to swine dramatically increases protein accretion and muscle mass, in addition to reducing adipose tissue growth.
- Brood patch development is related to both the gender that incubates and the form of steroid that is most effective, in combination with prolactin, to produce a full brood patch. In those species in which the female alone incubates, it is estrogen; in those species in which the male incubates, it is androgen.

check your understanding 7.5

- Hypothalamic TRH triggers the release of TSH secretion by the anterior pituitary, whereas T_3 , in negative-feedback fashion, "turns off" TSH secretion by inhibiting the anterior pituitary and hypothalamus.
- A primary role of thyroid hormone in endotherms is to regulate metabolic heat production, whereas in ectotherms, thyroid hormone may be elevated during periods of metabolically demanding activity. Some ectotherms (e.g., tadpoles) rely on a surge of thyroid hormone to induce metamorphosis.
- Thyroglobulin incorporates the thyroid hormones in their various stages of synthesis and then stores them until needed. Once freed from thyroglobulin, the hydrophilic thyroid hormones simply diffuse away into the circulation.

check your understanding 7.6

- See Figure 7-22, Table 7-3, and the discussion on p. 310.
- The catecholamine epinephrine strengthens sympathetic responses and reaches places not innervated by the sympathetic system to perform additional functions, such as mobilizing carbohydrate and fat stores.

check your understanding 7.7

- The pancreatic hormones insulin and glucagon shift the metabolic pathways back and forth from net anabolism to net catabolism and glucose sparing, depending on whether the body is feasting or fasting, respectively. See Figure 7-27.
- The fed state lowers blood levels of glucose, fatty acids, and amino acids and promotes their storage. As these nutrient molecules enter the blood during the absorptive state, insulin promotes their cellular uptake and conversion into glycogen, triglycerides, and protein, respectively. Insulin facilitates glucose transport into most cells, stimulates glycogenesis while decreasing glycogenolysis, and inhibits gluconeogenesis in the liver. During periods of fasting, glucagon increases hepatic glucose production and release and thus raises blood glucose levels. Glucagon exerts its hyperglycemic effects by decreasing glycogen synthesis, promoting glycogenolysis, and stimulating gluconeogenesis. Several other hormones also play a secondary role in fuel metabolism (Table 7-7). For example, in long-term starvation, cortisol helps maintain blood glucose concentrations by promoting gluconeogenesis through protein catabolism.

check your understanding 7.8

- Minor variations in the concentration of free ECF Ca^{2+} can profoundly and immediately affect the sensitivity of excitable tissues. For example, a fall in free Ca^{2+} results in overexcitability of nerves and muscles; conversely, a rise in free Ca^{2+} depresses neuromuscular excitability. Fluctuations in free ECF Ca^{2+} can also affect excitation-contraction coupling in cardiac and smooth muscle, stimulus-secretion coupling, maintenance of tight junctions between cells, and clotting of blood.
- The overall effect of PTH is to increase the Ca^{2+} concentration of plasma (and, accordingly, of the entire ECF), thereby preventing hypocalcemia. By its combined actions on bone, kidneys, and intestine (effectors), PTH raises the plasma Ca^{2+} level when it starts to fall, so hypocalcemia and its effects are normally avoided. Vitamin D is a steroidlike compound that is essential for Ca^{2+} absorption in the intestine.

check your understanding 8.1

- Almost all living cells have rudimentary intracellular machinery for producing movement. White blood cells and amoebas use intracellular contractile microfilaments to propel themselves through their environment with pseudopodia. Other cells such as sperm and paramecia move with microtubule-based propulsive structures called cilia and flagella. As the first animals evolved, larger-scale movements evolved from these intracellular ones. For example, Porifera (sponges) create large-scale water currents using numerous flagellated cells. Many aquatic larvae, flatworms, and comb jellies move slowly through the environment by the beating of coordinated cilia. However, other (especially faster) locomotory movements of animals required the evolution of a highly organized microfilament-based structure called a muscle: a specialized cell that contracts to pull an external structure or squeeze a fluid.

check your understanding 8.2

- The area between two Z lines is called a sarcomere, which is the functional unit of skeletal muscle. A functional unit of any organ is the smallest component that can perform all the

functions of that organ. Accordingly, a sarcomere is the smallest component of a muscle fiber that is capable of contraction.

- Muscle contraction is regulated by intracellular Ca^{2+} concentrations. When the troponin is not bound to Ca^{2+} , this protein complex stabilizes tropomyosin in its blocking position over actin's cross-bridge binding sites (Figure 8-6a). When Ca^{2+} binds to troponin, the shape of this complex is changed in such a way that tropomyosin is allowed to slide away from its blocking position (Figure 8-6b). With tropomyosin out of the way, the myosin head can bind to actin to form cross bridges, resulting in muscle contraction.

check your understanding 8.3

- During contraction in mammalian striated muscle, the thin filaments on each side of a sarcomere slide inward toward the A band's center (Figure 8-7). As they slide inward, the thin filaments pull closer together the Z discs to which they are attached, so the sarcomere shortens. Because all the sarcomeres throughout the muscle fiber's length shorten simultaneously, the entire fiber becomes shorter.
- An action potential on the outside of a muscle fiber triggers the contractile process on the inside by travelling down a T tubule, which triggers the release of Ca^{2+} from the sarcoplasmic reticulum into the cytosol to trigger contraction. A T tubule runs perpendicularly from the surface of the muscle cell membrane into the central portions of the muscle fiber (Figure 8-9).
- Foot proteins, known as ryanodine receptors, extend from the sarcoplasmic reticulum and span the gap between the lateral sac and T tubule and serve as Ca^{2+} -release channels. T tubule channels (dihydropyridine receptors) are located like mirror images in contact with every other foot protein protruding from the sarcoplasmic reticulum (Figure 8-10b, c). These Ca^{2+} channels are voltage-gated sensors. When an action potential is propagated down the T tubule, the local depolarization activates the voltage-gated dihydropyridine receptors. These activated T tubule channels, in turn, trigger the opening of the directly abutting foot proteins in the adjacent lateral sacs of the sarcoplasmic reticulum. Opening of half of these Ca^{2+} -release channels in direct contact with the dihydropyridine channels triggers the opening of the other half that are not in direct contact.
- Although mitochondria are positioned close to the Ca^{2+} release sites in the sarcoplasmic reticulum, they are not designed to respond to an action potential with a release of Ca^{2+} . With only a few specific exceptions, mitochondria keep up with the cytoplasmic Ca^{2+} transients with only a few milliseconds delay. An exception would be the repeated stimulation of a muscle fiber, which results in tetanus.

check your understanding 8.4

- This is an isometric contraction—the muscle is prevented from shortening because the shell is already closed, so tension develops at constant muscle length.
- A crab claw (a modified limb) is opened with an extensor and closed with a flexor. The claw opener muscle requires limited muscle effort (as with the opening of an alligator's mouth), but the claw closing muscle is used for fighting and is therefore comparatively much larger in size (as are the muscles that close an alligator's mouth).

check your understanding 8.5

- ATP is the only energy source that can be directly used for contractile activity: For con-

traction and relaxation to continue, ATP must constantly be supplied. The phosphagens creatine phosphate and arginine phosphate are often the first energy storehouse tapped at the onset of contractile activity.

- If the energy-dependent contractile activity is to be continued, most animal muscles shift from the phosphagens (brief anaerobic activity) to the pathway of oxidative phosphorylation to form ATP. Oxidative phosphorylation takes place within the muscle mitochondria; this multistep pathway requires time to pick up its rate of ATP formation to match the increased demands for energy, time provided by the immediate supply of energy from the one-step phosphagen system. Oxygen is required to support the mitochondrial electron transport system, which together with chemiosmosis by ATP synthase, efficiently harnesses energy captured from the breakdown of nutrient molecules and uses it to generate ATP. This pathway is fueled by glucose or fatty acids, depending on the intensity and duration of the activity.

check your understanding 8.6

- High-speed synchronous skeletal muscles are those in which each muscle action potential evoked by incoming neuronal activity results in a single mechanical contraction. The development of asynchronous muscle contractions (Figure 8-21) represents a solution for muscles that operate at extraordinarily high frequencies: Their design results in the generation of more power, although capacity for fine neural control declines. Associated with the rapid wing-beat frequency is a lowered number of nerve impulses that are now asynchronous with muscle contraction. In these circumstances, a single Ca^{2+} pulse maintains the muscle in an activated state for numerous successive cycles.
- Myofibrils generate the force, mitochondria are committed to supplying ATP for the cross bridges, while the sarcoplasmic reticulum is the "on-off" switch. In a powerful locomotive muscle, the myofibrils would be most represented.

check your understanding 8.7

- Muscle spindles, which are distributed throughout the fleshy part of a skeletal muscle, are collections of specialized muscle fibers known as intrafusal fibers. Whenever the whole muscle is passively stretched, the intrafusal fibers within its muscle spindles are likewise stretched, increasing the rate of firing in the afferent nerve fibers whose sensory endings terminate on the stretched spindle fibers. This stretch reflex serves as a local negative-feedback mechanism to resist any passive changes in muscle length so that optimal resting length can be maintained. Golgi tendon organs are located in the tendons of the muscle, where they can respond to changes in the muscle's externally applied tension rather than to changes in its length.
- The classic example of the stretch reflex is the patellar tendon, a monosynaptic reflex (no intermediate interneurons) in humans (Figure 8-26). The extensor muscle of the knee is the quadriceps femoris, which forms the anterior (front) portion of the thigh and is attached just below the knee to the tibia (shinbone) by the patellar tendon. Tapping this tendon with a rubber mallet passively stretches the quadriceps muscle. The resultant stretch reflex brings about contraction of this extensor muscle, causing the knee to extend and raise the foreleg in the well-known knee-jerk fashion.

check your understanding 8.8

- The exposure of skinned human skeletal muscle fibers to twitchin induces a catchlike state in the skeletal muscle fibers. The rate at which the myosin heads detach from the actin is greatly slowed by the presence of twitchin, a titinlike protein associated with the myosin. Phosphorylation of twitchin by protein kinase A, perhaps because of the actions of serotonin, inhibits the catch state by allowing the myosin heads to detach at a faster (noncatch) rate.
- Single-unit smooth muscle is supplied by the involuntary autonomic nervous system: Muscle fibers that make up this type of muscle become excited and contract as a single unit. Gap junctions electrically link the muscle fibers in single-unit smooth muscle. When an action potential occurs anywhere within a sheet of single-unit smooth muscle, it is quickly propagated via these special points of electrical contact throughout the entire group of interconnected cells, which then contract as a single coordinated unit.

check your understanding 9.1

- Circulatory systems overcome the slowness of diffusion by the much faster process of bulk transport: the movement of the medium that contains the molecules (and cells) of interest.
- In open systems (Figure 9-2), fluid called hemolymph moves via pumping through arteries (outgoing vessels) that open like garden hoses into extracellular spaces among the tissues, bathing them directly for molecular exchanges with cells. Veins (return vessels) may pick up the fluid. In closed systems, fluid called blood exits a heart through vessels that are continuous all the way back to the intake side of the heart, with capillaries joining arteries and veins.

check your understanding 9.2

- Plasma is typically 90% or more water, with various proteins, electrolytes (mainly NaCl), nutrients, waste products, and hormones.
- Low-density lipoproteins (LDLs) are blood complexes that deliver cholesterol and phospholipids to most body cells (e.g., for membrane synthesis). Pathological accumulations of LDL cholesterol in blood vessel walls are a leading cause of cardiovascular disease. High-density lipoproteins (HDLs), in contrast, remove excess cholesterol from cells and transport it to the liver for removal.
- Erythrocytes primarily transport gases for respiration: oxygen bound to hemoglobin; carbon dioxide primarily as bicarbonate ions (formed by carbonic anhydrase in the cells); and carbon dioxide bound to hemoglobin. The cells also transport NO and H_2S , which vasodilate vessels.

check your understanding 9.3

- Clotting transforms blood into a solid gel on top of a platelet plug. As shown in Figures 9-11 and 9-12, tissue damage, exposed collagen, and platelet aggregation activate protein factors in the blood, which ultimately convert prothrombin to thrombin. Thrombin, in turn, converts fibrinogen into fibrin, which forms a mesh (the clot). In positive-feedback fashion, thrombin also facilitates its own formation from prothrombin and enhances platelet aggregation.
- (1) ADP and other chemicals released by activated platelets stimulate the release of prostacyclin and NO from the adjacent normal endothelium. Both inhibit platelet aggregation, so a platelet plug is limited to the defect and does not spread. (2) Clotting factors convert

plasminogen into active plasmin, which slowly dissolves a clot's fibrin. At nonwound sites, inappropriate fibrin formation is stopped by plasmin activated by tissue plasminogen activator (tPA) from the tissues, especially the lungs.

check your understanding 9.4

- (1) Flagella, as in sponges; (2) extrinsic pumping of fluid by skeletal muscles, as in mammalian leg veins; (3) peristaltic pumping of vessel walls, as in annelids; (4) auxiliary hearts for blood, as in cephalopods for pumping blood to the gills
- Valves consist of flaps of connective tissue in a vessel that can open in one direction only, due to fluid pressure. A backward pressure causes the flaps to close together to prevent backflow.
- Individual cardiac muscle cells are interconnected as branching fibers, with adjacent cells joined end-to-end by these discs. Within a disc are two types of membrane junctions: (1) Desmosomes are a type of adhering junction that mechanically holds cells together under high mechanical stress, whereas (2) gap junctions are channels that allow action potentials to spread from one cardiac cell to the next, ensuring the cells beat in synchrony.

check your understanding 9.5

- The pacemaker fires repeatedly because its membrane potential slowly depolarizes between action potentials until threshold is reached, at which time the membrane “fires.” This, in turn, triggers the heartbeat so that the heart beats regularly without needing extrinsic triggers. The slow depolarization involves Na^+ and Ca^{2+} influx through channels as described on p. 407.
- As the cardiac membrane potential reaches its peak positive level, it remains there for several hundred msec in a plateau phase. It is maintained by activation of “slow” Ca^{2+} channels and a marked decrease in K^+ permeability. This plateau prolongs contraction for squeezing the heart chambers properly.
- Tetanus is a sustained full contraction of a muscle. Fibrillation is random, uncoordinated contraction–relaxation cycles.
- The P wave represents atrial depolarization. The QRS complex represents ventricular depolarization. The T wave represents ventricular repolarization.

check your understanding 9.6

- See Figure 9-27 and the discussion on p. 412.

check your understanding 9.7

- $\text{C.O.} = \text{heart rate} \times \text{stroke volume}$; the volume of blood per minute pumped by a heart to the body. This flow is critical because it is responsible for all blood or hemolymph transport functions.
- The Frank-Starling law says that the greater the volume of blood entering the heart during diastole, the greater the volume of blood ejected during systole. (1) This provides equalization of output between the right and left sides of the avian and mammalian hearts, so the blood pumped is equally distributed between the pulmonary and systemic circulation. (2) This response allows cardiac output to increase intrinsically when venous return increases during exercise.
- The parasympathetic system releases ACh onto muscarinic receptors, which favor resting conditions, while the sympathetic releases NE to α_1 -adrenergic receptors, which stimulate changes for action. See also Table 9-1.

check your understanding 9.8

- $Q = \text{flow rate of fluid through a vessel (quantity per unit time)}$. It is the outcome of ΔP , the pressure gradient, divided by R , the resistance of blood vessels. The pressure gradient is established by the force of the heart pumping and can be altered by gravity. The resistance is mainly determined by the radii and length of blood vessels and the viscosity of the blood.
- Parallel flow ensures that each organ/tissue receives an appropriate share of oxygenated blood rather than depleted blood that has already passed through other organs/tissues.
- Circulatory fluid force can create movement, as in extension of spider legs, pressure for ultrafiltration in kidneys, and inflation of erectile tissue.

check your understanding 9.9

- Most mollusks (except cephalopods) and insects have open circulation with large open spaces, with body muscles providing some directional flow, but large crustacea have many branching vessels leading to small local open spaces.

check your understanding 9.10

- The answer should involve the evolution from a two-chambered heart with one circulatory circuit (water-breathing fishes) to a four-chambered heart with separate pulmonary and systemic circuits (crocodilians, birds, mammals), as found in Figures 9-37 to 9-41. The special shunt of reptiles and fetal mammals should be included.

check your understanding 9.11

- The elasticity of arteries enables them to expand temporarily during systole, storing some of the pressure energy in their stretched walls (Figure 9-43). When the heart relaxes and ceases pumping blood into the arteries, the stretched arterial walls passively recoil, like an inflated balloon that is released. This recoil pushes the excess blood contained in the arteries into the vessels downstream, ensuring continued blood flow to the tissues when the heart is relaxing.

check your understanding 9.12

- Local myogenic activity and sympathetic stimulation cause partial contraction of arteriole muscles to give vascular tone, helping maintain normal systemic pressure. Tone can be altered intrinsically to match blood flow with local needs through (1) local metabolic changes, (2) histamine release, (3) exposure to heat or cold, and (4) stretch. For example, decreased O_2 reduces tone, so more blood flows to the tissue. Extrinsic regulation also works to adjust tone for whole-body needs. For example, during exercise, sympathetic nerves constrict arterioles to the gut more, while epinephrine dilates those to the skeletal muscles, diverting blood to the latter.

check your understanding 9.13

- Capillaries decrease ΔX by being very thin and narrow and numerous; increase D by greater permeability through pores; increase A by being numerous; and increase ΔC by increased perfusion of incoming blood having high levels of oxygen, glucose, etc.
- *Flow rate* refers to the volume of blood flowing through a given segment of the circulatory system per unit of time, but *velocity of flow* refers to the linear speed with which blood flows forward through a given segment of the circula-

tory system. Velocity slows as cross-sectional area of a vessel network increases. Because that area is much higher in a capillary bed compared with the incoming arteriole, blood slows in the bed. This is important to allow time for diffusion to occur between blood and tissues.

- The factors affecting bulk flow are described in Figure 9-57. This flow exiting the capillaries gives the fluid closer contact with cells, enhancing glucose and waste transport and pushing out pathogens into the lymph. The flow reentering capillaries prevents fluid buildup in tissues, although a small amount remains to create the lymph.

check your understanding 9.14

- Lymph forms from the small amount of exiting capillary bulk flow that is not reabsorbed by capillaries. The system is important for immune responses and fat transport from the small intestine.

check your understanding 9.15

- Veins return blood to the heart by (1) weak systemic pressure; (2) systemic constriction of vein walls; and (3) extrinsic pumping by skeletal muscles, respiratory pressure changes, and cardiac suction. One-way valves inside the veins ensure that flow does not reverse.

check your understanding 9.16

- Gas transport is essential for minute-to-minute survival of tissues and must increase when body activity increases. Blood pressure must not get too high; otherwise, vessel damage can occur and the heart can be stressed. Likewise, it must not get too low, because flow may be unable to overcome gravity and other resistance factors and because insufficient filtration pressure in the kidneys may result. Pressure is a lower priority since changes may be damaging over the long term, but rarely minute-to-minute.
- A substantial increase in cardiac output (C.O.) is triggered to increase oxygen delivery, and a large increase in skeletal muscle, heart, and skin blood flow accompanied by a decrease in blood flow to the digestive system are achieved by dilation of skeletal muscle, skin and heart arterioles, and constriction of gut arterioles. Changes occur extrinsically by sympathetic nerves and epinephrine, regulated antipathic brain centers via the cardiovascular center of the brainstem. Intrinsic factors discussed earlier also alter blood flow locally.

check your understanding 10.1

- Immune systems defend against invading pathogens (e.g., viruses, bacteria, parasites), worn-out body tissue, and cancer.
- Innate immune systems are “ready-to-go” responses that come into play on exposure to any threatening agent and do not depend on prior exposure to that agent. Acquired systems rely on learned immune responses selectively targeted against a particular foreign material following the first exposure. Learning takes considerably more time to be mounted.
- Recognition of nonself is accomplished by pattern recognition receptors, or PRRs, in plasma membranes. These sensor proteins recognize and bind with common macromolecules on pathogens, such as lipopolysaccharides (LPS) of the bacterial cell wall (Figure 10-1b).
- Immune cells communicate with cytokines (hormone-like secretions) and by direct contact through immunosynapses, both involving receptor proteins.

check your understanding 10.2

- Barrier tissues such as skin and respiratory linings are the first lines of defense; they physically block invaders and may have active defenses such as coughing. Second lines of defense are (1) phagocytotic cells that use PRRs to recognize and consume invaders, often in an inflammatory process; (2) antimicrobial peptides that destroy the invaders directly (e.g., by forming leaky pores); and (3) opsonin proteins that “tag” invaders to aid recognition by phagocytotic cells.
- Some antimicrobial peptides are attracted to particular glycoproteins found on bacterial surfaces, whereas others are attracted to the strong electrical charge that characterizes many bacterial membranes.

check your understanding 10.3

- The major functions of neutrophils, monocytes, NK cells, lymphocytes, mast cells, and dendritic cells are listed on pp. 464–465. Briefly, the first four are in the circulation, and the last two reside in barrier tissues (although dendritic cells become mobile upon activation).

check your understanding 10.4

- Active features of major barrier tissues include the following: (1) in skin, sweat glands and keratinocytes that make antimicrobial peptides, melanocytes to absorb UV, dendritic cells as sensors of acquired immunity; (2) in digestive tracts, enzyme and acidic secretions, symbiotic bacteria, and lymphoid tissues that make antimicrobial peptides; (3) in genitourinary tracts, acidic secretions, sticky mucus, and symbiotic bacteria; and (4) in respiratory tracts, antimicrobial peptides and cilia-driven mucus elevator with coughing, sneezing.
- The major steps of (1) inflammation and (2) complement responses are shown in Figures 10-7 and 10-8, respectively.
- NK cells destroy virus-infected cells and cancer cells by releasing chemicals that directly lyse the membranes of such cells on first exposure to them, by means largely unknown. Interferon transiently interferes with replication of viruses (Figure 10-9) and enhances action of cancer-killing NK and T cells.

check your understanding 10.5

- In antibody-mediated immunity, activated B cells recognizing a specific antigen secrete proteins called antibodies to attach to antigens to target them for destruction as opsonins, whereas in cell-mediated immunity, activated cytotoxic T cells recognize and destroy virus-invaded and cancerous body cells.
- B cells differentiate and mature in the bone marrow in mammals and in the bursa in birds. T cells do so primarily in the thymus.
- Lymphoid tissues (lymph nodes, spleen, thymus, tonsils, adenoids, bone marrow) store, produce, and/or process lymphocytes. Antigens are foreign molecules that induce an immune response against themselves.

check your understanding 10.6

- B cells become plasma either by direct activation by a specific antigen binding to its specific receptor or by activation by a helper T cell with the same receptor. Plasma cells make antibodies. Some activated B cells become dormant memory cells, becoming active if there is a later invasion by the same antigen.
- Antibodies are Y-shaped proteins, each arm having a tip with a binding site for a specific

antigen. They bind to antigen to neutralize their interactions, agglutinate them for mass engulfment by phagocytes, and amplify innate responses. They are genetically diversified into millions of variants from relatively few genetic sequences by gene recombination and mutation as described on pp. 479–480.

- Specific B cells get selected to produce specific antibodies most likely by the clonal selection mechanism, shown in Figure 10-16, in which unactivated B cells remain low in number while ones activated by specific antigens or helper T cells rapidly clone themselves into large numbers.

check your understanding 10.7

- (1) Cytotoxic T cells make destructive proteins such as hole-punching perforins to destroy body cells bearing foreign antigen, such as cells invaded by viruses, cancer cells with mutated proteins, and transplanted cells.
- (2) Helper T cells are integrators that recognize specific antigens and then activate appropriate effector B and cytotoxic T cells.
- (3) Regulatory T cells suppress both innate and acquired immune responses.
- MHCs (self-antigens) are necessary to trigger T-cell function. (1) Antigen-presenting cells (APCs) such as dendritic cells phagocytize invaders and place foreign protein fragments (antigens) on MHC class II in their membranes, which helper T cells with the right receptor can recognize. Compromised body cells may present viral or mutated self proteins on MHC class II to similarly activate the right cytotoxic T cells.
- T cells avoid attacking self-antigens through (1) clonal deletion, (2) clonal anergy, (3) receptor editing, (4) suppression by regulatory T cells, (5) immunological ignorance, and (6) immune privilege, as detailed on pp. 485–486.
- Immune surveillance relies on cytotoxic T cells, macrophages, NK cells, and interferon. The cells recognize newly arisen, potentially cancerous tumor cells and destroy them and/or release interferon before the cancer cells have a chance to multiply and spread.
- In neuro-endocrine-immune interactions, interleukins can activate the hypothalamus to trigger the release of adrenal cortisol, which mobilizes the body's nutrient stores for fuel and amino acids for repair during injury and illness. In turn, cortisol can suppress immune reactions, perhaps to dampen overreactions.

check your understanding 10.8

- Sharks have B and T cells with gene shuffling to make millions of different antibodies and receptors, but unlike other jawed vertebrates, they do not have increased mutation and they have far fewer gene segments to shuffle. However, they have many more gene clusters on many chromosomes, some of which are already joined to code for antibodies. Lampreys have lymphocytes that generate diverse defense proteins from relatively few genes, but those are from a class of PRR genes not closely related to antibody genes.
- In *Drosophila*, evidence of acquired immunity is shown by a sublethal dose of bacteria inducing changes that subsequently protect the flies from an otherwise-lethal dose of the same (but not other) bacteria. This may involve PRR-type genes called Dscam (Down syndrome cell-adhesion molecules), which can generate over 30,000 variants of receptors and antibody-like

proteins from a few genes by alternative splicing.

check your understanding 11.1

- The four possible steps in external respiration are (1) bulk transport of external media—ventilation; (2) exchange by diffusion between the environmental medium and internal body fluids, at a respiratory surface; (3) bulk transport of ECF in a circulatory system; and (4) exchange by diffusion between the ECF and ICF.
- As body size and metabolic rates increase in evolution, diffusion becomes increasingly too slow for O₂ delivery; therefore, better respiratory mechanisms are needed. Animal habitats vary in their O₂ availability of oxygen, from anoxic (“no oxygen”) aquatic mud to sea level air, again necessitating various respiratory adaptations.
- The limits of diffusion are overcome by ventilatory and circulatory bulk transport, which bypass diffusion altogether and also enhance gas diffusion gradients; respiratory organs that have a high permeability *D*, low distance ΔX , high surface area *A*; and special proteins that convert gases between diffusible and nondiffusible forms.
- Tidal ventilation involves breathing in and out of the same opening, so fresh medium is available only about half the time and may mix with stale medium. In contrast, in flow-through ventilation, the medium enters and exits through separate openings, so those problems are avoided.

check your understanding 11.2

- Some nongill methods of gas exchange in aquatic animals include integument (e.g., flatworms), mantle of mollusks, and respiratory tree of sea cucumbers.
- Three examples of gills in nonvertebrate phyla are external folded projections of sea slugs, dense external filaments of some annelids, and the folded external projections of crustacea that are protected inside an exoskeletal chamber.
- Fish create flow-through breathing by the mechanism of Figure 11-6. Countercurrent flow aids gas exchange because blood flow through lamellar capillaries is opposite to the stream of water, such that blood moving through the lamellae continually encounters water whose O₂ content is higher than what is present in the capillary. Thus, there is a positive gas gradient at every point, keeping gases diffusing into the blood.

check your understanding 11.3

- Fully terrestrial pulmonate snails have a lung as a well-perfused mantle tissue in a chamber with a small opening to the outside to reduce water loss. Gases move primarily by diffusion. Spiders may have book lungs, invaginated gill-like stacked lamellae appearing like pages of a book, with air spaces between the folds for gas exchange. Other spiders have internal air tubes called tracheae, as do insects. These start at openings called spiracles and branch to reach most internal cells. Book lungs and tracheae may be ventilated by diffusion or by active pumping.

check your understanding 11.4

- Bimodal breathers have gills and air-breathing systems and include certain fishes and most amphibians. Trimodal breathers such as redfish have gills and two air-

breathing systems such as skin and lungs. These modes evolved in the transition from water to land, particularly in aquatic animals whose habitats regularly dried up.

- To compare respiratory systems of frogs and nonavian reptiles excluding crocodilians, follow Figure 11-9 and the positive-pressure steps of Figure 11-10 for frogs. For nonavian reptiles, refer to the role of negative pressure as described on p. 507.
- Mammalian respiratory systems use tidal flow to alveoli as shown in Figure 11-11 for structure and in Figure 11-14 for respiratory muscles that create negative pressure for inhalation. Crocodilian and avian respiratory systems are partly flow-through systems with air capillaries, as explained for birds in Figures 11-15 and 11-16.

check your understanding 11.5

- To compare atmospheric, intra-alveolar, and intrapleural pressures and their roles, follow Figure 11-19.
- Lungs rebound (recoil) after they are stretched by inhalation due to (1) elastic fibers made of the protein elastin and (2) surface tension, in which water molecules attracted to each tend to draw stretched, wet surfaces (the alveolar linings) into smaller surface areas.
- Pulmonary surfactant is a detergent-like water-lipid-protein secretion from Type II alveolar cells; surfactant lowers the alveolar surface tension because the cohesive force between a water molecule and an adjacent pulmonary surfactant molecule is very low. By doing so, surfactant (1) increases pulmonary compliance, thus reducing the work of inflating the lungs, and (2) reduces the lungs' tendency to recoil so that they do not collapse as readily.

check your understanding 11.6

- The various lung volumes and capacities (TLC, TV, FRC, RV, VC) and their significances are listed on pp. 522–523 and in Figure 11-25.
- Pulmonary ventilation = tidal volume \times respiratory rate; alveolar ventilation, which takes into account the effect of dead space, = (tidal volume – dead-space volume/breath) \times respiratory rate. This is important because dead space does not exchange stale with fresh air, so it detracts from gas exchange. Some examples with actual animal data are listed on p. 526.

check your understanding 11.7

- Dead space is less in fishes compared with mammals due to flow-through mechanism, but dead space in birds is higher due to their long tracheae. Energy costs for air breathers (up to 5% of metabolic energy) are less than that in fishes (up to 50%) due to difficulty of pumping water. O_2 uptake efficiency is much higher in flow-through systems: up to 90% in fishes, 40% in birds, and 25% in mammals.

check your understanding 11.8

- Describe the gas gradients of Figure 11-27 by following the discussion on pp. 528–529. To apply them to fish, use the gas concentrations given on p. 529 for CO_2 and Figure 11-6f for O_2 .

check your understanding 11.9

- Hemoglobins (Hb) use iron to bind O_2 and are usually modest-size proteins within circulatory cells. Mammalian Hb is a tetramer (4 unit proteins together). Hemocyanins (Hc) use copper

and are often gigantic protein complexes in ECFs. Arthropod Hc's are hexamers that may assemble into large groups; annelid and mollusk Hc's are decamers that may assemble into large cylinders.

- O_2 is transported in blood in most vertebrates by iron within hemoglobins, with a small amount as dissolved gas. CO_2 is transported primarily as bicarbonate ion, less as bound to the end of hemoglobin proteins, and even less as dissolved gas.
- The plateau part of the O_2 –Hb dissociation curve is important if arterial P_{O_2} falls below normal: Within the plateau, there is little reduction in the total amount of O_2 transported by the blood until the P_{O_2} falls below 60 mm Hg (human example). In contrast, the steep portion of the curve aids gas delivery: In the range of tissue P_{O_2} (about 0–60 mm Hg), a modest drop in systemic capillary P_{O_2} can result in large amounts of O_2 immediately available to meet the O_2 needs of the actively metabolizing tissues.
- The hemoglobin P_{50} has evolved in vertebrates (Table 11-2) in two ways: (1) P_{50} increases and thus, affinity decreases as size decreases to better offload O_2 for high metabolic rates, and (2) P_{50} decreases and thus, affinity increases as environmental O_2 decreases.
- In the Bohr effect, acidity decreases affinity of Hb for O_2 in all vertebrates, boosting gas release at active tissues generating acid. In the Root effect for some fish Hb's, acidity also reduces the total Hb capacity, even further enhancing gas release to help fill swim bladders (Figure 11-32). In the Haldane effect, deoxy-Hb has a greater affinity for both CO_2 and H^+ than does Hb O_2 , so O_2 release at active tissue facilitates binding and transport of CO_2 and acid.
- The terms *hypoxic hypoxia*, *anemic hypoxia*, *histotoxic hypoxia*, *hypercapnia*, *hypocapnia*, *hyperventilation*, *hypoventilation*, and *apnea* are defined on pp. 542 and 543.

check your understanding 11.10

- Insect spiracles are regulated to be open during high activity but discontinuously at rest, perhaps to reduce water loss or buildup of ROS. Local and neural influences are involved.
- So that ventilation and perfusion are matched, the autonomic nervous system (from brainstem control centers) adjusts simultaneously both blood flow and airflow to suit the animal's current or anticipated respiratory needs. Intrinsic factors such as local decreases in blood and airway O_2 may also work at the same time to increase gas delivery.
- The respiratory brain centers of mammals are in the brainstem. They work by negative feedback using brainstem and arterial chemoreceptors for P_{O_2} , P_{CO_2} , and H^+ and by controlling airway and breathing muscles as effectors to adjust gas delivery. Table 11-3 shows the effects of these variables on the receptors. The centers' responses may be activated in anticipation of activity by higher centers such as the motor cortex to prevent delays in gas delivery.

check your understanding 12.1

- The major functions of excretory systems are maintenance of proper internal levels of inorganic solutes, plasma water volume, and osmotic balance, as well as removal of hormones and nonnutritive and harmful substances resulting from metabolism. The four organ systems that can serve this role are the respiratory

and digestive systems, integuments, and renal organs.

- The evolutionary patterns of ammonia, urea, and uric acid as nitrogenous (N) wastes are shown in Figure 12-1. Use tends to follow water availability, although with exceptions (see p. 561). Ammonia, the most toxic, is the primary N waste of most aquatic animals, since it is inexpensive in terms of ATP and can be diluted easily. Urea has intermediate toxicity and cost and is the major N waste in mammals. Uric acid is the least toxic but most costly, and it dominates in terrestrial insects and most reptiles, including all birds, possibly in part to reduce toxicity in eggs.
- The mechanisms by which transport epithelia move NaCl alone or NaCl and water are shown in Figure 12-3. In brief, Na is transported first, which electrically draws Cl; then in nonwaterproof cells, water follows the NaCl by osmosis.

check your understanding 12.2

- The four major renal processes are (1) filtration, in which solutes are selectively separated from a solution by passing through a boundary; (2) secretion, in which transport epithelia move specific solutes into a renal tubule lumen for excretion; (3) reabsorption, in which transport epithelia move specific solutes (and often water) back into the body from the lumen; and (4) osmoconcentration, in which water is removed from the lumen fluid while leaving solutes behind, producing an excretory fluid more concentrated than body fluids to conserve water.
- Protonephridia use ultrafiltration driven by cilia, with secretion and reabsorption. These are generally blind-end ducts that project into the body cavity. Mesonephridia and metanephridia, in contrast, have ultrafiltration typically driven by fluid pressure; the tubules begin with a filtering capsule or funnel-like opening of some kind that filters the circulatory fluid. This is followed by tubule segments that perform selective secretion and reabsorption (and osmoconcentration in some groups).

check your understanding 12.3

- Initial salt and water movements are created in Malpighian tubules secreting K^+ (via a proton gradient) into tubule lumen (Figure 12-6a), creating osmotic pressure to draw water. The fluid is modified by the tubules and hindgut in osmoconcentrating insects by various mechanisms in different species but typically involves complex tissue anatomy that uses active transport of ions (such as KCl), followed by water osmosis. Uric acid precipitates as crystals as water is removed. A detailed example is described in Figure 12-6b.

check your understanding 12.4

- A vertebrate nephron is the smallest functional unit capable of the kidney's basic functions, as shown in Figure 12-8. The capsule and glomerulus are responsible for ultrafiltration; proximal and distal tubules, for selective reabsorption (of desired molecules) and secretion (of wastes); and the loop of Henle and collecting ducts, for osmoconcentration.
- Marine elasmobranchs' kidneys retain urea and trimethylamine oxide as osmolytes to osmoconform to seawater; their gills, kidneys, and rectal glands excrete excess salts. Marine bony fish are very hypoosmotic; they drink seawater, and their gills remove excess salts. Freshwater bony fish are hyperosmotic; they

do not drink, their gills take up salts, and their kidneys excrete excess water. Amphibian adult kidneys conserve ions and excrete excess water and urea; in some, the bladder is a temporary water reservoir.

- Nonavian reptiles use amphibian-like kidneys, hindguts, and (in marine and desert species) salt glands for excretion and retention. Birds have kidneys with reptile- and mammal-like nephrons, hindguts, and (in marine species) salt glands for excretion and retention. See pp. 574–575 for details.

check your understanding 12.5

- The glomeruli of cortical nephrons lie in the outer layer of the cortex, whereas the glomeruli of juxtamedullary nephrons lie in the inner layer of the cortex. The hairpin loop of cortical nephrons dips only slightly into the outer medulla, whereas the loop of juxtamedullary nephrons plunges through into the inner medulla.
- The three layers of the glomerular membrane are (1) the glomerular capillary wall of a single layer of flattened endothelial cells, perforated by many pores that let out water and small solutes but not most proteins; (2) the basement membrane, an acellular gelatinous layer that provides structural strength and discourages the filtration of small plasma proteins; and (3) the inner layer of Bowman's capsule of podocytes, octopus-like cells that encircle the glomerular tuft to form filtration slits. Mesangial cells encircle glomerular capillaries and can constrict them to reduce filtration. Podocytes also can contract or relax to decrease or increase the number of filtration slits open for filtration control.
- The pressure forces in glomerular filtration are delineated on p. 579 and in Table 12-1. In autoregulation, spontaneous, inadvertent changes in GFR are largely prevented by intrinsic regulatory mechanisms of the kidneys themselves—the myogenic and tubuloglomerular feedback mechanisms described on p. 581. Extrinsic sympathetic regulation can override autoregulation to regulate overall body arterial pressure; see Figure 12-17, for an example.

check your understanding 12.6

- In reabsorption in the proximal tubule, Na^+ is moved by Na^+/K^+ ATPase pumps in the basolateral membrane but crosses the apical membrane passively. H_2O moves passively through aquaporins, drawn by Na^+ and plasma colloidal pressure. Glucose is transferred by secondary active transport utilizing a specialized cotransport carrier that simultaneously transfers both Na^+ (down its gradient) and glucose (against its gradient).
- The RAA system stimulates Na^+ reabsorption in distal tubules and collecting ducts, elevates blood pressure, and stimulates thirst and salt hunger (Figure 12-21). It is opposed by the ANP/BNP system, which inhibits Na^+ reabsorption and lowers blood pressure (Figure 12-22).

check your understanding 12.7

- K^+ secretion is regulated by aldosterone in the distal tubules and collecting ducts; it is coupled to Na^+ reabsorption by the basolateral Na^+/K^+ pump (Figure 12-23). That moves Na^+ into the lateral space while also transporting K^+ into the tubular cells. Regulation is important because K^+ plays a key role in the membrane potential and electrical activity of excitable tissues.
- Plasma clearance rate varies as follows: (1) It equals the GFR if a substance is freely filtered but not reabsorbed or secreted. (2) If a sub-

stance is filtered and reabsorbed but not secreted, its plasma clearance rate is always less than the GFR. (3) If a substance is filtered and secreted but not reabsorbed, its plasma clearance rate is always greater than the GFR.

check your understanding 12.8

- How countercurrent multiplication in the loop of Henle results in the osmotic gradient of the kidney medulla is described in detail in Figure 12-26. How the vasa recta prevents its dissipation is shown in Figure 12-29.
- How vasopressin regulation works in dehydration and overhydration is delineated in Figure 12-28.
- How urea recycles in the kidneys is described in Figure 12-30. This is important for prevention of urea-induced water loss associated with antidiuresis. It may also aid in osmoconcentration as discussed in the box on p. 603.
- Weak osmoconcentrators such as the beaver have primarily cortical nephrons, which produce fairly dilute urines only. Desert rodents usually have all juxtamedullary nephrons with very long loops within an elongated medulla. This anatomy, coupled with a high metabolic rate, provides a relatively long length over which the countercurrent effect can operate.

check your understanding 12.9

- How bladder urine fills and then empties, including external regulatory features, is summarized in Figure 12-33.

check your understanding 12.10

- General causes of renal problems include (1) cellular damage, for example, resulting from excessive glucose in diabetes; (2) toxic agents, such as long-term exposure to high doses of aspirin; (3) inappropriate immune responses, such as glomerulonephritis; (4) obstruction of urine flow because of kidney stones, for example; and (5) an insufficient renal blood supply that leads to inadequate filtration pressure, due for example to heart failure.

check your understanding 13.1

- The balance concept states that, if the quantity of a substance is to remain stable within the body, its input must be balanced by an equal output by means of excretion or metabolic consumption (Figure 13-1).
- The distribution of animal body H_2O in various fluid compartments is shown in Figure 13-2; that for a human is shown in Table 13-1.
- The ionic composition of plasma and interstitial fluid are similar (NaCl dominating), but intracellular fluid differs considerably, in particular due to K^+ dominating (Figure 13-3).

check your understanding 13.2

- The types of osmotic challenges faced by animals are (1) salinity of aquatic environments, (2) evaporation of body water into air, (3) ingestion and excretion, (4) freezing, and (5) pathologies such as diabetes.
- Osmoconformers have body fluids and cells generally equal in osmotic pressure to the environment, with adjustments to ECF and ICF made using small molecules called osmolytes. Osmoregulators have internal osmotic pressures homeostatically regulated and often very different from that of the external environment.
- The major types of organic osmolytes are small carbohydrates, free amino acids, methylamines, methylsulfonium solutes, and urea. In marine nonvertebrates, free amino acids such as glycine

and taurine are used as ICF osmolytes because they are compatible with cellular functions (unlike salts). In chondrichthyan fishes, urea (protein destabilizer) and methylamines (protein stabilizer) are used in ICFs to counteract each other's effects on cellular functions.

- Stenohaline animals such as Cnidaria have a limited tolerance to changes in salinity; they may die if exposed to significant changes in external salinity because their cells swell or shrink from osmosis. Euryhaline animals such as many intertidal crustaceans are relatively tolerant of changes in external salinity and can survive substantial dilution or concentration of their ECFs.

check your understanding 13.3

- The osmotic problems and solutions for marine, freshwater, and terrestrial vertebrates are summarized in Figures 13-9, 13-11, and 13-12. A deep-sea fish faces high hydrostatic pressure and has higher levels of trimethylamine oxide than shallow fish, possibly to stabilize proteins against pressure. A salmon alternates between hypo-osmotic and hyperosmotic conditions; they restructure their gills to reverse direction of salt transport.

check your understanding 13.4

- ECF osmolality must be closely regulated to prevent swelling or shrinking of the cells. ECF volume must be closely regulated to help maintain blood pressure.
- The causes of ECF hypertonicity, which can cause cells to shrink, are insufficient water intake, excessive water loss, consumption of hypersaline water, and alcohol consumption. The causes of ECF hypotonicity, which can cause cells to swell, are intake of more water than solutes and retention of excess water.
- The sources of input and output in daily H_2O balance in two mammals are shown in Table 13-3. Sources for daily salt balance for a human are shown in Table 13-4. Only oral intake and urine output can be regulated for water-solute balance of the body.
- The roles of vasopressin and thirst in fluid balance are shown in Figure 13-13. The role of the RAA hormone system, the major regulator of ECF volume and blood pressure, is to stimulate Na^+ retention, thirst, salt hunger, and vasoconstriction.

check your understanding 13.5

- Acids are hydrogen-containing substances that dissociate when in solution to liberate free H^+ and anions; bases, in contrast, have a strong affinity for H^+ . The term pH refers to the negative log of the hydrogen ion concentration (e.g., $\text{pH } 7$ indicates $[\text{H}^+]$ is 10^{-7} M).
- pH is important to animals because changes alter neuromuscular excitability, enzymatic activity, and K^+ levels. The sources of excess H^+ are carbonic acid from CO_2 , inorganic acids from nutrient breakdown, and organic acids such as lactate from metabolism.

check your understanding 13.6

- A buffer is a mixture in a solution of two chemical compounds that minimize pH changes from added acid or base: One substance reversibly yields free H^+ as the $[\text{H}^+]$ starts to fall, and the other reversibly binds with free H^+ when $[\text{H}^+]$ starts to rise. The Henderson-Hasselbalch equation for the bicarbonate system is $\text{pH} = \text{pK} + \log [\text{HCO}_3^-]/[\text{CO}_2]$.

- Animal buffers are (1) $\text{CO}_2\text{--HCO}_3^-$, primary ECF buffer for noncarbonic acids; (2) peptides and proteins, primary ICF buffer; (3) hemoglobin, primary erythrocyte buffer for carbonic acid changes; and (4) phosphate system, secondary ICF and primary urinary buffer.

check your understanding 13.7

- The role of lungs in acid–base balance is to alter ventilation to control exchange of H^+ –generating CO_2 in gills and lungs or to alter transport of H^+ and HCO_3^- in gills.
- In the proximal tubule, H^+ is secreted by both H^+ ATPase pumps and by Na^+/H^+ antiporters. The means by which H^+ and HCO_3^- are handled in the Type A and Type B intercalated cells of the distal and collecting tubule are summarized in Figure 13-20.
- Kidneys of most mammals cannot acidify the urine beyond a gradient-limited urinary pH of 4.5. Ammonia production in proximal tubule cells helps this because the NH_3 binds a proton. Since membranes are not very permeable to NH_4^+ , these ions remain in the tubular fluid and are lost in the urine, each one taking an H^+ with it. Thus, NH_3 secretion allows large amounts of H^+ to be secreted into the urine before the pH falls to the limit of 4.5.

check your understanding 13.8

- The six categories of acid–base imbalances are respiratory, environmental, and metabolic acidosis, plus the same three for alkalosis.
- Uremic acidosis is very serious because it results from severe renal failure, so even normal daily pH imbalances cannot be corrected.

check your understanding 14.1

- The different modes of animal feeding include filter or suspension feeders, detritivores or deposit feeders, fluid feeders, carnivores, herbivores, omnivores, and symbiotic autotroph-bearing animals. See also p. 655.

check your understanding 14.2

- The four basic digestive processes include motility, secretion, digestion, and absorption. *Motility* refers to the muscular contractions within the gut tube that mix and move forward the contents of the digestive tract. Digestive juices are *secreted* into the digestive tract lumen by exocrine glands located along the route, each with its own specific secretory product(s). *Digestion* is the process whereby the structurally complex foodstuffs of the diet are broken down into smaller, absorbable units by enzymes produced within the digestive system. *Absorption* refers to the transfer of nutrients from the digestive tract lumen into the blood or hemolymph or body cavity.
- Carbohydrates can be digested into monosaccharides such as glucose, fructose, and galactose, which are the absorbable units. Proteins—the second category of foodstuffs—are degraded primarily into their constituent amino acids as well as a few polypeptides, both of which are the primary absorbable units for digested protein. Fats are the third category of foodstuffs; the end products of fat digestion are monoglycerides and free fatty acids, which are the absorbable units of fat. Glycogen represents the polysaccharide storage form of glucose in animals.
- The gut tube in most animals can be divided into three specific regions: the foregut, midgut, and hindgut. See also Figure 14-1 and the discussion on p. 655.

check your understanding 14.3

- Mastication* is the motility (chewing) of the mouth that involves slicing, tearing, grinding, and mixing ingested foods by specialized mouthparts such as teeth. The purposes of mastication are (1) to grind and break food up into smaller pieces to facilitate swallowing and increase the food surface area on which salivary enzymes will act, (2) to mix food with saliva, and (3) to stimulate the taste buds, which reflexly increases salivary, gastric, pancreatic, and bile secretion to prepare for the arrival of food in the lower digestive tract.
- The functions of saliva include the moistening of food items, digestion of starch through the action of salivary amylase, defense against some bacteria, solubilization of molecules that stimulate the taste bud, and the neutralization of acids. In some species, saliva can be used as a means of temperature control, whereas in others, saliva can be used as venom to immobilize prey. Other uses may include anticoagulation, production of silk, and release of pheromones.

check your understanding 14.4

- See Figure 14-8 and the discussion on p. 667.
- The esophagus serves as a passageway for the rapid transit of a bolus of food from the mouth to the stomach (or the reverse in ruminants). The crop mainly serves a storage function that is particularly important in fluid-feeding insects, which have relatively large crops for storing blood or nectar.

check your understanding 14.5

- See Table 14-4 and the discussion on pp. 678–679.
- The enzyme pepsin is synthesized in the chief cells lining the stomach and is maintained in the inactive form of pepsinogen until it reaches the gastric lumen, where it is activated by HCl.
- See Figure 14-12 and the discussion on pp. 676–677.
- The proventriculus serves as the “glandular stomach,” whereas the separate gizzard serves as the “muscular stomach” to macerate and grind the ingesta.

check your understanding 14.6

- See the discussion in Section 14.6 for the contributions of the pancreas, liver, gallbladder, and fat body to digestion. Nondigestive functions of the liver include detoxification or degradation of body wastes and hormones, as well as drugs and other foreign compounds; synthesis of plasma proteins; activation of vitamin D; removal of bacteria and worn-out red blood cells; secretion of the hormones thrombopoietin, hepcidin, and insulin-like growth factor-I; synthesis of ascorbic acid in some species; and buoyancy in sharks.
- Bile salts aid fat digestion through their detergent action and facilitate fat absorption through their participation in the formation of micelles.

check your understanding 14.7

- See Figure 14-28 and the discussion on pp. 701–703.
- See the discussion on how the three major categories of nutrients (carbohydrates, proteins, and fats) are digested on pp. 694–699. See also Table 14-5 and Figures 14-25, 14-26, and 14-27.

check your understanding 14.8

- By positioning the fermentation chamber after the stomach (postgastric fermentation), the host animal loses the opportunity to exploit the high-quality microbially synthesized protein produced in the rumen (pregastric fermentation). Further, the digestive capabilities of the stomach and small intestine cannot contribute to the digestion of microbial products.
- The large intestine serves as a temporary storage site for excreta, functions in electrolyte and fluid balance, and harbors microbes for fermentation and production of volatile fatty acids.
- In carnivores, the major function of the colon is the absorption of electrolytes, water, and other materials that escaped absorption in the small intestine. In omnivores, and particularly in herbivores that ingest considerable amounts of complex polysaccharides, the structure of the large intestine tends to be voluminous, providing a site for microbial digestion. The environment within the colon/cecum of postgastric fermenters must also be able to support a substantial microbe population in a buffered environment. In many vertebrates, specialized transport mechanisms are not present in the colonic mucosa for absorption of glucose or amino acids, as there are in the small intestine. A notable exception is the colon of birds, where both glucose and amino acids are absorbed by secondary active transport.

check your understanding 14.9

- Ruminant species have evolved a stomach to house a population of microbes able to break down cellulose and other complex polysaccharides into end products of fermentation (VFAs), which contribute to the nutritional requirements of the host animal. VFAs provide energy by entering the TCA cycle as acetyl CoA, with the excess energy stored as body fat in the tissues. These microorganisms can also protect the host animal from some toxins that are ingested in the diet. Nonruminants are unable to exploit this food source, which restricts their habitat range.
- VFAs produced by the rumen microbes are passively absorbed through the rumen wall. Ammonia as well as amino acids also are readily absorbed through the lining of the rumen-reticulum and omasum.

check your understanding 14.10

- See Section 14.10 and the discussion on pp. 711–712.

check your understanding 15.1

- The First Law of Thermodynamics is that energy can be neither created nor destroyed. The Second Law is that the entropy (a measure of disorder or randomness) of a system plus its surroundings increases over time as the energy content degrades to unusable heat. The consequence is that life must continuously extract energy from the environment to maintain itself, whereas the rest of the universe degrades even faster than it would on its own.
- External work is the energy expended when skeletal muscles contract to move external objects or to move the body through the environment. Internal work constitutes all other forms of energy expenditure: skeletal muscle activity used for nonexternal purposes (e.g., breathing); pumping of blood; active transport across plasma membranes; and synthetic reactions

for maintenance, repair, and growth. Heat is the primary output because entropy increases for all processes except net growth (order).

check your understanding 15.2

- **Metabolic rate (MR)** is energy expenditure per unit time. *Standard* and *basal MR* (SMR, BMR) are the minimal amounts of energy needed per unit time to sustain waking (non-sleep) life under optimal conditions. BMR is for endotherms in thermal neutral zones; SMR is for ectotherms at a defined natural temperature, such as that the animal prefers. Diet-induced thermogenesis is an increase in MR above the SMR or BMR due to food processing. Indirect calorimetry by respirometry measures an animal's O_2 uptake per unit time, then makes an estimate of MR using physiological fuel values for a typical diet.
- Some physiological features depend on the organism size, because of scaled factors, such as surface area (increases with radius squared) and volume (increases with radius cubed). Although larger animals consume more energy than smaller animals, they have lower metabolic rates per unit mass than smaller ones. BMR scaling with body mass, with an exponent of 0.75, has been attributed to heat retention because heat is lost via surface area but produced by volume. Problems with this and alternative hypotheses are discussed in the box on p. 722.
- The three states of energy balance are (1) neutral (net food intake equals energy output), (2) positive (net food intake exceeds output, so body mass increases), and (3) negative (net food intake is less than output, so body mass decreases).
- Aerobic scope is the ratio of MR measured by O_2 consumption at its highest level to the BMR or SMR; it is larger in larger animals and may be limited by O_2 delivery. With increasing speed, running MR increases linearly, swimming MR exponentially, and flying MR in varying ways—for example, gliding saves energy after costly take-off. Hopping MR may not increase at all with speed.

check your understanding 15.3

- The arcuate nucleus in the hypothalamus has a pair of appetite centers and another pair of satiety centers. These monitor various signals (see next answer) and adjust eating behavior and energy expenditures to keep body energy levels at a set point.
- The roles in energy balance (along with sources) for leptin, insulin, ghrelin, PYY_{3-36} , and cholecystokinin (CCK) are given in Table 15-2.
- The effector that regulates energy input is primarily eating behavior. Effector actions (which may be increased or decreased) for regulating energy expenditures are BMR, gametogenesis, DIT resulting in part from brown adipose tissue, and exercise and nonexercise activity thermogenesis.
- The evolutionary differences in body-mass “set points” have two extremes. Lean animals evolve where food is plentiful much of the year; they are agile but can starve easily. Heavy animals evolve in “feast or famine” habitats; they readily store energy for famine times but are less agile.

check your understanding 15.4

- The basic effects of temperature on biological systems (Figure 15-7) are (1) increasing the rate of reactions with temperature rise due to kinetic

energy, and (2) at relatively high temperatures, causing macromolecules to begin denaturing.

- In homeoviscous adaptation, cold-adapted membranes have more unsaturated fatty acids to give them proper fluidity in the cold, but they are too fluid as temperature rises. Warm-adapted membranes have more saturated lipids to resist that problem, but they are too stiff to work in the cold. Similarly, cold-adapted proteins have fewer stabilizing bonds between folds to make them properly flexible in the cold, but they are too flexible as temperature rises. Warm-adapted proteins have more stabilizing bonds to resist that problem, but they are too stiff to work in the cold.
- *Endothermy*, *ectothermy*, *poikilothermy*, and *homeothermy* are defined on p. 733.
- Figure 15-12 summarizes heat transfers by four methods. Briefly, (1) radiation is light energy, particularly infrared, which transfers heat; (2) conduction is transfer of heat between objects of differing temperatures that are in direct contact with each other; (3) convection refers to the transfer of heat energy by currents of air or water; and (4) evaporation involves the heat required to transform water from a liquid to a gaseous state (and can be absorbed from the skin).
- Body heat balance depends on the sum of inputs and outputs (Figure 15-11). Animals may (1) gain external heat from the sun, warm rocks, etc.; (2) retain internal heat with insulation, behavior, reduced skin blood flow, etc.; (3) generate more heat with heat-generating tissues; and (4) lose excess heat by behavior, increased skin blood flow, evaporation (sweating, panting), etc.

check your understanding 15.5

- Pure poikilotherms' body temperatures follow the environment, and they must avoid extremes, enter dormant states, and/or compensate biochemically (see next answer). Ectothermic regulation involves regulation (mostly by behavior) of “gain, retain, and lose” mechanisms noted on pp. 736–737.
- Biochemical adjustments that account for metabolic compensation in the face of changing body temperatures include (1) increased enzyme concentrations in the cold; (2) homeoviscous membrane adaptation; (3) regulation of internal pH to a higher level— $[H^+]$ lower—in the cold to compensate for tighter H^+ binding by proteins; and (4) isoform regulation (activating different genes for similar proteins at different temperatures).
- Freeze tolerance involves actual freezing of some body fluids, but generally only ECF, as in the peeper frog whose fluids are flooded with glucose as an antifreeze, enough to keep ICFs unfrozen. Freeze avoidance involves compatible antifreeze carbohydrates to prevent all internal freezing without disrupting macromolecules, antifreeze proteins to block ice-crystal growth, supercooling, and cryoprotective dehydration. An example is the Arctic springtail, which dehydrates while building up the sugar trehalose.
- Heat shock proteins (HSPs) are small, thermally stable, hydrophobic proteins that bind to larger, unfolded proteins and assist their folding into functional conformations. HSP genes are induced by sudden rises in cell temperatures.

check your understanding 15.6

- To achieve homeothermy, birds and mammals may (1) gain external heat through behavior, dark skin, etc.; (2) retain internal heat by vaso-

constriction, insulation, behavior, larger body size, countercurrent exchangers; (3) generate more heat with high BMR, muscles shivering, and brown adipose with uncoupling proteins; and (4) lose excess heat by reducing insulation, vasodilation, sweating and panting, exchangers, behavior, light-colored skin, etc.

- The hypothalamus maintains homeothermy using negative feedback (Figure 15-20). It elevates temperature to create a fever during infections when leukocytes release a pyrogen. There is some evidence that fever inhibits growth of pathogens and augments inflammation.

check your understanding 15.7

- In regional heterothermy, a tuna and a bee heat only parts of their bodies. In tunas, red swimming muscles constantly produce considerable heat, whereas in bees, flight muscles do so during flight. Both retain heat with countercurrent exchanges between them and sites of heat loss (gills in tunas, the abdomen in bees).
- Hibernation and torpor involve endotherms becoming nearly poikilothermic in winter and daily, respectively. Most still thermoregulate, but at much lower body temperatures. This saves energy, especially in small endotherms with their high surface-area-to-volume ratios.

check your understanding 15.8

- Findings that show effects of recent global warming on animal physiology include (1) theoretical calculations showing that effects on metabolic rates of ectotherms will be worst in the tropics; (2) corals bleaching and dying from unprecedented warming of seawater; (3) dying out of populations of Mexican lizards in areas with increasing springtime temperatures; (4) temperate species of limpets and butterflies moving northwards; and (5) earlier breeding in springtime in grapevine moths and red squirrels in correlation with warmer springs.

check your understanding 16.1

- *Oviparous* refers to a reproductive strategy in which the parents release eggs from which the young hatch after expulsion from the body; *ovoviviparous* refers to the strategy of producing eggs (not necessarily with shells) that hatch within the body of the parent; and *viviparous* is the production of living young within the body.
- Strategies used to ensure that both sexes are ready to breed at the same time include photoperiod (day length), temperature, presence of the male, and availability of a particular food source.

check your understanding 16.2

- See Figures 16-3 and 16-4 and the discussion on pp. 762–764.
- Genotypic sex, which depends on the combination of sex chromosomes at the time of conception, determines gonadal sex, that is, whether testes or ovaries develop. The presence or absence of a Y chromosome determines gonadal differentiation in mammals. Phenotypic sex, the apparent anatomic sex of an individual, depends on the genotypically determined gonadal sex.
- Two primitive duct systems—the mesonephric ducts, or Wolffian ducts, and the paramesonephric, or Müllerian ducts—develop in all mammalian embryos. In males, the reproductive tract develops from the Wolffian ducts and

the Müllerian ducts degenerate, whereas in females, the Müllerian ducts differentiate into the reproductive tract and the Wolffian ducts regress (Figure 16-6).

check your understanding 16.3

- Spermatogenesis encompasses three major stages: mitotic proliferation (spermatocytogenesis), meiosis, and packaging (spermiogenesis). See also Figure 16-9 and the discussion on pp. 773–775.
- LH and FSH act on separate components of the testes (Figure 16-11). LH acts on the Leydig (interstitial) cells and regulates testosterone secretion. FSH acts on the Sertoli cells to enhance spermatogenesis. Secretion of both LH and FSH from the anterior pituitary is stimulated, in turn, by a single hypothalamic hormone, GnRH, or inhibited by a GnIH.
- Testosterone is synthesized in the Leydig cells of the testes. Its concentration is much higher in the testes than in the blood, because a substantial portion is retained in the intratubular fluid, complexed with androgen-binding protein secreted by the Sertoli cells. Only this high concentration of testicular testosterone is adequate to sustain sperm production. In some species, evolution of secondary sexual characteristics, the many external characteristics of vertebrates that are not directly involved in reproduction itself, are dependent on secretion of the sex steroid.

check your understanding 16.4

- Arterioles are typically supplied by sympathetic nerves, with increased sympathetic activity producing vasoconstriction and decreased sympathetic activity resulting in vasodilation. Concurrent parasympathetic stimulation and sympathetic inhibition of penile arterioles accomplish vasodilation more rapidly and in greater magnitude than is possible in other arterioles supplied only by sympathetic nerves.
- Both sexes experience the same four phases of the sexual cycle—excitement, plateau, orgasm, and resolution. The excitement phase can be initiated by either physical or psychological stimuli. During the plateau phase, the changes initiated during the excitement phase intensify (such as increased heart rate, blood pressure, respiratory rate, and muscle tension). If erotic stimulation continues, the sexual response culminates in orgasm as sympathetic impulses trigger rhythmic contractions of the pelvic musculature. During the resolution phase following orgasm, sympathetic vasoconstrictor impulses slow the inflow of blood into the penis, causing the erection to subside. Oxytocin appears to play roles in mating-related behaviors in both sexes. It is released during arousal and orgasm and may stimulate orgasmic muscle contractions in both sexes.

check your understanding 16.5

- See Figures 16-9 and 16-15 and the discussion on pp. 786–788.
- After the onset of puberty, the ovary alternates between two phases: the follicular phase, which is dominated by the presence of maturing follicles, and the luteal phase, which is characterized by the presence of the corpus luteum. See also Figure 16-16 and the discussion on pp. 788–790.
- See Figure 16-17 and the discussion on pp. 791 and 794. Key similarities include the hormonal pathway of reproduction. In birds and mammals, the pathway revolves around the hypothalamic–pituitary–gonadal axis. The hypothalamus is activated by specific environmental cues, including day length as a trigger for onset of gonadal development. One of the most obvious differences in follicular development between birds and mammals is that in the bird's ovary the follicles do not mature synchronously. Unlike the situation in female mammals, ovulation of the largest follicle in birds is preceded by an increase in the concentrations of progesterone and LH. LH, in turn, stimulates the secretion of more progesterone from the granulosa of the mature preovulatory follicle. Thus, in birds, it is the granulosa that produce progesterone, most of which diffuses to the thecal cells, where it is converted to estrogen.

check your understanding 16.6

- At ovulation the ovum is released into the abdominal cavity, but the oviduct picks it up quickly. The fimbriae (Figure 16-4c) contract in a sweeping motion to guide the released ovum into the oviduct. Sperm migrate up the cervical canal under their own power. Once the sperm have entered the uterus, contractions of the myometrium disperse the sperm throughout the uterine cavity. When sperm reach the uterotubal junction, they are moved up the oviduct toward the site of fertilization with the help of smooth muscle contractions and cilia that move in the direction of the ampullary–isthmic junction. See also Figure 16-21 and the discussion on p. 799.
- See Figures 16-22 and 16-23 and the discussion on p. 801. When the blastocyst is ready to implant, its surface becomes sticky. By this time, the endometrium is ready to accept the early embryo, and it too has become more adhesive through increased formation of cell adhesion molecules that help attach the blastocyst when it first contacts the uterine lining. By the time the embryo has attached to the uterine luminal epithelium, the trophoblastic layer is two cell layers thick and is called the chorion. As the chorion continues to expand, it fuses with a structure called the allantois (an outgrowth of the hindgut), forming the vascularized chorioallantoic membrane. Placentas can be classified according to their

degree of invasiveness and the anatomy of those regions of greatest maternal–fetal interaction (Figure 16-24).

- To sustain the growing embryo for the duration of its intrauterine life, the placenta, a specialized organ of exchange between the maternal and fetal blood, is rapidly developed (Figure 16-24). The most important hormones secreted by the placenta include chorionic gonadotropin, estrogen, and progesterone (Table 16-5).
- Chorionic gonadotropin is a polypeptide hormone that prolongs the life span of the corpus luteum and its secretion of progesterone until the placenta takes over.

check your understanding 16.7

- Corticotropin-releasing hormone (CRH) secreted by the fetal portion of the placenta into both the maternal and fetal circulation drives the synthesis of placental estrogen, ultimately dictating the timing of the onset of labor. Thus, pregnancy duration and delivery timing are determined largely by the placenta's rate of CRH production. In the immediate days before the onset of parturition, soaring levels of estrogens bring about changes in the uterus and cervix to prepare them for labor and delivery (Figure 16-25). First, high levels of estrogens promote the synthesis of connexons within the uterine smooth muscle cells. The newly manufactured connexons are inserted in the myometrial plasma membranes to form gap junctions so that the uterine smooth muscle cells become able to contract as a coordinated unit. Second, high levels of estrogens prior to parturition cause a progressive increase in the concentration of myometrial receptors for oxytocin. Together, these myometrial changes bring about the increased uterine responsiveness to oxytocin that ultimately initiates labor. A powerful uterine muscle stimulant, oxytocin plays the key role in the progression of labor. Labor begins when the oxytocin receptor concentration reaches a critical threshold that permits the onset of strong, coordinated contractions in response to ordinary concentrations of circulating oxytocin.
- Hormonal factors that play a role in lactation include the high concentration of estrogens, which promote extensive duct development in the mammary gland, as well as the high level of progesterone that stimulates abundant alveolar-lobular formation. Elevated concentrations of prolactin and chorionic somatomammotropin contribute to mammary gland development by inducing the synthesis of enzymes needed for milk production. Once milk production begins after delivery, two hormones maintain lactation: (1) prolactin, which acts on the alveolar epithelium to promote secretion of milk, and (2) oxytocin, which produces milk ejection.

Glossary

A band One of the dark bands that alternate with light (I) bands to create a striated appearance in skeletal or cardiac muscle fibers when these fibers are viewed with a light microscope

abomasum The fourth compartment of the ruminant stomach, which has functions similar to the glandular stomach of nonruminants

absorptive state The metabolic state following a meal when nutrients are being absorbed and stored; fed state

accessory digestive organs Exocrine organs outside the wall of the digestive tract that empty their secretions through ducts into the digestive tract lumen

accessory sex glands Glands that empty their secretions into the reproductive tract

acclimation A laboratory phenomenon in which the chronic response of an animal to a change in environment is measured; normally the old and new environments differ in one or two highly specific ways

acclimatization The (usually slow) process of changing physiological processes to function more optimally under new conditions

accommodation In the eye, the ability to adjust the strength of the lens so that both near and far sources can be focused on the retina

acetylcholine (ACh) (as'-uh-teal-KŌ-lēn) The neurotransmitter released from all autonomic preganglionic fibers, parasympathetic postganglionic fibers, and motor neurons

acetylcholinesterase (AChE) (as'uh-teal-kō-luh-NES-tuh-rās) An enzyme present in the motor end-plate membrane of a skeletal muscle fiber that inactivates acetylcholine

ACh See *acetylcholine*

achalasia A condition that occurs commonly in dogs (and in humans) in which the lower esophageal sphincter fails to relax during swallowing but instead contracts more vigorously

AChE See *acetylcholinesterase*

acid A hydrogen-containing substance that on dissociation yields a free hydrogen ion

acidosis (as-i-DŌ-sus) Blood pH below the normal range (<7.35 in most mammals)

acini (ĀS-i-nī) The secretory component of saclike exocrine glands, such as enzyme-producing pancreatic glands or milk-producing mammary glands

acquired immune responses Responses (also called *adaptive*) that are selectively targeted against particular foreign material to which the body has previously been exposed; see also *antibody-mediated immunity* and *cell-mediated immunity*

acrorhagia Special stinging “battle” tentacles in some Anthozoan Cnidarians (anemones, corals)

ACTH See *adrenocorticotrophic hormone*

actin The contractile protein that forms the backbone of the thin filaments in muscle fibers; also contributes to the motility of other kinds of cells

active expiration Emptying of the lungs more completely than when at rest by contracting the expiratory muscles; also called *forced expiration*

active reabsorption The condition when any step in the transepithelial transport of a substance requires energy expenditure

active transport Active carrier-mediated transport involving transport of a substance against its concentration gradient across the plasma membrane

acuity Discriminative ability; the ability to discern two different points of stimulation

adaptation (1) A reduction in receptor potential despite sustained stimulation of the same magnitude; (2) any feature of an organism that enhances evolutionary fitness

adenohypophysis See *anterior pituitary gland*

adenosine diphosphate (ADP) (uh-DEN-uh-sēn) The two phosphate products formed from the splitting of ATP to yield energy for the cell's use

adenosine triphosphate (ATP) The common energy “currency” of all life, which consists of an adenosine with three phosphate groups attached; splitting of the high-energy, terminal phosphate bond provides energy to power cell activities

adenylyl cyclase (ah-DEN-il-il sī-klās) The membrane-bound enzyme that is activated by a G-protein intermediary in response to binding of an extracellular messenger with a surface membrane receptor and that, in turn, activates cyclic AMP, an intracellular second messenger

adequate stimulus The main type of stimulus to which a particular receptor (sensory cell) is specialized to respond

ADH See *vasopressin*

adiponectin A hormone produced by adipose tissue in nonobese mammals; may serve in regulating energy balance

adipose tissue The tissue specialized for storage of triglyceride fat; found under the skin in the hypodermis

ADP See *adenosine diphosphate*

adrenal cortex (uh-DRE-nul) The outer portion of the vertebrate adrenal gland; secretes three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex hormones

adrenal medulla (muh-DUL-uh) The inner portion of the vertebrate adrenal gland; an endocrine gland that is a modified sympathetic ganglion that secretes the hormones epinephrine and norepinephrine into the blood in response to sympathetic stimulation

adrenergic fibers (ad'-ruh-NUR-jik) Nerve fibers that release norepinephrine as their neurotransmitter

adrenocorticotrophic hormone (ACTH) (ad-rē'-nō-kor'-tuh-kō-TRŌP-ik) An anterior pituitary hormone that stimulates cortisol secretion by the adrenal cortex and promotes growth of the adrenal cortex

aerobes Organisms that rely on oxygen-based metabolism

aerobic Referring to a condition in which oxygen is available; **aerobic metabolism** is the process in which ATP formation is accomplished through oxidative phosphorylation

afferent arteriole (AF-er-ent ar-TIR-ē-ōl) The vessel that carries blood into the glomerulus of the mammalian kidney's nephron

afferent division The portion of the peripheral nervous system that carries information from the periphery to the central nervous system; made of **afferent neurons**, which have sensory receptors at their peripheral endings

after hyperpolarization (hi'-pur-pō-luh-ruh-ZA-shun) A slight, transient hyperpolarization that sometimes occurs at the end of an action potential

agonist A nonnative signal molecule (e.g., a drug or toxin) that mimics the effects of a native signal molecule (for opposing term, see *antagonist*)

agranulocytes (ā-GRAN-yuh-lō-sīs') Leukocytes that do not contain granules, including lymphocytes and monocytes

air capillary Small airways that branch off from the principal respiratory tubules, the parabronchi, within the avian lung; these are the site of gas exchange between the air and blood

air sac A thin-walled, air-filled component of the avian respiratory system with little musculature and few blood vessels

albumin (al-BEW-min) The smallest and most abundant of the plasma proteins; binds and transports many water-insoluble substances in the blood; contributes extensively to plasma-colloid osmotic pressure

aldosterone (al-dō-steer-OWN or al-DOS-tuh-rōn) The adrenocortical hormone that stimulates Na⁺ reabsorption by the distal and collecting tubules of the kidney's nephron during urine formation

alkalosis (al'-kuh-LŌ-sus) Blood pH above the normal range (>7.45 in most mammals)

all-or-none law An excitable membrane either responds to a stimulus with a maximal action potential that spreads nondecrementally throughout the membrane or does not respond with an action potential at all

allosteric (“other site”) A noncatalytic binding site on an enzyme that binds regulatory molecules

alpha (α) cells The endocrine pancreatic islet cells that secrete the hormone glucagon

alpha (α) motor neuron A motor neuron that innervates ordinary skeletal muscle fibers

altricial Referring to young that are absolutely dependent on continued parental care

alveolar surface tension (al-VĒ-ō-lur) The surface tension of the fluid lining the alveoli in the lungs; see *surface tension*

alveolar ventilation Volume of air exchanged between the atmosphere and alveoli per minute; equals (tidal volume – dead-space volume) × respiratory rate

alveoli (al-VĒ-ō-li) The air sacs across which O₂ and CO₂ are exchanged between the blood and air in mammalian (and some other vertebrate) lungs

amines (ah-means) Hormones derived from amino acids, especially tyrosine; include thyroid hormone and catecholamines

ammonotelic Having ammonia as a primary nitrogenous waste product

amoebocyte Wandering immune cell in nonvertebrates

amoeboid movement (uh-MĒ-boid) “Crawling” movement of white blood cells, similar to the means by which amoebas move

ampullary electroreceptors Found in almost all nonteleost fishes and in some teleosts as well as in several amphibian species; respond to low-frequency electric signals that are typical of electrical output from animal nerves and hearts

amygdala Structure of mammalian forebrain (limbic system) located on the interior underside of the temporal lobe; believed to be the homologue of the reptilian and avian paleostriatum; appears to store memories of highly emotional events

anabolism (ah-NAB-ō-li-zum) The buildup, or synthesis, of larger organic molecules from the small organic molecular subunits

anaerobes Organisms that can survive on metabolism that does not require oxygen

anaerobic (an'-uh-RŌ-bik) Referring to a condition in which oxygen is not present; in **anaerobic metabolism**, ATP formation is accomplished by anaerobic glycolysis, usually only for brief periods of time when O₂ delivery is inadequate to support oxidative phosphorylation

analgesic (an-al-JEE-zic) Pain relieving

anatomy The study of body structure

androgen A vertebrate masculinizing “male” sex hormone; includes testosterone from the testes and dehydroepiandrosterone from the adrenal cortex

anemia A reduction below normal in the O₂-carrying capacity of the blood

anestrus Condition where a female mammal does not cycle into reproductive readiness, because of insufficient hormonal stimuli

angiotensin-converting enzyme (ACE) An enzyme in the lung that converts inactive angiotensin I to angiotensin II

anhydrobiotic Literally, life without water; referring to dormant stages of organisms with very little water content

anion (AN-i-on) Negatively charged ion that has gained one or more electrons in its outer shell

anoxia The complete lack of oxygen

ANP See *atrial natriuretic peptide*

antagonism A process opposing another; e.g., when one hormone causes the loss of another hormone's receptors, reducing the effectiveness of the second hormone

antagonist A process opposing another; e.g., (1) a nonnative signal molecule (such as a drug or toxin) blocking the effects of a native signal molecule (for opposite term, see *agonist*); (2) a muscle that moves in opposition to another

anterior pituitary The nonneural endocrine portion of the vertebrate pituitary gland, having three parts with variable representation in various species: pars tuberalis, pars intermedia, and pars distalis; stores and secretes six different hormones: GH, TSH, ACTH, FSH, LH, and prolactin

antibody A vertebrate immunoglobulin produced by a specific activated B lymphocyte (plasma cell) against a particular antigen; binds with the specific antigen against which it is produced and promotes the antigenic invader's destruction by augmenting nonspecific immune responses already initiated against the antigen

antibody-mediated immunity A specific immune response accomplished by antibody production by B cells

antidiuresis A state of low urine output

antidiuretic hormone (an'-ti-dī-yū-RET-ik) See *vasopressin*

antigen A large complex molecule that triggers a specific immune response against itself when it gains entry into a vertebrate body

antigen-presenting cell (APC) A vertebrate immune cell that can ingest and digest antigens, then “present” them to helper T cells to activate the acquired immune response

antimicrobial peptides Small defensive proteins produced by barrier tissues and some immune cells in many, if not all animals; many kill microbes by creating pores in their membranes

antioxidant A substance that helps inactivate biologically damaging free radicals

antiporter A transporter protein in a membrane that moves two (or more) molecules or ions in the opposite direction

antrum (of ovary) The fluid-filled cavity formed within a developing ovarian follicle

antrum (of stomach) The lower portion of the vertebrate stomach

aorta (a-OR-tah) The large vessel that carries blood from the vertebrate heart to the body

aortic valve A one-way valve that permits the flow of blood from the mammalian left ventricle into the aorta during ventricular emptying but prevents the backflow of blood from the aorta into the left ventricle during ventricular relaxation

apnea The absence of breathing

apodemes In arthropods, ridges that project from the inner face of the exoskeleton for the attachment of muscles

apoptosis (ā-pop-TŌ-sis) Programmed cell death; deliberate self-destruction of a cell (as opposed to necrosis, unintended cell death)

appetite centers Neuronal clusters in the lateral regions of the vertebrate hypothalamus that drive the animal to eat

aquaporin A protein that forms a channel in a membrane that allows water to diffuse through it

aqueous humor (Ā-kwē-us) The clear watery fluid in the anterior chamber of the vertebrate eye; provides nourishment for the cornea and lens

archaea Ancient prokaryotes forming one of three distinct forms of life (along with bacteria and eukarya), often found in extreme habitats

such as hot springs, salt brines; thought to be related to the ancestor of the main eukaryotic cell

aromatase The enzyme that converts androgens (e.g., testosterone) into estrogens (estradiol)

arterioles (ar-TIR-ē-ōlz) The highly muscular, high-resistance vessels of vertebrates, the caliber of which can be changed subject to control to determine how much of the cardiac output is distributed to each of the various tissues

artery A vessel that carries blood away from the heart

ascending tract A bundle of nerve fibers of similar function that travels up the vertebrate spinal cord to transmit signals derived from afferent input to the brain

astrocyte A type of glial cell in the vertebrate brain; major functions include holding the neurons together in proper spatial relationship and inducing the brain capillaries to form tight junctions important in the blood-brain barrier

asynchronous Out of step or phase control of flight muscles; a single Ca²⁺ release “turns on” the flight muscle; when in this state, the muscle becomes activated by stretch and deactivated by shortening

atherosclerosis (ath-uh-rō-skluh-RŌ-sus) A progressive, degenerative arterial disease that leads to gradual blockage of vertebrate vessels, reducing blood flow through them

atmospheric pressure The pressure exerted by the weight of the air in the atmosphere on objects on Earth's surface; equals 760 mm Hg at sea level

ATP See *adenosine triphosphate*

ATPase An enzyme that hydrolyses ATP into ADP and energy

ATP synthase (SIN-thās) The enzyme within the mitochondrial inner membrane that phosphorylates ADP to ATP

atrial natriuretic peptide (ANP) (Ā-trē-al NĀ-tree-ur-eh'tik) A peptide hormone released from the vertebrate cardiac atria that promotes urinary loss of Na⁺ in mammals

atrioventricular (AV) node (ā'-trē-ō-ven-TRIK-yuh-lur) A small bundle of specialized cardiac cells located at the junction of the atria and ventricles that serves as the only site of electrical contact between the atria and ventricles in vertebrates

atrioventricular (AV) valve A one-way valve that permits the flow of blood from the atrium to the ventricle during filling of the mammalian heart but prevents the backflow of blood from the ventricle to the atrium during emptying of the heart

atrium (pl., **atria**) (Ā-tree-um) A chamber of the heart that receives blood from the veins or hemolymph and transfers it to a ventricle

atrophy (AH-truh-fē) Decrease in mass of an organ by loss of cells

autocrine A locally acting signal molecule regulating a cellular process of the cell that secreted it (“self-stimulation”)

autoimmune disease Disease characterized by erroneous production of antibodies against one of the body's own tissues

autonomic nervous system The portion of the efferent division of the vertebrate peripheral nervous system that innervates smooth and cardiac muscle and exocrine glands; composed of two subdivisions, the sympathetic nervous system and the parasympathetic nervous system

autorhythmicity The ability of an excitable cell to rhythmically initiate its own action potentials

AV valve See *atrioventricular valve*

avoiders Organisms that reduce disturbances to a particular physiological state by behaviorally avoiding environmental changes

axon A single, elongated tubular extension of a neuron that conducts action potentials away from the cell body; also known as a *nerve fiber*

axon hillock The first portion of a neuronal axon plus the region of the cell body from which the axon leaves; the site of action potential initiation in most neurons

axon terminals The branched endings of a neuronal axon, which release a neurotransmitter that influences target cells in close association with the axon terminals

B lymphocytes (B cells) Vertebrate white blood cells that produce antibodies against specific *antigens* to which they have been exposed

bacteria Prokaryotes forming one of three distinct forms of life (along with archaea and eukarya); included are those related to the ancestors of the eukaryotic mitochondria and chloroplast

baculum Penis bone in some mammals

bag cells Two clusters of cells in crustacean connective tissue above the abdominal ganglion; produce egg-laying hormone (ELH)

baleen Parallel fused filaments of keratin, the same protein of hair fibers that hang from the upper jaws of baleen whales in place of teeth

baroreceptor reflex An autonomically mediated reflex response that influences the vertebrate heart and blood vessels to oppose a change in mean arterial blood pressure

baroreceptors Receptors located within the vertebrate circulatory system that monitor blood pressure

basal metabolic rate (BMR) ($B\bar{A}$ -sul) The minimal rate of internal energy expenditure; an endotherm body's "idling speed"

basal nuclei Several masses of gray matter located deep within the white matter of the cerebrum of the vertebrate brain; play an important inhibitory role in motor control

basal transcription complex An assembly of proteins that initiate gene transcription in eukaryotes

base A substance that can combine with a free hydrogen ion and remove it from solution

basic electrical rhythm (BER) Self-induced electrical activity of the digestive tract smooth muscle

basilar membrane (BAS -ih-lar) The membrane that forms the floor of the middle compartment of the vertebrate cochlea and bears the organ of Corti, the sense organ for hearing

basophils (BAY -so-fills) White blood cells of vertebrates that synthesize, store, and release histamine, which is important in allergic responses

BER See *basic electrical rhythm*

beta (β) cells The endocrine pancreatic cells that secrete the hormone insulin

bicarbonate (HCO_3^-) The anion resulting from dissociation of carbonic acid, H_2CO_3

bile salts Cholesterol derivatives secreted in vertebrate bile that facilitate fat digestion through their detergent action and facilitate fat absorption through their micellar formation

biliary system (BIL -ē-air'-ē) The bile-producing system, consisting of the liver, gallbladder, and associated ducts in vertebrates

bilirubin ($bill$ -eh-RŪ-bin) A bile pigment anti-oxidant and waste product derived from biliverdin

biliverdin A bile pigment that is a waste product derived from the degradation of hemoglobin during the breakdown of old red blood cells

bimodal Having two respiratory exchange surfaces, including the gills and either cutaneous exchange or lungs

blastocyst The developmental stage of the fertilized mammalian ovum by the time it is ready to implant; consists of a single-layered sphere of cells encircling a fluid-filled cavity

blood-brain barrier Special structural and functional features of vertebrate brain capillaries that limit access of materials from the blood into the brain tissue

body system A collection of organs that perform related functions and interact to accomplish a common activity that is essential for survival of the whole body; for example, the digestive system

bone marrow The soft, highly cellular tissue that fills the internal cavities of vertebrate bones and is the source of most blood cells in terrestrial vertebrates

book lung Respiratory organ in many arachnids consisting of numerous membranous folds arranged like the pages of a book with sheetlike air spaces

Bowman's capsule The beginning of the tubular component of the mammalian kidney's nephron that cups around the glomerulus and collects the glomerular filtrate as it is formed

Boyle's law (boilz) At any constant temperature, the pressure exerted by a gas varies inversely with the volume of the gas

brain The most anterior, most highly developed portion of a central nervous system

brainstem The portion of the vertebrate brain that is continuous with the spinal cord, serves as an integrating link between the spinal cord and higher brain levels, and controls many life-sustaining processes, such as breathing, circulation, and digestion

bronchioles ($BRONG$ -kē-ōlz) The small branching airways within vertebrate lungs

bronchoconstriction Narrowing of the respiratory airways

bronchodilation Widening of the respiratory airways

brush border The collection of microvilli projecting from the luminal border of epithelial cells lining the digestive tract and kidney tubules

buffer system A mixture in a solution of two or more chemical compounds that minimize pH changes when either an acid or a base is added to or removed from the solution

bulbourethral glands (bul -bo-you-RĒTH-ral) Male accessory sex glands that secrete mucus for lubrication (in mammals)

bulbus arteriosus In bony fish, a chambered extension of the ventricle through which blood exits the heart

bulk flow Movement in bulk of a protein-free plasma across the capillary walls between the

blood and surrounding interstitial fluid; encompasses ultrafiltration and reabsorption

bulk transport Active movement of the medium (gas or liquid)

bundle of His (hiss) A tract of specialized cardiac cells that rapidly transmits an action potential down the interventricular septum of the avian and mammalian heart

bursa of Fabricius A gut-related lymphoid tissue unique to birds; site of B-cell maturation

C cells The thyroid cells that secrete calcitonin

calcitonin (kal '-suh-TŌ-nun) A vertebrate hormone secreted by the thyroid C cells that lowers plasma Ca^{2+} levels

calcium homeostasis Maintenance of a constant free plasma Ca^{2+} concentration

calmodulin (kal '-MA-jew-lin) An intracellular Ca^{2+} -binding protein that, on activation by Ca^{2+} , induces a change in structure and function of another intracellular protein; especially important in smooth muscle excitation-contraction coupling

CAMs See *cell adhesion molecules*

capacitance The ability of an insulating material, such as the cell membrane, to store an electrical charge

capacitation The stage in which mammalian spermatozoa become capable of fertilization

capillaries The thin-walled, pore-lined, smallest blood vessels, across which exchange between the blood and surrounding tissues takes place

capsaicin The "hot"-tasting chemical of chili peppers

carbonic anhydrase (an -HĪ-drās) The enzyme that catalyzes the conversion of CO_2 and OH^- into HCO_3^-

cardiac cycle One period of systole and diastole

cardiac muscle The specialized muscle found only in the heart

cardiac output (C.O.) The volume of blood pumped by each ventricle each minute; equals stroke volume \times heart rate

cardiovascular control center The integrating center located in the medulla of the vertebrate brainstem that controls mean arterial blood pressure

carnivore Animal that captures and consumes live prey or that locates and consumes carrion

carrier molecules Membrane proteins that, by undergoing reversible changes in shape so that specific binding sites are alternately exposed at either side of the membrane, can bind with and transfer particular substances unable to cross the plasma membrane on their own

carrier-mediated transport Transport of a substance across the plasma membrane facilitated by a carrier molecule

cascade A series of sequential reactions that culminates in a final product, such as a clot

catabolism (kuh -TAB-ō-li-zum) The breakdown, or degradation, of large energy-rich molecules within cells

catalase (KAT -ah-lās) An antioxidant enzyme found in peroxisomes that decomposes potent hydrogen peroxide into harmless H_2O and O_2

catch state In some nonvertebrates such as bivalve mollusks, a state of continuous contraction of smooth muscle that maintains tension with little metabolic cost

catecholamines (kat'-uh-KŌ-luh-means) The chemical classification of the vertebrates adreno-medullary hormones

cations (KAT-i-onz) Positively charged ions that have lost one or more electrons from their outer shell

caveolae (kā-vē-Ō-lē) Cavellike indentations in the outer surface of the plasma membrane that contain an abundance of membrane receptors and serve as important sites for signal transduction

cDNA DNA code that is synthesized in the laboratory as a complementary copy of an RNA isolated from a tissue

cell The smallest unit capable of carrying out the processes associated with life; the basic unit of both structure and function of living organisms

cell adhesion molecules (CAMs) Proteins that protrude from the surface of the plasma membrane and form loops or other appendages that the cells use to grip each other and the surrounding connective tissue fibers

cell body The portion of a neuron that houses the nucleus and organelles

cell-mediated immunity A specific immune response accomplished by activated T lymphocytes, which directly attack unwanted cells

center A functional collection of cell bodies within the central nervous system

central chemoreceptors (kē-mō-rē-SEP-turz) Receptors located in the vertebrate medulla near the respiratory center that respond to changes in ECF H^+ concentration resulting from changes in arterial P_{CO_2} and adjust respiration accordingly

central lacteal (LAK-tē-ul) The initial lymphatic vessel that supplies each of the vertebrate small intestinal villi

central nervous system (CNS) The brain and longitudinal nerve cord(s), which integrate input from sensory neurons and output to effectors

central sulcus (SUL-kus) A deep infolding of the mammalian brain surface that runs roughly down the middle of the lateral surface of each cerebral hemisphere and separates the parietal and frontal lobes

centrioles (SEN-tree-ōls) A pair of short, cylindrical structures within a cell that form the mitotic spindle during cell division

cerebellum (ser'-uh-BEL-um) The portion of the vertebrate brain attached to the brainstem and concerned with maintaining proper position of the body in space and subconscious coordination of motor activity

cerebral cortex The outer shell of gray matter in the vertebrate cerebrum; site of initiation of all voluntary motor output and final perceptual processing of all sensory input as well as integration of most higher neural activity

cerebral hemispheres The cerebrum's two halves, which are connected by a thick band of neuronal axons

cerebrospinal fluid (CSF) (ser'-uh-brō-SPĭ-nul or sah-REE-brō-SPĭ-nul) A special cushioning fluid that is produced by, surrounds, and flows through the central nervous system of vertebrates

cerebrum (SER-uh-brum or sah-REE-brum) The division of the vertebrate brain that consists of the basal nuclei and cerebral cortex

channel Small water-filled passageway through the plasma membrane; formed by membrane pro-

teins that span the membrane and provide a highly selective passage for small water-soluble substances such as ions

chemically gated Referring to channels in the plasma membrane that open or close in response to the binding of a specific chemical messenger with a membrane receptor site that is in close association with the channel

chemoreceptor (kē-mo-rē-sep'-tur) A sensory receptor sensitive to specific chemicals

chemotaxin (kē-mō-TAK-sin) A chemical released at an inflammatory site that attracts phagocytes to the area

chemotaxis Movement of an organism toward or away from a chemical substance

chief cells The vertebrate stomach cells that secrete pepsinogen

chitin A polymer of repeating *N*-acetylglucosamine, serving as the primary structural molecule of arthropod exoskeletons

chloride cells Specialized cells, which transport NaCl, in the gill epithelia of fishes

cholecystokinin (CCK) (kō'-luh-sis-tuh-kī-nun) A hormone released from the vertebrate duodenal mucosa primarily in response to the presence of fat; inhibits gastric motility and secretion, stimulates pancreatic enzyme secretion, and stimulates gallbladder contraction

cholesterol A type of lipid molecule that serves as a precursor for steroid hormones and bile salts and is a stabilizing component of the plasma membrane

cholinergic fibers (kō'-lin-ER-jik) Nerve fibers that release acetylcholine as their neurotransmitter

chorionic gonadotropin (CG) (kō-rē-ON-ik gō-nad'-uh-TRŌ-pin) A hormone secreted by the early mammalian embryo and developing placenta that stimulates and maintains the corpus luteum of pregnancy

chromatophores Pigment-containing cells that are found in the integument of some animals and are responsible for physiological color change; the color granules are dispersed or concentrated depending on the animal's perception of its surroundings

chronic obstructive pulmonary disease A group of lung diseases characterized by increased airway resistance resulting from narrowing of the lumen of the lower airways; includes asthma, chronic bronchitis, and emphysema

chyme (kīm) A thick liquid mixture of food and digestive juices

cilia (SILL-ee-ah) Motile hairlike protrusions from the surface of many cells, such as in ciliate protozoa, flatworm integument, and linings of mammalian respiratory airways and oviducts

ciliary body The portion of the vertebrate eye that produces aqueous humor and contains the ciliary muscle

ciliary muscle A circular ring of smooth muscle, within the vertebrate eye, whose contraction increases the strength of the lens to accommodate for near vision

circadian rhythm (sir-KĀ-dē-un) Repetitive oscillations in the set point of various body activities, such as hormone levels and body temperature, that are very regular and have an approximate frequency of 24 hours, usually linked to light-dark cycles; diurnal rhythm; biological rhythm

circannual Biological rhythm that fluctuates yearly

cistern Structure associated with the mammalian teat; permits pooling of milk from several ducts before exiting the gland

citric acid cycle A cyclical series of biochemical reactions that involves the further processing of intermediate breakdown products of nutrient molecules, resulting in the generation of carbon dioxide and the preparation of hydrogen carrier molecules for entry into the high-energy-yielding electron transport chain

cloaca The final chamber of the hindgut of birds and reptiles

clone An exact genetic copy of a gene, or an organism arising from an exact copy of a genome

clutch The number of eggs incubated at one time

CNS See *central nervous system*

cochlea (KOK-lē-uh) The snail-shaped portion of the vertebrate inner ear that houses the receptors for sound

coevolution The process in which adaptive changes in one organism favor selection for adaptations in a second organism, which, in turn, favor selection for a different adaptation in the first organism, and so on

collecting tubule The last portion of tubule in the mammalian kidney's nephron that empties into the renal pelvis

colligative properties Solution properties of an idealized solute at 1 mole in 1 kg of water (defined as 1 molal), which has an osmotic pressure of 22.4 atmospheres (atm), raises boiling point by 0.54°C, depresses freezing point by 1.86°C, and also reduces vapor pressure

colloid (KOL-oid) The thyroglobulin-containing substance enclosed within the thyroid follicles

colloid osmotic pressure The difference in osmotic pressure that exists between the ECF and ICF due to differences in their concentrations of nonpermeating proteins

compatible osmolyte An organic osmolyte that elevates the osmotic pressure of a body fluid without perturbing cell functions

complement system A collection of vertebrate plasma proteins that are activated in cascade fashion on exposure to invading microorganisms, ultimately producing a membrane attack complex that destroys the invaders

compliance The distensibility of a hollow, elastic structure, such as a blood vessel or the lungs; a measure of how easily the structure can be stretched

compound eye Multifaceted arthropod eye composed of numerous optical units called *ommatidia*

concentration gradient A difference in concentration of a particular substance between two adjacent areas

conduction Transfer of heat between objects of differing temperatures that are in direct contact with each other

cones The vertebrate eye's photoreceptors used for color vision in the light

conformers Organisms in which a particular physiological state matches that of the environment

congestive heart failure The inability of the cardiac output to keep pace with the body's needs for blood delivery, with blood damming up in the veins behind the failing heart

connective tissue Tissue that serves to connect, support, and anchor various body parts; distinguished by relatively few cells dispersed within an abundance of extracellular material

contiguous conduction The means by which an action potential is propagated throughout a non-myelinated nerve fiber; local current flow between an active and adjacent inactive area brings the inactive area to threshold, triggering an action potential in a previously inactive area

contractile proteins Myosin and actin, whose interaction brings about shortening (contraction) of a muscle fiber

conus arteriosus In cartilaginous fish, a chambered extension of the ventricle through which blood exits the heart

convection Transfer of heat energy by air or water currents

convergence (1) The converging of many presynaptic terminals from thousands of other neurons on a single neuronal cell body and its dendrites so that activity in the single neuron is influenced by the activity from many other neurons; (2) the independent evolution of similar structures in different species without a common ancestral structure

convex Curved out, as a surface in a lens that converges light rays

cooperativity The binding of a ligand, such as O₂, to its binding site on a multisubunit protein, such as hemoglobin, subsequently affecting the ability of other binding sites on the same protein to associate with additional ligand

coprodaeum Anterior portion of the avian cloaca, receives the excreta from the digestive tract

coprophagy Reingestion of feces

copulatory plug Temporary mating plug that forms after fertilization, which prevents both the loss of semen from the female tract as well as entry of sperm into the vagina (genital chamber) from a competing male

core temperature The temperature within the inner core of a body (abdominal and thoracic organs, central nervous system, and skeletal muscles)

cornea (KOR-nee-ah) The clear, most anterior, outer layer of an eye, through which light rays pass to the interior of the eye

coronary circulation The blood vessels that supply the vertebrate heart muscle

corpus luteum (LOO-tē-um) The ovarian structure that develops from a ruptured follicle following ovulation in a mammal

cortisol (KORT-uh-sol) The vertebrate adrenocortical hormone that plays an important role in carbohydrate, protein, and fat metabolism and helps the body resist stress; functionally similar to corticosterone

cotransport See *symporter* and *antiporter*

counteracting osmolyte An organic osmolyte that elevates the osmotic pressure of a body fluid and that counteracts the effects of a perturbant of cellular macromolecules

countercurrent A design in which fluid in two juxtaposed tubes flows in opposite directions (alternatively, in which flow in a single tube alternates between inflow and outflow)

cranial nerves The 12 pairs of vertebrate peripheral nerves, the majority of which arise from the brainstem

crop An enlarged posterior portion of the foregut, just anterior to the esophagus

crop milk Lipid material synthesized by epithelial cells of the crop of adult pigeons and doves; these cells are sloughed off and mixed with food already present in the crop and fed by regurgitation to juveniles

cross bridges The myosin molecules' globular heads that protrude from a thick filament within a muscle fiber and interact with the actin molecules in the thin filaments to shorten the muscle fiber during contraction

crosscurrent exchange Airflow and blood flow in the parabronchi of the avian lung that occur perpendicular to one another

cryoprotectant A molecule that is used to prevent freezing by lowering the freezing point in a body fluid

cyclic adenosine monophosphate (cyclic AMP or cAMP) An intracellular second messenger derived from adenosine triphosphate (ATP)

cytokines Signal molecules not produced by classic or distinct endocrine glands

cytoplasm (SĪ-tō-plaz'-um) The portion of the cell interior not occupied by the nucleus

cytoskeleton A complex intracellular protein network that acts as the "bone and muscle" of the cell

cytosol (SĪ-tuh-sol') The semiliquid portion of the cytoplasm not occupied by organelles

cytotoxic T cells (sī-tō-TOK-sik) The population of T cells (T lymphocytes) that destroys host cells bearing foreign antigen, such as body cells invaded by viruses or cancer cells

dead-space volume The volume of medium that occupies the respiratory pathways as air or water is moved in and out and that is not available to participate in exchange of O₂ and CO₂ between the respiratory surfaces and external medium

decompression sickness, or "the bends" Pathology caused by the presence of nitrogen bubbles in the tissues, inducing a state of profound stupor, unconsciousness, or arrested activity

defensin A general term for antimicrobial peptides in all animals, with numerous positive charges that are attracted to negatively charged bacterial membranes to form pores

dehydration A water deficit in the body

dehydroepiandrosterone (DHEA) (dē-HĪ-drōp-i-and-row-steer-own) The androgen (masculinizing hormone) secreted by the vertebrate adrenal cortex in both sexes

dendrites Projections from the surface of a neuron's cell body that carry signals toward the cell body

dendritic cell A major antigen-presenting cell in vertebrate skin and other barrier tissues

deoxyhemoglobin Hemoglobin that is not combined with O₂

deoxyribonucleic acid (DNA) (dē-OK-sē-rī-bō-new-klā-ik) The cell's genetic material, which is found within the nucleus, mitochondria, and chloroplasts in eukarya, provides codes for protein synthesis, and serves as a blueprint for cell replication

depolarization (de'-pō-luh-ruh-ZĀ-shun) A reduction in membrane potential from resting potential; movement of the potential from resting toward 0 mV

dermis The connective tissue layer that lies under the epidermis in the skin; in vertebrates, it contains the skin's blood vessels and nerves

descending tract A bundle of nerve fibers of similar function that travels down the vertebrate spinal cord to relay messages from the brain to efferent neurons

desmosome (dez'-muh-sōm) An adhering junction between two adjacent but nontouching cells formed by the extension of filaments between the cells' plasma membranes; most abundant in tissues that are subject to considerable stretching

detritivore Animal that consumes dead and living organic material in sediments

DHEA See *dehydroepiandrosterone*

diabetes mellitus (muh-LĪ-tus) An endocrine disorder characterized by inadequate insulin action

diaphragm (DIE-uh-fram) A dome-shaped sheet of skeletal muscle that forms the posterior end of the thoracic cavity in many air-breathing vertebrates; a major inspiratory muscle

diaphragmaticus muscle A muscle attached between the liver and a distinctive elongated region of the pubis bone in crocodiles; pulls the liver away from the lungs in a pistonlike manner that results in expansion of the lungs

diastema Gap that extends between the front teeth and the cheek teeth (premolars and molars) of ruminants

diastole (dī-AS-tō-lē) The period of cardiac relaxation and filling

diencephalon (dī'-un-SEF-uh-lan) The division of the vertebrate brain that consists of the thalamus and hypothalamus

diestrus Associated with a functioning corpus luteum (dominance of progesterone) in a mammal and begins about four days after ovulation and ends with regression of the corpus luteum

diet-induced thermogenesis The increase in metabolism that follows ingestion of a meal; obligatory form is associated with the costs of processing the food, whereas the regulatory form is activated for the purpose of removing excess calories as heat; also called *specific dynamic action* (SDA)

diffusion Random collisions and intermingling of molecules as a result of their continuous, thermally induced random motion

digestion The conversion process whereby the structurally complex foodstuffs of the diet are broken down into smaller absorbable units by the enzymes produced within the digestive system

2,3-diphosphoglycerate (DPG) An organic phosphate synthesized in erythrocytes that reduces the affinity of most vertebrate hemoglobins for O₂

diploid number (DIP-loid) A complete set of chromosomes (e.g., 23 pairs in humans), as found in all somatic cells

distal tubule A highly convoluted tubule that extends between the loop of Henle and the collecting duct in the mammalian kidney's nephron

diuresis A state of high urine output

divergence The diverging, or branching, of a neuron's axon terminals so that activity in this single neuron influences the many other cells with which its terminals synapse

diverticula Blind tubules that arise from the main passage of the midgut in insects and contain the gastric caecae

DMS (dimethyl sulfide) A gas produced by the breakdown of DMSP; triggers cloud formation and so is important in climate regulation

DMSP (dimethylsulfoniopropionate) A major compatible osmolyte in many marine algae

DNA See *deoxyribonucleic acid*

dormancy A temporary state of very low metabolic rate

dorsal root ganglion A cluster of afferent neuronal cell bodies located adjacent to the vertebrate spinal cord

dorsobronchi Caudal group of secondary bronchi in birds that branch to form a fan-shaped covering of the mediodorsal surface of the avian lung

downregulation A decrease in the capacity of a cellular or organ function

DPG See *2,3-diphosphoglycerate (DPG)*

ecdysis The shedding of the old exoskeleton

ecdysone Hormone secreted by the prothoracic gland of insects

ECF See *extracellular fluid*

ECG See *electrocardiogram*

ectotherm An organism dependent on external heat for body temperature

edema (i-DẼ-muh) Swelling of tissues as a result of excess interstitial fluid

EDV See *end-diastolic volume*

EEG See *electroencephalogram*

effector organs The organs, especially muscles or glands, that are controlled by a regulatory system and that carry out that system's orders to bring about a desired effect, such as a particular movement or secretion

efferent division (EF-er-ent) The portion of the peripheral nervous system that carries instructions from the central nervous system to effector organs

efferent neuron Neuron that carries information from the central nervous system to an effector organ

efflux (Ē-flux) Movement out of a cell

egest Discharge of indigestible matter from the digestive tract

eicosanoid A class of signal molecules derived from lipids such as arachidonic acid

elastic recoil Rebound of the lungs after having been stretched

electrical gradient A difference in charge between two adjacent areas

electrocardiogram (ECG) The graphic record of the electrical activity that reaches the surface of the body as a result of cardiac depolarization and repolarization

electrochemical gradient The simultaneous existence of an electrical gradient and concentration (chemical) gradient for a particular ion

electrocyte Modified neurons of electric fish that, when linked in series, are capable of generating a substantial electrical discharge

electrolytes Solutes that form ions in solution and conduct electricity

enantiotaxis A form of regulation in which changes in one physiological state help offset a disturbance to another physiological state

end-diastolic volume (EDV) The volume of blood in the ventricle at the end of diastole, when filling is complete

endocrine glands Ductless glands that secrete hormones into the blood or hemolymph

endocrine-disrupting chemicals (EDCs) Human-made substances that are released into the environment (or generated in sewage) and that interfere with the endocrine functions of animals

endocytosis (en'-dō-si-TŌ-sis) Internalization of extracellular material within a cell as a result of the plasma membrane forming a pouch that contains the extracellular material, then sealing at the surface of the pouch to form a small, intracellular, membrane-enclosed vesicle with the contents of the pouch trapped inside

endogenous opiates (en-DAJ'-eh-nus ō'-pē-ātz) Endorphins and enkephalins, which bind with opiate receptors and are important in the vertebrate body's natural analgesic system

endogenous pyrogen (pi'-ruh-jun) A chemical released from vertebrate macrophages during inflammation that acts by means of local prostaglandins to raise the set point of the hypothalamic thermostat to produce a fever

endometrial cup Temporary endocrine units in the uterine horn of the mare (placental origin), ranging in size from millimeters to several centimeters that produce eCG (equine chorionic gonadotropin)

endometrium (en'-dō-MĒ-trē-um) The lining of the mammalian uterus

endoplasmic reticulum (en'-dō-PLAZ-mik ri-TIK-yuh-lum) An organelle consisting of a continuous membranous network of fluid-filled tubules and flattened sacs, partially studded with ribosomes; synthesizes proteins and lipids for formation of new cell membrane and other cell components and manufactures products for secretion

endothelium (en'-dō-THĒ-lē-um) The thin, single-celled layer of epithelial cells that lines the entire vertebrate circulatory system

endotherm An organism that uses internal heat to regulate body temperature

end-plate potential (EPP) The graded receptor potential that occurs at the motor end plate of a skeletal muscle fiber in response to binding with acetylcholine

end-systolic volume (ESV) The volume of blood in the ventricle at the end of systole, when emptying is complete

enhancer A promoter DNA sequence that is specific for a particular gene, helping regulate that gene's transcription (by binding of transcription factors) in a tissue-specific manner

enterogastrones (ent'-uh-rō-GAS-trōnz) Hormones secreted by the vertebrate duodenal mucosa that inhibit gastric motility and secretion; include secretin, cholecystokinin, and gastric inhibitory peptide

enterohepatic circulation (en'-tur-ō-hi-PAT-ik) The recycling of bile salts and other bile constituents between the vertebrate small intestine and liver by means of the hepatic portal vein

entropy A measure of disorder in a system

enzyme A protein molecule that speeds up (catalyzes) a particular chemical reaction in an organism

eosinophils (ē'-uh-SIN-uh-fils) White blood cells that are important in allergic responses and in combating internal parasite infestations

epidermis (ep'-uh-DER-mus) The outer layer of the skin, consisting of numerous layers of epithelial cells

epinephrine (ep'-uh-NEF-rin) The primary hormone secreted by the vertebrate adrenal medulla;

important in preparing the body for "fight-or-flight" responses and in regulation of arterial blood pressure; adrenaline

epiphyseal plate (eh-pif-i-SEE-al) A layer of cartilage that separates the diaphysis (shaft) of a vertebrate long bone from the epiphysis (flared end); the site of growth of bones in length before the cartilage ossifies (turns into bone)

epithelial tissue (ep'-uh-THĒ-lē-ul) A functional grouping of cells specialized in the exchange of materials between the cell and its environment; lines and covers various body surfaces and cavities and forms secretory glands

EPSP See *excitatory postsynaptic potential*

equilibrium potential The potential that exists when the concentration gradient and opposing electrical gradient for a given ion exactly counterbalance each other so that there is no net movement of the ion

equine chorionic gonadotropin (eCG) A peptide hormone secreted by the developing chorion of the mare; see *chorionic gonadotropin*

eructation Belching

erythrocyte (i-RITH-ruh-sīt) A red blood cell, which is a plasma membrane-enclosed bag of hemoglobin that transports O₂ and to a lesser extent CO₂ and H⁺ in the blood

erythropoiesis (i-rith'-rō-poi-Ē-sus) Erythrocyte production by the bone marrow

erythropoietin (EPO) The hormone released from vertebrate kidneys in response to a reduction in O₂ delivery to the kidneys; stimulates the bone marrow to increase erythrocyte production

esophagus (i-SOF-uh-gus) A straight, muscular tube that extends between the pharynx and stomach

estivation A dormant or low-metabolism state of an animal, usually during dry summer months

estrogens A group of feminizing "female" sex hormones such as **estradiol**

estrous cycle The time from one period of sexual receptivity to the next

estrus The period of sexual receptivity in a mammalian female

ESV See *end-systolic volume*

eukarya One of three distinct forms of life (along with archaea and bacteria); eukaryotic cells have organelles including a nucleus, mitochondria, and endoplasmic reticulum; Protista, Plantae, Animalia, and Fungi

euryhaline Capable of surviving over a wide range of external salinities

evolutionary explanation In biology, the evolutionary reason for the existence of a structure or process ("why it arose this way"), as opposed to the *mechanistic explanation*

excitable tissue Tissue capable of producing electrical signals when excited; includes nervous and muscle tissue

excitation-contraction coupling The series of events linking muscle excitation (the presence of an action potential) to muscle contraction (filament sliding and sarcomere shortening)

excitatory postsynaptic potential (EPSP) (pōst'-si-NAP-tik) A small depolarization of the postsynaptic membrane in response to neurotransmitter binding, thereby bringing the membrane closer to threshold

excitatory synapse (SIN-aps') Synapse in which the postsynaptic neuron's response to neurotrans-

mitter release is a small depolarization of the postsynaptic membrane, bringing the membrane closer to threshold

exocrine glands Glands that secrete through ducts to the outside of the body or into a cavity that communicates with the outside

exocytosis (eks'-ō-si-TŌ-sis) Fusion of a membrane-enclosed intracellular vesicle with the plasma membrane, followed by the opening of the vesicle and the emptying of its contents to the outside

expiration A breath out (exhalation)

expiratory muscles The skeletal muscles whose contraction moves respiratory air or water out of a respiratory chamber

extensors Skeletal muscles that straighten a limb out

external intercostal muscles Inspiratory muscles whose contraction expands the vertebrate rib cage, thereby enlarging the thoracic cavity (in most air-breathing vertebrates)

external work Energy expended by contracting skeletal muscles to move external objects or to move the body in relation to the environment

exteroceptors The “classic” senses that detect external stimuli such as light, chemicals, touch, temperature, and sound

extracellular fluid All the body’s fluid found outside the cells; consists of interstitial fluid and plasma; ECF

extracellular matrix An intricate meshwork of fibrous proteins embedded in a watery, gel-like substance; secreted by local cells

extrafusal muscle fiber A vertebrate muscle fiber not associated with a muscle-spindle stretch receptor

extrinsic controls Regulatory mechanisms initiated outside of an organ that alter the activity of the organ; accomplished by the nervous and endocrine systems

facilitated diffusion Passive carrier-mediated transport involving transport of a substance down its concentration gradient across the plasma membrane

fat body The insect equivalent of a liver; it stores large amounts of triglycerides and carbohydrates

fatigue Inability to maintain muscle tension at a given level despite sustained stimulation

feedforward mechanism A response designed to prevent an anticipated harmful change, or activate an anticipated useful change, in a controlled variable

fibrinogen (fi-BRIN-uh-jun) A large soluble plasma protein that is converted into an insoluble, threadlike molecule that forms the meshwork of a clot during blood coagulation

Fick’s law of diffusion The rate of net diffusion of a substance across a membrane is directly proportional to the substance’s concentration gradient, the membrane’s permeability to the substance, and the surface area of the membrane and inversely proportional to the substance’s molecular weight and the diffusion distance

fight-or-flight response The changes in activity of the various organs innervated by the vertebrate autonomic nervous system in response to sympathetic stimulation, which collectively prepare the body for strenuous physical activity in the face of an emergency or stressful situation, such as a physical threat from the outside environment

filter chamber A modification of the digestive tract of Homoptera, insects that feed on large quantities of plant juices; the filter chamber permits water from the ingested sap to pass directly from the anterior region of the midgut to the hindgut

filter feeding Trapping of dead and/or living material suspended in water by straining through specialized entrapment devices; also called suspension feeding

firing The event when an excitable cell undergoes an action potential

first messenger An extracellular messenger, such as a hormone, that binds with a surface membrane receptor and activates an intracellular second messenger to carry out the desired cellular response

flagellum (fluh-JEL-um) The single, long, whip-like appendage of some cells, serving, for example, as the tail of a spermatozoon or the current producer of a sponge cell

flexors Skeletal muscles that bend a limb

flow-through breathing Movement of air or water in and out of a respiratory chamber through separate openings, for the purposes of gas exchange

follicle (of ovary) A developing ovum and the surrounding specialized cells

follicle-stimulating hormone (FSH) An anterior pituitary hormone that stimulates ovarian follicular development and estrogen secretion in females and stimulates sperm production in males

follicular cells (of ovary) (fah-LIK-you-lar) Collectively, the granulosa and thecal cells

follicular cells (of thyroid gland) The cells that form the walls of the colloid-filled follicles in the thyroid gland and secrete thyroid hormone

follicular phase The phase of the mammalian ovarian cycle dominated by the presence of maturing follicles prior to ovulation

forestomach Ruminoreticular region of the ruminant stomach; contains the populations of microbes involved in the fermentation of foodstuffs

fovea A small depression or pit in the vertebrate retina containing densely packed cones; the region of the eye with the greatest visual resolution

Frank-Starling law of the heart Intrinsic control of the heart, such that increased venous return resulting in increased end-diastolic volume leads to an increased strength of contraction and increased stroke volume; that is, the heart normally pumps out all the blood returned to it

free radicals Very unstable electron-deficient particles that are highly reactive and destructive

freemartin Sterile female calf twin born with a male

frontal lobes The lobes of the vertebrate cerebral cortex that lie at the top of the brain in front of the central sulcus and that, in mammals, are responsible for nonreflexive motor output and complex planning

FSH See *follicle-stimulating hormone*

functional syncytium (sin-sish'-ē-um) A group of cells that are interconnected by gap junctions and function electrically and mechanically as a single unit

functional unit The smallest component of an organ that can perform all the functions of the organ

G protein A membrane-bound intermediary, which, when activated on binding of an extracel-

lular first messenger to a surface receptor, activates the enzyme adenylyl cyclase on the intracellular side of the membrane in the cAMP second-messenger system

gametes (GAM-ētz) Reproductive or germ cells, each containing a haploid set of chromosomes; sperm and ova

gamma motor neuron A motor neuron that innervates the fibers of a muscle spindle receptor

ganglion (pl., ganglia) (1) A group or cluster of nerve cell bodies, often with related functions; (2) in the vertebrate eye, the nerve cells in the outermost layer of the retina and whose axons form the optic nerve

gap junction A communicating junction formed between adjacent cells by small connecting tunnels that permit passage of charge-carrying ions between the cells so that electrical activity in one cell is spread to the adjacent cell

gas bladder (swim bladder) A large centrally located sac ventral to the spinal column, in the abdominal cavity of teleost fish, used for buoyancy control

gastrin A hormone secreted by the pyloric gland area of the vertebrate stomach that stimulates the parietal and chief cells to secrete a highly acidic gastric juice

genome The complete set of genetic codes in a particular species

genomics The study of the structure, regulation, and information content of genes

gestation Pregnancy

gill Evaginated respiratory organ of water-breathing animals

gill arch Fish tissue that provides skeletal support for a double series of gill filaments, each of which carries a row of secondary lamellae on either side

gizzard Muscular portion of the stomach of most birds where food (e.g., grains, seeds) is ground up with the aid of ingested pebbles

gland Epithelial tissue derivative specialized for secretion

glial cells (glē-ul) Cells that serve as the connective tissue of the vertebrate CNS and help support the neurons both physically and metabolically; include astrocytes, oligodendrocytes, ependymal cells, and microglia

glomerular filtration (glow-MER-yū-lur) Filtration of a protein-free plasma from the glomerular capillaries into the tubular component of the vertebrate kidney’s nephron as the first step in urine formation

glomerular filtration rate (GFR) The rate at which glomerular filtrate is formed

glomerulus (glow-MER-yū-lus) (1) A ball-like tuft of capillaries in the vertebrate kidney’s nephron that filters water and solute from the blood as the first step in urine formation; (2) small ball-like neural junction in the vertebrate olfactory bulb

glucagon (GLOO-kuh-gon) The vertebrate pancreatic hormone that raises blood glucose and blood fatty-acid levels

glucocorticoids (gloo'-kō-KOR-ti-koidz) The adrenocortical hormones that are important in intermediary metabolism and in helping the body resist stress; primarily cortisol

gluconeogenesis (gloo'-kō-nē-ō-JEN-uh-sus) The “new formation of glucose”; the conversion of pyruvate or amino acids into glucose, running glycolysis essentially in reverse

glycation A reaction in which glucose and other reducing sugars spontaneously bind with proteins such as collagen and hemoglobin, forming a covalent bond that can alter its structure and function

glycogen (GLĭ-kō-jen) The storage form of glucose in the liver and muscle

glycogenesis (gli'-kō-JEN-i-sus) The conversion of glucose into glycogen

glycogenolysis (gli'-kō-juh-NOL-i-sus) The conversion of glycogen to glucose

glycolysis (gli-KOL-uh-sus) A biochemical process that takes place in the cell's cytosol and involves the breakdown of glucose into two pyruvic acid molecules

glycoprotein A protein that has sugars covalently bound to it; common on outer sides of cell membranes

GnRH See *gonadotropin-releasing hormone*

Golgi complex (GOL-jē) An organelle consisting of sets of stacked, flattened membranous sacs; processes raw materials transported to it from the endoplasmic reticulum into finished products and sorts and directs the finished products to their final destination

gonad The primary reproductive organ, which produces the gametes; testes and ovaries

gonadotropin-releasing hormone (GnRH) (gō-nad'-uh-TRŌ-pin) The hypothalamic hormone that stimulates the release of FSH and LH from the vertebrate anterior pituitary

gonadotropins FSH and LH; vertebrate hormones that are tropic to the gonads

gradation of contraction Variable magnitudes of tension produced in a single whole muscle

graded potential A local change in membrane potential that occurs in varying grades of magnitude; serves as a short-distance signal in excitable tissues

granulocyte (gran'-yuh-lō-sīt) Vertebrate leukocyte that contains granules, including neutrophils, eosinophils, and basophils

granulosa cell (gran'-yuh-LŌ-suh) A cell immediately surrounding a developing oocyte within a vertebrate ovarian follicle

gray matter The portion of the vertebrate central nervous system composed primarily of densely packaged neuronal cell bodies and dendrites

grit Hard granules, such as sand and pebbles found in the gizzard of birds

growth hormone (GH) An anterior pituitary hormone that is primarily responsible for regulating overall body growth and is also important in intermediary metabolism; somatotropin

gular fluttering Panting with a rapid fluttering of the well-vascularized esophageal region of the hyoid apparatus, in birds

gustation Taste, or detection of molecules in objects in contact with the body

H⁺ See *hydrogen ion*

habituation Decreased responsiveness to repetitive presentation of an indifferent stimulus (neither rewarding nor punishing), resulting in a decrease in synaptic activity

haploid number (HAP-loid) The number of chromosomes found in gametes; a half set of chromosomes, one member of each pair

Hb See *hemoglobin*

hCG Human version of *chorionic gonadotropin*

heat shock proteins (HSPs) See *stress proteins*

helper T cells The population of T cells that enhances the activity of other immune-response effector cells

hematocrit (hi-mat'-uh-krit) The percentage of blood volume occupied by erythrocytes as they are packed down in a centrifuged blood sample

hemerythrin Iron-containing respiratory pigment found in several nonvertebrate phyla, including annelid worms

hemipenis Organ used by the drake to deposit semen in the female duck

hemocoel The body cavity of an animal with a circulating hemolymph

hemocyanin An oxygen-transporting protein in many mollusks and arthropods such as crustaceans that uses two copper atoms to bind one oxygen molecule

hemodynamic Pertaining to the physics of blood flow

hemoglobin (Hb) (HĒ-muh-glō'-bun) A large iron-bearing protein molecule that binds with and transports most O₂ in blood; in vertebrates, it is contained within erythrocytes, and it also carries some of the CO₂ and H⁺

hemolymph The circulatory fluid in an animal that does not have capillaries

hemolysis (hē-MOL-uh-sus) Rupture of red blood cells

hemostasis (hē'-mō-STĀ-sus) The stopping of bleeding from an injured vessel

hepatic portal system (hi-PAT-ik) A complex vascular connection between the vertebrate digestive tract and liver such that venous blood from the digestive system drains into the liver for processing of absorbed nutrients before being returned to the heart

hepatopancreas An organ in crustaceans that secretes digestive enzymes, stores glycogen and lipids, and absorbs nutrient molecules

herbivore Animal that depends on the intake of algal or plant materials

hermaphroditism State in which an animal has both functional male and female reproductive tracts, although not necessarily at the same time

heterogametic Producing two or more different kinds of gametes that differ in their sex chromosome content

heterotherm An animal that has some degree of endothermy but that is not fully homeothermic

hibernation A state of dormancy in an animal usually associated with winter months; involves lower body temperatures in endotherms

hippocampus (hip-oh-CAM-pus) The elongated, medial portion of the temporal lobe that is a part of the vertebrate limbic system and is especially crucial for forming long-term memories

histamine A chemical released from vertebrate mast cells or basophils that brings about vasodilation and increased capillary permeability; important in allergic responses

homeostasis (hō'-mē-ō-STĀ-sus) Maintenance by coordinated, regulated actions of body systems of relatively stable (though rarely constant) chemical and physical conditions in the internal fluid environment and in other body states

homeotherm Animal with narrowly varying body temperatures

homeoviscous Having the same fluidity or viscosity; referring to cell membranes being altered

at different temperatures to maintain an optimal fluidity

homogametic Producing one type of gamete with respect to sex chromosome content

homunculus Orderly distribution of cortical sensory processing in the vertebrate brain; for each species of vertebrate, the extent of each body part is indicative of the relative proportion and location of the somatosensory cortex devoted to that area

honeydew Nutritious liquid discharged from the anus of some Homoptera

hormone A long-distance chemical mediator that is secreted by an endocrine gland into the blood or hemolymph, which transports it to its target cells

host cell A body cell infected by a virus

HRE See *response element*

hydrogen ion (H⁺) The cationic portion of a dissociated acid; a proton without an electron

hydrolysis (hī-DROL-uh-sis) The digestion of a nutrient molecule by the addition of water at a bond site

hydrostatic pressure (hī-dro-STAT-ik) The pressure exerted by a fluid on the walls that contain it

hyperglycemia (hī'-pur-gli-SĒ-mē-uh) Elevated blood glucose concentration

hyperplasia (hī-pur-PLĀ-zē-uh) An increase in the number of cells

hyperpolarization An increase in membrane potential from resting potential; potential becomes even more negative than at resting potential

hypertension (hī'-pur-TEN-shun) Sustained, above-normal mean arterial blood pressure

hyperthermia Abnormally high body temperature

hypertonic (hī'-pur-TON-ik) Having an osmolarity greater than normal body fluids; more concentrated than normal

hypertrophy (hī-PUR-truh-fē) Increase in the size of an organ

hyperventilation Overbreathing; when the rate of ventilation is in excess of the body's metabolic needs for CO₂ removal

hypomagnesemic tetany, or grass tetany A pathological state in herbivores such as cattle, characterized by low magnesium concentrations in the blood and cerebrospinal fluid; affected animals appear nervous and show muscular twitching around the face and ears

hyponatremia A pathologically low level of sodium in the blood

hypophysiostropic hormones (hi-PŌ-fiz-ē-oh-TRO-pik) Vertebrate hormones secreted by the hypothalamus that regulate the secretion of anterior pituitary hormones; see also *releasing hormone*

hypotension (hi-po-TEN-chun) Sustained, below-normal mean arterial blood pressure

hypothalamic-hypophyseal portal system (hī-pō-thuh-LAM-ik hī-pō-FIZ-ē-ul) The vascular connection between the hypothalamus and anterior pituitary gland used for the pickup and delivery of hypophysiostropic hormones

hypothalamus (hī'-pō-THAL-uh-mus) The vertebrate brain region located beneath the thalamus that is concerned with regulating many aspects of the internal fluid environment, such as water and salt balance and food intake; serves as an impor-

tant link between the autonomic nervous system and endocrine system

hypothermia Abnormally low body temperature

hypothetico-deductive method The most widely accepted version of “the scientific method”; data are gathered about an aspect of nature in the “discovery” phase, then alternative hypotheses are made to explain them; testable deductions must be made from the hypotheses, with experiments and observations designed to test them, leading to support, refinement, or rejection of hypotheses

hypotonic (hī'-pō-TON-ik) Having an osmolarity less than normal body fluids

hypoventilation Underbreathing; ventilation inadequate to meet the metabolic needs for O₂ delivery and CO₂ removal

hypoxia (hī-POK-sē-uh) Insufficient O₂ at the cellular level

I band One of the light bands that alternate with dark (A) bands to create a striated appearance in skeletal or cardiac muscle fibers when these fibers are viewed with a light microscope

ice-nucleating agent Small proteins in some animals that trigger the formation of small ice crystals once temperatures have dropped to the freezing point

ICF See *intracellular fluid*

IGF See *insulin-like growth factor*

immune surveillance Recognition and destruction of newly arisen cancer cells by the immune system

immunity Ability to resist or eliminate potentially harmful foreign materials or abnormal cells

immunoglobulins (im'-ū-nō-GLOB-yū-lunz) Antibodies; gamma globulins

impermeable Prohibiting passage of a particular substance through the plasma membrane

implantation The burrowing of a mammalian blastocyst into the endometrial lining

inflammation An innate, nonspecific series of highly interrelated events in vertebrates, especially involving neutrophils, macrophages, and local vascular changes, that are set into motion in response to foreign invasion or tissue damage

influx Movement into a cell

inhibin (in-HIB-un) A vertebrate hormone secreted by the Sertoli cells of the testes or by the ovarian follicles that inhibits FSH secretion

inhibitory postsynaptic potential (IPSP) (pōst'-si-NAP-tik) A small hyperpolarization of the postsynaptic membrane in response to neurotransmitter binding, thereby moving the membrane farther from threshold

inhibitory synapse (SIN-aps') Synapse in which the postsynaptic neuron's response to neurotransmitter release is a small hyperpolarization of the postsynaptic membrane, moving the membrane farther from threshold

innate immune responses Inherent defense responses that nonselectively defend against foreign or abnormal material, even on initial exposure to it; see also *inflammation*, *interferon*, *natural killer cells*

inorganic Referring to substances that do not contain carbon (and usually hydrogen)

insensible Referring to body water loss that is not sensed or regulated by an animal

inspiration An inward breath (inhalation)

inspiratory muscles The vertebrate skeletal muscles whose contraction enlarges the thoracic cavity, bringing about lung expansion and movement of air into the lungs from the atmosphere

instar The period between molts, or ecdysis, in arthropod development

insulin (IN-suh-lin) The vertebrate pancreatic hormone that lowers blood levels of glucose, fatty acids, and amino acids and promotes their storage

insulin-like growth factor (IGF) See *somatomedins*

integrating center A region that determines efferent output based on processing of afferent input

integument (in-TEG-yuh-munt) The skin and underlying connective tissue

intercostal muscles (int-ur-KOS-tul) The muscles that lie between the vertebrate ribs; see also *external intercostal muscles* and *internal intercostal muscles*

interferon (in'-tur-FĒR-on) A chemical released from virus-invaded vertebrate cells that provides nonspecific resistance to viral infections by transiently interfering with replication of the same or unrelated viruses in other host cells

interleukins (int-ur-LOO-kins) Chemical mediators released from immune cells that enhance immune responses; for example, interleukin-1 (IL-1) in vertebrates is made by macrophages and enhances B cells, whereas interleukin-2 (IL-2) is secreted by helper T cells and augments the activity of all T cells

intermediary metabolism The collective set of intracellular chemical reactions that involve the degradation, synthesis, and transformation of small nutrient molecules

intermediate filaments Threadlike cytoskeletal elements that play a structural role in parts of the cell subject to mechanical stress

internal intercostal muscles Expiratory muscles whose contraction pulls the ribs inward, thereby reducing the size of the thoracic cavity (in most air-breathing vertebrates)

internal respiration The intracellular metabolic processes carried out within the mitochondria that use O₂ and produce CO₂ during the derivation of energy from nutrient molecules

internal work All forms of biological energy expenditure that do not accomplish mechanical work outside of the body

interneuron Neuron that lies entirely within the central nervous system and is important for integrating responses to peripheral information

interoceptors Sensors that detect information about the internal body fluids usually crucial to homeostasis, such as blood pressure and O₂ concentration inhalation

interstitial fluid (in'-tur-STISH-ul) The portion of the extracellular fluid that surrounds and bathes all the body's cells

intima The cuticular lining of the insect foregut, tracheae, and hindgut

intra-alveolar pressure (in'-truh-al-VĒ-uh-lur) The pressure within alveoli (in mammals, some reptiles)

intracellular fluid The fluid collectively contained within all the body's cells; ICF

intrafusal muscle fiber A specialized muscle fiber associated with a muscle-spindle stretch re-

ceptor that can be activated by a gamma motor neuron

intrapleural pressure (in'-truh-PLOOR-ul) The pressure within the pleural sac (in mammalian lungs)

intrinsic controls Local control mechanisms inherent to an organ

intrinsic factor A special substance secreted by the parietal cells of the vertebrate stomach that must be combined with vitamin B₁₂ for this vitamin to be absorbed by the intestine; deficiency produces pernicious anemia

intrinsic nerve plexuses Interconnecting networks of nerve fibers within the vertebrate digestive-tract wall

inulin A naturally occurring polysaccharide used to determine the glomerular filtration rate, as it is neither secreted nor absorbed

ion An atom that has gained or lost one or more of its electrons, so it is not electrically balanced

IPSP See *inhibitory postsynaptic potential*

iris A pigmented smooth muscle that forms the colored portion of the vertebrate eye and controls pupillary size

islets of Langerhans (LAHNG-er-honz) The endocrine portion of the vertebrate pancreas that secretes the hormones insulin and glucagon into the blood

isoacids Branched-chain fatty acids generated by the deamination of some amino acids such as valine and leucine

isometric contraction (i'-sō-MET-rik) A muscle contraction in which the development of tension occurs at constant muscle length

isotonic (i'-sō-TON-ik) Having an osmolarity equal to normal body fluids

isotonic contraction A muscle contraction in which muscle tension remains constant as the muscle fiber changes length

joule The international unit for energy of any kind, equal to 0.239 calorie

juvenile hormone Insect hormone secreted by the corpora allata gland that stimulates its target tissues to retain immature characteristics

juxtaganglionic organ A crustacean organ composed of scattered cells in the connective tissue around the cerebral ganglion; the cells release peptides of uncertain function into the hemolymph during egg laying

juxtaglomerular apparatus (juks'-tuh-glō-MER-yū-lur) A cluster of specialized vascular and tubular cells at a point where the ascending limb of the loop of Henle passes through the fork formed by the afferent and efferent arterioles of the same nephron in the mammalian kidney

keratin (CARE-uh-tin) The protein found in the intermediate filaments in vertebrate skin cells that gives the skin strength and helps form a waterproof outer layer

ketone bodies A group of fatty-acid derivatives produced by the vertebrate liver during glucose sparing

kinase An enzyme that phosphorylates (adds a phosphate group to) other proteins, thereby increasing or decreasing the activity of those proteins

kinesin (ki-NĒ'-sin) The transport or motor protein that transports secretory vesicles along the microtubular highway within neuronal axons by “walking” along the microtubule

kinocilium A type of cilium that extends from the apex of all sensory hair cells in all vertebrates except mammals

knockout genetics A procedure in which a specific gene is removed from an organism's genome, usually in the fertilized egg stage; a means of testing a gene's and its coded protein's function by the consequences of its absence

koilin Mucosal lining of the gizzard; a tough protein-polysaccharide complex that has an amino acid composition similar to that of feather protein

Krogh principle "For a large number of problems there will be some animal of choice, or a few such animals, on which it can be most conveniently studied"; formulated by German physiologist Hans Krogh in 1915

K-selected Referring to species that produce relatively few offspring, with most of the parental reproductive energy used for nourishing and/or protecting the offspring

lactate An end product formed from pyruvic acid during the anaerobic process of glycolysis

lactation Milk production by the mammary glands

larynx (LARE-inks) The "voicebox" at the entrance of the mammalian trachea

latch state In vertebrates, a state of continuous contraction of smooth muscle that maintains tension with little metabolic cost

lateral geniculate nucleus The first stop in the mammalian brain for information in the visual pathway; in the thalamus

lateral inhibition The phenomenon in which the most strongly activated signal pathway originating from the center of a stimulus area inhibits the less excited pathways from the fringe areas by means of lateral inhibitory connections within sensory pathways

lateral sacs The expanded saclike regions of a muscle fiber's sarcoplasmic reticulum; store and release calcium, which plays a key role in triggering muscle contraction

law of mass action If the concentration of one of the substances involved in a reversible reaction is increased, the reaction is driven toward the opposite side, and if the concentration of one of the substances is decreased, the reaction is driven toward that side

left ventricle The heart chamber that pumps blood into the systemic circulation (in reptiles, birds, mammals)

length-tension relationship The relationship between the length of a muscle fiber at the onset of contraction and the tension the fiber can achieve on a subsequent tetanic contraction

lens A transparent, biconvex structure of a camera-type eye that refracts (bends) light rays and (in some animals) whose strength can be adjusted to accommodate for vision at different distances

leptin An endocrine signal originating from mammalian adipose tissue that informs the hypothalamus that metabolic stores are sufficient for normal energy homeostasis or for the initiation of reproduction at puberty

leukocyte endogenous mediator (LEM) (LOO-kō-sit en-DAJ-eh-nus MĒ-de-ā-tor) A chemical mediator secreted by vertebrate macrophages that is identical to endogenous pyrogen and exerts a wide array of effects associated with inflammation

leukocytes (LOO-kuh-sits) White blood cells of vertebrates; the immune system's mobile defense units

Leydig cells (LĪ-dig) The interstitial cells of vertebrate testes that secrete testosterone

LH See *luteinizing hormone*

LH surge The burst in LH secretion that occurs at midcycle of the mammalian ovarian cycle and triggers ovulation

lignin Rigid polymer derived from phenylalanine and tyrosine; with cellulose, forms the woody cell walls of plants and cements them together

limbic system (LIM-bik) A functionally interconnected ring of vertebrate forebrain structures that surrounds the brainstem and is concerned with emotions, basic survival, and sociosexual behavioral patterns, motivation, and learning

lipid emulsion A suspension of small fat droplets held apart as a result of adsorption of bile salts on their surface

long-term potentiation A long-lasting amplification in signal transmission between two neurons that results from stimulating them synchronously

loop of Henle (HEN-lē) A hairpin loop that extends between the proximal and distal tubule of the mammalian kidney's nephron

lordosis Mating posture assumed by a female

lower critical temperature In an endotherm, the temperature at which internal heat-generating mechanisms are activated to maintain thermal homeostasis

lumen (LOO-men) The interior space of a hollow organ or tube

luteal phase (LOO-tē-ul) The phase of the mammalian ovarian cycle dominated by the presence of a corpus luteum

luteinization (loo'tē-un-uh-ZĀ-shun) Formation of a postovulatory corpus luteum in the mammalian ovary

luteinizing hormone (LH) An anterior pituitary hormone of vertebrates that stimulates ovulation, luteinization, and secretion of estrogen and progesterone in females and stimulates testosterone secretion in males

lymph Interstitial fluid that is picked up by vertebrate lymphatic vessels and returned to the venous system, meanwhile passing through the lymph nodes for defense purposes

lymphocyte Vertebrate white blood cell that provides immune defense against targets for which it is specifically programmed; B and T cells

lymphoid tissue Tissue that produces and stores lymphocytes, such as lymph nodes and tonsils (in vertebrates)

lysosomes (LĪ-sō-sōmz) Organelles consisting of membrane-enclosed sacs containing powerful hydrolytic enzymes that destroy unwanted material within the cell, such as internalized foreign material or cellular debris

macrophage (MAK-ruh-fāj) Large tissue-bound phagocyte

magnetosome Magnetic crystals arranged in a chain

Maillard product Glucose covalently bound to a protein (browning reaction)

Malpighian tubules Filtering excretory tubules that begin filtration driven by secretion of ions from an arthropod's hemolymph

mantle External body wall lining the shell of mollusks, or the mantle chamber in shell-less cephalopods

mast cells Cells located within vertebrate connective tissue that synthesize, store, and release histamine, as during allergic responses

Mauthner neurons Paired giant interneurons found in some teleost fish and salamanders that elicit the startle response; activity generated in one neuron simultaneously inhibits the activity in the other

maxilloturbinal Thin curl of bone deep within the avian and mammalian nasal cavity, used to retain heat and water

mean arterial blood pressure The average pressure responsible for driving blood forward through the arteries into the tissues throughout the cardiac cycle; equals cardiac output \times total peripheral resistance

mechanically gated Referring to a channel that opens or closes in response to stretching or other mechanical deformation

mechanistic (or proximate) explanation Explanation of body functions in terms of mechanisms of action, that is, the "how" of events that occur in the body

mechanoreceptor (meh-CAN-oh-rē-SEP-tur or mek'-uh-nō-rē-SEP-tur) A sensory receptor sensitive to mechanical energy, such as stretching or bending

Meckel's diverticulum Vestige of the yolk sac; forms a tube connected to the lower ileum of birds

medullary respiratory center (MED-you-LAIR-ē) Several aggregations of neuronal cell bodies within the vertebrate medulla oblongata that provide output to the respiratory muscles and receive input important for regulating the magnitude of ventilation

meiosis (mī-ō-sis) Cell division in which the chromosomes replicate followed by two nuclear divisions so that only a half set of chromosomes is distributed to each of four new daughter cells

melanocyte-stimulating hormone (MSH) (mel-AH-nō-sit) A vertebrate hormone produced by the anterior pituitary in humans and by the intermediate lobe of the pituitary in lower vertebrates; regulates skin coloration by controlling the dispersion of melanin granules in lower vertebrates; involved with control of food intake and possibly memory and learning in humans

melatonin (mel-uh-TŌ-nin) A vertebrate hormone secreted by the pineal gland during darkness that helps entrain the body's biological rhythms with the external light/dark cues

membrane attack complex A collection of the five final activated components of the vertebrate complement system that aggregate to form a porelike channel in the plasma membrane of an invading microorganism, with the resultant leakage leading to destruction of the invader

membrane potential A separation of charges across the membrane; a slight excess of negative charges lined up along the inside of the plasma membrane and separated from a slight excess of positive charges on the outside

memory cells B or T cells of vertebrates that are newly produced in response to a microbial invader but that do not participate in the current immune response against the invader; instead they remain dormant, ready to launch a swift, powerful attack should the same microorganism invade again in the future

menstrual cycle (men'-stroo-ul) The cyclical changes in the uterus that accompany the hor-

monal changes in the ovarian cycle of humans and some other primates

mesenteron The midgut, or middle portion of the insect digestive tract

mesotocin (MT) A hormone that influences the blood flow to some organs in nonmammalian vertebrates

messenger RNA (mRNA) Carries the transcribed genetic blueprint for synthesis of a particular protein from nuclear DNA to the cytoplasmic ribosomes, where the protein synthesis takes place

metabolic acidosis (met-uh-bol'-ik) Acidosis resulting from any cause other than excess accumulation of carbonic acid in the body

metabolic alkalosis (al'-kuh-LŌ-sus) Alkalosis caused by a relative deficiency of noncarbonic acid

metabolic rate Energy expenditure per unit of time

metabolic scope The degree to which an animal's metabolism can be activated above the resting level, as in maximal muscular activity in an emergency

metanephridia Filtering excretory tubules that begin with a filtering capsule or funnel-like opening of some kind, followed by tubules that perform selective secretion and reabsorption; generally found in larger, more complex animals including adult mollusks, annelids (segmented worms), some arthropods (e.g., crustaceans), and vertebrates

metathoracic ganglia Ganglia located in the posterior segment of the insect thorax

metestrus Stage of the mammalian estrous cycle between ovulation and formation of a functional corpus luteum

methanogen A microbe that produces methane from degrading organic material; usually archaea; found in many anaerobic habitats, including ruminant stomachs

micelle (mi-SEL) A water-soluble aggregation of bile salts, lecithin, and cholesterol that has a hydrophilic shell and a hydrophobic core; carries the water-insoluble products of fat digestion to their site of absorption

microarray A glass slide on which has been fixed, in a grid, a set of cDNAs from an organism

microfilaments Cytoskeletal elements made of actin molecules (as well as myosin molecules in muscle cells); play a major role in various cellular contractile systems and serve as a mechanical stiffener for microvilli

microtubules Cytoskeletal elements made of tubulin molecules arranged into long, slender, unbranched tubes that help maintain asymmetric cell shapes and coordinate complex cell movements

microvilli (mī'-krō-VIL-i) Actin-stiffened, non-motile, hairlike projections from the luminal surface of epithelial cells lining the digestive tract and kidney tubules; tremendously increase the surface area of the cell exposed to the lumen

micturition (mik-too-RISH-un or mik-chuh-RISH-un) The process of bladder emptying; urination

mineralocorticoids (min-uh-rul-ō-KOR-ti-koidz) The vertebrate adrenocortical hormones that are important in Na⁺ and K⁺ balance; primarily aldosterone

mitochondria (mī-tō-KON-drē-uh) The energy organelles of eukaryotic cells, which contain the enzymes for oxidative phosphorylation

mitosis (mī-TŌ-sis) Cell division in which the chromosomes replicate before nuclear division, so each of the two daughter cells receives a full set of chromosomes

mitotic spindle The system of microtubules assembled during mitosis along which the replicated chromosomes are directed away from each other toward opposite sides of the cell prior to cell division

modality The kind of stimulus a sensor cell or organ reacts to

molting The process of replacing an old exoskeleton with a new one (see *ecdysis*)

monocyte (MAH-nō-sit) Vertebrate white blood cell that emigrates from the blood, enlarges, and becomes a macrophage

monoestrous Displaying one period of sexual receptivity (estrus) during a year in a mammal

monomer A unit molecule used to make a larger molecule called a *polymer*

monosaccharide (mah'-nō-SAK-uh-rīd) Simple sugar, such as glucose; the absorbable unit of digested carbohydrates

motor activity Movement of the body accomplished by contraction of skeletal muscles

motor end plate The specialized portion of a skeletal muscle fiber that lies immediately underneath the terminal button of the motor neuron and has receptor sites for binding acetylcholine released from the terminal button

motor neuron A neuron that innervates skeletal muscle and whose axons constitute the somatic nervous system

motor unit One motor neuron plus all the muscle fibers it innervates

motor unit recruitment The progressive activation of a muscle fiber's motor units to accomplish increasing gradations of contractile strength

mucosa (mew-KŌ-sah) The innermost layer of the digestive tract that lines the lumen

multiunit smooth muscle A smooth muscle mass that consists of multiple discrete units that function independently of each other and that must be separately stimulated by autonomic nerves to contract

muscarinic receptor Type of cholinergic receptor found at the effector organs of all parasympathetic postganglionic fibers

muscle fiber A relatively long and cylindrical single muscle cell

muscle tension See *tension*

muscle tissue A functional grouping of cells specialized for contraction and force generation

myelin (Mī-uh-lun) An insulative lipid covering that surrounds myelinated nerve fibers at regular intervals along the axon's length (in vertebrates and in a few nonvertebrates)

myelinated fiber Neuronal axon covered at regular intervals with insulative myelin

myocardium (mī'-ō-KAR-dē-um) The cardiac muscle layer within heart walls

myofibril (mī'-ō-FĪB-rul) A specialized intracellular structure of muscle cells that contains the contractile apparatus

myogenic Muscle contraction that is initiated by the muscle cell itself

myometrium (mī'-ō-mē-TRĒ-um) The smooth muscle layer of the mammalian uterus

myosin (Mī-uh-sun) The contractile protein that forms the thick filaments in muscle fibers

Na⁺/K⁺ pump (ATPase) A carrier that actively transports Na⁺ out of the cell and K⁺ into the cell, using ATP for energy

nanotube Long tubes with an internal actin-filament support surrounded by a plasma membrane that permits contiguous contact between two cells

nasal fossae Uppermost tract of the respiratory airways

natriuretic Loss of sodium in the urine

natural killer (NK) cells Naturally occurring, vertebrate lymphocyte-like cells that nonspecifically destroy virus-infected cells and cancer cells by directly lysing their membranes on first exposure to them

natural selection The process in which members of a species having genetic characteristics that enhance survival are able to produce more surviving offspring than other members not having those characteristics; the primary mechanism of Darwinian evolution

negative balance Situation in which the losses for a substance exceed its gains so that the total amount of the substance in the body decreases

negative feedback A regulatory mechanism in which a change in a controlled variable triggers a response that opposes the change, thus maintaining a relatively steady set point for the regulated factor

nephron (NEF-ron') The functional unit of the vertebrate kidney; consisting of an interrelated vascular and tubular component; the smallest unit that can form urine

nerve A bundle of peripheral neuronal axons, some afferent and some efferent, enclosed by a connective tissue covering and following the same pathway

nerve net A network of interconnected neurons that are distributed throughout a body or organ; characterized by a diffuse spread of excitation; occurs in most lower organisms, including Cnidarians, and in visceral organs of most higher phyla

nerve plexus Network of interwoven nerves

nervous system One of the two major regulatory systems of an animal body; in general, coordinates rapid activities of the body, especially those involving interactions with the external environment

nervous tissue One of four animal tissue types (along with epithelial, connective, and muscular); a functional grouping of cells specialized for initiation and transmission of electrical signals

net filtration pressure The net difference in the hydrostatic and osmotic forces acting across the vertebrate glomerular membrane that favors the filtration of a protein-free plasma into Bowman's capsule

neuroendocrinology The study of the interaction between the nervous and endocrine systems

neurogenic Producing a pacemaking electrical signal from neural tissue

neuroglia See *glial cells*

neuroglobin Oxygen-binding protein found in vertebrate neurons

neurohormones Hormones released into the blood by neurosecretory neurons

neuromodulator Chemical messenger that binds to neuronal receptors at nonsynaptic sites and brings about long-term changes that subtly depress or enhance synaptic effectiveness

neuromuscular junction The juncture between a motor neuron and a skeletal muscle fiber; a highly specialized synapse

neuron (NER-on) A nerve cell, typically consisting of a cell body, dendrites, and an axon and specialized to initiate, propagate, and transmit electrical signals

neuropeptides Large slow-acting peptide molecules released from axon terminals along with classical neurotransmitters; most neuropeptides function as neuromodulators

neuropil Region of the nervous system where the synapses between axons and dendrites are concentrated

neurotransmitter The chemical messenger that is released from the axon terminal of a neuron in response to an action potential and influences another neuron or an effector with which the neuron is anatomically linked

neutrophils (new'-truh-filz) Vertebrate white blood cells that are phagocytic specialists and important in inflammatory responses and defense against bacterial invasion

nicotinic receptor (nick'-o-TIN-ik) Type of cholinergic receptor found at all vertebrate autonomic ganglia and the motor end plates of skeletal muscle fibers

nitric oxide A local chemical mediator released from endothelial cells and other tissues; exerts a wide array of effects, ranging from causing local arteriolar vasodilation to acting as a toxic agent against foreign invaders to serving as a unique type of neurotransmitter

nitrogen narcosis Syndrome of reduced neural excitability in human divers with increasing depth, caused by the highly lipid-soluble N_2 dissolving in neural membranes

nociceptor (nō-sē-SEP-tur) A pain receptor, sensitive to tissue damage

node of Ranvier (RAN-vē-ā) The portions of a myelinated neuronal axon between the segments of insulative myelin; the axonal regions where the axonal membrane is exposed to the ECF and membrane potential exists

nontropic hormone A hormone that exerts its effects on nonendocrine target tissues

norepinephrine (nor'-ep-uh-NEF-run) The neurotransmitter released from vertebrate sympathetic postganglionic fibers; noradrenergic

nucleus (of brain) (NŪ-klē-us) A functional aggregation of neuronal cell bodies within the brain

nucleus (of cells) A distinct spherical or oval structure that is usually located near the center of a cell and that contains the cell's genetic material, deoxyribonucleic acid (DNA)

O_2 -Hb dissociation curve A plot of the relationship between arterial P_{O_2} and percent hemoglobin (Hb) saturation

occipital lobes (ok-SIP'-ut-ul) The lobes of the vertebrate cerebral cortex that are located posteriorly and are responsible for initially processing visual input

olfaction Smell, or detection of molecules released from a distant object

oligodendrocytes (ol-i-gō'-DEN-drō-sitz) The myelin-forming cells of the vertebrate central nervous system

omasum The third chamber of the ruminant stomach

ommatidium The structural unit of the nonvertebrate compound eye, composed of a cornea, a focusing cone and several receptor cells connected to the optic nerve

omnivore Animal that can eat both animals and other organisms such as plants or fungi

oncotic pressure Form of osmotic pressure exerted by proteins in the blood that attracts water into the circulatory system

oogenesis (ō'-ō-JEN-uh-sus) Egg production

ootheca The covering or case of an egg mass

operculum (1) Bony plate that covers fish gill arches; (2) hardened protein disc on the foot of a gastropod that seals up the shell opening when the animal is withdrawn

opsonin (OP'-suh-nun) Immune chemicals that "tag" bacteria for destruction, making the bacteria more susceptible to phagocytosis

optic chiasm Located underneath the vertebrate hypothalamus where the two optic nerves meet; depending on the species, some axons cross the midline at this point and project to the contralateral side of the brain

optic nerve The bundle of nerve fibers that leaves the retina, relaying information about visual input

optimal length The length before the onset of contraction of a muscle fiber at which maximal force can be developed on a subsequent tetanic contraction

organ A distinct structural unit composed of two or more types of primary tissue organized to perform one or more particular functions; for example, the stomach

organ of Corti (KOR-tē) The sense organ of hearing within the vertebrate inner ear that contains hair cells whose hairs are bent in response to sound waves, setting up action potentials in the auditory nerve

organelle (or'-gan-EL) Distinct, highly organized, membrane-bound intracellular compartment, containing a specific set of chemicals for carrying out a particular cellular function

organic Referring to substances that contain carbon (and usually hydrogen)

organism A living entity, either single-celled (unicellular) or made up of many cells (multicellular)

osmolarity (oz'-mō-LAR-ut-ē) A measure of the concentration of solute molecules in a solution; also known as **osmotic pressure**

osmolyte A molecule used to elevate a cell's or body fluid's osmotic pressure in order to balance a high external osmolarity; can be inorganic or organic

osmosis (os-MŌ-sis) Movement of water across a membrane down its own concentration gradient toward the area of higher solute concentration, exerting an **osmotic pressure** in doing so

osteoblasts (OS-tē-ō-blasts') Bone cells that produce the organic matrix of bone

osteoclasts Bone cells that dissolve bone in their vicinity

ostium (pl., ostia) Large porelike opening, such as that which allows hemolymph to reenter the arthropod heart after passing through the body

otolith organs (ŌT'-ul-ith) Sense organs in the vertebrate inner ear that provide information

about rotational changes in head movement; include the utricle and saccule

oval window The membrane-covered opening that separates the air-filled vertebrate middle ear from the upper compartment of the fluid-filled cochlea in the inner ear

ovarioles Tubular structures forming the insect ovary

overhydration Water excess in the body

oviparous Referring to females that release eggs from which the young hatch after expulsion from the body

oviposition In birds, the act of laying an egg

ovipositor An extension of the female insect abdomen used to lay eggs, for example, by insertion into the ground or into a host animal

ovoviviparous Referring to production of eggs that hatch within the body of the parent

ovulation (ov'-yuh-LĀ-shun) Release of an ovum from a mature ovarian follicle

oxidative phosphorylation (fos'-fōr-i-LĀ-shun) The entire sequence of mitochondrial biochemical reactions that uses oxygen to extract energy from the nutrients in food and transforms it into ATP, producing CO_2 and H_2O in the process

oxygen debt Condition in which oxygen demand is greater than oxygen supply to a tissue

oxyhemoglobin (ok-si-HĒ-muh-glō-bun) Hemoglobin combined with O_2

oxyntic mucosa (ok-SIN-tic) The mucosa that lines the body and fundus of the vertebrate stomach; contains gastric pits lined by mucous neck cells, parietal cells, and chief cells

oxytocin (ok'-sē-TŌ-sun) A hypothalamic neurohormone that is stored in the posterior pituitary and, in mammals, stimulates uterine contraction and milk ejection

pacemaker activity Self-excitable activity of an excitable cell in which its membrane potential gradually depolarizes to threshold on its own

Pacinian corpuscle (pa-SIN-ē-un) A rapidly adapting skin receptor in mammals that detects pressure and vibration

papilla A long, cone-shaped inner medulla in the kidneys of some mammals, such as rodents

parabronchi Open-ended, small parallel tubes in bird lungs, each several millimeters long and 0.5 mm wide

paracrine (PEAR-uh-krin) A local chemical messenger whose effect is exerted only on neighboring cells in the immediate vicinity of its site of secretion

parasympathetic nervous system (pear'-uh-sim-puh-THET-ik) The subdivision of the vertebrate autonomic nervous system that dominates in quiet, relaxed situations and promotes body maintenance activities such as digestion and emptying of the urinary bladder

parathyroid glands (pear'-uh-THĪ-roid) Small glands, located on or near the posterior surface of the vertebrate thyroid gland, that secrete parathyroid hormone

parathyroid hormone (PTH) A vertebrate hormone that raises plasma Ca^{2+} levels

parietal cells (puh-RĪ-ut-ul) The vertebrate stomach cells that secrete hydrochloric acid and intrinsic factor

parietal lobes The lobes of the vertebrate cerebral cortex that lie at the top of the brain behind the

central sulcus and contain the somatosensory cortex

parthenogenesis Sexual reproduction in which an egg develops without entry of a sperm; common among ants, bees, wasps, and aphids

partial pressure The individual pressure exerted independently by a particular gas within a mixture of gases

partial pressure gradient A difference in the partial pressure of a gas between two regions that promotes the movement of the gas from the region of higher partial pressure to the region of lower partial pressure

parturition (par'-too-RISH-un) Delivery of a newborn mammal

passive expiration Expiration accomplished during quiet breathing as a result of elastic recoil of the lungs on relaxation of the inspiratory muscles, with no energy expenditure required

passive force A force that does not require expenditure of cellular energy to accomplish transport of a substance across the plasma membrane

passive reabsorption When none of the steps in the transepithelial transport of a substance reabsorbed requires energy expenditure

patch clamping A process in which a tiny pipette is attached to a plasma membrane with gentle suction, forming a tight seal around one patch of a membrane; with a fine enough pipette, a single ion channel or receptor protein can be isolated

pathogens (PATH-uh-junz) Disease-causing microorganisms, such as bacteria or viruses

pathophysiology (path'-ō-fiz-ē-OL-ō-gē) Abnormal functioning of the body associated with disease

pecten Thin, comblike projections from the choroid into the vitreous humor (avian retina)

pepsinogen (pep-SIN-uh-jun) An enzyme secreted in inactive form by the stomach that, once activated, becomes **pepsin**, which begins protein digestion

peptide hormones Hormones that consist of a chain of specific amino acids of varying length

percent hemoglobin saturation A measure of the extent to which the hemoglobin present is combined with O₂

perception The brain's interpretation of the external world as created from a pattern of nerve impulses delivered to it

perfusion The pumping of a fluid through a tissue or organ by means of a circulatory vessel

peripheral chemoreceptors (kē'-mō-rē-SEP-turz) The carotid and aortic bodies, which respond to changes in arterial P_{O₂}, P_{CO₂}, and H⁺ and that adjust respiration accordingly (in vertebrates)

peripheral nervous system (PNS) Nerve fibers that carry information between the central nervous system and other parts of the body

peristalsis (per'-uh-STOL-sus) Ringlike contractions of the circular smooth muscle of a tubular organ that move progressively forward with a stripping motion, pushing the contents of the organ ahead of the contraction

peritrophic membrane Layer that separates the midgut epithelium from the food in insects

peritubular capillaries (per'-i-TŪ-bŭ-lur) Capillaries that intertwine around the tubules of the mammalian kidney's nephron; they supply the renal tissue and participate in exchanges between the tubular fluid and blood during the formation of urine

permeable Permitting passage of a particular substance

permissiveness The condition when one hormone must be present in adequate amounts for the full exertion of another hormone's effect

peroxisomes (puh-ROK'-suh-sōmz) Organelles consisting of membrane-bound sacs that contain powerful oxidative enzymes that detoxify various wastes produced within the cell or foreign compounds that have entered the cell

pH The logarithm to the base 10 of the reciprocal of the hydrogen ion concentration; pH log 1/[H⁺] or pH log[H⁺]

phagocytosis (fag'-oh-si-TŌ-sus) A type of endocytosis in which large multimolecular solid particles are engulfed by a cell

pharynx (FARE-inks) The throat, which in vertebrates serves as a common passageway for the digestive and respiratory systems

phasic receptors Sensory receptors that produce action potentials at the onset and offset of a sustained stimulus

pheromone Chemical signal released into the environment, usually by glands, which travels through the air or water to sensory cells in another animal; used for sexual activity (e.g., signaling of readiness to mate), marking of territories, and other behaviors related to interactions among individuals of a species

phosphagen An energy-storing cellular molecule with a phosphate attached by a high-energy bond, such as creatine phosphate and arginine phosphate; its phosphate can be transferred to ADP to make ATP

phosphorylation (fos'-fōr-i-LĀ-shun) Addition of a phosphate group to a molecule

photoperiod The amount of time during the day when there is light

photoreceptor A sensory receptor responsive to light

phototransduction The mechanism of converting light stimuli into electrical activity by the rods and cones of the eye

physiology (fiz-ē-OL-ō-gē) The study of organismal functions

phytoestrogen Natural estrogenic-like compounds synthesized by some plant species

pineal gland (PIN-ē-ul) A small endocrine gland located in the center of the vertebrate brain that secretes the hormone melatonin

pinna A skin-covered flap of cartilage around the entrance to the mammalian ear, collects sound

pinocytosis (pin-oh-ci-TŌ-sus) Type of endocytosis in which the cell internalizes fluid

pitch The tone of a sound, determined by the frequency of vibrations (i.e., whether a sound is a C or G note)

pituitary gland (pih-TWO-ih-tair-ee) A small vertebrate endocrine gland connected by a stalk to the hypothalamus; consists of the anterior pituitary and posterior pituitary

placenta (plah-SEN-tah) The organ of exchange between the maternal and fetal blood in placental mammals and some sharks

plasma The liquid portion of the blood or hemolymph

plasma cell An antibody-producing derivative of an activated vertebrate B lymphocyte

plasma clearance The volume of plasma that is completely cleared of a given substance by the kidneys per minute

plasma membrane A protein-studded lipid bilayer that encloses each cell, separating it from the extracellular fluid

plasma proteins The proteins that remain within the plasma, where they perform a number of important functions; include albumins, globulins, and fibrinogen in vertebrates

plasma-colloid osmotic pressure (KOL-oid os-MOT-ik) The force caused by the unequal distribution of plasma proteins between the blood and surrounding fluid that encourages fluid movement into the capillaries

plasticity (plas-TIS-uh-tē) The ability of portions of the nervous system to assume new responsibilities in response to the demands placed on it

platelet (PLĀT-let) Specialized cell fragment in mammalian blood that participates in hemostasis by forming a plug at a vessel defect

pleural sac (PLOOR-ul) A double-walled, closed sac that separates each lung from the thoracic wall in air-breathing vertebrates

pluripotent stem cell Precursor cell that resides in certain adult tissues (e.g., bone marrow in mammals) and continuously divides and differentiates to give rise to specialized cells (e.g., blood cells in mammals)

poikilotherm Animal whose body temperature varies with environmental temperature

polarity Unequal sharing of electrons between atoms

polarized light Light in which the waves are all oriented at the same angle

polyestrous Mammalian estrous cycles occurring uniformly throughout the year without seasonal influence

polymer A chain of monomers linked together

polysaccharide (pol'-i-SAK-uh-rid) Complex carbohydrate consisting of chains of interconnected glucose molecules (starch, glycogen, cellulose)

polyunsaturated fatty acid (PUFA) A fatty acid in which more than one of the bonds between carbon atoms in the carbon chain backbone of the molecules are double bonds

positive balance Situation in which the gains via input for a substance exceed its losses via output, so the total amount of the substance in the body increases

positive feedback A regulatory mechanism in which the input and the output in a control system continue to enhance each other so that the controlled variable is progressively moved further from a steady state

postabsorptive state The metabolic state after a meal is absorbed during which endogenous energy stores must be mobilized (and glucose must be spared for the glucose-dependent brain in vertebrates); fasting state

posterior pituitary The neural portion of the pituitary that stores and releases into the blood on hypothalamic stimulation two hormones produced by the hypothalamus, vasopressin and oxytocin (in vertebrates)

postganglionic fiber (pōst'-gan-glē-ON-ik) The second neuron in the two-neuron autonomic nerve pathway; originates in an autonomic ganglion and terminates on an effector organ (in vertebrates)

postsynaptic neuron (pōst'-si-NAP-tik) The neuron that conducts its action potentials away from a synapse

precocial Referring to young (hatchlings) with well-developed legs, open eyes, and alertness; able to leave the nest and feed independently

preganglionic fiber The first neuron in the two-neuron autonomic nerve pathway; originates in the central nervous system and terminates on an autonomic ganglion (in vertebrates)

pregastric fermentation Positioning the microbe-containing fermentation chamber of ruminants before the acid-secreting stomach

preprohormones Large precursor proteins that undergo a series of posttranslational modifications to yield the biologically active hormone end product

pressure gradient A difference in pressure between two regions that drives the movement of blood or air from the region of higher pressure to the region of lower pressure

presynaptic facilitation Enhanced release of neurotransmitter from a presynaptic axon terminal as a result of excitation of another neuron that terminates on the axon terminal

presynaptic inhibition A reduction in the release of neurotransmitter from a presynaptic axon terminal as a result of excitation of another neuron that terminates on the axon terminal

presynaptic neuron (prē-si-NAP-tik) The neuron that conducts its action potentials toward a synapse

primary active transport A carrier-mediated transport system in which energy is directly required to operate the carrier and move the transported substance against its concentration gradient; see *secondary active transport*

primary follicle A primary oocyte surrounded by a single layer of granulosa cells in the ovary (in vertebrates)

primary motor cortex The portion of the vertebrate cerebral cortex that lies anterior to the central sulcus and is responsible for voluntary motor output

proctodaeum In birds, the hind portion of the cloaca, stores the excreta; in insects, the hindgut from the Malpighian tubules to the anus

proestrus The stage of the estrous cycle between the regression of the corpus luteum and the onset of estrus

prokaryote A microbial cell that has no classic organelles such as a nucleus; bacteria and archaea

prolactin (PRL) (prō-LAK-tun) An anterior pituitary hormone with numerous roles; for example, stimulates mammary gland development and milk production in female mammals, and regulates osmoregulation in fishes (among other effects)

promoter A regulatory or “switch” section of DNA that can be bound by specific transcription-regulating proteins, thereby regulating the transcription of a nearby RNA-coding gene

pro-opiomelanocortin (POMC) (prō-op'Ē-ō-ma-LAN-oh-kor'-tin) A large precursor molecule produced by the anterior pituitary that is cleaved into adrenocorticotrophic hormone, melanocyte-stimulating hormone, and endorphin (in vertebrates)

proPOs Inactive forms of POs (phenoloxidases) that are activated during exoskeletal synthesis and immune responses in arthropods

proprioception (prō'-prē-ō-SEP-shun) Sensing of position of body parts in relation to each other and to surroundings

proprioceptors Sensors that send information about movement and position of an animal's body or certain parts such as limbs

prostaglandins (pros'-tuh-GLAN-dins) Local chemical mediators (paracrine) that are derived from a component of the plasma membrane, arachidonic acid

prostate gland A vertebrate male accessory sex gland that secretes an alkaline fluid, which neutralizes acidic vaginal secretions in internal fertilizers

protandry Process in which a male becomes a female

proteasome An organelle that destroys unwanted cell proteins that have been tagged by ubiquitin

protein kinase (KĪ-nase) An enzyme that phosphorylates and thereby induces a change in the shape and function of a particular intracellular protein

proteolytic enzymes (prōt'-ē-uh-LIT-ik) Enzymes that digest protein

proteomics (proteonomics) The study of the structure, regulation, and functions of proteins

protogyny Process in which a female becomes a male

protonephridia Blind-end ducts that project into the body cavity and that filter wastes using ultrafiltration driven by cilia, followed by secretion, and reabsorption; generally found in more primitive animals having one internal fluid compartment, such as rotifers, flatworms, larval annelids, and larval mollusks

proventriculus (1) True stomach of a bird; (2) in some nonvertebrates, a dilation of the foregut

proximal tubule A highly convoluted tubule that extends between Bowman's capsule and the loop of Henle in the mammalian kidney's nephron

proximate explanation See *mechanistic explanation*

pseudogene A gene sequence that once coded for a protein but no longer does so

PTH See *parathyroid hormone*

pubertin See *leptin*

pulmonary artery (PULL-mah-nair-ē) The large vessel that carries blood from the heart to the lungs (in air-breathing vertebrates)

pulmonary circulation The loop of blood vessels carrying blood between the heart and lungs (in air-breathing vertebrates)

pulmonary surfactant (sur-FAK-tunt) A phospholipoprotein complex secreted by the Type II alveolar cells that intersperses between the water molecules that line the alveoli, thereby lowering the surface tension within the lungs (in mammals)

pulmonary valve A one-way valve that permits the flow of blood from the right ventricle into the pulmonary artery during ventricular emptying but prevents the backflow of blood from the pulmonary artery into the right ventricle during ventricular relaxation (in mammals, birds)

pulmonary vein The large vessel that carries blood from the lungs to the heart (in air-breathing vertebrates)

pulmonary ventilation The volume of air breathed in and out of the lungs in one minute; equals tidal volume \times respiratory rate

pupil A round opening in the center of the iris through which light passes to the interior portions of the eye (adjustable in some animals)

Purkinje fibers (pur-KIN-jē) Small terminal fibers that extend from the bundle of His and rapidly transmit an action potential throughout the mammalian ventricular myocardium

pyloric gland area (PGA) (pī-LÖR-ik) The specialized region of the mucosa in the antrum of the mammalian stomach that secretes gastrin

pyloric sphincter (pī-lör'-ik SFINGK-tur) The juncture between the stomach and duodenum (in vertebrates)

radiation Emission of heat energy from the surface of a warm body in the form of electromagnetic waves

reabsorption The net movement of interstitial fluid into the capillary

receptor See *sensory receptor* or *receptor site*

receptor potential The graded potential change that occurs in a sensory receptor in response to a stimulus; generates action potentials in the afferent neuron fiber

receptor site Membrane protein that binds with a specific extracellular chemical messenger, thereby bringing about a series of membrane and intracellular events that alter the activity of the particular cell

rectal gland A specialized hindgut organ of cartilaginous fishes, which has numerous blind-end tubules that remove and excrete NaCl using active transport

reflex Any response that occurs automatically without modification by “higher” control centers; the components of a reflex arc include a receptor, afferent pathway, integrating center, efferent pathway, and effector

reflex arc A neuronal pathway that controls the reflex motor response to a specific sensory stimulus

refraction Bending of a light ray

refractory period (rē-FRAK-tuh-rē) The time period when a recently activated patch of membrane is refractory (unresponsive) to further stimulation, preventing the action potential from spreading backward into the area through which it has just passed, thereby ensuring the unidirectional propagation of the action potential away from the initial site of activation

regulators Organisms in which a particular physiological state is kept relatively constant in the face of a changing environment

regulatory T cell A type of T cell that suppresses the actions of other T cells, keeping them in check

regulatory volume decrease (RVD) A process in which cells subjected to osmotic swelling decrease their internal osmotic pressure by removing osmolytes in order to restore cell volume

regulatory volume increase (RVI) A process in which cells subjected to osmotic shrinkage increase their internal osmotic pressure by accumulating osmolytes in order to restore cell volume

releasing hormone A hypothalamic hormone that stimulates the secretion of a particular anterior pituitary hormone (in vertebrates)

renal cortex An outer, granular-appearing region of the mammalian and avian kidney

renal medulla (RĒ-nul muh-DUL-uh) An inner, striated-appearing region of the mammalian and avian kidney

renal threshold The plasma concentration at which the T_m (tubular maximum) of a particular substance is reached and the substance first starts appearing in the urine

renin (RĒ-nin) An enzymatic hormone released from mammalian kidneys in response to a decrease in NaCl/ECF volume/arterial blood pressure; activates angiotensinogen

renin-angiotensin-aldosterone system (RAAS) (an'jē-ō-TEN-sun al-dō-steer-OWN) The salt-conserving system triggered by the release of renin from mammalian kidneys, which activates angiotensin, which stimulates aldosterone secretion, which stimulates Na^+ reabsorption by the kidney tubules

repolarization (rē'pō-luh-ruh-ZĀ-shun) Return of membrane potential to resting potential following a depolarization

reset In physiological negative-feedback regulation, the process of changing the set point from one level to another

residual volume The minimum volume of air remaining in respiratory pathways even after a maximal expiration

resistance Hindrance of flow of liquid or air through a passageway (e.g., a blood vessel or respiratory airway)

respiration The sum of processes that accomplish ongoing movement of O_2 from the atmosphere to the tissues, as well as the continual movement of metabolically produced CO_2 from the tissues to the atmosphere

respiratory acidosis (as-i-DŌ-sus) Acidosis resulting from abnormal retention of CO_2 arising from hypoventilation

respiratory airways The system of tubes that conducts air between the atmosphere and the alveoli of the lungs

respiratory alkalosis (al'-kuh-LŌ-sus) Alkalosis caused by excessive loss of CO_2 from the body as a result of hyperventilation

respiratory rate Breaths per minute

response element A promoter DNA sequence that is the target of action of signal molecules such as hormones; binds to a hormone and its nuclear receptor; also termed hormone response element (HRE)

resting membrane potential The membrane potential that exists when an excitable cell is not displaying an electrical signal

rete mirabile Extensive countercurrent network of arterial and venous capillaries

reticular activating system (RAS) (ri-TIK-ū-lur) Ascending fibers that originate in the reticular formation and carry signals upward to arouse and activate the cerebral cortex (in vertebrates)

reticular formation A network of interconnected neurons that runs throughout the vertebrate brainstem and initially receives and integrates all synaptic input to the brain

reticulum The second stomach of ruminants (see *rumen*)

retina The innermost layer in the posterior region of an eye that contains the eye's photoreceptors, the rods and cones

rhabdomere Specialized region of the retinal cell of a nonvertebrate compound eye

rheostasis Regulated change of a physiological state

rhopalium Cnidarian medusa sense organ; has ocelli (simple eye structures) and statocysts

ribonucleic acid (RNA) (ri-bō-new-KLĀ-ik) A nucleic acid that exists in three major forms (messenger RNA, ribosomal RNA, and transfer RNA), which participate in gene transcription and protein synthesis (other forms have also been recently discovered, such as small nuclear and microRNAs)

ribosomes (RĪ-bō-sōms) Special ribosomal RNA-protein complexes that synthesize proteins under the direction of nuclear DNA

right atrium (Ā'-trē-um) The heart chamber that receives venous blood from the systemic circulation (in reptiles, birds, mammals)

right ventricle The heart chamber that pumps blood into the pulmonary circulation (in reptiles, birds, mammals)

rigor mortis "Stiffness of death"; a generalized locking-in-place of the skeletal muscles that begins sometime after death

RNA See *ribonucleic acid*

rods The eye's photoreceptors used for night vision

root effect A decrease in the O_2 -carrying capacity of hemoglobin in response to a decrease in pH

round window In higher vertebrates, the membrane-covered opening that separates the lower chamber of the cochlea in the inner ear from the middle ear

r-selected Referring to species that place virtually all reproductive resources into producing hundreds to thousands (or more) of offspring, with no parental care and minimal nourishment

rumen The first compartment of the ruminant stomach; microbial populations found in the rumen include anaerobic species of bacteria, protozoa, and fungi

ruminant Various hoofed mammals that chew food already swallowed and that have a stomach divided into four (or three) compartments

ruminoreticulum The rumen and its continuation, the reticulum; two compartments of the ruminant stomach

SA node See *sinoatrial node*

salivary amylase (AM-uh-lās') An enzyme produced by salivary glands that begins carbohydrate digestion in the mouth and continues in the digestive tract after the food and saliva have been swallowed

salt gland A specialized gland associated with the eyes or nasal cavities of marine birds and reptiles; it removes excess NaCl from the blood

saltatory conduction (SAL-tuh-tōr'-ē) The means by which an action potential is propagated throughout a myelinated fiber, with the impulse jumping over the myelinated regions from one node of Ranvier to the next (in vertebrates)

sarcomere (SAR-kō-mir) The functional unit of skeletal muscle; the area between two Z lines within a myofibril

sarcoplasmic reticulum (ri-TIK-yuh-lum) A fine meshwork of interconnected tubules that surrounds a muscle fiber's myofibrils; contains expanded lateral sacs, which store calcium that is released into the cytosol in response to a local action potential

satiety centers (suh-TĪ-ut-ē) Neuronal clusters in the ventromedial region of the hypothalamus that inhibit feeding behavior (in vertebrates)

saturation The condition when all the binding sites on a carrier molecule are occupied

scaling The phenomenon that many anatomical and physiological parameters vary with other parameters (e.g., body mass) in nonproportional relationships

Schwann cells (shwah'-n) The myelin-forming cells of the vertebrate peripheral nervous system

second messenger An intracellular chemical that is activated by binding of an extracellular first messenger to a surface receptor site and that triggers a preprogrammed series of biochemical events, which result in altered activity of intracellular proteins to control a particular cell activity

secondary active transport A transport mechanism in which a carrier molecule for glucose or an amino acid is driven by an Na^+ concentration gradient established by the energy-dependent Na^+ pump to transfer the glucose or amino acid uphill without directly expending energy to operate the carrier

secondary follicle A developing ovarian follicle that is secreting estrogen and forming an antrum (in vertebrates)

secondary sexual characteristics The many external characteristics that are not directly involved in reproduction but that distinguish males and females

secretin (si-KRĒT-'n) A hormone released from the vertebrate duodenal mucosa primarily in response to the presence of acid; inhibits gastric motility and secretion and stimulates secretion of an NaHCO_3 solution from the pancreas

secretion Release to a cell's exterior, on appropriate stimulation, of substances that have been produced by the cell

secretory vesicles (VES-i-kuls) Membrane-enclosed sacs containing proteins that have been synthesized and processed by the endoplasmic reticulum/Golgi complex of the cell and that will be released to the cell's exterior by exocytosis on appropriate stimulation

segmentation The vertebrate small intestine's primary method of motility; consists of oscillating, ringlike contractions of the circular smooth muscle along the small intestine's length

self-antigens Antigens that are characteristic of an animal's own cells

semen (SĒ-men) A mixture of accessory sex-gland secretions and sperm

semicircular canal Sense organ in the inner ear that detects rotational or angular acceleration or deceleration of the head (in vertebrates)

semilunar valves (sem'-i-LEW-nur) The aortic and pulmonary valves (in the avian and mammalian heart)

seminal vesicles (VES-i-kuls) Male accessory sex glands that supply fructose to ejaculated sperm and secrete prostaglandins (in vertebrates)

semiferous tubules (sem'-uh-NIF-uh-rus) The highly coiled tubules within vertebrate testes that produce spermatozoa

sensilla Specialized projections from insect cuticles for tasting

sensory afferent Pathway coming into the central nervous system that carries information

sensory input Includes somatic sensation and special senses

sensory receptor An afferent neuron's peripheral ending, which is specialized to respond to a particular stimulus in its environment

septum (pl., *septa*) Dividing wall or partition

series-elastic component The noncontractile portions of a skeletal muscle fiber, including the connective tissue and sarcoplasmic reticulum

Sertoli cell (sur-TŌ-lē) Cell located in the seminiferous tubules that supports spermatozoa during their development (in vertebrates)

set point The desired level at which homeostatic control mechanisms maintain a controlled variable

signal transduction The sequence of events in which incoming signals (instructions from extracellular chemical messengers such as hormones) are conveyed to the cell's interior for execution

single-unit smooth muscle The most abundant type of smooth muscle; made up of muscle fibers that are interconnected by gap junctions so that they become excited and contract as a unit; also known as *visceral smooth muscle*

sinoatrial (SA) node (sī-nō-Ā-trē-ul) A small specialized autorhythmic region in the right atrial wall of the heart that has the fastest rate of spontaneous depolarizations and serves as the normal pacemaker of the heart (in reptiles, birds, mammals)

sinus venosus In all fishes, a chambered extension of the atrium into which blood first enters the heart

skeletal muscle Striated muscle, which is attached to the endoskeleton or exoskeleton and is responsible for movement of the parts of the skeleton in purposeful relation to one another; innervated by the somatic nervous system and under both reflex and nonreflex control

slow-wave potentials Self-excitability activity of an excitable cell in which its membrane potential undergoes gradually alternating depolarizing and hyperpolarizing swings

Smith predictor A control device that predicts the next step in a regulated process and triggers it to begin before feedback information is received about the immediately preceding step; thought to be the mechanism by which the mammalian cerebellum controls skilled locomotory movements

smooth muscle Muscle without organized sarcomeres; found in the walls of hollow organs and tubes; innervated by the autonomic nervous system in vertebrates

solutes Molecules dissolved in liquid (e.g., water)

somatic cells (sō-MAT-ik) Body cells, as contrasted with reproductive cells

somatic nervous system The portion of the efferent division of the vertebrate peripheral nervous system that innervates skeletal muscles; consists of the axonal fibers of the alpha motor neurons

somatic sensation Sensory information arising from the body surface or interior, including somesthetic sensation and proprioception

somatomedins (sō'-mat-uh-MĒ-dinz) Hormones secreted by the vertebrate liver or other tissues, in response to growth hormone, that act directly on the target cells to promote growth

somatosensory cortex The region of the vertebrate parietal lobe immediately behind the central sulcus; the site of initial processing of somesthetic and proprioceptive input

somesthetic sensation Sensory information arising mainly from the body surface (touch, pressure, temperature, pain, and electrical fields)

sound waves Traveling vibrations of air that consist of regions of high pressure caused by compression of air molecules alternating with regions

of low pressure caused by rarefaction of the molecules

spatial summation The summing of several postsynaptic potentials arising from the simultaneous activation of several excitatory (or several inhibitory) synapses

specific dynamic action See *diet-induced thermogenesis*

specificity Ability of carrier molecules to transport only specific substances across the plasma membrane

spermatheca Organ that stores the sperm prior to entry into the vagina

spermatogenesis (spur'-mat-uh-JEN-uh-sus) Sperm production

spermatophore Sperm-containing capsule formed by hardened seminal fluid

sphincter (sfink-tur) A ring of muscle that controls passage of contents through an opening into or out of a hollow organ or tube

spiracle Surface opening of the tracheal system in insects and certain arachnids

spleen A vertebrate lymphoid tissue in the upper left part of the abdomen that stores lymphocytes and platelets and destroys old red blood cells

stanniocalcin A hormone regulating calcium homeostasis in bony fish (formerly called *hypocalcin*); synthesized in small organs termed the corporacles of Stannius located within the kidney

state of equilibrium A condition in which no net change in a system is occurring

statolith Small dense particle, that readily moves within the fluid content of a statocyst, to provide directional information

stem cell Relatively undifferentiated precursor cell that gives rise to highly differentiated, specialized cells

stenohaline Having a limited tolerance to changes in salinity

stereocilia Nonmotile, ciliary projections of a hair cell

steroid (STEER-oid) Hormone derived from cholesterol

stimulus A detectable physical or chemical change in the environment of a sensory receptor

stomodaeum The foregut of an insect

stress The generalized, nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory abilities to maintain homeostasis

stress proteins Low-molecular-weight proteins synthesized in many types of organisms after a sudden increase in a stress factor such as temperature, pollutants, or oxygen deprivation; help properly fold other proteins perturbed by the stress factor; if associated with heat stress, these are called *heat shock proteins* (HSPs)

stretch reflex A monosynaptic reflex in which an afferent neuron originating at a stretch-detecting receptor in a skeletal muscle terminates directly on the efferent neuron supplying the same muscle to cause it to contract and counteract the stretch

stroke volume (SV) The volume of blood pumped out of a ventricle with each contraction, or beat, of the heart

subcortical regions The vertebrate brain regions that lie under the cerebral cortex, including the basal nuclei, thalamus, and hypothalamus

submucosa The connective tissue layer of the digestive tract that lies under the mucosa and (in vertebrates) contains the larger blood and lymph vessels and a nerve network

substance P The neurotransmitter released from mammalian pain fibers

subsynaptic membrane (sub-sih-NAP-tik) The portion of the postsynaptic cell membrane that lies immediately underneath a synapse and contains receptor sites for the synapse's neurotransmitter

supercooling A state of water in which the temperature is below the freezing point, but with no trigger or nucleation site to begin ice formation

suprachiasmatic nucleus (SCN) (soup'-ra-kī-as-MAT-ik) A cluster of nerve cell bodies in the hypothalamus that serves as the master biological clock, acting as the pacemaker that establishes many of the mammalian body's circadian rhythms

surface tension The force at the liquid surface of an air-water interface resulting from the greater attraction of water molecules to the surrounding water molecules than to the air above the surface; a force that tends to decrease the area of a liquid surface and resists stretching of the surface

sympathetic nervous system The subdivision of the vertebrate autonomic nervous system that dominates in emergency ("fight-or-flight") or stressful situations and prepares the body for strenuous physical activity

symporter A transporter protein in a membrane that moves two (or more) molecules or ions in the same direction

synapse (SIN-aps') The specialized junction between two neurons where an action potential in the presynaptic neuron influences the membrane potential of the postsynaptic neuron by means of the release of a chemical messenger that diffuses across the small cleft that separates the two neurons

synchronous In step or in phase control of flight muscles, which are activated by the release of Ca²⁺ and deactivated by Ca²⁺ reuptake

synergism (SIN-er-jiz'-um) When several actions are complementary, causing their combined effect to be greater than the sum of their separate effects

syrix Vocal organ of birds, located at the lower end of the trachea, where the two bronchi join; acts as a sound-producing valve in which air forced by pressure from the lungs sets the tympanic membranes in motion

systemic circulation (sis-TEM-ik) The closed loop of vertebrate blood vessels carrying blood between the heart and body systems

systole (SIS-tō-lē) The period of cardiac contraction and emptying

T lymphocytes (T cells) Vertebrate white blood cells that accomplish cell-mediated immune responses against targets to which they have been previously exposed; see also *cytotoxic T cells* and *helper T cells*

T tubule See *transverse tubule*

T₃ See *tri-iodothyronine*

T₄ See *thyroxine*

taeniae coli Three separate, conspicuous, longitudinal bands of muscle lining the large intestine

tapetum lucidum Reflecting structure found in the choroid coat of some nocturnal animals

target cell receptors Receptors located on a target cell that are specific for a particular chemical mediator

target cells The cells that a particular extracellular chemical messenger, such as a hormone or a neurotransmitter, influences

TATA box A promoter found next to almost all eukaryotic RNA-coding genes; site for the initial binding of RNA polymerase, an enzyme that makes an RNA copy of the coding gene sequence

teleological approach (tē'-lē-ō-LĀ-jī-kul) Explanation of body functions in terms of their particular purpose in fulfilling a bodily need, that is, the "why" of body processes (in contrast to *mechanistic* and *evolutionary explanations*)

telomere The end section of eukaryotic chromosomes; pieces of it are lost during cell replication

temporal lobes The lobes of the mammalian cerebral cortex that are located laterally and that are responsible for initially processing auditory input

temporal summation The summing of several postsynaptic potentials occurring very close together in time because of successive firing of a single presynaptic neuron

tension In muscles, the force produced during muscle contraction by shortening of the sarcomeres, resulting in stretching and tightening of the muscle's elastic connective tissue and tendon, which transmit the tension to the bone to which the muscle is attached

terminal button A vertebrate motor neuron's enlarged knoblike ending that terminates near a skeletal muscle fiber and releases acetylcholine in response to an action potential in the neuron

testosterone (tes-TOS-tuh-rōn) The vertebrate male sex hormone, secreted by the Leydig cells of the testes

tetanus (TET'-n-us) A smooth, maximal muscle contraction that occurs when the fiber is stimulated so rapidly that it does not have a chance to relax at all between stimuli

thalamus (THAL-uh-mus) The vertebrate brain region that serves as a synaptic integrating center for preliminary processing of all sensory input on its way to the cerebral cortex

thecal cells (THAY-kel) The outer layer of specialized ovarian connective tissue cells in a maturing follicle (in vertebrates)

thermal neutral zone (TNZ) A range of environmental temperatures in which an animal does not need to expend significant energy for thermoregulation

thermogenin An uncoupling protein in brown adipose tissue of mammals

thermoreceptor (thur'-mō-rē-SEP-tur) A sensory receptor sensitive to heat and cold

thick filaments Specialized cytoskeletal structures within skeletal muscle that are made up of myosin molecules and interact with the thin filaments to accomplish shortening of the fiber during muscle contraction

thin filaments Specialized cytoskeletal structures within skeletal muscle that are made up of actin, tropomyosin, and troponin molecules and interact with the thick filaments to accomplish shortening of the fiber during muscle contraction

thoracic cavity (thō-RAS-ik) Chest cavity

threshold potential The critical potential that must be reached before an action potential is initiated in an excitable cell

thrombocyte A blood cell in nonmammalian vertebrates that participates in clotting

thrombus An abnormal clot attached to the inner lining of a blood vessel

thymus (THIGH-mus) A vertebrate lymphoid gland located midline in the chest cavity that processes T lymphocytes and produces the hormone thymosin, which maintains the T-cell lineage

thyroglobulin (thi'-rō-GLOB-yuh-lun) A large complex molecule on which all steps of thyroid hormone synthesis and storage take place

thyroid gland An endocrine gland that traps and stores iodide from the blood of vertebrates and that secretes thyroxine and tri-iodothyronine, hormones that regulate vertebrate development and metabolism

thyroid hormone Collectively, the vertebrate hormones secreted by the thyroid follicular cells, namely, thyroxine and tri-iodothyronine

thyroid-stimulating hormone (TSH) An anterior pituitary hormone that stimulates secretion of thyroid hormone and promotes growth of the thyroid gland; thyrotropin

thyroxine (thi-ROCKS-in) The most abundant hormone secreted by the vertebrate thyroid gland; important in the regulation of overall metabolic rate; also known as tetraiodothyronine, or T₄

tidal breathing Movement of air or water in and out of a respiratory chamber via the same opening, in two distinct steps termed *inspiration* and *expiration*, for the purposes of gas exchange

tidal volume The volume of air entering or leaving tidal-type lungs during a single breath

tight junction An impermeable junction between two adjacent epithelial cells formed by the sealing together of the cells' lateral edges near their luminal borders; prevents passage of substances between the cells

tissue (1) A functional aggregation of cells of a single specialized type, such as nerve cells forming nervous tissue; (2) the aggregate of various cellular and extracellular components that make up a particular organ, such as lung tissue

titin Cytoskeletal elastic protein in the myofibril; forms a flexible filamentous network that can stretch under tension; may act as a locomotory spring that assists in the return of the sarcomere to its relaxed conformation

T_m See *transport maximum* and *tubular maximum*

TMAO (trimethylamine oxide) A counteracting osmolyte in many marine organisms, capable of offsetting the perturbing effects of urea, pressure, and other stressors on proteins

tone The ongoing baseline of activity in a given system or structure, as in muscle tone, sympathetic tone, or vascular tone

tonic receptors Sensory receptors that continue to generate action potentials throughout the duration of a stimulus; directly convey information about the duration of the stimulus

torpor A state of reduced metabolic rate in an animal occurring on a daily basis; involves lower body temperatures in endotherms

total peripheral resistance The resistance offered by all the peripheral blood vessels, with arteriolar resistance contributing most extensively

trachea (TRĀ-kē-uh) (1) The "windpipe"; the conducting airway that extends from the pharynx and branches into two bronchi, each entering a lung (in air-breathing vertebrates); (2) an air tube

in an air-breathing arthropod that leads directly to a tissue requiring oxygen

tracheole System of air-filled tubules that exchange respiratory gases from the outside world with insect tissues

tract A bundle of nerve fibers (axons of long interneurons) with a similar function within a long nerve cord (e.g., the spinal cord)

transducin G protein that links the excitation of rhodopsin molecules by light with a change in the current flowing across the membrane of photoreceptors

transduction Conversion of stimuli into action potentials by sensory receptors

transepithelial transport (tranz-ep-i-THĒ-lē-al) The entire sequence of steps involved in the transfer of a substance across the epithelium between either the renal tubular lumen or digestive tract lumen and the blood

transgenic organism An organism that has had genes from another species incorporated into its genome

transmural pressure gradient The pressure difference across the lung wall (intra-alveolar pressure is greater than intrapleural pressure) that stretches the lungs to fill the thoracic cavity, which is larger than the unstretched lungs (in air-breathing vertebrates)

transport maximum (T_m) The maximum rate of a substance's carrier-mediated transport across the membrane when the carrier is saturated; in the kidney tubules, known as *tubular maximum*

transporter recruitment The phenomenon of inserting additional transporters (carriers) for a particular substance into the plasma membrane, thereby increasing membrane permeability to the substance, in response to an appropriate stimulus

transverse tubule (T tubule) A perpendicular infolding of the surface membrane of a muscle fiber; rapidly spreads surface electric activity into the central portions of the muscle fiber

trehalose Diglucose (a disaccharide); in insects, synthesized in the fat body as a metabolic substrate for flight

triglyceride (trī-GLIS-uh-rid) Neutral fat composed of one glycerol molecule with three fatty-acid molecules attached

tri-iodothyronine (T₃) (trī-ī-ō-dō-THĪ-rō-nēn) The most potent hormone secreted by the vertebrate thyroid follicular cells; important in the regulation of overall metabolic rate in birds and mammals

trimodal Three respiratory exchange surfaces, including the gills, lungs, and some cutaneous surfaces

trophic hormone "Nourishing" hormone involved in triggering cell growth and development; not to be confused with *tropic* hormone

trophoblast (TRŌ-fuh-blast') The outer layer of cells in a mammalian blastocyst, responsible for accomplishing implantation and developing the fetal portion of the placenta

trophocytes Cells in the fat body of insects that perform a role in intermediary metabolism

tropic hormone (TRŌ-pik) A hormone that regulates the secretion of another hormone; not to be confused with *trophic* hormone

tropomyosin (trōp'-uh-MĪ-uh-sun) One of the regulatory proteins found in the thin filaments of muscle fibers

troponin (tro-PŌ-nun) One of the regulatory proteins found in the thin filaments of muscle fibers

TSH See *thyroid-stimulating hormone*

tuberosus electroreceptors Found on the anterior body surface in the lateral line system, these receptors respond to the high-frequency signals from the fish's own electric organ discharge

tubular maximum (T_m) The maximum amount of a substance that renal tubular cells can actively transport within a given time period; the kidney cells' equivalent of transport maximum

tubular reabsorption The selective transfer of substances from the tubular fluid into the peritubular capillaries during the formation of urine

tubular secretion The selective transfer of substances from the peritubular capillaries into the tubular lumen during the formation of urine

twitch A brief, weak contraction that occurs in response to a single action potential in a muscle fiber

twitch summation The addition of two or more muscle twitches as a result of rapidly repetitive stimulation, resulting in greater tension in the fiber than that produced by a single action potential

twitchin A titinlike protein associated with the myosin for regulating catch states

tympanum A vibrating membrane; (1) an auditory membrane of certain insects, or eardrum of the vertebrate middle ear; (2) a rigid structure composed of three to six enlarged rings at the base of the trachea; used for song production in some species of birds

Type I alveolar cells (al-VĒ-ō-lur) The single layer of flattened epithelial cells that forms the wall of the alveoli within the mammalian lungs

Type II alveolar cells The cells within the mammalian alveolar walls that secrete pulmonary surfactant

ubiquitin A molecular tag that is added to cell proteins that are no longer needed, targeting them for destruction in proteasomes

ultrafiltration The net movement of a protein-free fluid across a tissue boundary

umami One of the five taste qualities in mammals; savoriness taste stimulated by amino acids

uncoupling protein A gated channel for hydrogen ions found in the inner membrane of mitochondria in some tissues in mammals; serves to dissipate the mitochondrial H^+ gradient into heat

upper critical temperature In an endotherm, the temperature at which internal heat-removing (active) mechanisms are activated to maintain thermal homeostasis

upregulation An increase in the capacity of a cellular or organ function

ureotelic Having urea as a primary nitrogenous waste product

ureter (yū-RĒ-tur) A duct that transmits urine from the kidney to the bladder

urethra (yū-RĒ-thruh) A tube that carries urine from the bladder to outside the body

uricotelic Having uric acid as a primary nitrogenous waste product

urinary excretion The elimination of substances from the body in the urine; anything filtered or secreted and not reabsorbed is excreted

urodaeum Middle portion of the avian cloaca; receives the fluid from the kidneys through the ureters in addition to material from the oviduct

vagus nerve (VĀ-gus) The vertebrate 10th cranial nerve, which serves as the major parasympathetic nerve

vasoconstriction (vā'-zō-kun-STRIK-shun) The narrowing of a blood vessel lumen as a result of contraction of the vascular circular smooth muscle

vasodilation The enlargement of a blood vessel lumen as a result of relaxation of the vascular circular smooth muscle

vasopressin (vā-zō-PRES-sin) A vertebrate hormone secreted by the hypothalamus, then stored and released from the posterior pituitary; increases the permeability of the distal and collecting tubules of mammalian kidneys to water and promotes arteriolar vasoconstriction; also known as *antidiuretic hormone* (ADH)

vasotocin A water-conserving hormone in many vertebrates, closely related to vasopressin in mammals

vault Organelle shaped like octagonal barrel; believed to serve as transporters for messenger RNA and/or the ribosomal subunits from the nucleus to sites of protein synthesis

vein A vessel that carries blood toward the heart

venous return (VĒ-nus) The volume of blood returned to each atrium per minute from the veins

ventilation The movement of air in and out of the lungs, or water across gills; called *breathing* if actively produced by the animal

ventricle (VEN-tri-kul) A lower chamber of the heart that pumps circulatory fluid into the arteries

ventrobronchi Cranial group of secondary bronchi in birds, that branch to form a fan-shaped covering of the mediobasal surface of the avian lung

vesicle (VES-i-kul) A small intracellular, fluid-filled, membrane-enclosed sac

vesicular transport Movement of large molecules or multimolecular materials into or out of the cell by means of being enclosed in a vesicle, as in endocytosis or exocytosis

vestibular apparatus (veh-STIB-yuh-lur) The component of the vertebrate's inner ear that provides information essential for the sense of equilibrium and for coordinating head movements with eye and postural movements; consists of the semicircular canals, utricle, and saccule

vestigial Having no (or very minimal) useful function; evolved from useful features in ancestors but not yet eliminated by natural selection

villus (pl., villi) (VIL-us) Microscopic fingerlike projection from the inner surface of the small intestine

virulence (VIR-you-lentz) The disease-producing power of a pathogen

visceral afferent A pathway coming into the central nervous system that carries information derived from the internal viscera

visceral smooth muscle (VIS-uh-rul) See *single-unit smooth muscle*

viscosity (vis-KOS-i-tē) The friction developed between molecules of a fluid as they slide over each other during flow of the fluid; the greater the viscosity, the greater the resistance to flow

visual field Field of view that can be seen without moving the head

vital capacity The maximum volume of air that can be moved out during a single breath following a maximal inspiration

vitellogenesis Deposition of yolk in an oocyte

viviparous Referring to production and nourishment of living young within the body

voltage clamp A procedure in which the potential across a membrane is held at a constant value by an electronic circuit

voltage-gated channel Channel in the plasma membrane that opens or closes in response to changes in membrane potential

vomerinasal organ (VNO) Accessory olfactory organ in some mammals that detects pheromones; connected to two small openings in the anterior of the mouth behind the upper lip

white matter The portion of the central nervous system composed of myelinated nerve fibers

X-organs Organs in crustacean eyestalks that send axons into sinus glands (also in eyestalks) to release several neurohormones

Y-organs Organs in the crustacean head that make crustecdysone to promote molting

Z line A flattened, disclike cytoskeletal protein that connects the thin filaments of two adjoining sarcomeres

zeitgeber Any environmental factor that entrains a biological rhythm

zona fasciculata (zō-nah fa-SIK-ū-lah-ta) The middle and largest layer of the adrenal cortex; major source of glucocorticoids

zona glomerulosa (glō-MER-yū-lō-sah) The outermost layer of the adrenal cortex; sole source of aldosterone

zona reticularis (ri-TIK-yuh-lair-us) The innermost layer of the adrenal cortex; produces the sex steroid DHEA

C

C (cytosine), 27, 30, 33

C-16 unsaturated androgens, 773

Ca²⁺ ATPase pump, 346

Ca²⁺ channels, 209, 214

Ca²⁺ sparks, 410

Cadherins, 65, 74

Caffeine, 93, 101–102, 143

Calbindin D_{28k}, 329

Calcineurin, 366

Calcitonin (CT), calcium and, 323, 324, 327–329, 332

Calcitriol, 329–330

Calcium (Ca²⁺)

- bones and, 324–325, 330–331
 - calcitonin and, 323, 324, 327–329
 - in cardiac action potential, 323
 - concentration gradient, 379
 - egg laying and, 323
 - excessive demands for, 331–332
 - in excitation–contraction coupling, 323–324, 342–344
 - flight adaptation of muscles for, 367–368
 - hyperparathyroidism and, 330
 - intestines, absorption by, 327, 467
 - intracellular calcium, 95, 98, 117, 258, 324
 - metabolism of, 323–332, 324, 329, 467
 - movement of, 22, 326, 328, 329
 - muscle cells and, 323–324, 330
 - neuromuscular excitability and, 323–324
 - pacemaker potential and, 407
 - in plasma, 323–324, 326
 - pregnancy needs, 805
 - relaxation of muscles and, 346–348
 - renal failure and, 608
 - rigor mortis, 346–347
 - sarcoplasmic reticulum, releasing, 343–344
 - second-messenger pathway, 95, 97, 98, 99–100, 199, 324
 - smooth muscle and, 41
 - taste receptor, 235
 - tight junctions, 324
 - troponin binding to, 339, 340
 - in twitch summation, 352–353
 - vitamin D and, 323, 324, 329
- See also* Parathyroid hormone (PTH)

Calcium phosphate, 324

Calmodulin, 98, 375

Calories, 717

Calorigenic effect, 304

Calving intervals, 786

Camelids, 786

Camera eyes, 239–240, 255–256

cAMP (cyclic adenosine monophosphate), 97–102

- as chemoattractant, 209

- heart rate and, 416

- in insects, 568

- learning and, 199–200

- with serotonin, 133–134

cAMP-dependent protein kinase, 198, 381

cAMP response-element binding protein (CREB-1), 201, 202–203

Canaliculi, 326, 327, 328, 687

Canal pores, 219

Cancer

- immune surveillance and, 486–488
- interferon and, 472
- mammary gland cancer, 785, 813
- natural killer cells and, 471
- telomerase activity and, 33

Canine teeth, 663–664

Cannon, Walter B., 11, 13

Canunculus, 192

Capacitance, 115, 116, 263, 446

Capacitation, 778, 799

Capillaries, 437–444

- anatomy of, 439

- blood pressure (Pc), 443, 444

- branching of, 437, 440

- bulk flow exchange, 442–444

- Fick's law of diffusion and, 437, 441

- gas exchange and, 513–514, 529

- interstitial fluid and, 442–444

- net exchange of fluid, 444

- permeability of walls, 438

- precapillary sphincters, 436, 440, 441

- renal capillaries, 443, 571

- solute exchange and, 440, 444

- velocity of flow through, 441–442

- to villi, 692

- water-filled pores in walls, 439

Capsaicin, 261

Carbamino hemoglobin (HbCO₂), 540

Carbohydrates

- absorptive/postabsorptive states and, 695, 696
- digestion of, 657–658, 673, 680–681, 695, 696, 697
- glucagon effect of, 314, 320
- hydrolysis of, 656–657
- insulin and, 320
- liver and digestion of, 685
- membrane carbohydrate, 73, 74
- as organic osmolytes, 617
- role of, 26
- ruminants and, 708
- small intestine and, 695, 696, 697
- stomach, digestion in, 680–681
- surface markers containing, 74
- types of, 657–658

Carbon, 25, 26, 27, 72, 233, 741, 779, 780

Carbon dioxide (CO₂)

- acid–base balance and, 647–651
 - arterioles, effect on, 434
 - bicarbonate, transport as, 540–543
 - bronchiolar smooth muscle effect on, 546
 - capillary diffusion and, 440
 - chemosensors, monitoring, 449, 452
 - CO₂–HCO₃[–] buffer system, 639–642
 - erythrocytes, transporting, 391, 392
 - global warming and, 651
 - O₂–Hb dissociation curve and, 533, 537–539
 - ventilation and, 13, 551–553
- See also* Gas exchange; Gas transport; Respiratory system

Carbonic acid (H₂CO₃), 540–541

- hydrogen (H⁺) and, 636, 639

Carbonic anhydrase (CA), 392, 541, 639, 677

Carbon monoxide (CO), 93, 544–545, 688

Carboxylic amino acids, 26

Carboxypeptidase, 682

Carcinogenic factors, 487

Carcinolectins, 463

Cardiac cycle, 412–414

Cardiac muscle, 9

- action potentials, 406, 409–410
 - calcium (Ca²⁺) in, 98, 323–324, 409–410
 - characteristic plateau of, 409
 - comparison to other muscle types, 374–375
 - excitation of, 407–409
 - function of heart and, 382
 - organization of, 405–406
 - tetanus, prevention of, 410–411
- See also* Heart

Cardiac output (C.O.), 414–415, 414–419, 448, 450, 452

Cardiac sphincter, 668

Cardioacceleratory peptide b (CAPb), 568

Cardiotonic steroids (CTS), 587

Cardiovascular control center, 416

- arterial blood pressure and, 449

- arterioles, control of, 437

Cardiovascular system, 302, 448–455

ANATOMICAL TERMS USED TO INDICATE DIRECTION AND ORIENTATION

<i>Anterior</i>	situated in front of or in the front part of
<i>Posterior</i>	situated behind or toward the rear
<i>Ventral</i>	toward the belly or front surface of the body; synonymous with <i>anterior</i>
<i>Dorsal</i>	toward the back surface of the body; synonymous with <i>posterior</i>
<i>Medial</i>	denoting a position nearer the midline of the body or a body structure
<i>Lateral</i>	denoting a position toward the side or farther from the midline of the body or a body structure
<i>Superior</i>	toward the head
<i>Inferior</i>	away from the head
<i>Proximal</i>	closer to a reference point
<i>Distal</i>	farther from a reference point
<i>Sagittal section</i>	a vertical plane that divides the body or a body structure into right and left sides
<i>Longitudinal section</i>	a plane that lies parallel to the length of the body or a body structure
<i>Cross section</i>	a plane that runs perpendicular to the length of the body or a body structure
<i>Frontal or coronal section</i>	a plane parallel to and facing the front part of the body
<i>Apical</i>	surface of the plasma membrane that faces the lumen
<i>Basolateral</i>	surface of the plasma membrane that faces toward the interstitium

WORD DERIVATIVES COMMONLY USED IN PHYSIOLOGY

<i>a; an-</i>	absence or lack	<i>epi-</i>	above; over	<i>osteo-</i>	bone
<i>ad-; af-</i>	toward	<i>erythro-</i>	red	<i>oto-</i>	ear
<i>adeno-</i>	glandular	<i>gastr-</i>	stomach	<i>para-</i>	near
<i>angi-</i>	vessel	<i>-gen; -genic</i>	produce	<i>pariet-</i>	wall
<i>anti-</i>	against	<i>gluc-; glyc-</i>	sweet	<i>peri-</i>	around
<i>archi-</i>	old	<i>hemi-</i>	half	<i>phago-</i>	eat
<i>-ase</i>	splitter	<i>hemo-</i>	blood	<i>-pod</i>	footlike
<i>auto-</i>	self	<i>hepat-</i>	liver	<i>-poiesis</i>	formation
<i>bi-</i>	two; double	<i>homeo-</i>	similar	<i>poly-</i>	many
<i>-blast</i>	former	<i>homo-</i>	same	<i>post-</i>	behind; after
<i>brady-</i>	slow	<i>hyper-</i>	above; excess	<i>pre-</i>	ahead of; before
<i>cardi-</i>	heart	<i>hypo-</i>	below; deficient	<i>pro-</i>	before
<i>cephal-</i>	head	<i>inter-</i>	between	<i>pseudo-</i>	false
<i>cerebr-</i>	brain	<i>intra-</i>	within	<i>pulmon-</i>	lung
<i>chondr-</i>	cartilage	<i>kal-</i>	potassium	<i>rect-</i>	straight
<i>-cide</i>	kill; destroy	<i>leuko-</i>	white	<i>ren-</i>	kidney
<i>contra-</i>	against	<i>lip-</i>	fat	<i>reticul-</i>	network
<i>cost-</i>	rib	<i>macro-</i>	large	<i>retro-</i>	backward
<i>crani-</i>	skull	<i>mamm-</i>	breast	<i>sacchar-</i>	sugar
<i>-crine</i>	secretion	<i>mening-</i>	membrane	<i>sarc-</i>	muscle
<i>crypt-</i>	hidden	<i>micro-</i>	small	<i>semi-</i>	half
<i>cutan-</i>	skin	<i>mono-</i>	single	<i>-some</i>	body
<i>-cyte</i>	cell	<i>multi-</i>	many	<i>sub-</i>	under
<i>de-</i>	lack of	<i>myo-</i>	muscle	<i>supra-</i>	upon; above
<i>di-</i>	two; double	<i>natr-</i>	sodium	<i>tachy-</i>	rapid
<i>dys-</i>	difficult; faulty	<i>neo-</i>	new	<i>therm-</i>	temperature
<i>ecto-; exo-; extra-</i>	outside; away from	<i>nephro-</i>	kidney	<i>-tion</i>	act or process of
<i>ef-</i>	away from	<i>neuro-</i>	nerve	<i>trans-</i>	across
<i>-elle</i>	tiny; miniature	<i>oculo-</i>	eye	<i>tri-</i>	three
<i>-emia</i>	blood	<i>-oid</i>	resembling	<i>vaso-</i>	vessel
<i>encephalo-</i>	brain	<i>ophthalmo-</i>	eye	<i>-uria</i>	urine
<i>endo-</i>	within; inside	<i>oral-</i>	mouth		

Metric Measures and English Equivalents

METRIC UNIT	MEASURE	SYMBOL	ENGLISH EQUIVALENT
Length			
1 kilometer	= 1,000 meters	10 ³ m km	0.62 mile
1 meter		10 ⁰ m m	39.37 inches, 1.09 yards
1 centimeter	= 1/100 meter	10 ⁻² m cm	0.39 inch
1 millimeter	= 1/1,000 meter	10 ⁻³ m mm	
1 micrometer (or micron)	= 1/1,000,000 meter	10 ⁻⁶ m μm (or μ)	
1 nanometer	= 1/1,000,000,000 meter	10 ⁻⁹ m nm	
Volume and Capacity			
1 liter		L	1.06 quarts
1 milliliter	= 1/1,000 liter = volume of 1 g of water at stp* = 1 cubic centimeter (cc)	mL	0.034 fluid ounce = 1/5 teaspoon
Mass/Weight			
1 kilogram	= 1,000 grams	kg	2.20 pounds
1 gram		g	0.035 ounce = 15.43 grains
1 milligram	= 1/1,000 gram	mg	0.01 grain (about)

*stp = standard temperature and pressure

English–Metric Equivalents

LENGTH

English

Metric

1 inch	=	2.54 centimeters
1 foot	=	0.30 meter
1 yard	=	0.91 meter
1 mile (5,280 feet)	=	1.61 kilometers

VOLUME AND CAPACITY

English

Metric

1 fluid ounce	=	0.03 liter, 29.57 milliliters
1 pint	=	0.47 liter
1 quart	=	0.95 liter, 946 milliliters
1 gallon	=	3.79 liters
1 measuring cup	=	0.24 liter

MASS/WEIGHT

English

Metric

1 grain	=	64.80 milligrams
1 ounce	=	28.35 grams
1 pound	=	453.60 grams, 0.45 kilogram

Temperature Conversions

To convert Fahrenheit (°F) to Celsius (°C):
 $^{\circ}\text{C} = (^{\circ}\text{F} - 32)/1.8$

To convert Celsius (°C) to Fahrenheit (°F):
 $^{\circ}\text{F} = (^{\circ}\text{C} \times 1.8) + 32$

Comparison of human height in meters with sizes of the world's largest animal and some biological and molecular structures.
