Animal Physiology

From Genes to Organisms 2e

Make the grade with CourseMate!

Biology CourseMate... for *Animal Physiology*, Second Edition

ISBN: 978-1-133-00123-2

The more you study, the better the results. Make the most of your study time by accessing everything you need to succeed in one place. Cengage Learning's **Biology CourseMate** brings course concepts to life with interactive learning, study, and exam preparation tools that support the printed textbook. Your comprehension will soar as you work with the printed textbook and the textbook-specific website.

Biology CourseMate includes interactive learning, study, and exam preparation tools that support *Animal Physiology*:

- Quizzes
- Animations
- Flashcards
- Videos

These assets help you review for tests, prepare for class, and address your own unique learning style—so you have every chance to succeed.

Interactive eBook

In addition to interactive and study learning tools, **Biology CourseMate** includes an interactive eBook. You can take notes, highlight, search and interact with embedded media specific to the book. Use it as a supplement to the printed text, or as a substitute—the choice is yours with **CourseMate**.

Visit www.cengagebrain.com to find resources related to your text in **Biology CourseMate**.

Dedication

To my family, for all they have done for me in the past, all they mean to me in the present, and all I hope will yet be in the future.

And to Hillar and Paul for taking the ball and running with it. Their expertise and dedication made this book a reality.

Lauralee Sherwood

To my family, Britt, Alex, and Emma.

To the many individuals who have contributed to this edition, particularly our editors, Yolanda Cossio and Suzannah Alexander.

A special thank you to Paul and Laurie for making this work possible. It remains a privilege to share this undertaking with you. Your insights and clarity of thought are amazing!

And finally to one of the best scientists I know, Gerald Lincoln, whose contribution to the subject of seasonal breeding in animals was brilliant. His enthusiasm for life is infectious.

Hillar Klandorf

To my wife, son, and parents for all their support, and Hillar and Laurie for their hard work and dedication.

Paul H. Yancey

Brief Contents

Section I: Foundations

- 1 Homeostasis and Integration: The Foundations of Physiology **1**
- 2 Cellular and Molecular Physiology **25**
- 3 Membrane Physiology **70**
- 4 Neuronal Physiology **111**

Section II: Whole-Body Regulation and Integration

- 5 Nervous Systems **148**
- 6 Sensory Physiology **208**
- 7 Endocrine Systems **268**

Section III: Support and Movement

- 8 Muscle Physiology **335**

Section IV: Self-Maintenance

- 9 Circulatory Systems **385**
- 10 Defense Systems **458**
- 11 Respiratory Systems **493**
- 12 Excretory Systems **557**
- 13 Fluid and Acid–Base Balance **612**
- 14 Digestive Systems **654**
- 15 Energy Balance and Thermal Physiology **715**

Section V: Reproduction

Contents

Section I: Foundations

1 Homeostasis and Integration: The Foundations of Physiology 1

1.1 Introduction 1

Biological adaptations have two levels of explanation: the mechanistic (or proximate) and the evolutionary (or ultimate) 1
Adaptations reflect evolutionary history including cost–benefit trade-offs 2
Physiology is an integrative discipline 3
Physiology is also a comparative discipline, often following the Krogh principle 3

A Closer Look at Adaptation: Geckos on Glass 4

1.2 Methods in Physiology 6

The hypothetico-deductive method is the most widely accepted version of “the scientific method” 6

1.3 Levels of Organization in Organisms 7

Life has the properties of self-organization, self-regulation, self-support and movement, and self-reproduction 7
Cells are progressively organized into tissues, organs, systems, and finally the whole body 8

1.4 Size and Scale among Organisms 10

The larger the organism, the smaller the surface-area-to-volume ratio 10

1.5 Homeostasis: Basic Mechanisms and Enhancements 11

Body cells are in contact with a privately maintained internal environment instead of with the external environment that surrounds organisms 11
Homeostasis is essential for proper cell function, and most cells, as part of an organized system, contribute to homeostasis 12
Animals vary in their homeostatic abilities 13
Negative feedback is the main regulatory mechanism for homeostasis 13

Challenges and Controversies: Can a Planet Have Physiology? 14

Feedback effectors can be antagonistic and can include behaviors as well as internal organs 16
Inadequacies in negative-feedback systems can be improved by anticipation and acclimatization 16

1.6 Regulated Change 17

Some internal processes are not always homeostatic but may be changed by reset and positive-feedback systems 17
Disruptions in regulation can lead to illness and death 19

1.7 Organization of Regulatory and Organ Systems 19

Homeostasis (and other regulation) is hierarchically distributed 19
Organ systems can be grouped according to whole-body contributions 21

Making Connections: How Homeostasis and Integration Contribute to the Body as a Whole 22

Chapter Summary 23

Review, Synthesize, and Analyze 23

Suggested Readings 23

2 Cellular and Molecular Physiology 25

2.1 Introduction 25

Water, other inorganic chemicals, and four types of organic molecules are the universal components of cells 25

All cells have two major subdivisions: the plasma membrane and the cytoplasm 27

Many macromolecular structures need to be flexible to function and to be regulated, and protecting those structures is the basis for many forms of homeostasis 27

Archaeal and bacterial cells have a simpler organization than eukaryotic cells 27

Eukaryotic cells are subdivided into the plasma membrane, nucleus, and cytoplasm 29

2.2 Nucleus, Chromosomes, and Genes 30

DNA contains codes in the form of genes for making RNAs and proteins through the processes of transcription and translation 30

Different genes are expressed in different tissues and organs 30

Alternative splicing of RNA and some “junk” DNA are important in gene expression and evolution 32

Telomeres protect chromosome ends, and their loss is associated with aging 33

2.3 Methodology 33

Molecular Biology and Genomics: Genomics and Evolution 34

Unanswered Questions: Are cloning and genetic engineering ethical? 38

2.4 Ribosomes and Endoplasmic Reticulum 38

The rough endoplasmic reticulum and its ribosomes synthesize proteins for secretion and membrane construction 38

The smooth endoplasmic reticulum packages new proteins in transport vesicles 39

2.5 Golgi Complex 41

Transport vesicles carry their cargo to the Golgi complex for further processing 41

The Golgi complex packages secretory vesicles for release by exocytosis 41

2.6 Lysosomes and Proteasomes 44

Lysosomes digest extracellular material brought into the cell by phagocytosis 44

Lysosomes remove worn out organelles 45

Proteasomes destroy internal proteins 46

2.7 Peroxisomes 46

2.8 Mitochondria and Energy Metabolism 47

Mitochondria are enclosed by two membranes 47

Aerobic metabolism in mitochondria relies on O₂ to convert energy in food into ATP 47

Mitochondrial metabolism can create oxidative stress 53

Mitochondrial densities vary among tissue and organ types such as muscles 54

Phosphagens provide a rapid source for ATP production 55

Oxygen deficiency forces cells to rely on glycolysis and other anaerobic reactions, producing lactate, propionic acid, octopine, or other end products 55

Tolerance of oxygen deficiency varies widely among organisms 56

A Closer Look at Adaptation: Anoxic Animals 57

2.9 Vaults 57

2.10 Cytosol 58

The cytosol is important in intermediary metabolism, ribosomal protein synthesis, and storage of fat and glycogen 58

2.11 Centrosome, Centrioles, and Microtubule Organization 59

2.12 Cytoskeleton: Cell “Bone and Muscle” 59

Microtubules are essential for maintaining asymmetric cell shapes and are important in complex cell movements **59**

Microfilaments are important to cellular contractile systems and as mechanical stiffeners **62**

Intermediate filaments are important in regions of the cell subject to mechanical stress **63**

The cytoskeleton functions as an integrated whole, links other parts of the cell, and contributes to cytosolic “crowding” **64**

2.13 Cell-to-Cell Adhesions 65

The extracellular matrix serves as the biological “glue” **65**

Some cells are directly linked together by specialized cell junctions **65**

Making Connections: How Cellular and Molecular Physiology Contribute to the Body as a Whole 67

Chapter Summary **68**

Review, Synthesize, and Analyze **68**

Suggested Readings **69**

3 Membrane Physiology 70**3.1 Membrane Structure and Composition 70**

The plasma membrane is a fluid lipid bilayer embedded with proteins **70**

The mosaic model and membrane-skeleton fence model describe membrane structure and function **73**

The lipid bilayer forms the basic structural barrier that encloses the cell **73**

The membrane proteins perform a variety of specific membrane functions **73**

The membrane carbohydrates serve as self-identity markers **74**

3.2 Unassisted Membrane Transport 74

Lipid-soluble substances and small polar molecules can passively diffuse through the plasma membrane down their electrochemical gradient **74**

In unassisted membrane transport, particles that can permeate the membrane diffuse passively down their concentration gradient **75**

Ions that can permeate the membrane also conduct passively along their electrical gradient **77**

Osmosis is the net movement of water through a membrane **77**

Osmosis across membranes results between solutions with different concentrations of a nonpenetrating solute **78**

Colligative properties of solutions are dependent solely on the number of dissolved particles **79**

Tonicity refers to the effect the concentration of nonpenetrating solutes in a solution has on cell volume **79**

[Unanswered Questions: Is osmosis really the simple diffusion of water down its concentration gradient? 80](#)

3.3 Assisted Membrane Transport 81

Channel transport is accomplished by protein pores, while carrier-mediated transport generally requires proteins that “flip-flop” **81**

Facilitated diffusion is passive carrier-mediated transport **84**

Active transport is carrier-mediated transport that uses energy and moves a substance against its concentration gradient **84**

With vesicular transport, material is moved into or out of the cell wrapped in membrane **89**

3.4 Intercellular Communication and Signal Transduction 91

Communication between cells is orchestrated by direct contact and by extracellular chemical messengers **91**

Chemical messengers can have multiple, unrelated effects because of the “same key, different locks” principle **93**

Extracellular chemical messengers bring about cell responses primarily by signal transduction **94**

Internal receptors bind lipophilic and gaseous external messengers that enter the cell **94**

Some lipophobic external messengers bind to plasma membrane receptors, which alter ion channels or trigger phosphorylating enzymes (kinases) **94**

A Closer Look at Adaptation: Lighting Up the Night 96

Other lipophobic external messengers bind to plasma membrane receptors, which stimulate second-messenger production, often via G proteins **97**

Pharmacological agents and toxins are often agonists or antagonists affecting communication mechanisms **100**

Molecular Biology and Genomics: Programmed Cell Suicide 101**3.5 Membrane Potential 102**

Membrane potential is a separation of opposite charges across the plasma membrane **102**

Membrane potential is primarily due to differences in the distribution and permeability of key ions **102**

Making Connections: How Membrane Physiology Contributes to the Body as a Whole 108

Chapter Summary **109**

Review, Synthesize, and Analyze **110**

Suggested Readings **110**

4 Neuronal Physiology 111**4.1 Introduction 111**

Excitable cells such as neurons and muscles evolved for rapid signaling, coordination, and movement **111**

Electrical signals are produced by changes in ion movement through ion channels across the plasma membrane **112**

4.2 Graded Potentials 113

The stronger a triggering event, the larger the resultant graded potential **113**

Graded potentials spread by passive current flow and are impeded by resistances **113**

Graded potentials die out over short distances **114**

4.3 Action Potentials 116

During an action potential, the membrane potential rapidly and transiently reverses **116**

Marked changes in membrane permeability and ion movement enhanced by positive feedback lead to an action potential **117**

[Unanswered Questions: How do voltage gates actually open and close? 118](#)

The Na^+/K^+ ATPase pump gradually restores the concentration gradients disrupted by action potentials **120**

Action potentials are propagated from the axon hillock to the axon terminals **121**

Once initiated, action potentials are conducted over the surface of an axon **122**

The refractory period ensures unidirectional propagation of the action potential **124**

The refractory period also limits the frequency of action potentials **125**

Action potentials occur in all-or-none fashion **125**

The strength of a stimulus is coded primarily by the frequency of action potentials **125**

Myelination increases the speed of conduction of action potentials and conserves energy in the process **126**

Insect neurons are coated with a sheath that regulates ion balance **126**

[Unanswered Questions: How many animal groups have myelin? 128](#)

Fiber diameter also influences the velocity of action potential propagation **129**

4.4 Electrical and Chemical Synapses 129

Electrical synapses transfer action potential waveforms through gap junctions **129**

Chemical synapses convert action potentials into organic chemical messengers that are exocytosed into the synaptic gap **130**

4.5 Neuron-to-Neuron Synapses 130

A neurotransmitter carries the signal across a fast synapse and opens a chemically gated channel **130**

Some neurotransmitters excite the postsynaptic neuron, whereas others inhibit the postsynaptic neuron **132**

Each neurotransmitter–receptor combination always produces the same response **133**

Neurotransmitters are quickly removed from the synaptic cleft **133**

Neurotransmitters in slow synapses function through intracellular second-messenger systems **133**

4.6 Neuromuscular Synapses 134

Acetylcholine, a fast excitatory neurotransmitter, links electrical signals in motor neurons with electrical signals in skeletal muscle cells **134**

Acetylcholinesterase terminates acetylcholine activity at the neuromuscular junction **136**

4.7 Synapses and Integration **136**

The grand postsynaptic potential depends on the sum of the activities of all presynaptic inputs **136**

Action potentials are initiated at the axon hillock because it has the lowest threshold **138**

Neuropeptides act primarily as neuromodulators **138**

Presynaptic inhibition or facilitation can selectively alter the effectiveness of a given presynaptic input **140**

Retrograde messengers travel “backward” and also modulate synaptic function **141**

Neurons are linked to each other through convergence and divergence to form complex nerve pathways **141**

4.8 Neural Signaling and External Agents **142**

Synthetic and natural toxins can alter resting potentials and action potentials **142**

Drugs, natural toxins, and pollutants can modify synaptic transmission between neurons **142**

Molecular Biology and Genomics: Neurotoxins in War and Peace **143**

Challenges and Controversies: Synaptic Solutions to Pet Problems **144**

The neuromuscular junction is vulnerable to several chemical agents and diseases **144**

Temperature and pressure also influence action potentials and synapses **145**

Making Connections: How Neuronal Physiology Contributes to the Body as a Whole **145**

Chapter Summary **146**

Review, Synthesize, and Analyze **146**

Suggested Readings **147**

Section II: Whole-Body Regulation and Integration

5 Nervous Systems **148**

5.1 Evolution of Nervous Systems **148**

Nervous systems evolved from simple reflex arcs to centralized brains with distributed, hierarchic regulation **148**

Sponges have no nerves but can respond to stimuli using electrical signals **150**

Nerve nets are the simplest nervous systems and are found in most animals **150**

Unanswered Questions: How did nervous systems evolve? **152**

Simple ganglia and nerve rings evolved for more complex behavior **152**

A true CNS first evolved with bilateral symmetry **152**

True brains evolved at the anterior end of complex animals **154**

Cephalopod brains have complex structures supporting complex behaviors **154**

Vertebrate brain size varies up to 30-fold for a given body size **155**

Relative brain size may be explained by the expensive-tissue hypothesis **156**

Some nervous systems exhibit plasticity **156**

5.2 The Vertebrate Nervous System: Overview and Peripheral System **156**

The three classes of neurons are afferent neurons, efferent neurons, and interneurons **157**

The efferent division of the vertebrate PNS controls the activities of various effector organs **158**

The sympathetic and parasympathetic branches of the autonomic system innervate most visceral organs to control essential visceral functions **158**

The sympathetic system dominates in times of “fight or flight” **159**

The parasympathetic system dominates in times of “rest and digest” **159**

Dual innervation gives precise, antagonistic control **161**

An autonomic nerve pathway consists of a two-neuron chain **162**

Parasympathetic postganglionic fibers release acetylcholine; sympathetic ones release norepinephrine **162**

The adrenal medulla, an endocrine gland, is a modified part of the sympathetic nervous system **164**

Several different receptor types are available for each autonomic neurotransmitter **164**

Many regions of the central nervous system are involved in the control of autonomic activities **165**

The vertebrate somatic system controls skeletal muscles **166**

Motor neurons are the final common pathway **166**

5.3 The Vertebrate Nervous System: Central System **167**

Glial cells support the interneurons physically, metabolically, and functionally **167**

The delicate central nervous tissue is well protected **169**

The brain floats in its own special cerebrospinal fluid **169**

A highly selective blood–brain barrier carefully regulates exchanges between the blood and brain **169**

The brain depends on delivery of oxygen and glucose by the blood **170**

Brains of virtually all vertebrates display a degree of plasticity **171**

Neurogenesis is a normal function of several regions of the brain **171**

Challenges and Controversies: Strokes: Not Always a Deadly Domino Effect **172**

Challenges and Controversies: Neural Plasticity: A Song for All Seasons **173**

Mammalian neural tissue is susceptible to neurodegenerative disorders **173**

5.4 Brain Evolution in Vertebrates **174**

Newer, more sophisticated regions of the vertebrate brain are piled on top of older, more primitive regions **174**

5.5 Spinal Cord **176**

The spinal cord retains an inherent segmental organization characteristic of many nonvertebrates **176**

The white matter of the spinal cord is organized into tracts **176**

Each horn of the spinal cord gray matter houses a different type of neuronal cell body **177**

Spinal nerves contain both afferent and efferent fibers **177**

Many reflex responses and patterned movements in vertebrates are integrated in the spinal cord **180**

Activity of command fibers elicits a fixed action pattern **182**

5.6 Brainstem and Cerebellum **183**

The cerebellum is important in balance as well as in coordination of movement **184**

5.7 Basal Nuclei, Thalamus, Hypothalamus, and Limbic System **184**

The basal nuclei play an important inhibitory role in motor control **184**

Challenges and Controversies: Is the Cerebellum a “Smith Predictor”? **185**

The thalamus is a sensory relay station and is important in motor control **186**

The hypothalamus regulates many homeostatic functions **186**

The limbic system plays a key role in animal motivation and memory **187**

The amygdala processes and learns inputs that give rise to the sensation of fear **187**

The limbic system and higher cortex participate in the control of basic behavioral patterns **188**

Motivated behaviors are goal directed **188**

Norepinephrine, dopamine, and serotonin are neurotransmitters in pathways for emotion and behavior **189**

5.8 Mammalian Cerebral Cortex **189**

The cerebral cortex is an outer shell of gray matter covering an inner core of white matter **189**

The cerebral cortex is organized into layers and functional columns **189**
 The four pairs of lobes in the cerebral cortex are specialized for different activities **189**
 The parietal lobes are responsible for somatosensory processing **192**
 The primary motor cortex located in the frontal lobes controls the skeletal muscles **192**
 The higher motor areas are important in motor control **192**
 The cerebral hemispheres have some degree of specialization **194**
 Avian intelligence evolved differently than mammalian intelligence **194**

5.9 Learning, Memory, and Sleep **194**

Memory comes in two forms—declarative and procedural—and is laid down in stages **195**
 Memory traces are present in multiple regions of the brain **196**
 Short-term and long-term memory involve different molecular mechanisms **197**
 Short-term memory involves transient changes in synaptic activity **197**

Molecular Biology and Genomics: A Smarter Rodent **201**

Long-term memory involves formation of new, permanent synaptic connections **201**
 Complex memories and learning may reside in neuronal networks **203**
 Sleep is a nearly universal phenomenon, and has two states in birds and mammals **203**
 The function of sleep is unclear **204**
 The term *consciousness* refers to a subjective awareness of the world and self **205**

Making Connections: How Nervous Systems Contribute to the Body as a Whole **205**

Chapter Summary **206**

Review, Synthesize, and Analyze **207**

Suggested Readings **207**

6 Sensory Physiology **208**

6.1 Evolution and Roles of Senses **208**

Sensory cells have ion channels and receptor proteins with specific modalities **208**
 Animal senses can be classified into three roles: sensing the external environment, the internal environment, and body motion and position **209**
 Perception is not reality **210**
 Unanswered Questions: Do fish perceive pain? **210**

6.2 Receptor Cell Physiology **211**

Receptors have differential sensitivities to various stimuli **211**
 A stimulus alters the receptor's permeability, leading to a graded receptor potential **211**
 Receptor potentials may initiate action potentials in the afferent neuron **212**
 Receptors may fire continuously or adapt slowly or rapidly to sustained stimulation **213**
 Each somatosensory pathway is "labeled" according to modality and location **215**
 Acuity is influenced by receptive field size and filtered by lateral inhibition **215**

6.3 Mechanoreception: Touch, Pressure, and Proprioception **217**

Animal integuments may have both touch and pressure receptors **217**
 Proprioceptors in the muscles, tendons, and joints give information on limb position and motion **218**
 The statocyst is the simplest organ that can monitor an animal's position in space **218**
 The lateral line system of amphibians and fish detects motion in the surrounding water **218**
 The vestibular apparatus of vertebrates detects position and motion of the head and is important for equilibrium and coordination of head, eye, and body movements **219**

6.4 Mechanoreception: Ears and Hearing **224**

Fishes hear with lateral lines and otolith organs, aided by the gas bladder in some species **224**

Many terrestrial vertebrates and insects receive sound initially with a tympanic membrane, aided by other external features in some groups **225**

Sound is characterized by its intensity (loudness), pitch (tone), and timbre (quality) **225**

The external ear and middle ear convert airborne sound waves into fluid vibrations in the inner ear **227**

The cochlea of the inner ear contains the organ of Corti, the sense organ for hearing **229**

Hair cells in the organ of Corti transduce fluid movements into neural signals **229**

Pitch discrimination depends on the region of the basilar membrane that vibrates **231**

Loudness discrimination depends on the amplitude of vibration **231**

Molecular Biology and Genomics: The Smell and Taste of Evolution **232**

The auditory cortex is mapped according to tone **232**

Insect ears are derived from the respiratory tracheal system **232**

6.5 Chemoreception: Taste and Smell **233**

Taste and smell have numerous roles such as sensing food, kin, mates, and direction **233**

Taste sensation is coded by patterns of activity in various taste receptors **233**

Mammalian taste is based on five (and perhaps more) primary tastes **234**

The olfactory receptors in the nose are specialized endings of renewable afferent neurons **236**

Various parts of an odor are detected by different olfactory receptors and sorted into "smell files" **237**

Odor discrimination is coded by patterns of activity in the olfactory bulb glomeruli **238**

The olfactory system adapts quickly, and odorants are rapidly cleared **238**

The vomeronasal organ detects pheromones **238**

6.6 Photoreception: Eyes and Vision **239**

Light detection uses universal photopigments in ciliary or rhabdomeric receptor cells **239**

Dedicated light-sensing organs range from simple eyespots to complex eyes **239**

The vertebrate eye is a fluid-filled sphere enclosed by three specialized tissue layers **240**

Molecular Biology and Genomics: The Eyes Have It **241**

The amount of light entering many vertebrate eyes is controlled by the iris **241**

The cornea and lens refract the entering light to focus the image on the retina **242**

Accommodation increases the strength of the lens for near vision **244**

Light must pass through several retinal layers in vertebrates before reaching the photoreceptors **245**

Phototransduction by opsin and retinene in retinal cells converts light stimuli into neural signals **247**

Rods provide indistinct gray vision at night, whereas cones provide sharp color vision during the day **248**

The sensitivity of eyes can vary markedly through dark and light adaptation **250**

Color vision depends on the ratios of stimulation of the various cone types **251**

Color discrimination abilities vary greatly among types of animals **251**

Unanswered Questions: Why did whales lose the blues? **252**

Some animals can see ultraviolet and/or polarized light **252**

Visual information is separated and modified within the visual pathway before it is integrated into a perceptual image of the visual field by the vertebrate cortex **253**

The thalamus and visual cortices elaborate the visual message **253**

Visual input goes to other areas of the vertebrate brain not involved in vision perception **255**

Cephalopod camera eyes have light-sensing cells on top of neural cells **255**

Compound eyes of arthropods and some annelids and bivalves consist of multiple image-forming units **256**

Phototransduction in rhabdomeric eyes uses rhodopsin but otherwise differs from that in vertebrate eyes **258**

6.7 Thermoreception 258

Warmth and cold thermoreceptors give information about the temperature of the environment near the body **258**

Infrared thermoreceptors give pit vipers the ability to detect prey and desirable thermal habitats **259**

6.8 Nociception: Pain 260

Stimulation of mammalian nociceptors elicits two types of pain signals **260**

A Closer Look at Adaptation: Why Are Hot Spices Hot? 261

The mammalian brain has a built-in analgesic system **261**

6.9 Electoreception and Magnetoreception 261

Electoreception can be passive or active, and can be used for navigation, prey detection, and communication **261**

Electric organs use specialized electrocytes to generate electric organ discharges **263**

Some animals can detect magnetic fields for long-range navigation, possibly by magnetic induction, magnetic minerals in receptors, or magnetochemical reactions **264**

Making Connections: How Senses Contribute to the Body as a Whole 266

Chapter Summary **266**

Review, Synthesize, and Analyze **267**

Suggested Readings **267**

7 Endocrine Systems 268**7.1 Introduction: Principles of Endocrinology 268**

Hormones are chemically classified into three categories: peptides and proteins, amines, steroids **268**

The mechanisms of hormone synthesis, storage, and secretion vary according to the class of hormone **270**

Hydrophilic hormones are transported dissolved in the plasma, whereas lipid-soluble hormones are almost always transported bound to plasma proteins **271**

Hormones exert a variety of regulatory effects throughout the body **272**

Hormones produce their effects by altering intracellular proteins through ion fluxes, second messengers, and transcription factors **273**

By stimulating genes, lipophilic hormones promote synthesis of new proteins **274**

Hormone actions are greatly amplified at the target cell **275**

Endocrine-disrupting chemicals can mimic the effects of native hormones **275**

The effective plasma concentration of a hormone is normally regulated by changes in its rate of secretion **275**

The effective plasma concentration of a hormone can be influenced by the hormone's transport, metabolism, and excretion **277**

The responsiveness of a target cell to its hormone can be varied by regulating the number of its hormone-specific receptors **277**

Endocrine disorders are attributable to hormonal excess, hormonal deficiency, or decreased responsiveness of the target cells **278**

7.2 Nonvertebrate Endocrinology 279

Molting is the process of replacing one exoskeleton with another **280**

The quantity of JH released determines the quality of the molt **281**

Pheromones are used in mating and colonial interactions **281**

7.3 Vertebrate Endocrinology: Central Endocrine Glands 281

Biological clocks involve the pineal gland and the suprachiasmatic nuclei **282**

All eukaryotic cells, including all those within an animal, express clock genes **283**

The biological clock must be synchronized with environmental cues **283**

The pituitary gland descends from the hypothalamus and consists of two or three lobes **283**

Molecular Biology and Genomics: Clocks and Genes 284

The hypothalamus and posterior pituitary form a neurosecretory system that secretes vasopressin and oxytocin **285**

The anterior pituitary secretes six established hormones, many of which are tropic **286**

Hypothalamic releasing and inhibiting hormones that regulate secretion in the anterior pituitary are delivered to it by the hypothalamic–hypophyseal portal system **288**

Target gland hormones inhibit hypothalamic and anterior pituitary hormone secretion via negative feedback **290**

7.4 Endocrine Control of Growth and Development in Vertebrates 291

Growth depends on growth hormone but is influenced by other factors as well **291**

Growth hormone exerts metabolic effects not related to growth **292**

Indirect effects of growth hormone are exerted through insulin-like growth factors **292**

Growth hormone/IGF-I promote growth of soft tissues by stimulating hyperplasia and hypertrophy **293**

Growth hormone secretion is regulated by two hypophysiotropic hormones and influenced by a variety of other factors **294**

Prolactin has a wide range of growth-related effects, including lactogenesis **296**

A Closer Look at Adaptation: Brood Patch Development: Some Have It, Others Don't! 297**7.5 Thyroid Gland 297**

The major thyroid hormone secretory cells are organized into colloid-filled follicles **298**

Thyroid hormone is synthesized and stored on the thyroglobulin molecule **298**

Molecular Biology and Genomics: Crosstalk between the Pituitary and Hypothalamus 300

To secrete thyroid hormone, the follicular cells phagocytize thyroglobulin-laden colloid **300**

For the most part, both T_4 and T_3 are transported bound to specific plasma proteins **300**

Most of the secreted T_4 is converted into T_3 outside the thyroid **301**

Thyroid hormone is the primary determinant of overall metabolic rate and exerts other effects as well **301**

Thyroid hormone is regulated by the hypothalamus–pituitary–thyroid axis **303**

Abnormalities of thyroid function include both hypothyroidism and hyperthyroidism **303**

7.6 Adrenal Glands 304

In most vertebrates, the adrenal gland consists of a steroid-secreting cortex intermingled with chromaffin tissue **304**

The adrenal cortex secretes mineralocorticoids, glucocorticoids, and sex hormones **304**

Glucocorticoids exert metabolic effects and have an important role in adaptation to stress **305**

Glucocorticoid secretion is directly regulated by the hypothalamic–pituitary–adrenal axis **307**

The adrenal cortex secretes both male and female sex hormones in both sexes **307**

The adrenal cortex may secrete too much or too little of any of its hormones **308**

The catecholamine-secreting adrenal medulla is a modified sympathetic ganglion **308**

Sympathetic stimulation of the adrenal medulla is solely responsible for epinephrine release **308**

Epinephrine reinforces the sympathetic nervous system in “fight-or-flight” short-term stress, and exerts additional metabolic effects **308**

Epinephrine and norepinephrine vary in their affinities for the different adrenergic receptor types **309**

The stress response is a generalized, nonspecific pattern of neural and hormonal reactions to any situation that threatens homeostasis **310**

The multifaceted stress response is coordinated by the hypothalamus **310**

Activation of the stress response by chronic psychosocial stressors may be harmful **311**

7.7 Endocrine Control of Fuel Metabolism in Vertebrates 312

Fuel metabolism includes anabolism, catabolism, and interconversions among energy-rich organic molecules **312**

Because food intake is intermittent, nutrients must be stored for use between meals, primarily as adipose tissue **314**

Glucose is homeostatically regulated to supply the brain and to prevent damaging processes at high concentrations **315**

Metabolic fuels are stored during the absorptive state and are mobilized during the postabsorptive state **315**

Lesser energy sources are tapped as needed **316**
 The pancreatic hormones, insulin and glucagon, are most important in regulating fuel metabolism **316**
 Insulin lowers blood levels of glucose, amino acids, and fatty acids, and promotes their storage **317**
 The primary stimulus for increased insulin secretion is an increase in blood glucose concentration **319**
 Glucagon in general opposes the actions of insulin **320**
 Glucagon secretion is increased during the postabsorptive state **320**
 Insulin and glucagon work as a team to maintain blood glucose and fatty acid levels **320**
 Epinephrine, cortisol, growth hormone, and thyroid hormone also exert direct metabolic effects **320**
 The symptoms of diabetes mellitus are characteristic of an exaggerated postabsorptive state **322**
7.8 Endocrine Control of Calcium Metabolism in Vertebrates 323
 Plasma calcium must be closely regulated to prevent changes in neuromuscular excitability **323**
 Control of Ca^{2+} metabolism includes regulation of both calcium homeostasis and Ca^{2+} balance **324**
 Parathyroid hormone raises free plasma calcium levels by its effects on bone, kidneys, and intestine **324**
 Bone continuously undergoes remodeling **324**

PTH raises plasma Ca^{2+} by withdrawing Ca^{2+} from the bone **326**
 The immediate effect of PTH is to promote the transfer of Ca^{2+} from bone fluid into plasma **326**
 PTH's chronic effect is to promote localized dissolution of bone to release Ca^{2+} into plasma **326**
 PTH acts on the kidneys to conserve Ca^{2+} and to eliminate PO_4^{3-} **326**
 PTH indirectly promotes absorption of Ca^{2+} and PO_4^{3-} by the intestine **327**
 The primary signal for regulating PTH secretion is the plasma concentration of free Ca^{2+} **327**
 Calcitonin lowers the plasma Ca^{2+} concentration, but may not be essential **327**
 Vitamin D is actually a hormone that increases calcium absorption in the intestine **329**
 Phosphate metabolism is controlled by the same mechanisms that regulate Ca^{2+} metabolism **330**
 Disorders in Ca^{2+} metabolism may arise from abnormal levels of parathyroid hormone or vitamin D **330**

Making Connections: How the Endocrine System Contributes to the Body as a Whole **332**

Chapter Summary **333**
 Review, Synthesize, and Analyze **334**
 Suggested Readings **334**

Section III: Support and Movement

8 Muscle Physiology **335**

8.1 Introduction 335
 Three types of muscle create a wide range of movements **335**
8.2 Skeletal Muscle 336
 Skeletal muscle consists of muscle fibers lying parallel to each other **336**
 Myosin forms the thick filaments **338**
 Actin, along with tropomyosin and troponin, forms the thin filaments **338**

Molecular Biology and Genomics: What Are the Functions of Titin? **339**

8.3 Molecular Basis of Skeletal Muscle Contraction 341
 During contraction, cycles of cross-bridge binding and bending pull the thin filaments closer together between the stationary thick filaments, causing shortening of the sarcomeres **341**
 Complete shortening is accomplished by repeated cycles of cross-bridge binding and bending **342**
 Calcium is the link between excitation and contraction **342**
 Removal of calcium is the key to muscle relaxation **346**

Beyond the Basics: Conversion of Muscle into Meat **347**

Contractile activity far outlasts the electrical activity that initiated it **347**

8.4 Skeletal Muscle Mechanics **348**

A Closer Look at Adaptation: Muscles Evolved for Speed **349**

Muscle organs are groups of muscle fibers bundled together by connective tissue, often attached to skeletal elements in antagonistic pairs **349**
 Contractions of a whole muscle can be of varying strength **350**
 The number of fibers contracting within a vertebrate muscle depends on the extent of motor unit recruitment **350**
 The frequency of stimulation can influence the tension developed by each vertebrate skeletal muscle fiber **351**
 Twitch summation results from a sustained elevation in cytosolic calcium **352**
 Arthropod muscle tension is controlled by gradation of contraction within a motor unit **353**
 There is an optimal muscle length at which maximal tension can be developed on a subsequent contraction **353**
 Muscle tension is transmitted to skeletal elements as the contractile component tightens the series-elastic component **355**

The two primary types of contraction are isotonic and isometric **355**
 The velocity of shortening is related to the load **356**
 Skeletons include endoskeletons, exoskeletons, and hydrostatic skeletons **356**
 Interactive units of skeletal muscles, tendons, skeletons, and joints form lever systems **357**
 Elastic storage structures can greatly increase the efficiency and speed of locomotion **357**

8.5 Skeletal Muscle Metabolism and Fiber Types **358**

Muscle fibers have alternate pathways for forming ATP **359**
 Fatigue may be of muscle or central origin **361**
 Increased oxygen consumption is necessary to recover from activity **362**

Although muscles can accomplish work, much of the energy is converted to heat **362**

There are three types of skeletal muscle fibers, which differ in ATP hydrolysis and synthesis **362**

Molecular Biology and Genomics: Myosin Family Genetics **364**

Muscle fibers adapt considerably in response to the demands placed on them **365**

Unanswered Questions: What signals trigger changes in muscle mass and fiber type? **366**

8.6 Adaptations for Flight: Continuous High Power at High Contraction Frequencies **366**

Asynchronous muscle contractions are characterized by a nearly constant myoplasmic Ca^{2+} concentration **367**

8.7 Control of Motor Movement **368**

Multiple motor inputs influence vertebrate motor unit output **368**
 Muscle spindles and the Golgi tendon organs provide afferent information essential for controlling skeletal muscle activity **370**

8.8 Smooth Muscle and Cardiac Muscle **373**

Smooth and cardiac muscle share some basic properties with skeletal muscle **373**

Smooth muscle cells are small and unstriated **373**

Smooth muscle cells are turned on by Ca^{2+} -dependent phosphorylation of myosin **375**

Phasic smooth muscle contracts in bursts of activity; tonic smooth muscle maintains an ongoing level of contraction **376**

Multiunit smooth muscle is neurogenic **377**

Single-unit smooth muscle cells form functional syncytia **378**

Single-unit smooth muscle is myogenic **378**

Gradation of single-unit smooth muscle contraction differs considerably from that of skeletal muscle **379**

Smooth muscle activity can be modified by the autonomic nervous system **379**
 Smooth muscle can still develop tension, yet inherently relaxes when stretched **380**
 Smooth muscle is slow and economical, especially in latch and catch types **381**
 Cardiac muscle is striated but also has some smooth-muscle characteristics **382**

Making Connections: How Muscle Physiology Contributes to the Body as a Whole **382**

Chapter Summary **383**

Review, Synthesize, and Analyze **383**

Suggested Readings **383**

Section IV: Self-Maintenance

9 Circulatory Systems **385**

9.1 Evolution of Circulation **385**

Circulatory systems evolved to overcome the limits of diffusion **385**
 Circulatory systems have up to three distinct components: fluid, pump, and vessels **385**
 Circulatory systems can be open or closed **386**

9.2 Circulatory Fluids and Cells **387**

Plasma is an aqueous medium for inorganic ions, gases, and numerous organic solutes **387**

Plasma proteins carry out many of the functions of plasma **388**

Lipoprotein complexes carry energy lipids and structural lipids for biosynthesis **389**

Respiratory pigments carry oxygen **391**

Erythrocytes serve primarily to transport oxygen **391**

Unanswered Questions: Why are erythrocytes in birds and mammals so different? **391**

Hemoglobins and erythrocytes have additional transport functions **392**

Hemopoietic tissues continuously replace worn-out erythrocytes **392**

Erythropoiesis in mammals and probably other vertebrates is controlled by erythropoietin from the kidneys **392**

Leukocytes are key components of vertebrate immune systems **393**

Thrombocytes and platelets function in clotting **393**

9.3 Circulatory Fluids: Hemostasis **394**

Vascular spasm reduces blood flow through an injured vessel **395**

Platelets aggregate to form a plug at a vessel defect by positive feedback **395**

A triggered chain reaction and positive feedback involving clotting factors in the plasma results in blood coagulation **395**

The clotting cascade may be triggered by the intrinsic pathway or the extrinsic pathway **397**

Unanswered Questions: Why is mammalian clotting so complex? **397**

Fibrinolytic plasmin dissolves clots and prevents inappropriate clot formation **398**

Hemocytes and hemolymph proteins provide hemostasis in arthropods **399**

A Closer Look at Adaptation: Vampires and Medicine **400**

9.4 Circulatory Pumps: Evolution **400**

Pumping mechanisms include flagella, extrinsic skeletal muscles, peristaltic muscular pumps, and hearts (chamber muscle pumps) **400**

Many animals have primary hearts aided by auxiliary pumps **401**

Arthropod systemic hearts are dorsally located and have many valved openings **402**

Vertebrate systemic hearts evolved from a two-chambered to a four-chambered structure **402**

Avian and mammalian hearts are dual pumps **402**

Heart valves ensure that the blood flows in the proper direction through the heart **403**

Vertebrate heart walls are composed primarily of spirally arranged cardiac muscle fibers interconnected by intercalated discs **405**

9.5 Circulatory Pumps: Heart Electrical Activity **406**

Pacemaker cells have channels that cyclically move them to “firing” threshold **407**

The sinoatrial node is the normal pacemaker of the vertebrate heart **407**

The spread of cardiac excitation is coordinated to ensure efficient pumping **408**

The action potential of contractile cardiac muscle cells shows a characteristic plateau **409**

Ca^{2+} entry from the ECF induces a much larger Ca^{2+} release from the sarcoplasmic reticulum **409**

Tetanus of cardiac muscle is prevented by a long refractory period **410**

9.6 Circulatory Pumps: Heart Mechanics and the Cardiac Cycle **412**

Hearts alternately contract in systole to empty and relax in diastole to fill **412**

9.7 Circulatory Pumps: Cardiac Output and Its Control **414**

Cardiac output is a product of heart rate and stroke volume **414**

Heart rate is determined primarily by antagonistic regulation of autonomic influences on the SA node **415**

Stroke volume is determined by the extent of venous return and by sympathetic activity **416**

Increased end-diastolic volume intrinsically results in increased stroke volume **417**

The contractility of the heart and venous return are increased by sympathetic stimulation **417**

The heart receives most of its own blood supply through the coronary circulation **418**

9.8 Circulatory Pathways and Vessels: Hemodynamics and Evolution **419**

Blood flow varies directly with the pressure gradient and inversely with resistance **419**

Unanswered Questions: How could a brachiosaur pump blood to its brain? **420**

Circulatory fluids transport materials in a parallel manner, especially in closed systems **421**

Circulatory fluids are driven by pressure and can transmit useful force **422**

9.9 Circulatory Pathways and Vessels: Open Circulation **422**

9.10 Circulatory Pathways and Vessels: Closed Circulation **425**

Parallel and series flow are both important for reconditioning the blood **425**

The vertebrate vascular system evolved from one circuit to two separate circuits **425**

Molecular Biology and Genomics: From Three to Four **428**

9.11 Circulatory Vessels: Arteries **429**

Arteries are wide with low total cross-sectional area and store and release pressure for high-velocity delivery **429**

Mean arterial pressure is the main driving force for blood flow **432**

9.12 Circulatory Vessels: Arterioles **432**

Arterioles are the major resistance vessels and can be dilated or constricted **432**

Local (intrinsic) influences on arteriolar radius help match blood flow with the tissues’ “selfish” needs **434**

Extrinsic sympathetic control of arteriolar radius is important in the regulation of both blood flow during activity and arterial blood pressure **435**

The medullary cardiovascular control center, other brain regions, and hormones regulate blood flow and pressure **437**

9.13 Circulatory Vessels: Capillaries **437**

Capillary anatomy increases diffusion rates by minimizing distance ΔX while maximizing surface area A and the diffusion coefficient D of Fick’s law **437**

Blood composition and perfusion regulation enhance capillary-tissue concentration gradients ΔC **439**

Capillary anatomy increases time for diffusion by slowing blood flow due to a high total cross-sectional area **441**

Interstitial fluid is a passive intermediary between the blood and cells **442**

Bulk flow across the capillary wall is important in extracellular fluid distribution **442**

9.14 Circulatory Vessels: Lymphatic System **444**

The lymphatic system is an accessory route by which interstitial fluid can be returned to the blood **444**

The lymphatic system is important for immune functions and fat transport **445**

9.15 Circulatory Vessels: Venules and Veins **445**

Veins serve as a blood reservoir as well as passageways back to the heart **445**

Venous return is enhanced by a number of extrinsic factors **446**

9.16 Integrated Cardiovascular Function **448**

Proper gas and heat transport is the first priority and regulation of mean arterial pressure is the second priority of the cardiovascular system **448**

Gas transport and blood pressure are monitored by arterial sensors and regulated in part by the cardiovascular control center **449**

The baroreflex is the most important mechanism for short-term regulation of blood pressure during rest or low activity **449**

Regulation of gas transport and blood pressure are coordinated during locomotory activity by higher brain centers **450**

Blood pressure regulation must integrate both short-term and long-term influences **453**

Making Connections: How Circulation Contributes to the Body as a Whole **455**

Chapter Summary **455**

Review, Synthesize, and Analyze **456**

Suggested Readings **457**

10 Defense Systems **458**

10.1 Evolution of Defense Systems **458**

Animal defenses target external as well as internal threats including pathogenic bacteria, viruses, parasites, and cancer **459**

Immune responses can be either innate or acquired **459**

Immune responses use pattern-recognition receptors to distinguish “self” from “nonself” **460**

Immune cells communicate with cytokines and by direct contact **460**

Some animals behaviorally acquire defense components from other organisms **460**

10.2 Innate Immune Systems in Nonvertebrates **461**

Barrier tissues are the first line of defense, using passive and active mechanisms **461**

Phagocytotic cells and inflammatory responses are the major form of cell-mediated second lines of defense **461**

Antimicrobial and other defensive peptides of barrier tissues and immune cells are common noncellular second lines of defense **463**

Opsonin proteins “tag” invaders for destruction by phagocytotic cells **463**

10.3 Immune Systems in Vertebrates: Overview **464**

Active immune responses are regulated by feedback systems with sensors, integrators, and effectors that are primarily leukocytes and proteins **464**

Leukocytes of innate and acquired immunity are found in circulation and localized in tissues **464**

10.4 Innate Immunity in Mammals **465**

Barrier tissues form passive walls and can have active mechanisms to kill or remove invaders **466**

Inflammation in part is triggered by histamine released by mast cells **467**

The complement system punches holes in microorganisms directly, acts as opsonins, works with antibodies, and augments inflammation **469**

NSAIDs and glucocorticoid drugs suppress the inflammatory response **470**

Natural killer cells destroy virus-infected cells and cancer cells on first exposure to them **471**

Interferon transiently inhibits multiplication of viruses in most cells **471**

10.5 Acquired Immunity in Mammals: Overview **472**

Acquired immunity includes antibody-mediated and cell-mediated responses **472**

Lymphoid tissues store, produce, and/or process lymphocytes **472**

An antigen induces an immune response against itself **473**

10.6 Acquired Immunity in Mammals: B-Lymphocytes **474**

The antigens to which B cells respond can be T-independent or T-dependent **474**

Antigens stimulate B cells to convert into plasma cells that produce antibodies **474**

Antibodies are Y-shaped and classified according to properties of their tail portion **474**

Antibodies largely amplify innate immune responses to promote antigen destruction **475**

Clonal selection accounts for the specificity of antibody production **476**

Selected clones differentiate into active plasma cells and dormant memory cells **476**

The huge repertoire of B cells is built by recombination of a small set of gene fragments **479**

Active immunity is self-generated; passive immunity is “borrowed” **480**

10.7 Acquired Immunity in Mammals: T-Lymphocytes **480**

T cells bind directly with their targets and effector cells via immunosynapses **480**

The three types of T cells are cytotoxic T cells, helper T cells, and regulatory T cells **480**

Cytotoxic T cells secrete chemicals that destroy target cells **481**

Helper T cells secrete chemicals that amplify the activity of other immune cells **482**

T-lymphocytes respond only to antigens presented to them by antigen-presenting cells **482**

The major histocompatibility complex (MHC) is the code for self-antigens **483**

The immune system is normally tolerant of self-antigens **485**

Immune surveillance against cancer cells involves an interplay among immune cells and interferon **486**

A regulatory loop links the immune system with the nervous and endocrine systems **488**

10.8 Acquired Immunity in Other Animals **489**

[Unanswered Questions: How did the acquired immune system arise in jawed vertebrates?](#) **489**

Sharks generate diverse B and T cells with a lower diversity but a greater number of gene fragments than mammals **489**

Lamprey lymphocytes shuffle ancient PRR genes to generate variable receptors and antibody-like proteins **489**

Some arthropods and mollusks have immunity mechanisms resembling vertebrate acquired processes **489**

Molecular Biology and Genomics: An Accidental Origin for Acquired Immunity? **490**

Making Connections: How Defense Systems Contribute to the Body as a Whole **491**

Chapter Summary **491**

Review, Synthesize, and Analyze **492**

Suggested Readings **492**

11 Respiratory Systems **493**

11.1 Gas Demands: General Problems and Evolutionary Solutions **493**

External respiration involves up to four major steps of transport and exchange **493**

Gas diffusion follows Fick’s law for partial pressure gradients **494**

External respiratory processes must meet the demands of size, metabolism, and habitat **496**

Gas exchange may be increased by respiratory organs, bulk transport, and diffusion-enhancing proteins **497**

Breathing as a form of bulk transport can be tidal or flow-through **498**

11.2 Water Respirers 498

Water is a more difficult medium than air for gas exchange **498**

The limitations of diffusion in water are overcome with gills and other external thin, high-surface-area structures, internal circulation, and flow-through breathing **499**

Breathing muscles in water provide rapid and often flow-through transport **501**

Countercurrent blood flow enhances gas pressure gradients in fishes **502**

Aquatic respiratory systems can perform numerous nonrespiratory functions **502**

11.3 Air Respirers: Overview and Nonvertebrates 502

Air breathers may have less efficient exchange surfaces and breathing mechanisms, and their exchange surfaces must be protected from drying out **502**

Land slugs and snails use skin, mantle tissue, or lungs **503**

Arachnids use book lungs or tracheae **503**

In insects, internal air-filled tubes—tracheae—supply oxygen directly to the tissues **504**

11.4 Air Respirers: Vertebrates 504**Challenges and Controversies: Why Are There No Large Insects? 505**

The first air-breathing vertebrates were bimodal **505**

Frog lungs may be simple or moderately folded and are inflated by positive pressure **506**

Reptiles and mammals have respiratory systems ranging from simple to elaborately folded chambers inflated by negative pressure **507**

Mammalian airways terminate in alveoli, which are involved in both ventilation and gas exchange **508**

A pleural sac separates each lung from the thoracic wall **510**

Mammalian lungs are inflated and deflated tidally by cyclical changes in intra-alveolar pressure generated indirectly by respiratory muscles **510**

Ventilation and gas exchange are separated in avian respiratory systems due to air sacs and parabronchi with air capillaries **511**

Flow-through breathing plus crosscurrent blood flow enhances gas exchange in birds **514**

Unanswered Questions: Soaring birds from Saurischian dinosaurs? **515**

Aerial respiratory systems can perform numerous nonrespiratory functions **515**

11.5 Breathing: Respiratory Mechanics in Mammals 517

Interrelationships among atmospheric, intra-alveolar, and intrapleural pressures are important in respiratory mechanics of mammals **517**

The lungs are normally stretched to fill the larger thorax **517**

Intrapleural and lung pressures decrease during inhalation and increase during exhalation **519**

Respiratory diseases often increase airway resistance **519**

Elasticity in mammalian lungs depends on connective tissue and alveolar surface tension, which is reduced by surfactant **520**

11.6 Breathing: Lung Volumes in Mammals 521

Changes in lung volumes are important for analyzing different respiratory efforts, disease states, aerobic activity capacities, and species differences **521**

Alveolar ventilation is less than pulmonary ventilation because of the presence of dead space **523**

11.7 Breathing: Flow-Through versus Tidal Respirers 526

Dead-space volumes are lower in fishes but higher in birds compared to mammals **526**

The work of normal breathing requires as little as 2% of total energy expenditure in some mammals to as much as 50% in some fishes **527**

Flow-through ventilation yields a greater oxygen uptake than tidal breathing **527**

11.8 Gas Exchange at Vertebrate Respiratory Organs and Body Tissues 527

Lung air has a lower partial pressure of oxygen than atmospheric air **527**

O₂ enters and CO₂/HCO₃[−] leaves the capillaries in the lungs or gills passively down partial pressure or concentration gradients **529**

Factors other than the partial pressure gradient influence the rate of gas transfer **529**

Gas exchange across the systemic capillaries also occurs down partial pressure gradients **530**

11.9 Circulatory Transport and Gas Exchange 530

Most O₂ in many animal circulatory systems is transported bound to hemoglobins, hemocyanins, and other metal-containing respiratory pigments **530**

A Closer Look at Adaptation: Life in the Cold: The Hemoglobinless Icefish 532

Myoglobin stores oxygen in aerobic muscle and may facilitate diffusion from the blood to the mitochondria **533**

Neurons contain neuroglobin, while fibroblasts contain cytoglobin **533**

The P_{O₂} is the primary factor determining the percent hemoglobin saturation **533**

Cooperativity among hemoglobin subunits allows for effective delivery of oxygen **533**

Evolutionary adaptation results in different hemoglobin P₅₀ values **535**

By acting as a storage depot, respiratory pigments promote the net transfer of O₂ from the respiratory surfaces to the circulatory fluid **536**

Increased CO₂, acidity, temperature, and organic phosphates shift the O₂–Hb dissociation curve to the right, favoring unloading **537**

Filling of the gas bladder is aided by the Root effect **539**

Most CO₂ is transported in the blood as bicarbonate **540**

Various respiratory states are characterized by abnormal blood gas levels **542**

Other unusual respiratory states such as apnea are not necessarily pathological **543**

A Closer Look at Adaptation: High Fliers and Deep Divers 544**11.10 Control of Respiration 546**

Spiracles that control tracheal ventilation in insects are regulated intrinsically and extrinsically for both gas exchange and evaporation control **546**

Extrinsic and intrinsic controls act on the smooth muscle of mammalian airways and arterioles to maximally match ventilation to perfusion **546**

Respiratory centers in the vertebrate brain stem establish a rhythmic breathing pattern **547**

Molecular Biology and Genomics: HIF to the Rescue 549

The magnitude of ventilation is adjusted in response to three chemical factors: P_{O₂}, P_{CO₂}, and H⁺ **550**

Feedback monitoring of blood gases and H⁺ occurs both peripherally and centrally **550**

Decreased arterial P_{O₂} increases ventilation more strongly in fish than in air breathers **550**

Carbon dioxide–generated H⁺ in the brain is normally the main regulator of ventilation in air breathers **551**

Adjustments in ventilation in response to changes in arterial H⁺ are important in acid–base balance **553**

Activity profoundly increases ventilation, possibly due to anticipatory mechanisms **553**

Making Connections: How Respiratory Systems Contribute to the Body as a Whole 554

Chapter Summary **554**

Review, Synthesize, and Analyze **555**

Suggested Readings **556**

12 Excretory Systems 557**12.1 Evolution of Excretory Systems 557**

Selective excretion is crucial to internal fluid homeostasis and involves several systems **557**

Nitrogen metabolism creates special stresses and produces three major end products: ammonia, urea, and uric acid **558**

Excretory organs have transport epithelia, which typically use Na⁺/K⁺ ATPases **561**

12.2 Renal Excretory Organs: Overview 563

Renal tubules produce urine using the processes of filtration, secretion, reabsorption, and osmoconcentration **563**

The major renal organs are protonephridia, meso- and metanephridia, and Malpighian tubules **563**

A Closer Look at Adaptation: Avian Longevity: Unraveling the Mystery 564

12.3 Insect Malpighian Tubules 566

Malpighian tubules initiate excretion by ion secretion, which causes osmosis 566

The tubules and hindgut modify the lumen fluid by specific secretion and reabsorption 567

Unanswered Questions: Why are there virtually no marine insects? 568

Insect excretion is regulated by diuretic and antidiuretic hormones 568

12.4 Vertebrate Urinary Systems and Extrarenal Organs 569

Vertebrate kidneys form the urine; the remainder of the urinary system is ductwork that carries the urine to the bladder or hindgut 569

The nephron is the functional unit of the vertebrate kidney, using three or four of the basic renal processes 571

Elasmobranch fishes retain urea and trimethylamine oxide, and use gills, kidneys, and rectal glands for excretion and retention 572

Marine bony fishes use gills for most excretion and retention processes 572

Freshwater bony fishes excrete water with their kidneys, and their gills excrete wastes and take up salts 573

Terrestrial vertebrates evolved new renal and extrarenal mechanisms to maintain an “internal sea” 574

Amphibians use kidneys and bladders for excretion and retention 574

Nonavian reptiles use amphibian-like kidneys, hindguts, and (in marine and desert species) salt glands for excretion and retention 574

Birds have kidneys with reptile- and mammal-like nephrons, hindguts, and (in marine species) salt glands for excretion and retention 574

12.5 Mammalian Urinary System: Overview and Glomerular Filtration 576

Mammalian (and avian) kidneys have cortical and juxtamedullary nephrons 576

The glomerular membrane has three layers forming a fine molecular sieve 577

The glomerular capillary blood pressure is the major force that causes glomerular ultrafiltration 579

Changes in the GFR result primarily from changes in glomerular capillary blood pressure 579

The GFR can be influenced by changes in the filtration coefficient 582

12.6 Mammalian Kidneys: Tubular Reabsorption 583

Tubular reabsorption involves passive and active transepithelial transport and is tremendous, highly selective, and variable 583

Sodium reabsorption is essential for the reabsorption of nutrients, Cl^- , and H_2O , and for the regulation of ECF osmolality and volume 584

Glucose and amino acids are reabsorbed by Na^+ -dependent secondary active transport 585

With the exception of Na^+ , actively reabsorbed substances exhibit a tubular maximum 585

Glucose reabsorption is not regulated by the kidneys and has a T_m that is exceeded in diabetes 586

PO_4^{3-} (phosphate) reabsorption is regulated by the kidneys 586

In general, unwanted waste products, except urea, are not reabsorbed 586

The renin–angiotensin–aldosterone system stimulates Na^+ reabsorption in distal tubules and collecting ducts, elevates blood pressure, and stimulates thirst and salt hunger 587

Atrial and brain natriuretic peptides antagonize the RAAS, inhibiting Na^+ reabsorption and reducing blood pressure 589

12.7 Mammalian Kidneys: Tubular Secretion 589

Hydrogen ion secretion is important in acid–base balance 589

Potassium secretion is controlled by aldosterone 589

Organic anion and cation secretion helps eliminate foreign compounds from the body 592

Plasma clearance is the volume of plasma cleared of a particular substance per minute 592

12.8 Mammalian Kidneys: Osmoconcentration 593

The ability to excrete urine of varying concentrations varies among species and depends on hydration state 593

The medullary vertical osmotic gradient is established by countercurrent multiplication 594

Vasopressin-controlled, variable H_2O reabsorption occurs in the final tubular segments 597

Countercurrent exchange within the vasa recta conserves the medullary vertical osmotic gradient 599

Passive urea recycling in the renal medulla contributes to medullary hypertonicity 599

Different osmoconcentrating abilities among species depend on nephron anatomy and metabolic rates 601

Challenges and Controversies: The Inner Mystery 603

12.9 Mammalian Urinary System: Bladder Storage and Micturition 605

Urine is temporarily stored in the bladder, which is emptied by micturition 605

Molecular Biology and Genomics: Surviving Salt and Urea: Organic Osmolytes and Gene Regulation 606

12.10 Renal Diseases 607

Renal diseases are numerous and have wide-ranging consequences 607

Making Connections: How Excretory Systems Contribute to the Body as a Whole 609

Chapter Summary 609

Review, Synthesize, and Analyze 610

Suggested Readings 610

13 Fluid and Acid–Base Balance 612

13.1 Introduction 612

If balance is to be maintained, input must equal output 612

Body water is distributed between the intracellular and extracellular fluid compartments 613

A Closer Look at Adaptation: The Sweet Solution to Desiccation 614

In vertebrates, the plasma and interstitial fluid are similar in composition, but the ECF and ICF are markedly different in all animals 615

13.2 Osmotic and Volume Balance: Overview and Osmoconformers 616

Osmotic problems that threaten cells and animals include salinity, evaporation, ingestion and excretion, freezing, and certain pathologies 616

Animals have evolved two strategies to cope with osmotic challenges: osmoconforming and osmoregulating 617

Osmoconformers use compatible and counteracting organic osmolytes in their cells 617

Strict osmoconformers include most marine nonvertebrates and hagfish 620

Hypo-ionic osmoconformers include marine chondrichthyans and coelacanths and some arthropods 621

A Closer Look at Adaptation: Life at the Top 622

Molecular Biology and Genomics: A Worm in Saltwater 624

13.3 Osmotic and Volume Balance: Osmoregulators 624

Hypo-osmotic regulators include most marine vertebrates and some arthropods 624

Hypo-osmotic osmoregulators use special transport epithelia to remove excess salt 624

Some osmoregulating vertebrates have high levels of organic osmolytes 625

Unanswered Questions: Why are most marine vertebrates hypo-osmotic? 626

Hyperosmotic regulation is found in all freshwater animals 626

Some animals such as salmon alternate between modes of osmotic adaptation 626

Many terrestrial animals osmoregulate in the face of both low water and salt availability 627

13.4 Osmotic and Volume Balance in Mammals 628

Fluid balance is maintained by regulating ECF volume and osmolality 628

Control of ECF osmolality prevents changes in ICF volume from hyper- or hypotonicity 628

Control of ECF volume is important in the long-term regulation of blood pressure 630

Water balance depends on input from food, drink, and metabolism, and output via urine, feces, and insensible and sensible cutaneous and respiratory losses **630**

Water balance is regulated primarily by the kidneys and thirst **631**
 Salt balance is regulated primarily by the kidneys and salt hunger **632**
 During hemorrhagic shock, circulatory functions and fluid balance are coordinately regulated **634**

13.5 Acid–Base Balance: General Concepts **636**

Acids liberate free hydrogen ions, whereas bases accept them **636**
 The pH designation is used to express hydrogen ion concentration **637**

Fluctuations in $[H^+]$ alter nerve, enzyme, and K^+ activity **638**
 Hydrogen ions are continually being added to body fluids from metabolic activities **638**

13.6 pH Regulation: Buffers **639**

Chemical buffer systems act as the first line of defense against changes in $[H^+]$ by binding with or releasing free H^+ **639**
 The CO_2 – HCO_3^- buffer system is the primary ECF buffer for noncarbonic acids **640**
 The peptide and protein buffer system, including hemoglobin in erythrocytes, is primarily important intracellularly **641**
 The phosphate buffer system is important in the ICF and urine **642**
 Buffers are a temporary mechanism because they do not eliminate excess $[H^+]$ **642**

13.7 pH Regulation: Respiration and Excretion **642**

Respiratory systems as a second line of defense regulate $[H^+]$ through adjustments in ventilation **642**
 Excretory systems are a powerful third line of defense that aid acid–base balance by controlling both $[H^+]$ and $[HCO_3^-]$ in the ECF **643**

13.8 Acid–Base Imbalances: Respiratory, Environmental, and Metabolic Disturbances **647**

Respiratory acidosis arises from an increase in $[CO_2]$ **647**
 Respiratory alkalosis usually arises from a decrease in $[CO_2]$ **647**
 Metabolic acidosis is associated with a reduction in plasma $[HCO_3^-]$ **649**
 Metabolic alkalosis is associated with an elevation in $[HCO_3^-]$ **650**
 Environmental acidosis arises from natural and anthropogenic increases in environmental $[CO_2]$ and sulfuric acid **650**
 Environmental alkalosis arises from basic minerals **651**

Making Connections: How Fluid and Acid–Base Regulation Contribute to the Body as a Whole **651**

Chapter Summary **652**

Review, Synthesize, and Analyze **653**

Suggested Readings **653**

14 Digestive Systems **654**

14.1 Introduction: Feeding Strategies and Evolution **654**

Animal digestion evolved from an intracellular to an extracellular process in a specialized sac or tube connected to the environment **654**
 Animals can be classified according to their primary feeding methods **655**

14.2 General Aspects of Digestion **656**

Digestive systems perform four basic digestive processes **656**
 The digestive tract and accessory digestive organs make up digestive systems **658**
 Some smooth muscles of digestive tracts have autonomous activity **660**
 Regulation of digestive functions is synergistic and occurs both intrinsically and extrinsically **660**

14.3 Mouth **662**

Saliva aids in mastication but plays a more important role in lubricating food boluses before swallowing **664**
 The continuous low level of salivary secretion can be increased by simple and conditioned reflexes **665**
 Digestion in the mouth is minimal **666**

14.4 Pharynx, Esophagus, and Crop **666**

Swallowing in vertebrates is a sequentially programmed all-or-none reflex **666**

During the oropharyngeal stage of swallowing, food is directed into the esophagus and prevented from entering the wrong passageways **667**

The esophagus is a muscular tube guarded by sphincters at both ends **667**

Peristaltic waves push the food through the esophagus **668**

The gastroesophageal sphincter prevents reflux of gastric contents **668**

Esophageal secretion is entirely protective **668**

The crop is a modified section of the esophagus and functions mainly as a storage organ **668**

Challenges and Controversies: Global Warming and the Rumen **669**

14.5 Stomach or Midgut **670**

Digestion in many insect midguts is aided by peritrophic membranes and filter chambers **670**

The vertebrate stomach stores food, begins protein digestion, and forms chyme **670**

Gastric filling involves receptive relaxation **671**

Gastric storage takes place in the body of the stomach **671**

Gastric mixing takes place in the antrum of the stomach **671**

Gastric emptying is largely controlled by factors in the duodenum **671**

Emptying and stress can influence gastric motility **674**

The act of vomiting is powered by respiratory muscles, not the stomach **674**

Gastric digestive juice is secreted by glands located at the base of gastric pits **674**

Pepsinogen, once activated, begins protein digestion **677**

Stomach mucus is protective **678**

Control of gastric secretion involves three phases **678**

Gastric secretion gradually decreases as food empties from the stomach into the intestine **679**

The stomach lining is protected from gastric secretions by the gastric mucosal barrier **679**

Carbohydrate digestion continues in the body of the stomach, whereas protein digestion begins in the antrum **680**

The proventriculus and gizzard begin the process of digestion in birds and insects **681**

14.6 Digestive Accessory Organs: Pancreas, Liver, Gallbladder, Fat Body **682**

The (hepato)pancreas is a mixture of exocrine and endocrine tissue **682**

The exocrine pancreas secretes digestive enzymes and an aqueous alkaline fluid **682**

Pancreatic exocrine secretion is hormonally regulated to maintain neutrality of the duodenal contents and to optimize digestion **684**

The vertebrate liver performs various important functions, including bile production, nutrient processing, and detoxification **685**

The liver lobules are delineated by vascular and bile channels **685**

Bile is continuously secreted by the vertebrate liver and is diverted to the gallbladder between meals **686**

Bile salts are recycled through the enterohepatic circulation **686**

Bile salts aid fat digestion and absorption through their detergent action and micellar formation, respectively **686**

Biliverdin and bilirubin are waste products of hemoglobin excreted in the bile **688**

The fat body of insects plays a major role in intermediary metabolism and is the central storage depot of nutrients and energy reserves **688**

Unanswered Questions: A solar-powered hornet? **690**

14.7 Small Intestine **690**

The digestive tract wall has four layers: mucosa, submucosa, muscularis externa, and serosa **690**

Segmentation contractions mix and slowly propel the chyme **692**

The migrating motility complex sweeps the intestine clean between meals **693**

The ileocecal juncture prevents contamination of the small intestine by colonic bacteria **693**

Small-intestine secretions do not contain any digestive enzymes **694**

Small-intestine enzymes complete the process of digestion at the brush border membrane **694**

The small intestine is highly adaptable for its primary role in absorption **694**

The mucosal lining experiences rapid turnover **695**

Energy-dependent Na^+ absorption drives passive H_2O absorption **696**

Carbohydrate and protein are both absorbed by secondary active transport and enter the blood **696**
 Vitamin absorption is largely passive **699**
 Most absorbed nutrients immediately pass through the liver for processing **699**
 Extensive absorption by the small intestine keeps pace with secretion **701**
 Biochemical balance among the stomach, pancreas, and small intestine is normally maintained **701**
 Diarrhea results in loss of fluid and electrolytes **701**

14.8 Hindgut/Large Intestine **701**

The hindgut of insects actively transports nutrients and may house symbionts **701**

Molecular Biology and Genomics: Big Bugs Have Little Bugs... **702**

The vertebrate hindgut or large intestine consists of the colon, cecum, and rectum or cloaca **702**
 The large intestine serves as a temporary storage site for excreta, functions in electrolyte and fluid balance, and harbors microbes for fermentation and production of volatile fatty acids **702**
 Diet composition governs variation in structure of the large intestine **703**
 Haustral contractions prolong the retention of digesta **703**
 Postgastric fermentation is not as efficient as pregastric fermentation in obtaining nutrients **704**
 Mass movements propel colonic contents long distances **704**
 Feces are eliminated by the defecation reflex **704**
 Large-intestine secretion is protective in nature **705**
 The large intestine converts the luminal contents into feces **705**

14.9 Ruminant Digestion **705**

The rumen is divided into separate compartments **705**
 The abomasum is similar in function to the stomachs of nonruminants **707**
 Motility of the ruminant stomach is predominantly regulated by central nervous system reflex mechanisms **707**
 Rumination is the regurgitation, remastication, and reswallowing of ingesta **707**
 The environment of the rumen fosters the growth of anaerobic microbes **707**
 Nutrients for the host ruminant are generated by anaerobic microbes **708**
 Rumen microbes synthesize vitamins for their host and detoxify some ingested toxins **710**
 Some ruminants are selective in what they eat, whereas others simply graze the available forage **710**

14.10 Overview of the Gastrointestinal Hormones **711**

Making Connections: How Digestive Systems Contribute to the Body as a Whole **712**

Chapter Summary **712**

Review, Synthesize, and Analyze **713**

Suggested Readings **714**

15 Energy Balance and Thermal Physiology **715**

15.1 Introduction: Thermodynamics and Life **715**

Life follows the laws of thermodynamics **715**
 To compensate for entropy, animals require input of food energy, most of which is ultimately converted to heat output **716**

15.2 Energy Balance: General Principles **717**

Energy input must equal energy output, which is measured as metabolic rates of basal metabolism, activity, diet-induced thermogenesis, and production **717**
 Energy of production determines net energy balance **719**
 BMR and SMR are regulated in part by thyroid hormones **720**
 BMR and SMR scale with body mass **720**
 Increased muscle activity is the factor that can most increase metabolic rate, as indicated by metabolic scope **720**

Challenges and Controversies: A Universal Scale of Life? **722**

Diet-induced thermogenesis occurs after eating in most animals **722**

15.3 Energy Balance: Regulation **724**

Some adult animals maintain long-term neutral energy balance, while others undergo regulated periods of positive or negative energy balance **724**
 Food intake in mammals is controlled primarily by the hypothalamus in response to numerous inputs **724**
 Leptin and insulin are signals of long-term energy balance **725**

Molecular Biology and Genomics: Discovering the Obesity Gene **726**

Effectors for energy balance are mechanisms to regulate eating and expenditures **728**
 Different energy-balance set points among species result from evolutionary adaptations to different food supplies **729**

15.4 Thermal Physiology: General Principles **730**

Temperature alters rates of chemical reactions and denatures macromolecules **730**
 Biomolecules can be altered to work optimally at different temperatures **731**
 The thermal adaptation strategies of animals depend on their primary source of heat **733**
 Heat exchange between the body and the environment takes place by radiation, conduction, convection, and evaporation **734**
 Heat gain versus heat loss determines core body temperature, with mechanisms to gain external heat, retain internal heat, generate more internal heat, and lose excess heat **735**

15.5 Ectothermy **736**

Body temperatures of ectotherms may follow the environment, or may be regulated by heat gains, retention, and losses **736**
 Some ectotherms can compensate biochemically for changes in body temperatures **737**
 Ectotherms survive extreme cold by metabolic dormancy and by either freeze avoidance or freeze tolerance **739**
 Ectotherms may survive temporary extreme heat with the heat shock response **740**

15.6 Endothermy and Homeothermy **740**

Challenges and Controversies: What Is the Maximum Temperature for Life? **741**

Unanswered Questions: How, when, and why did endothermy evolve? **741**

Birds and mammals maintain a consistent internal core temperature (homeothermy) **741**
 To maintain a stable core temperature, heat gains must balance heat loss, with mechanisms to gain, retain, generate, and lose excess heat **743**
 The hypothalamus and/or spine integrates a multitude of thermosensory inputs from both the core and the surface of the body **748**
 To regulate core temperature homeostatically, the hypothalamus simultaneously coordinates heat production, heat loss, and heat conservation mechanisms **748**
 During a fever, the hypothalamic thermostat is “reset” to an elevated temperature, which can be beneficial **750**

15.7 Heterothermy **750**

Regional heterotherms heat only some parts of their bodies **750**
 Temporal heterotherms maintain high body temperatures only for certain time periods **750**
 Some colonial heterotherms create homeothermic “superorganisms” **752**

15.8 Thermal Physiology and Climate Change **752**

Arctic regions have warmed the most, and climate is becoming more extreme **752**

A Closer Look at Adaptation: The Naked Mole Rat—Mammalian Hive Ectotherm **753**

Animal physiology, behavior, and genes are already being affected by warming trends **754**

Making Connections: How Energy Balance and Thermal Adaptations Contribute to the Body as a Whole **754**

Chapter Summary **755**

Review, Synthesize, and Analyze **755**

Suggested Readings **756**

Section V: Reproduction

16 Reproductive Systems 757

16.1 Introduction: Reproductive Processes 757

Animals may reproduce asexually or sexually 757

Animals may reproduce by *r*-selected, *K*-selected, or intermediate ecological strategies 758

Animals may reproduce physiologically by oviparity, ovoviviparity, or viviparity 758

Animals use various strategies to ensure breeding at the appropriate time 760

16.2 Reproductive Systems and Genetics 761

The reproductive system of vertebrates includes the hypothalamus, gonads, and reproductive tract 761

Reproductive systems in insects include the neuroendocrine organs, gonads, and reproductive tract 764

Reproductive cells each contain a half set of chromosomes 765
Gametogenesis occurs by meiosis, resulting in genetically unique sperm and ova 765

The sex of an individual is determined by the combination of sex chromosomes or by environmental stimuli 766

An unfertilized egg can develop into a male or female in parthenogenesis 767

Sex differentiation in mammals depends on the presence or absence of Y-chromosome masculinizing determinants during critical periods of embryonic development 767

16.3 Male Reproductive Physiology 770

Testes in most mammals descend into the scrotum to become external 770

The scrotal location of the testes provides a cooler environment essential for temperature-sensitive spermatogenesis in mammals 770

Unanswered Questions: Why can't sperm develop at core body temperatures? 770

The testicular Leydig cells secrete masculinizing testosterone during the breeding season 771

Spermatogenesis yields an abundance of highly specialized, mobile sperm 773

Throughout their development, vertebrate sperm remain intimately associated with Sertoli cells 775

LH and FSH from the anterior pituitary control testosterone secretion and spermatogenesis 776

Gonadotropin-releasing hormone activity increases at puberty 777
The ducts of the reproductive tract store and concentrate sperm and increase their fertility 778

The accessory sex glands contribute the bulk of the semen 778
Prostaglandins are ubiquitous, locally acting chemical messengers 779

The penis in many vertebrates is both erectile and extendible 779

16.4 Mating 780

The male sex act is characterized by erection and ejaculation 780

Erection is accomplished by penis vasocongestion 781

Ejaculation includes emission and expulsion 782

The female sex act is similar to the male sex act 783

Oxytocin has several roles in mating and other social interactions 783

16.5 Female Reproductive Physiology 783

Complex cycling characterizes female reproductive physiology in many vertebrates, including estrous cycles in most mammals 783

Concepts and Controversies: Environmental Estrogens: Bad News for Reproduction 785

The steps of gametogenesis are the same in both sexes, but the timing and outcome differ sharply 786

The ovarian cycle of mammals consists of alternating follicular and luteal phases 788

The follicular phase is characterized by the development of maturing follicles 788

The luteal phase is characterized by the presence of a corpus luteum and secretion of progesterone 790

The estrous cycle is regulated by complex hormonal interactions among the hypothalamus, anterior pituitary, and ovarian endocrine units 790

The uterine changes that occur during the estrous cycle reflect hormonal changes during the ovarian cycle 794

Fluctuating concentrations of estrogens and progesterone produce cyclic changes in cervical mucus 794

The reproductive cycles of nonviviparous vertebrates are fundamentally similar but have some unique differences 794

A Closer Look at Adaptation: A Rut for One Season 795

Sexual maturity events in mammalian females are similar to those in males 798

16.6 Fertilization and Implantation 799

The oviduct is the site of fertilization 799

Sperm may compete among males 801

The mammalian blastocyst implants in the endometrium through the action of its trophoblastic enzymes 801

The placenta is the organ of exchange between maternal and fetal blood 803

Modes of placentation differ among species 803

Hormones secreted by the corpus luteum and placenta play a critical role in maintaining pregnancy 804

Maternal body systems respond to the increased demands of gestation 805

16.7 Parturition and Lactation 805

Changes during late gestation prepare for parturition 805

The factors that trigger the onset of parturition are only partially understood 806

Parturition is accomplished by a positive-feedback cycle 809

Lactation requires multiple hormonal inputs 809

Mammary gland feeding is advantageous to both the infant and the parent 812

Molecular Biology and Genomics: Prolactin: A Key with Many Locks in Females and Males 813

The end is a new beginning 813

Making Connections: How Reproductive Systems Contribute to the Body as a Whole 814

Storage, Replication, and Expression of Genetic Information

Glossary A-15

Index A-33

Preface

“There is grandeur in this view of life, with its several powers, having been originally breathed into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved.” —Charles Darwin, last line of *The Origin of Species*.

Even though the authors of this text have been teaching biology for many years, we continue to be awed by the grandeur of life as so eloquently expressed by Charles Darwin. As animal physiologists, we are continually amazed by the wondrously intricate functions that mesh together to sustain an animal’s body. As biologists, we are also fascinated by the powerful and yet quirky mechanisms of evolution, which have allowed life to adapt from the bitter cold of Antarctica to the scalding heat of hydrothermal vents. Moreover, the fact that we humans have structures, processes, and genes in our cells that connect us to every life form on this planet is both humbling and inspiring. It is the grand view of life that we try to convey to our students.

This second edition of *Animal Physiology: From Genes to Organisms* focuses on the mechanisms and evolutionary histories of animal body functions from genes to organ systems to the whole organism interacting with its environment. This text is designed for mid- to upper-level undergraduate courses. Because this book may be the only exposure many undergraduate students will have to physiology beyond the introductory level, all aspects of physiology and many types of animals are covered. This text serves for general biology and zoology programs, preprofessional programs in animal husbandry, veterinary medicine and science, marine biology, and wildlife and fisheries biology, as well as for human health sciences.

We have three major goals in writing this second edition. First, to better understand scientific knowledge, students should realize that our knowledge is incomplete and yet continually advancing, and they should know how that knowledge is obtained. Therefore, pertinent information based on recent discoveries, as well as new research methodologies, has been included in all chapters, with new controversial ideas and hypotheses presented to illustrate that physiology is a dynamic, changing discipline. Students can be assured of the timeliness and accuracy of the material presented. Our second goal has been to clarify and modify figures and text as needed to strengthen our coverage of physiological features and to ensure that the text and art work well together. Third, we have sought to strengthen our comparative, evolutionary approach with greater emphasis on some nonmammalian systems as some of the more remarkable recent discoveries have been made in this arena.

Even the most tantalizing subject can be difficult to comprehend if not effectively presented. Thus, this book has a logical, understandable format with an emphasis on how each concept is an integral part of the entire subject. Too often, students view the components and functions of an animal as isolated entities; by understanding how each component depends on the others, students can appreciate the integrated functioning of the whole organism. Moreover, this text is designed to promote understanding of the basic principles and concepts of physiology rather than memorization of details. The text is written in simple, straightforward language, and every effort has been made to ensure smooth reading through good transitions, logical reasoning, and integration of ideas throughout the text.

Major Organizing Principles

This text follows an “integrative systems” approach, which involves both vertical and horizontal integration. *Vertical integration* concerns the hierarchical nature of physiology, in which organ systems and their functions arise from cells and their molecular components, and from the evolutionary forces that gave rise to those components. After an introduction to the major themes of physiology, the chapters proceed from molecular and cellular physiology to classical organ systems. Organ systems are grouped according to universal functions of whole-body regulation and integration, support and movement, maintenance, and reproduction. For each organ system, both the evolutionary forces and the cellular and molecular underpinnings are discussed, including new research in genomics, which is having a major impact on all areas of biology. Where necessary, sufficient relevant anatomy is included to make the inseparable relation between structure and function meaningful.

Horizontal integration concerns the interactions of all organ systems to yield a whole functioning organism. As we noted earlier, it is all too easy to view each system as an isolated entity. This text works to overcome this in two ways. First, this text’s central themes are homeostasis and other integrated forms of regulation—how processes from the genetic to the behavioral level allow an animal’s body to meet changing demands while maintaining the internal consistency necessary for all cells and organs to function. Each chapter not only emphasizes these themes but also indicates interactions with other systems. Second, special integrative chapters—Fluid and Acid–Base Balance and Energy Balance and Thermal Physiology—focus on crucial whole-body phenomena that are dependent on more than one organ system.

In addition to an integrated systems organization, this text also incorporates a *comparative approach* throughout

that illustrates respective solutions animals have evolved to cope with the environment. Mechanisms used by major and exemplary groups of vertebrates, insects, and other illustrative groups are included for three purposes. First, comparisons among types of animals are selected to illuminate important universal functions and principles, emphasizing the unity of life. Second, unique or striking adaptations that reveal the diversity that can result from evolutionary adaptation are featured. Finally, this text incorporates detailed coverage of animal species of relevance to those preparing for animal-related careers, especially vertebrates.

The scope of this text has been limited by judicious selection of pertinent content that students can reasonably be expected to assimilate in a one-semester course. To keep pace with today's rapid advances in the biological sciences, students interested in careers related to animal physiology must be able to draw on their overall understanding of concepts instead of merely recalling isolated facts. For this reason, this text is designed to promote understanding of the basic principles and concepts of physiology rather than the memorization of details. Yet depth, where needed, is not sacrificed. All aspects of physiology receive coverage, including separate chapters on immune and reproductive systems and detailed coverage of pregastric and postgastric digestion.

Learning Aids and High-Interest Features

Pedagogical Illustrations Anatomic illustrations, schematic representations, photographs, tables, and graphs complement and reinforce the written material. Widespread use of integrated descriptions within figures, including numerous process-oriented figures with step-by-step descriptions, allows visually oriented students to review processes through figures. Flow diagrams are used extensively to help students integrate the written information. In the flow diagrams, lighter and darker shades of the same color denote a decrease or increase in a controlled variable, such as blood pressure or the concentration of blood glucose. Physical entities, such as body structures and chemicals, are distinguished visually from actions.

Feedforward Statements as Subsection Titles Instead of traditional short topic titles for each major subsection (for example, “Heart valves”), feedforward statements alert students to the main point of the subsection to come (for example, “Heart valves ensure that the blood flows in the proper direction through the heart”). These headings also break up large concepts into smaller, more manageable pieces for the student, and as an added bonus, the listing of these headings in the Contents at the beginning of the book serves as a set of objectives for each chapter.

Cross-Referencing Many chapters build on material presented in preceding chapters, yet each chapter is designed to stand on its own to allow the instructor flexibility in curriculum design. With extensive cross-references provided, the

sequence of presentation can be varied at the instructor's discretion.

Unanswered Questions The physiological sciences are changing constantly due to new discoveries and challenges of old ideas. In most chapters, *Unanswered Questions* present short overviews and questions on controversial ideas and new hypotheses to illustrate the dynamic nature of physiology research and to stimulate students to propose their own ideas. Many of these have been updated for the second edition.

Boxed Features More detailed boxed features are inserted where appropriate within chapters. *Beyond the Basics* exposes students to high-interest, tangentially relevant information on diverse topics, including historical perspectives, environmental issues, and common diseases. *Challenges and Controversies* boxes introduce the frontiers of physiological research with new hypotheses and unsolved questions, going in more depth than in the *Unanswered Questions*. *A Closer Look at Adaptation* illustrates the scope and limits of evolutionary adaptation with selected illustrative examples. *Molecular Biology and Genomics* provides examples of cutting-edge research resulting from the animal genome projects and related research to uncover the physiological functions of newly discovered genes. Most of these boxes are new or updated in this second edition.

Evolutionary Foundations Most chapters have an overview of major evolutionary events and selective forces, typically at the chapter start. All topics are placed in a true biological context that melds both the proximate (mechanistic) approach of traditional physiology with the evolutionary explanations behind them; this helps explain not only the power of natural selection but also the often quirky and even illogical features of life.

Cellular, Molecular, and Genomic Foundations Even though this text is primarily organized according to body systems, it provides coverage of cellular, molecular, and genomic topics in early chapters and incorporates these throughout as a basis for understanding organ function. The current tools used to explore molecular physiology are also outlined in most chapters. This is the cutting edge of physiology research.

Pathophysiology This text is also designed to help students realize that they are learning worthwhile and applicable material. Because many students using this text will have a clinical component to their careers, reference to important pathophysiological issues demonstrates the content's relevance to their professional goals. For example, this text includes the effects of environmental toxins on some body systems, an issue of increasing concern.

Key Terms, Word Derivations, and Glossary with Phonetic Pronunciations Key terms are defined as they appear in the text. A glossary at the end of the book, which includes phonetic pronunciations of the entries, enables students to quickly review key terms. Because physiology is laden with new vocabulary words, many of which are rather intimidating at first glance, word derivations are often provided to enhance understanding.

Integration Following our integrated systems approach, each chapter includes a *Making Connections* section that helps students put into perspective how the system just discussed contributes to the whole animal and important regulatory functions.

Chapter Summaries Each chapter now ends with a *Chapter Summary* of the key concepts as a bulleted list.

Review Questions Two new features help the student retain information. First, *Check Your Understanding* questions have been added after each major section to help review the main ideas just discussed. Answers to these questions appear in an appendix at the end of the book. Second, at each chapter's end are *Review, Synthesize, and Analyze* essay questions that integrate the chapter material or delve deeper into a topic and challenge the student on a higher level.

Suggested Readings Each chapter concludes with a list of both recent and classic articles as well as books that give important details on the chapter material.

Online Review The following online materials are designed to help students review foundation concepts presumably covered in prerequisite courses:

- **A Review of Chemical Principles:** This review is offered online at CengageBrain.com as a reference for students who need to go over basic chemistry concepts that are essential to understanding physiology.
- **Storage, Replication, and Expression of Genetic Information:** This review includes a discussion of DNA and chromosomes, protein synthesis, cell division, and mutations and is also offered online at CengageBrain.com.

New to the Second Edition

This edition has undergone extensive revision. Some of the changes are as follows:

New and Enhanced Artwork More than 90% of the art has been upgraded in this edition, with more three-dimensional art; many conceptually redesigned figures to enhance student understanding; brighter, more contemporary, and more visually appealing colors; and more consistent style throughout. New pictures of various animals that illustrate key physiological adaptations have been added. Also, icons of physical entities are incorporated into many of the flow diagrams to aid students in learning what structures are involved in specific actions.

In addition, many new figures have been added, such as those on the following topics: a cell's response to oxidative stress under normal and pathological states and the effects of chronic stress on cellular aging; the mechanism by which new synaptic connections are formed in association with long-term memory; cephalopod eye formation; pineal function in seasonally breeding animals; new insights into the mechanism by which the "catch state" is generated in bivalves; lipid transport for insects and mammals; a possible acquired immune response in insects; crosscurrent flow in a bird lung; protein and carbohydrate metabolism in the rumen; and global warming and animal metabolism.

New and Updated Content We have incorporated appropriate, timely material throughout, as the following examples illustrate: Chapter 2 has a new section on generating stem cells and new findings on microRNAs and small interfering RNAs; Chapter 5 contains updated material on learning and a new section on sleep; Chapter 6 includes updates on TRP-type receptor channels in most types of sensory cells; Chapter 7 contains new material on TSH in seasonally breeding animals, updates on nonvertebrate hormones, and new coverage of epigenetics; Chapter 8 includes updates on the role of titin and new concepts in muscle fatigue; Chapter 9 contains new information on genes in the evolution of the four-chambered heart; Chapter 10 has updates on dendritic cells, regulatory T cells, nanotubes, lamprey immunity, and insect immunity; Chapter 11 includes recent findings on insect respiration, birdlike crocodile lungs, and mammoth hemoglobin; Chapter 12 includes recent findings on insect (anti)diuretic hormones and exciting new hypotheses on the mammalian renal countercurrent mechanism; Chapter 13 has a new section on the effects of ocean acidification on animals; Chapter 14 presents updated material on methane production in ruminants and climate change; Chapter 15 includes a major new section on the effects of climate change on thermal physiology and updates on hypotheses about metabolic scaling and on gastrointestinal hormones in energy regulation; and Chapter 16 includes novel material on seasonal breeding in mammals, the female sexual act, and more depth on the topic of reproduction in nonvertebrates as well as new information on the rut in deer and the multiple roles of prolactin.

Increased Evolutionary and Comparative Aspects We have added additional detail on physiological adaptations, including the following examples: Chapter 1 has added information on vestigial features, cost-benefit trade-offs in evolution, and the Krogh principle; Chapter 6 contains new material on the use of infrasound and ultrasound in various animals, Pax6 genes in animal eye evolution, electroreception and magnetoreception mechanisms and electric organs, and color and UV vision in fish, reptiles, birds, mammals (including whales), and mantis shrimp; Chapter 7 has incorporated additional comparative aspects of thyroid function; Chapter 9 contains new material on hemolymph proteins in arthropods, the evolution of clotting in mammals, and cardiac output in various endotherms and ectotherms; Chapter 10 has been extensively rewritten with an evolutionary overview of universal and nonvertebrate immune functions; Chapter 11 has been extensively rewritten with an evolutionary overview of respiratory functions and more comparative and evolutionary details such as dinosaur and bird connections, nonhemoglobin respiratory pigments, hemoglobin oxygen affinities in various species, and comparisons of high flyers and deep divers; Chapter 12 includes more comparative examples on urea excretion and vertebrate renal development and evolution, and the entire chapter has been reorganized to reflect a more explicit evolutionary framework; Chapter 13 includes a table comparing water balance in humans and kangaroo rats and a new box on the evolution of osmoregulation in vertebrates; and Chapter 15 includes a new table comparing energy metabolism in humans and hummingbirds and new boxes on the evolution of endothermy and the thermal maximum for animal life.

Instructor and Student Ancillaries

PowerLecture This convenient tool makes it easy for instructors to create customized lectures. Each chapter includes the following features, all organized by chapter:

- Lecture slides
- All chapter art and photos
- Animations and videos
- *Test Bank*, which includes more than 900 questions in multiple-choice, true/false, matching, fill-in-the-blank, and essay formats

This single disc places all the media resources at your fingertips.

CourseMate Cengage Learning's Biology CourseMate brings course concepts to life with interactive learning, study, and exam preparation tools that support the printed textbook or the included eBook. With CourseMate, professors can use the included Engagement Tracker to assess student preparation and engagement either for the class as a whole or for individual students. Students can access an interactive eBook, chapter-specific interactive learning tools, including flash cards, quizzes, videos, and more in their Biology CourseMate, accessed through **CengageBrain.com**.

Acknowledgments

It takes the effort of many individuals to create a textbook. The authors would like to thank the following reviewers who provided excellent feedback during the various stages of the writing process.

About the Authors

L. Sherwood

Lauralee Sherwood is a Professor Emerita of Physiology at West Virginia University. Having earned a D.V.M. degree from Michigan State University, she continued to have an interest in animals even though her faculty appointment for 43 years was in the School of Medicine. She participated as a guest lecturer in Animal Science classes regularly. Dr. Sherwood has authored two human physiology textbooks: *Human Physiology: From Cells to Systems*, Eighth Edition, Brooks/Cole Publishing, and *Fundamentals of Human Physiology*, Fourth Edition, Brooks/Cole Publishing. She brings to this animal physiology textbook her knowledge of veterinary medicine, her years of classroom teaching experience, and her text-writing expertise. She has received numerous teaching awards, including an Amoco Foundation Outstanding Teacher Award, a Golden Key National Honor Society Outstanding Faculty Award, several listings in Who's Who Among America's Teachers, and the Dean's Award for Excellence in Education.

H. Klandorf

Hillar Klandorf is a Professor of Animal and Nutritional Sciences at West Virginia University. He completed his B.Sc. at UCLA and his Ph.D. degree at the Roslin Research Institute in Edinburgh, Scotland, in Avian Physiology. After completing two postdoctoral research programs, he returned to UCLA to investigate agents that affect the onset of diabetes in animal models. Currently, he is at West Virginia University, investigating the role of uric acid in limiting oxidative stress and tissue aging in birds. He instructs animal physiology and animal behavior classes.

Paul H. Yancey is a Professor of Biology at Whitman College. After earning a Ph.D. in Marine Biology (Animal Physiology and Biochemistry emphasis) from UCSD, he has conducted research at the University of St. Andrews (Scotland), the National Institutes of Health, the Mt. Desert Island Biological Laboratory, the Monterey Bay Aquarium Research Institute, the University of Otago (New Zealand), and the University of Hawai'i, as well as at Whitman. His research is on biochemical and physiological adaptations to water stress, temperature, and pressure in the deep sea. His research includes coral, mollusks, crustacea, hydrothermal vent clams and worms, hagfish, bony fish, cartilaginous fish, and mammalian kidneys in health and disease (including diabetes). He teaches animal physiology, human anatomy and physiology, marine biology, and bioethics, and he has won several teaching awards. He brings to this text a broad evolutionary perspective, and 30 years of teaching animal physiology using texts supplemented with a wide variety of external materials.

P. Yancey

Size Matters. A tiny mouse, sitting on an elephant's trunk, has a much greater surface-area:volume ratio than the elephant. This difference profoundly affects their physiologies.

Homeostasis and Integration: The Foundations of Physiology

1.1 Introduction

Life. The word *life* is the essence of the biological sciences, and yet has no clear definition. We seem to recognize instinctively what is alive and what is not alive on Earth, but we founder when contemplating how alien life on another planet could be recognized. How might we define life? Most attempts to define it focus on the **functions** of living systems, that is, on the dynamic processes that life forms have and that nonliving things do not. Living things organize themselves using energy and raw materials from their surroundings (a set of processes called *metabolism*), maintain integrity in the face of disturbances (a process called *homeostasis*), and reproduce. Such abilities are what physiology is all about—the study of the functions of organisms, or how life works.

Biological adaptations have two levels of explanation: the mechanistic (or proximate) and the evolutionary (or ultimate)

Physiologists often view organisms as organic machines whose mechanisms of action can be explained in terms of cause-and-effect sequences of physical and chemical processes—the same types of processes that occur in other components of the universe. However, biological traits, such as pelage coloration or visual acuity, differ from the rest of the universe in one crucial way: They are the result of millions of years of evolution through random variation and **natural selection**: the process in which members of a species having genetic characteristics that enhance survival are able to produce more surviving offspring than other members not expressing those characteristics. Therefore, scientists must recognize that biological phenomena always

have two different levels of explanation or description:

- The ***mechanistic or proximate explanation***: This is the answer to “How does it work?” This focus emphasizes the mechanism or composition of a function or structure, and is the traditional core of the physiological and medical sciences.
- The ***evolutionary or ultimate explanation***: This is the answer to “How did it get to be this way?” This emphasis recognizes that biological features are the result of variation and natural selection, that is, evolutionary history. A species must cope with a variety of ***selective pressures*** (environmental stresses, mating, and so on). Many genes within a species differ among individuals, and under a particular selective pressure some gene variants better equip an animal for survival, which allows it to reproduce better than do other variants.

Those gene variants get passed on to more offspring and thus the species gradually changes genetically over time. This process never ends, because selective pressures (such as climate and predator–prey interactions) change over time. As you’ll see, to fully understand why a certain feature is the way it is, we often need to know a species’ history.

Because of this process of natural selection, physiologists assume that most organismal traits are **adaptations**, that is, beneficial features that enhance overall survival of the species. When conducting an evolutionary analysis, biologists distinguish between two kinds of adaptations. **Homologous** traits in two different organisms are those that are related by common ancestry, such as bird wings and human arms: Both have the same basic bony components because both evolved from limbs of four-legged reptiles. In contrast, **analogous** traits are those with similar structures and/or functions but which evolved independently; for example, bird and insect wings serve similar functions but share no common ancestral structure.

Natural selection is a powerful force, which often results in exquisite adaptations such as wings. However, it is important to recognize that selection is also constrained by the past. That is, evolution works primarily through modifications of previously evolved features and variations of these features and so does not always result in the most logical or optimal design. We’ll look at examples shortly, but first warn you about another kind of explanation.

Adaptations reflect evolutionary history including cost–benefit trade-offs

In addition to mechanistic and evolutionary explanations, there are purely teleological approaches to explaining the various features of organisms. In a **teleological approach**, phenomena that occur in organisms are explained in terms of their particular **purpose** (a function that is useful or beneficial) in fulfilling an organismal need, without necessarily considering how this outcome is accomplished (mechanism) or how it evolved. Teleology is commonly used because most biological mechanisms do serve a useful purpose (having been selected through evolutionary time to do so). If you try to find the thread of “purpose” in what you are studying, you can avoid a good deal of pure memorization!

However, be aware of a pitfall: Teleology can be dangerous thinking because it assumes that features are always logical, having evolved for idealized purposes. But there are at least two reasons this may not be so. First, adaptations are often a record of historical compromises; that is, they are not necessarily the most logical solution to a problem. Second, some structures may be **vestigial**, that is, having *no* (or very minimal) useful function. They likely evolved from useful features in ancestors but have not been eliminated by selection. These constraints on natural selection have been often overlooked in the physiological sciences, especially since the modern physiological sciences started in the 1600s, long before Charles Darwin presented his theory of evolution (in 1859, the year he published *On the Origin of Species*). However, a recent movement called *evolutionary physiology*, and its applied counterpart *Darwinian medicine*, is re-evaluating many teleological explanations in traditional physiology. As we shall see in later chapters, this has often profound implications for the understanding of physiology.

Simple examples can help you to distinguish among these approaches (mechanistic/proximate, evolutionary, teleological) and the role of historical constraints. First, let’s take a reasonably logical, useful adaptation: shivering in mammals. The *mechanistic* or *proximate* explanation of why a mammal shivers is that, when temperature-sensitive nerve cells detect a fall in body temperature, they signal the *hypothalamus*, the part of the brain responsible for temperature regulation. In turn, the hypothalamus activates nerve pathways that trigger rapid oscillating muscle contractions (that is, shivering) to produce heat (in a process called *negative feedback homeostasis*, a topic we explain in detail shortly). A *teleological* explanation of why a mammal shivers when it is cold is “to keep warm” to maintain a relatively constant, warm interior. But this does not answer the question of why it is useful for most mammals to keep constantly warm. It is not necessary for the vast majority of life in variable temperate habitats, or even for a hibernating mammal in winter. To explain this, we must analyze the course of evolution among mammals to try to determine why regulation of body temperature enhanced survival in this group, and why 37° to 39°C (about 99° to 102°F) was the ideal temperature selected for most placental (but not other) mammals.

Now let’s take a less logical example, the human spinal column and its series of bony vertebrae joined by cushioning pads. The mechanistic description is that the spine is a movable support device for the upper body and a protective conduit for the major nerve cords. Teleologically, we might say that vertebrae are a logical way to provide both flexibility for movement and rigidity for support and protection of the nerves. But this ignores the fact that the spine in humans is a suboptimal design! Back problems—pinched nerves, damaged cushioning pads, and so on—are among the most common ailments of humankind. To explain this, we must look at the course of evolution. The spine originally evolved as a *horizontal* flexible swimming device in fishes, animals that are not concerned with gravity because they float. Later the spine became adapted into a (still horizontal) support system against gravity in four-legged land vertebrates. But it only recently began evolving into a *vertical* support in our hominid ancestors, and thus has not been optimized. Indeed, it may never be, because the spine is fundamentally a horizontal system in its inception.

Adaptations that are not “perfect” show another aspect of evolutionary history called *cost–benefit trade-offs*. Essentially, adaptations have costs that may negatively impact other adaptations. The most basic trade-off involves energy, which is typically limited. It takes energy to make structures such as large brains, skeletons, and embryos, and an organism cannot “do it all.” For example, animals like seastars that produce thousands or millions of embryos do not protect nor provide much yolk (energy) for them, while animals such as birds or primates that spend considerable energy nourishing and protecting their young consequently do not have many offspring. Large structures may also have other costs such as reduced speed and maneuverability; for example, a large thick shell on a snail’s body clearly slows that animal down. You are familiar with similar cost–benefit trade-offs in human engineering. Consider that small, lightweight automobiles get high mileage but are more likely to suffer damage in an accident than a large well-armored (but low-mileage) vehicle.

Finally, consider vestigial features. Their origins are usually revealed by useful homologous features in other species. An example is the *dewclaw*, a tiny digit on the side of the foot in many mammals and reptiles (including birds). Dewclaws evolved from useful fifth digits, and may still provide a gripping function in some species, but in many dogs, rear dewclaws hang loosely with little muscle or bone and have no discernable function. There can even be vestigial genes called *pseudogenes* (although see Chapter 2 for a possible remnant function of these). For example, humans cannot synthesize vitamin C (needed for survival; see p. 65) and so must have it in their diets, and yet their genetic codes contain a nonfunctional gene for a protein to make the vitamin. Presumably, our ancestors ate enough dietary vitamin C (e.g., in fruit) so that when this gene mutated and shut off, it did not impair survival. As another example, short-lived mammals express the gene for uricase, which inactivates uric acid (a potent antioxidant; Chapter 12), while long-lived primates, birds, and reptiles do not express this gene. In this case, we can only speculate on what events led to the suppression of this gene product.

As we examine animal adaptations throughout this text, keep in mind these lessons of the human spine, the slow snail's shell, and the dog dewclaw: *Evolution builds on the past* and therefore is often constrained by it, and *selection often involves trade-offs and compromises*.

Physiology is an integrative discipline

As the example of the spine shows, physiology is closely interrelated with *anatomy*, the study of the structure of organisms. Just as the functioning of an automobile depends on the shapes, organization, and interactions of its various parts, the structure and function of an animal's body are inseparable. But physiology also integrates many other scientific fields. *Physics* is necessary to understand processes in organisms such as electrical conduction, fluid dynamics, and leverage exerted by musculoskeletal systems. Of course, all life processes depend on chemical reactions, so a solid understanding of *chemistry* is crucial. Also, biological functions depend on large biological molecules such as DNA and proteins (see Chapter 2), and therefore *biochemistry* and *molecular biology* provide a major foundation for physiological understanding. At the other end of the spectrum, we need to know something about an organism's *ecology* to explain, for example, why certain functions evolved.

Molecular biology is the most rapidly growing biological science, and its integration with physiology is now the dominant force in many physiological studies. Driving much of this growth are organismal **genome projects** (the complete analysis of genetic codes of key species, including humans). The genetic code ultimately gives rise to crucial parts of the functioning organism, and those functions in turn affect how that code is used (see Chapter 2 for details). Many physiologists are dedicating their research to understanding how genes are regulated and how they are used in physiological processes.

Genome studies are also having a major impact on human understanding of evolution. In particular, these studies are revealing the stunningly complex and often illogical nature of evolution at the most fundamental level. The human genome, for example, appears riddled with formerly functional genes that have mutated into pseudogenes and

contains a large percentage of code that seems to have no function at all now or in the past (although certain recent studies hint at some functions for these codes, as we'll describe later). Furthermore, at least some genes seem to have arisen from bacteria and viruses!

Physiology is also a comparative discipline, often following the Krogh principle

As we have just seen, complete physiological understanding must integrate in a “vertical” sense: from the atomic level to the whole organism to its environmental interactions to the evolutionary forces that have acted on that organism's ancestors. But another major approach in physiology—*comparative physiology*—works in a “horizontal” sense, by comparing physiological features in different types of organisms. Such research is important in at least three ways. First, we learn about the uniqueness and diversity of life on Earth by discovering the amazing features that one or a few types of organism have evolved but that others have not. For example, one of the pioneers of modern comparative physiology in the mid-20th century, Per Scholander (1905–1980; a naturalized U.S. citizen born in Sweden) analyzed (among many other things) physiological adaptations of diving mammals, the filling mechanism of fish swim bladders, and thermal adaptations of Arctic mammals and insects.

Such basic knowledge is fascinating in its own right but can sometimes have practical applications. See the box, *A Closer Look at Adaptation: Geckos on Glass*.

Second, comparative studies help us understand the trade-offs and constraints found in many biological features, as you've seen. Thirdly, comparative studies help us find out what physiological functions are universal rather than unique. This broadens our understanding of the basic nature of life. For example, from studying the adaptations of other animals to environmental temperature we learn that the mammalian need to maintain a nearly constant body temperature is not universal, but we also learn (as we will see in Chapter 15) that there are universal effects of temperature on biological molecules to which all life must adapt.

Comparative physiology research on both the diversity and universality of adaptation is often motivated by the **August Krogh principle**, formulated by German physiologist Hans Krebs in 1975: “For a large number of problems there will be some animal of choice, or a few such animals, on which it can be most conveniently studied.” This principle was based on remarks made by the great Danish physiologist August Krogh (1874–1949), founder of Denmark's first animal physiology laboratory, who championed the integrative and comparative approaches to physiology. He believed that the diversity of adaptations on Earth is such that, for any particular physiological process, some species will have adapted in such a way that it provides an ideal model system for studying that process. In turn, this knowledge can provide insight into that process in a much wider variety of organisms. For example, to understand how animal neurons (nerve cells) produce electrical signals, the English physiologist John Zachary Young in the 1930s chose the giant squid axon because it was much easier to pierce with electrodes than the much smaller mammalian neurons. As you'll learn in Chapter 4, Young and his followers using squid axons discovered basic principles that apply to all animal neurons, including our own.

A Closer Look at Adaptation

Geckos on Glass

Very few animals can climb up glass windows and walk upside down on smooth ceilings. You have undoubtedly noticed flies and spiders doing this. If you've lived in or visited tropical habitats, you may have seen much larger animals—geckos—performing the same remarkable feat. How do they do it? Only recently has the mechanism for these lizards' phenomenal abilities been uncovered. The feet of geckos have small pads studded with millions of hairlike

bristles called *setae*. In turn, *setae* tips sprout hundreds of tiny branches, called *spatulae*, each only 200 nanometers wide. Flies and spiders have similar structures. Kellar Autumn and colleagues have found that spatulae provide a huge surface area for weak molecular attractions called *van der Waals* forces (about which you probably learned in a chemistry class). Not only do these forces allow a gecko to cling against gravity, but they also allow rapid

detachment of the spatulae as the animal runs up the window. Here we see how basic chemistry directly explains whole-animal structure and function. Moreover, the unique ability of gecko feet to attach and detach repeatedly has inspired scientists to design reusable adhesive tape based on this mechanism. This is an example of a growing movement called **biomimicry**—the emulation of organismal adaptations by humans to create useful products.

(a) A tokay gecko.

(b) The foot of the gecko. Each pad consists of many lamellae (folds), which in turn have millions of tiny bristles that adhere to surfaces through van der Waals interactions.

Working on a variety of animals, Krogh made major discoveries about (among other things) the use of radioactive isotopes in metabolic research, oxygen movement from the lungs to the blood by diffusion (work aided by his wife, Marie), metabolism in insect flight, and the regulation of capillary blood flow (for which he was awarded the Nobel Prize in Physiology or Medicine in 1920). He inspired generations of comparative physiologists, for example his daughter, Bodil Schmidt-Nielsen (1918–) and her husband Knut (1915–2007), a Norwegian who came to work in Krogh's laboratory. The Schmidt-Nielsens came to America at Per Scholander's invitation, where they pioneered studies of (among other things) animals in extreme environments such as deserts (we'll see some of their work in later chapters). In concert with the Krogh principle, broadly used mechanisms are often best revealed by studying them at the extremes of adaptation.

The inherently broad nature of physiology presents a major challenge to learning. To help handle this challenge, as we tell the story of how animals work, we integrate the physical, chemical, molecular/genetic, anatomic, ecological, and evolutionary features necessary for understanding function. Also, to provide breadth in the comparative sense we discuss a variety of animal types. To fully understand these compari-

sons, you should develop a grasp of the basic evolutionary relationships of animal phyla. If you have not learned about these, or need a review, look at Figure 1-1. In particular, be aware that the dichotomy of “vertebrates” and “invertebrates,” widely used for the animal kingdom, is evolutionarily meaningless. In fact, there are over 30 animal phyla (groups distinguished by major body plans), and vertebrates are only a subphylum within one of those, the phylum Chordata (unified by all members having a dorsal *notochord* at some stage in their life cycles). Also, the phylum Arthropoda (“jointed legs”), which includes insects, is by far the most successful in terms of numbers of species and sheer mass of animal life. We will use instead the terms vertebrate and non-vertebrate in this text, and we also name the pertinent phyla.

check your understanding 1.1

Explain the terms “proximate” and “evolutionary” explanations and give an example of each.

What are *adaptations* and why aren't they always logical, optimal features?

Describe the Krogh principle and give an example.

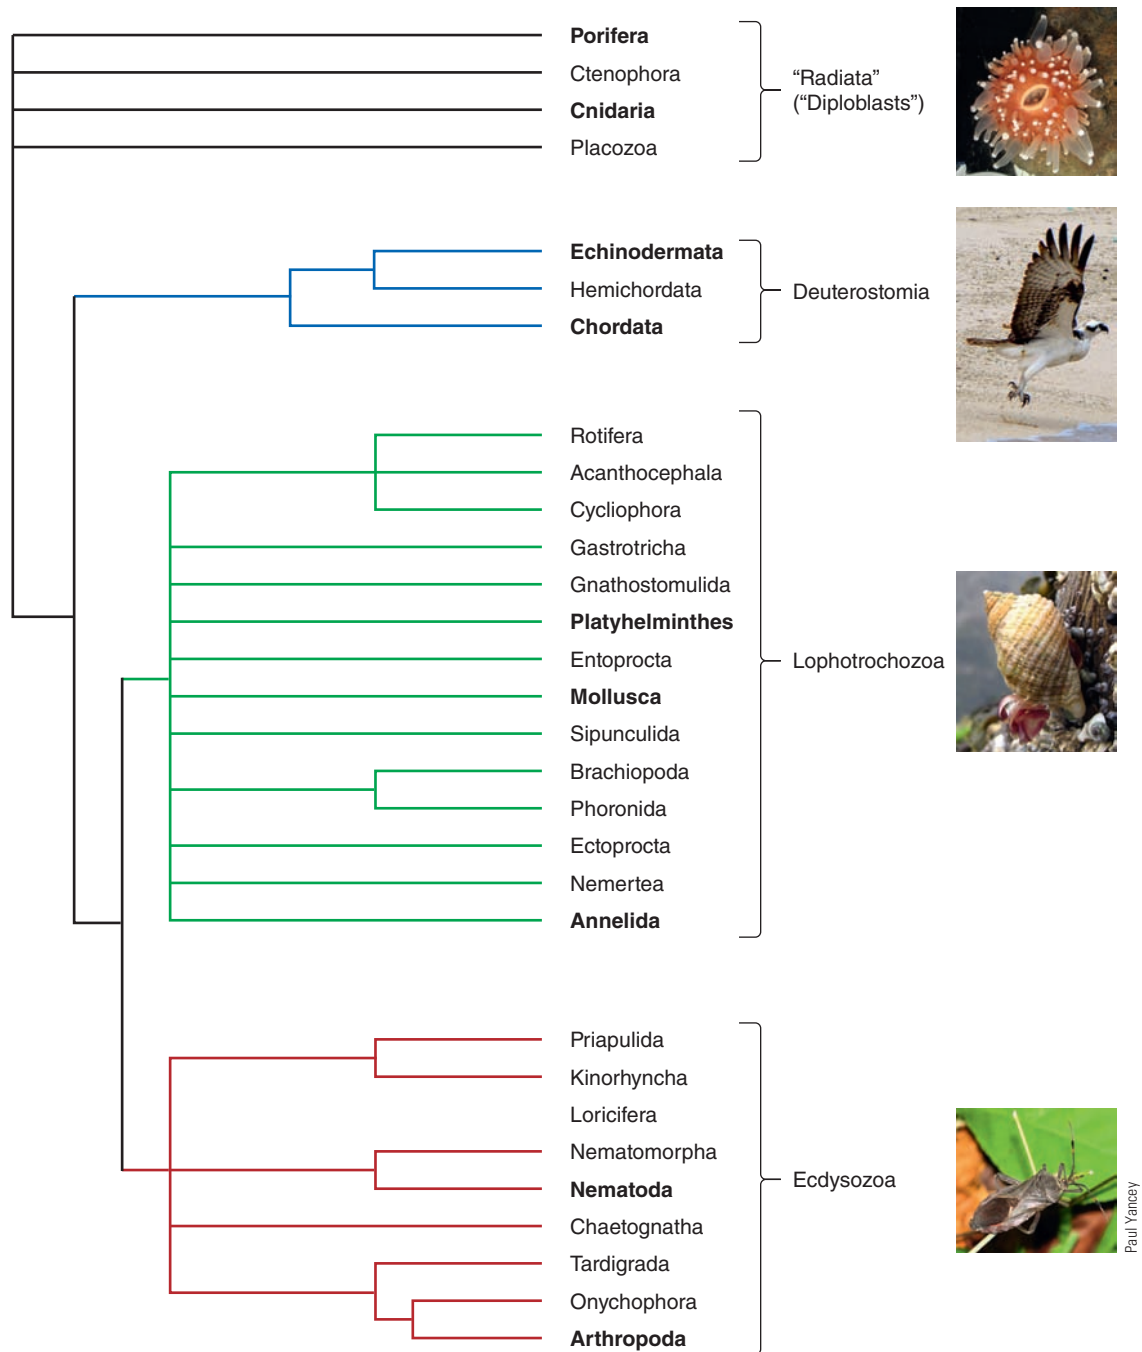

FIGURE 1-1 Animal evolutionary tree, showing the relationship among phyla as deduced from morphology coupled with molecular analyses. The three major branches are the Radiata, the Deuterostomia, and the Protostomia (not labeled, but containing the Ecdysozoa—groups that molt—and Lophotrochozoa). The nine most successful phyla, to which we refer most often in this text, are **bold**; these are the **Porifera** (sponges), **Cnidaria** (jellies, hydras, corals, anemones, etc.), **Echinodermata** (seastars, sea urchins, sea cucumbers, etc.), **Chordata** (tunicates, vertebrates, etc.), **Platyhelminthes** (flatworms), **Mollusca** (snails, octopods, bivalves, etc.), **Annelida** (segmented worms), **Nematoda** (round worms), and **Arthropoda** (crustacea, insects, arachnids, etc.).

1.2 Methods in Physiology

Physiology is, of course, a science and thus employs the same philosophical logic that other scientists use to study the world. But because of physiology's broad, integrative nature, we can fairly say it employs a wider range of specific techniques (from genetic to behavioral) than most other biological disciplines. We will introduce key methods in later chapters. Here we provide a brief overview of the essential aspects of "doing science."

The hypothetico-deductive method is the most widely accepted version of "the scientific method"

Science is above all else a *way of thinking* about the world. First, it assumes that consistent processes in nature explain structures and phenomena and that we can uncover and understand these processes. Second, science provides a logical approach (the "scientific method") for this investigation of the universe. Several versions of the scientific method have been put forth, but the most widely used is termed the **hypothetico-deductive method**. It can be stated in these steps:

1. *Ask a question about nature.* This is sometimes called the **discovery phase** of science. The scientist finds an aspect of nature that has not been studied or fully explained. This step requires gathering all accessible information that has been discovered previously, any existing hypotheses, and (if there is little knowledge yet) *exploration* of the unknown. Exploration involves the gathering of data (by both observation and experimentation) about the world without necessarily having a hypothesis. For example, biologists exploring the deep sea today are often asking, "What lives in the deep?" and are finding new species on a regular basis, without necessarily testing a hypothesis at all times.
2. *Propose alternative hypotheses to explain the phenomenon.* **Hypotheses** are, in essence, tentative explanations about some aspect of nature. Unless all reasonable hypotheses already exist, the scientist must create them. This process is called **induction**: taking specific information and creating a general explanation. There are two important corollaries to making hypotheses. First, *alternative* explanations or predictions should be made, or else the testing steps (which follow) may focus on an erroneous explanation and miss a correct one. For example, a deep-sea physiologist might ask how life survives the crushing pressures of the deep, which are known to inhibit the functions of biomolecules such as proteins. He or she might propose that deep-sea organisms (1) have evolved proteins that are resistant to pressure, or (2) suffer from pressure inhibition and thus have sluggish metabolisms. (Can you think of other hypotheses?)

Second, scientific hypotheses must be **testable** (amenable to experiments or observation), and, in principle, **falsifiable** (capable in principle of being disproved by experiment or observation), or they are of little use in science (whether they are true or not!). For example, *vitalism*, a view of life prominent before the 20th century, hypothesized that living entities get their dynamic

natures from an unseen life force or spirit. No experiment could be devised that detected such a force, and vitalists proposed that the force is beyond ordinary nature and thus unmeasurable. Thus, vitalism is today considered nonscientific, not because it is false (it may actually be true, although living processes have been found to be consistent with and explainable by physicochemical processes), but because it cannot be tested or (even in principle) falsified.

3. *Design experiments or observations that test the hypothesis or hypotheses by making testable predictions.* This process is called **deduction**: taking a general explanation, making specific testable predictions based on it, and testing those predictions. In physiological experiments, an organism or natural process is often perturbed in a clearly defined way, and the outcome measured. It is vital to have **controls** in such testing. Controls come in different forms but typically involve organisms or processes that are not altered or perturbed or that are not adapted to an aspect of nature being tested. In our deep-sea example, proteins from both deep-sea and shallow-living animals are studied in the laboratory with and without high pressure to determine whether pressure resistance has in fact evolved in deep-living (but not shallow-living) animals.
4. *Conduct the observations or experiments.* This can require sophisticated equipment and techniques (for example, pressure chambers in which scientists can analyze protein functions), though not always. We briefly discuss this aspect in the next section.
5. *Using the outcome of these tests, refine the earlier questions and hypotheses, and design new tests.* Often this process can take months or even decades, often because results are not clear or test only one small aspect of a larger question. For example, deep-sea physiologists have found that many proteins from deep-sea animals are indeed more resistant to pressure than are proteins from shallow-living animals. The researchers are now trying to find out how those proteins can resist pressure. However, some deep-sea proteins are *not* pressure resistant, and now researchers are asking whether other protective mechanisms exist.

Once a single hypothesis has been consistently supported by test after test, and all alternative (and testable) hypotheses have been falsified, a hypothesis may be elevated to a scientific **theory**—accepted as essentially correct, but with details yet to discover.

Physiological observations and experiments use techniques from the molecular to the behavioral level, for both discovery and hypothesis testing. As we noted earlier, the integrative nature of physiology presents a challenge to the researcher. Understanding the full scope of physiology requires that scientists conduct observations and experiments that range from the functions of specific molecules to the behaviors that animals use with internal processes. Understanding the methods can be important to understanding the knowledge they yield. Although this text does not focus heavily on such methods, we cover selected ones in the appropriate chapters. For example, Chapter 2 discusses a number of important techniques scientists use in genomic and other molecular studies.

It is worth repeating that scientific experiments and observations are used for both discovery (before there are detailed hypotheses) and hypothesis testing. The analysis of organismal genomes, for example, was largely a discovery process in the initial phases.

Describe the hypothetico-deductive method.

1.3 Levels of Organization in Organisms

One triumph of scientific study in the 19th century was the development of the cell theory of life. Regardless of the difficulties in defining “life,” the foundation of all functions of life, and thus of all living organisms, is the **cell**—the smallest unit capable of carrying out the processes associated with life on Earth. A cell consists of an outer barrier called a **membrane** and an internal (semigelatinous) fluid called the **cytosol**, which contains water, salts, small organic molecules, and **macromolecules**. Macromolecules include **deoxyribonucleic** and **ribonucleic acid** (DNA and RNA), which carry the genetic instructions for making most cell components, and **proteins**, molecules with complex shapes, which carry out those instructions by assembling into many cell structures, regulating most cell functions, and catalyzing most cell reactions (see Chapter 2).

Life has the properties of self-organization, self-regulation, self-support and movement, and self-reproduction

Cells are classified traditionally in two distinct forms: **prokaryotic cells** (in two groups, the Bacteria and Archaea), which for the most part lack complex internal membranous structures such as nuclei; and **eukaryotic cells**, which do have these structures, found in the kingdoms Protista (an awkward kingdom that includes protozoa and unicellular and multicellular algae), Fungi, Plantae (higher plants), and Animalia. However, because the two prokaryotic groups are fundamentally different from each other, biologists now classify all life in three *domains*: archaea, bacteria, and eukarya. The simplest life forms are **unicellular** (single-celled) or colonial (loose collections of similar cells), typically prokaryotes and many protists (eukaryotes) such as amoebae. More complex organisms such as animals are **multicellular** (many-celled)—an aggregate of hundreds (in certain worms) to trillions (in mammals) of cooperating eukaryotic cells with distinct specializations in structure and function. As you will see later (p. 385), physical constraints such as *diffusion* limit the size of a single cell, so that large body size depended on the evolution of multicellularity.

All cells, whether they exist as solitary cells or as part of a multicellular organism, perform certain basic functions essential for survival of the cell, which in turn aid in survival of the organism. These basic cell functions include the following:

1. **Self-organization:** Using resources from the environment to create the cell. This function includes many steps, including:
 - Obtaining energy and raw materials from the environment surrounding the cell (for plants, these are light and inorganic nutrients; for most animals, these come from food and oxygen). Initially, this uptake occurs through the cell's membrane.
 - Performing various chemical reactions that use energy and raw materials to provide energy stores and building blocks for the cell's other needs. Most cell reactions are catalyzed by large molecules called **enzymes**, which in most cases are complex proteins that increase the rate of specific chemical reactions. In most animal cells, the overall process can be roughly summarized thus:

$$\text{Food} + \text{O}_2 \rightarrow \text{CO}_2 + \text{H}_2\text{O} + \text{energy stores} + \text{building-block molecules}$$
 - Eliminating to the cell's surrounding environment (through the membrane) any waste products of metabolism, such as carbon dioxide and ammonia or other nitrogenous waste.
 - Synthesizing proteins and other components needed for cell structure, for growth, and for carrying out particular cell functions (using energy stores and building blocks).
2. **Self-regulation:** Maintaining self-integrity in the face of disturbances, including:
 - Being sensitive and responsive to changes in the environment surrounding the cell (such as temperature, osmotic status).
 - Controlling the exchange of materials between the cell and its surrounding environment.
 - Repairing damage to the cell.
 - Correcting deviations in internal conditions, which threaten other functions (*homeostasis*).
3. **Self-support and movement:** Having structures that give specific form to the cell, the ability to move materials within the cell, and (in some cases) the ability to move the whole cell or organism through the surrounding environment.
4. **Self-replication:** Reproducing to carry on the species, and to repair damage. Some animal cells, such as nerve cells and muscle cells in mammals, are unable or have greatly restricted abilities to replicate. When trauma or disease processes destroy these cells, they are generally not replaced.

Cells are remarkable in the similarity with which they carry out these functions. Thus, all cells share many common characteristics. In multicellular organisms, each cell also performs a specialized function, which is usually a modification or elaboration of a basic cell function. Here are a few examples in animals:

- As a specialization of basic cell protein-synthesizing ability, *gland cells of digestive systems* secrete digestive enzymes.
- By enhancing the basic ability of cells to respond to changes in their environments, *neurons* generate and transmit to other regions electrical impulses that relay information about stimuli such as light, temperature, nutrient concentrations, and so on.

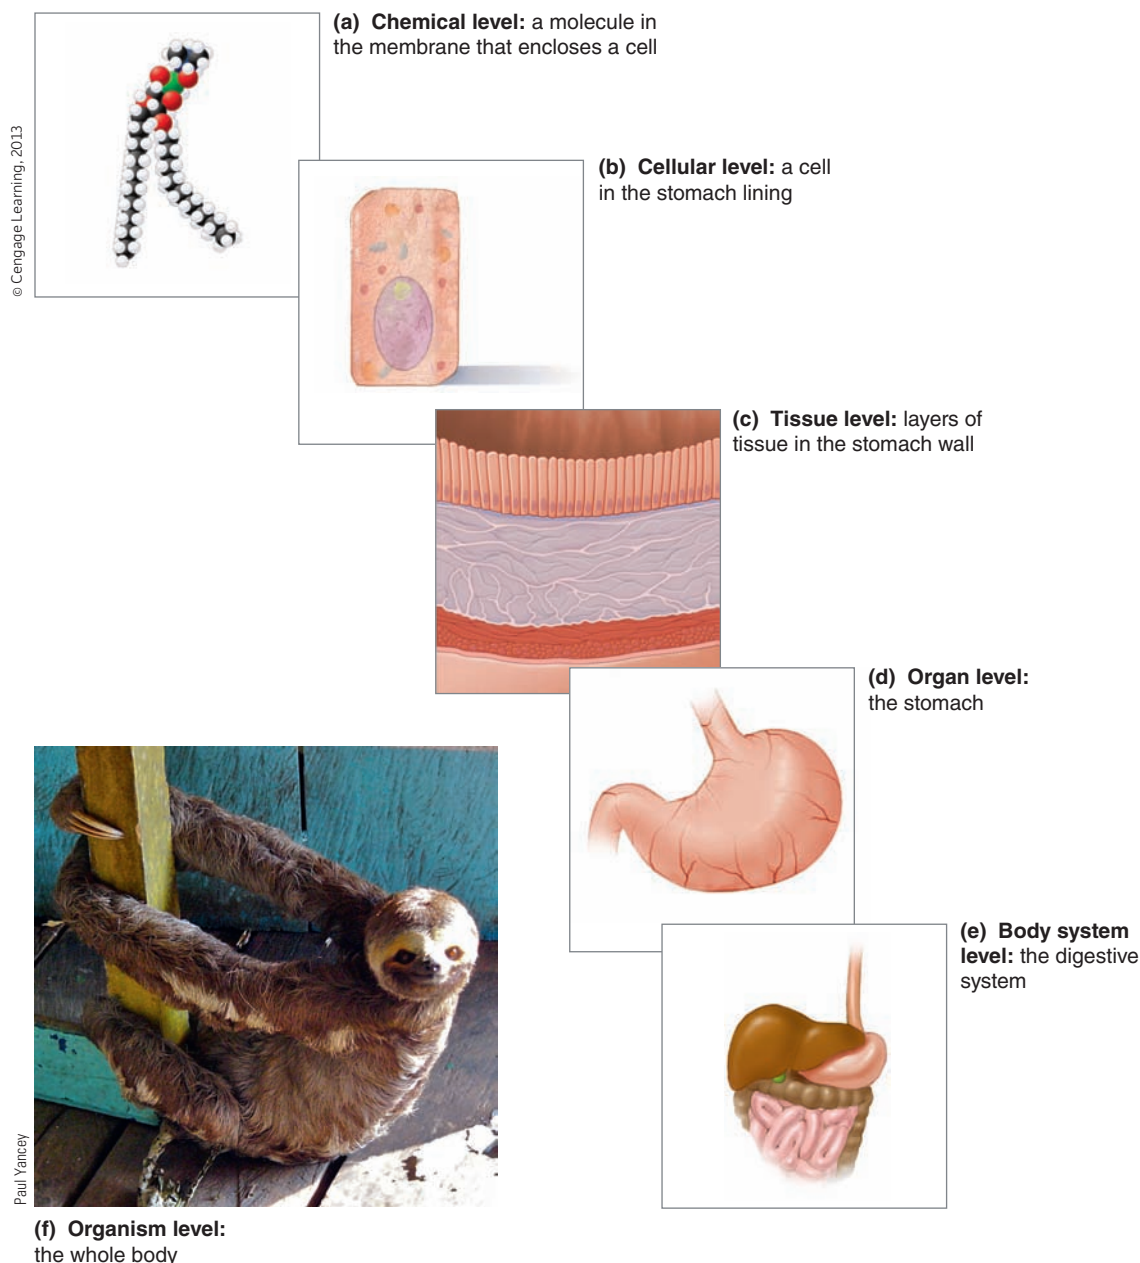

FIGURE 1-2 Levels of organization in an animal body, showing an example for each level.

- Through specializations in the basic ability of cells to transport molecules through membranes, *kidney cells* and *tubules* selectively retain substances needed by animals while eliminating unwanted substances in the urine.
- Based on the inherent capability of eukaryotic cells to produce intracellular movement, *muscles* use movement of internal protein filaments to bring about shortening of the whole organ.

It is important to recognize that cells perform these specialized activities in addition to carrying on the unceasing, fundamental activities required of all cells. The fundamental cell activities are essential for the survival of each individual cell, whereas the specialized contributions and interactions among the cells of a multicellular organism contribute to the survival of the whole organism.

Cells are progressively organized into tissues, organs, systems, and finally the whole body

Just as a machine does not function unless all its various parts are properly assembled, the cells of organisms must be specifically organized to carry out the life-sustaining processes of the whole, such as (in animals) digestion, respiration, and circulation. Multicellular organisms have four levels of organization: cells, tissues, organs, and systems (Figure 1-2).

In animals, cells of similar structure and function are organized into **tissues** (groups of cells with similar structures and functions), of which there are four primary types: *epithelial*, *connective*, *muscular*, and *nervous*. Each tissue consists of specialized cells along with varying amounts of extracellular (“outside the cell”) material (Figure 1-3).

Organ: Body structure that integrates different tissues and carries out a specific function

FIGURE 1-3 The stomach as an organ made up of all four primary tissue types. (a) The four tissue components; (b) Low-power microscope view of the mammalian stomach, showing three of the primary tissue layers (left folded layer = epithelial, middle layer = connective, right darker layer = muscle).

1. **Epithelial tissue** is made up of cells specialized in the exchange of materials. This tissue is organized into two general types of structures: *sheets* and *secretory glands*. Epithelial cells are joined together very tightly to form **epithelial sheets** that cover and line various organs. For example, the outer layer of the skin is epithelial tissue, as is the inner lining of the digestive tract. In general, these epithelial sheets serve as boundaries that separate animals from the external environment and from the contents of cavities that communicate with the external environment, such as the digestive tract lumen. (A **lumen** is the cavity within a hollow organ or tube, and in the case of digestive tracts, is technically outside of the body!). Only selected transfer of materials is permitted between the regions separated by an epithelial barrier. The type and extent of controlled exchange varies, depending on the location and function of the epithelial tissue. For example, very little can be exchanged across the skin and the external environment in most animals, whereas the epithelial cells lining the digestive tract are specialized for absorbing water and nutrients.

- **Glands** are epithelial tissue derivatives that are specialized for secretion. Secretion is the release from a cell, in response to appropriate stimulation, of specific products that have in large part been synthesized by the cell. Glands are formed during embryonic development by pockets of epithelial tissue that dip inward from the surface. There are two categories of glands: *exocrine* and *endocrine*. If during development the connecting cells between the epithelial surface cells and the secretory gland cells within the depths of the invagination remain intact as a duct between the gland and the surface, an exocrine gland is formed.
- **Exocrine glands** (*exo* means “external”; *crine* means “secretion”) secrete through ducts to the outside of organisms (or into a cavity that communicates with

the outside). Examples are sweat and digestive glands. If, in contrast, the connecting cells disappear during development and the secretory gland cells are isolated from the surface, an endocrine gland is formed. **Endocrine glands** (*endo*, “internal”) lack ducts and release their secretory products, known as **hormones**, internally into the blood within the animal (see Chapter 7). For example, the vertebrate parathyroid gland secretes parathyroid hormone into the blood, which transports this hormone to its sites of action at the bones and kidneys.

2. **Connective tissue** is distinguished by having relatively few cells dispersed within an abundance of extracellular material that they secrete. As its name implies, connective tissue connects, supports, and anchors various body parts. It includes such diverse structures as the **loose connective tissue** that attaches epithelial tissue to underlying structures; **tendons**, which attach skeletal muscles to bones; **bone**, which gives vertebrates shape, support, and protection; and **blood** (or **hemolymph**), which transports materials from one part of a body to another, and in a sense, connects all cells of the body. Except for blood, the cells within connective tissue produce specific molecules that they release into the extracellular spaces between the cells. One such molecule is the rubber-band-like protein fiber **elastin**, whose elastic properties facilitate the stretching and recoiling of structures such as lungs, which alternately inflate and deflate during breathing (see p. 520).
3. **Muscular tissue** consists of cells specialized for contraction and force generation. Vertebrates have three types of muscle tissue (Chapter 8): **skeletal muscle**, which causes movement of the skeleton; **cardiac muscle**, which is responsible for pumping blood out of the heart; and **smooth muscle**, which encloses and controls movement of contents through hollow tubes and organs, such as the digestive tract.

4. **Nervous tissue** consists of cells specialized for initiation and transmission of electrical impulses, sometimes over long distances (Chapters 4, 5). These electrical impulses act as signals that relay information from one part of an organism to another. Nervous tissue in vertebrates is found in (1) the brain; (2) the spinal cord; (3) epithelial linings that monitor the external environment as well as the status of various internal factors that are subject to regulation, such as temperature, blood pressure, and gut contents; and (4) muscles, glands, and other *effector* organs (see p. 14).

Epithelial, connective, muscular, and nervous tissue are the primary tissues in a classical sense. The term *tissue* is also frequently used to refer to the aggregate of various cellular and extracellular components that make up a particular organ (for example, lung tissue or liver tissue).

Organs consist of two or more types of primary tissue organized to perform a particular function or functions. The stomach is an example of an organ made up of all four primary tissue types (Figure 1-3), which function collectively to store ingested food and begin digestion as well as to move it forward into the rest of the digestive tract. Vertebrate stomachs are lined with epithelial tissue that restricts the transfer of harsh digestive chemicals and undigested food from the stomach lumen into the blood. Gland cells, derived from epithelia in the stomach, include exocrine cells, which secrete digesting juices into the lumen, and endocrine cells, which secrete hormones that help regulate the stomach's exocrine secretion and muscle contraction. The walls of the stomach contain smooth muscle tissue whose contraction mixes ingested food with the digestive juices and propels the mixture forward into the intestine. Also within the walls is nervous tissue, which, along with hormones, controls muscle contraction and gland secretion. These various tissues are all bound together by connective tissue.

Organs are further organized into **organ systems**, each of which is a collection of organs that perform related functions and interact to accomplish a common activity that is essential for survival of the whole body. For example, the digestive system consists (in vertebrates) of the mouth, salivary glands, pharynx (throat), esophagus, stomach, pancreas, liver, gallbladder, small intestine, and large intestine (and sometimes other organs). These organs collectively break down food into small nutrient molecules that can be absorbed into the blood. We end this chapter with a closer look at these systems.

The total animal body—a single, independently living individual—consists of the various organ systems structurally and functionally linked together as an entity that is separate from the external (outside organisms) environment. Thus, an animal is made up of living cells organized into life-sustaining systems.

1.4 Size and Scale among Organisms

Because life on Earth ranges from unicellular prokaryotes to large multicellular eukaryotes such as whales, organisms range in mass (using the metric weights in grams) over a scale of 10^{20} (the number 10 followed by 20 zeroes)! The table inside the back cover gives examples of the size of some organisms to give you a sense of this enormous range. Independent of other factors, the size of an organism has important implications for its structures and functions. For example, why are there huge mammals, but no huge insects? The study of the effects of size on anatomy and physiology is called **scaling**. An example is lifespan: Larger animals generally live longer than smaller ones. Even more interestingly, a bird lives about 2.5 times longer than a mammal of comparable body size. Scaling phenomena such as this one show up in many chapters of this book (the lifespan of birds, for example, appears in Chapters 2 and 12), so it is important to examine this principle now. The most important size effect may be a simple mathematical concept known as the **surface-area-to-volume ratio**.

The larger the organism, the smaller the surface-area-to-volume ratio

Consider a small spherical cell of minute size. It has a certain volume and mass, and a certain surface area of its outer boundary (Figure 1-4). From simple mathematics, we know the volume is related to the *cube of the radius* of the object. The surface area is related to the *square of the radius*. Now consider a cell (or organism) 10 times bigger (see Figure 1-4). Because of the cubed factor, the volume of it is 1,000 (10^3) times bigger than the first object, but because of the squared factor, the surface area is only 100 times (10^2) bigger. Its surface-area-to-volume ratio is one tenth that of the smaller sphere. This has tremendous implications for a variety of living functions. For instance, the entire mass of both cells needs to obtain nutrients and get rid of wastes through the surface boundary, but the larger object is at a 10-fold disadvantage because of its relatively smaller ratio (that is, relatively smaller surface area to support the volume). This is one reason why larger animals have evolved highly branched (that is, increased surface area) circulatory and respiratory systems. We examine this development in Chapters 9 and 11.

However, if there is something that each cell or organism needs to retain, such as heat, the larger object is at a 10-fold advantage because heat is typically produced by the volume of the cell and lost through its surface area. In Chapter 15 we examine this aspect of physiology in detail.

Scaling also affects skeletal mechanics. The ability of a skeleton (or a tree trunk, for that matter) to support mass against gravity increases with the cross-sectional area of the skeletal element (such as a leg bone or insect limb exoskeleton). But the weight being supported increases as the cube of the animal size. Thus, a large animal such as an elephant must have massive limbs in comparison to its body, whereas a tiny spider can support itself with limbs that are much thinner in comparison to its body.

It is important to remember this basic phenomenon—Note that larger objects have larger surface areas on an absolute scale, but it is the ratio that matters. Put simply, all other things being equal, *larger organisms have smaller surface-area-to-volume ratios*.

1.5 Homeostasis: Basic Mechanisms and Enhancements

Earlier we discussed several functions of cells (and thus life): self-organization, self-regulation, support and movement, and self-replication. To many biologists, the ability to self-regulate is the most crucial of these functions for distinguishing living from nonliving things. For example, a fire can arise spontaneously (given an initial energy source such as lightning) and can maintain itself by using combustible materials in the environment, can move by spreading to nearby fuel sources, and can replicate through sparks. But it takes no corrective action when water is dumped on it. Living systems, in contrast, can correct for at least some disturbances. Indeed, one recent definition of life that has been proposed is “a system that tries to regulate itself to preserve its identity.”

Maintenance of a desired state in the face of disturbances has been given a term that is central to physiology: **homeostasis** (*homeo*, “similar”; *stasis*, “to stand or stay,” although used here to mean “state”). The concept began with the French scientist Claude Bernard (1813–1878). His ambition was to be a playwright, but he turned to medicine and then to physiological research, which he termed “experimental medicine.” Indeed, he pioneered the application of the scientific method to medicine and so is often called “the father of modern physiology.” He documented the abilities of mammals to maintain a relatively constant state of the internal environment (which he called *le milieu*

interieur). The concept languished until the American physiologist Walter B. Cannon (1871–1945) took an integrative approach to physiological function, further developing Bernard’s ideas and coining the term *homeostasis*. It is important to note that Cannon used *homeo* for “similar,” not *homo* for “same”. We’ll see why shortly.

Unicellular organisms have some homeostatic abilities, such as the ability to maintain energy levels, acid–base balance, and volume. In animals, although individual cells also have some homeostatic abilities, many regulatory processes occur at the level of the whole organism. Let’s now examine this crucial concept in detail.

Body cells are in contact with a privately maintained internal environment instead of with the external environment that surrounds organisms

If each cell has basic survival skills, why must cells perform specialized tasks and be organized according to specialization into systems dedicated to the whole body’s survival? The vast majority of cells are not in direct contact with the external environment and cannot function without contributions from the other cells. In contrast, a unicellular organism such as an amoeba can directly obtain nutrients and O₂ from its immediate external surroundings and eliminate wastes back into those surroundings. In a multicellular animal, a muscle cell has the same need for life-supporting nutrients and O₂ uptake and waste elimination, yet the muscle cannot directly make these exchanges with the external environment, because the cells are physically isolated from it.

How can a muscle cell make vital exchanges with the external environment with which it has no contact? The key is the presence of an aqueous internal environment with

FIGURE 1-5 Components of the extracellular fluid (ECF; internal environment), and location of the intracellular fluid (ICF).

© Cengage Learning, 2013

which body cells are in direct contact. This internal environment is outside the cells but inside bodies. It consists of the **extracellular** (*extra* means “outside of”) **fluid**, or ECF, which in vertebrates is made up of *plasma*, the fluid portion of the blood, and *interstitial fluid*, which surrounds and bathes the cells (Figure 1-5). Various epithelial layers accomplish exchanges between the external environment and the internal environment. For example, a digestive system transfers the nutrients required by all body cells from the external environment into the ECF (such as blood, which is part of the internal body environment). Likewise, a respiratory system transfers O_2 from the external environment into the ECF. A circulatory system, if present, distributes these nutrients and O_2 throughout the body. As a result, the nutrients and O_2 originally obtained from the external environment are delivered to the interstitial fluid that surrounds the cells. Membranes of cells, in turn, make life-sustaining exchanges between the ECF and their interiors, the **ICF (intracellular fluid)**, see Figure 1-5). (Note that although the term *intracellular fluid* is widely used, the fluid inside cells is actually somewhat gelatinous.) No matter how remote a cell is from the external surface, it can take in from the internal environment the nutrients and O_2 needed to support its own existence. Similarly, metabolic end products produced by the cells (such as CO_2 and ammonia) are extruded into the interstitial fluid, where (in more complex animals) they are picked up by the circulation and transported to organs that specialize in eliminating these wastes from the internal environment to the external environment. For example, lungs (in air breathers) remove CO_2 from the blood, and kidneys remove many other wastes for elimination in urine.

Thus, a body cell takes in essential nutrients from and eliminates wastes into its watery surroundings, just as an amoeba does. The major difference is that body systems must help maintain the composition of the internal environment so that this fluid continuously remains suitable to support the existence of all body cells. In contrast, an amoeba does nothing to regulate its surroundings, which are essentially infinite.

FIGURE 1-6 Interdependent relationship of cells, body systems, and homeostasis. The depicted interdependent relationship serves as a key foundation for modern-day physiology: *Homeostasis is essential for the survival of cells, body systems maintain homeostasis, and cells make up body systems.*

© Cengage Learning, 2013

Homeostasis is essential for proper cell function, and most cells, as part of an organized system, contribute to homeostasis

Animal cells can live and function only when they are bathed by an ECF that is compatible with their survival; thus, many aspects of the chemical composition and physical state of the internal environment can be allowed to deviate only within narrow limits. As cells remove nutrients and O_2 from the internal environment, these essential materials must constantly be replenished for each cell's ongoing maintenance of life processes to continue. Likewise, wastes must be removed from the internal environment so they do not reach toxic levels. Other elements in the internal environment that are important for maintaining life also must be kept relatively constant.

The functions performed by the various body systems contribute to homeostasis, thereby maintaining within animals the environment required for the survival and function of all the cells of which organisms consist. This is one of the most important themes of physiology and of this book: *Homeostasis is essential for the survival of each cell, and each cell, through its specialized activities, contributes as part of a body system to the maintenance of the internal environment shared by all cells* (Figure 1-6).

The factors of the internal environment that are often homeostatically regulated include the following:

1. **Concentration of energy-rich molecules.** Nondormant cells need a consistent supply of such molecules (both externally and internally) to serve as a metabolic fuel for life-sustaining and specialized cell activities.
2. **Concentration of O_2 and CO_2 .** Cells need O_2 to perform chemical reactions that extract from nutrient molecules the most energy possible for use by the cell. The CO_2 produced during these chemical reactions must be balanced by removal of CO_2 from the body (for example, by lungs or gills) so that CO_2 does not increase the acidity (H^+ concentration) of the internal environment. This balance is accomplished through these reactions:

3. *Concentration of waste products.* Various chemical reactions produce end products that can be toxic to cells if these wastes are allowed to accumulate beyond a certain limit.
4. *pH.* Among the most pronounced effects of changes in the pH (acidity) of the internal fluid environment are alterations in the electrical signaling mechanism of nerve cells and in the enzyme activities of all cells.
5. *Concentration of water, salt, and other electrolytes.* Because the relative concentrations of salt ions (mainly Na^+ and Cl^-), organic solutes, and water in the ECF influence how much water enters or leaves the cells, these concentrations may be regulated to maintain the proper volume of the cells. Cells do not function normally when they are swollen or shrunk. Other ions perform numerous vital functions. For example, the rhythmic beating of a vertebrate heart depends on a relatively constant concentration of potassium (K^+) in the ECF.

In addition, some animals regulate the following:

6. *Volume and pressure.* The circulating component of the internal environment, the plasma in animals with circulatory systems, must be maintained at an adequate volume and pressure to ensure bodywide distribution of this link between the external environment and the cells.
7. *Temperature.* Cells function optimally within a narrow temperature range. Chemical reactions slow down if they are too cold, and, worse yet, membrane and protein structures are disrupted if the environment gets too hot.
8. *Social parameters.* Sometimes homeostasis can extend beyond the individual to a social level. This has been documented in social insects—in termite mounds, for example. In what has been termed *social homeostasis*, the colony of termites acts as a single “superorganism,” regulating its population density and number of different termite types (such as workers, soldiers) to nearly constant levels (moreover, temperature of the mound is also regulated).

The fact that the internal environment has some stable features does not mean that its composition, volume, and other characteristics are absolutely unchanging. First, external and internal factors continuously threaten to disrupt homeostasis. When this occurs, appropriate opposing reactions (or behaviors) are initiated to restore these conditions. For example, exposure to a cold environmental temperature tends to reduce a mammal’s internal temperature. To counter this, compensatory shivering may be initiated, which internally generates heat that restores body temperature to normal. (Alternatively or in conjunction with shivering, the animal may seek a warmer location.) Likewise, addition of CO_2 into the internal environment as a result of energy-generating chemical reactions tends to raise the concentration of this gas (and the acid level) within organisms. This triggers an increase in breathing rate in many animals. As a result, the extra CO_2 (or HCO_3^-) is released to the external environment, restoring the CO_2 concentration in the ECF to normal. Thus, *homeostasis should be viewed not as a fixed state but as a dynamic steady state* in which the changes that do occur are minimized by compensatory physiological responses. This is why Cannon chose the prefix *homeo* (“similar”) instead of *homo* (“same”). For each factor in the internal environment, the small fluctuations around the optimal level are normally kept within the narrow limits compatible with life by carefully regulated mechanisms.

Animals vary in their homeostatic abilities

The term *homeostasis* was developed primarily from research on mammals, which do exhibit a remarkably consistent (though nevertheless modestly varying) internal environment. However, many kinds of multicellular organisms exhibit far more variability in their internal environment than do mammals, yet they survive. Physiologists use specific terms to describe these abilities.

Regulators, Conformers, Avoiders There are two strategies that can be utilized by organisms from the viewpoint of internal environments: *regulators*, which use internal mechanisms to defend a relatively constant state, and *conformers*, whose internal state varies with that of the environment. Some physiologists recognize a third category, *avoiders*, which may not be capable of internal regulation but which nevertheless can minimize internal variations by avoiding environmental disturbances (Figure 1-7). For example, most organisms (including nonanimals) are thermoconformers (body temperatures equal to that of the environment), whereas birds and mammals are generally thermoregulators, maintaining a stable internal temperature regardless of the environmental temperature. But some thermoconformers (such as some fish and insects) can avoid large changes in body temperature by changing their locations in the environment (see Chapter 15).

Enantiostasis Some animals have variable internal components that achieve a kind of homeostasis termed *enantiostasis* (*enantio*, “opposing”). This term refers to consistency of function achieved by changing one physiological variable to counteract a change in another. The term was first used for blue crabs, which suffer a decrease in internal salt composition when they leave the ocean and enter a lower-salinity environment (an estuary). Researchers have found that reduced salt-ion levels inhibit oxygen binding by *hemocyanin* (Chapter 9), a large biomolecule (a protein similar to hemoglobin in your red blood cells), which transports oxygen in the crabs’ circulatory fluid. Yet the crabs do not suffer from this, because they make their internal fluids more alkaline (less acidic) by increasing production of ammonia, a strong base. Higher alkalinity in turn increases oxygen binding by hemocyanin and thus offsets the ion effects. Thus, a functional homeostasis of hemocyanin is achieved.

Negative feedback is the main regulatory mechanism for homeostasis

In order to maintain homeostasis, organisms must be able to detect any deviations in internal factors that need to be held within narrow limits, and must be able to control the various body systems that respond to these deviations. For example, to maintain body temperature at an optimal value, mammals must be able to detect a change in internal temperature and then appropriately alter heat production or loss so that internal temperature returns to the desirable level.

Homeostatic control mechanisms primarily operate on the principle of negative feedback. **Negative feedback** occurs when a change in a controlled variable triggers a response that opposes the change, driving the variable in the opposite direction of the initial change. Feedback systems can be very simple *unreferenced* ones, with imprecise control, or *refer-*

Challenges and Controversies

Can a Planet Have Physiology?

As we have discussed, one of the main features that seems to define life itself is the ability to react to, and adjust for, environmental disturbances. In recent years, a number of scientists headed by James Lovelock have proposed that planet Earth itself exhibits this key property of life. Called the Gaia hypothesis, this concept is based on the observation that the conditions of weather and nutrient cycling that favor life have been relatively constant for hundreds of millions, perhaps billions of years. Although periods of prolonged cold (ice ages) have been interspersed with eons of global warmth, at no time have conditions deviated from the range necessary for life. Lovelock and his supporters propose

that life itself, in conjunction with larger geologic and atmospheric processes, maintains this favorable state in homeostatic feedback processes some collectively call “geophysiology.” As an example of such a feedback process, researchers have found that cloud formation can be triggered by an atmospheric gas called *dimethyl sulfide* (DMS). DMS in turn is a breakdown product of an *osmolyte* (a molecule used to regulate cell water content; see Chapter 13) in marine phytoplankton (single-cell algae such as diatoms that are Earth’s most common photosynthesizers). The hypothesis is that, as Earth’s climate enters any warming trend, plankton growth increases and so,

therefore, does DMS production. In turn, more clouds form that, by blocking sunlight, oppose the heating trend. Thus, the temperature of the planet’s atmosphere is prevented from extreme changes:

Increasing atmospheric temperature →
more DMS release from phytoplankton →
more clouds form → less sunlight reaches
Earth → atmospheric cooling

If this is correct, would it be fair to think of Earth itself as a giant living organism (called Gaia)? The other properties of life such as reproduction and evolution may influence your answer to this intriguing question.

(c)

FIGURE 1-7 Examples of regulators, avoiders, and conformers. (a) Regulator: a capuchin monkey’s internal body temperature is relatively constant regardless of environment; (b) Avoider: monarch butterflies migrate in the autumn from freezing northern habitats to warm southern habitats to avoid extreme body temperatures. (c) Conformer: a marine snail’s body temperature matches that of the external aquatic environment. (The monarch also can regulate its body temperature daily by basking in the sun, but at night it becomes a conformer.)

enced with a built-in **set point** that gives the ideal state. An example of an unreferenced system has been proposed for Earth’s climate and global warming. As Earth’s atmosphere begins to heat up from excess carbon dioxide, certain processes may be triggered that produce more clouds (see box, *Challenges and Controversies: Can a Planet Have Physiology?*). Clouds may reduce input from the sun and so oppose the warming trend. But there is no precise regulation, because there is no set point.

In contrast, a referenced negative-feedback system typically has these components: a **sensor** to measure the variable being regulated, an **integrator** that compares the sensed information with a set point, and an **effector**, the device or process that actually makes the corrective response (Figure

1-8a). A common example of a negative feedback is control of room temperature (the controlled variable) by a system that includes a sensing and integrating thermostatic device, a furnace and an air conditioner, and all their electrical connections (Figure 1-8b). The room temperature is altered by the activity of the effectors—the furnace (a heat source) and air conditioner (a heat remover). Suppose someone opens the room door, and too much cold air enters. To switch the effectors on or off appropriately, the control system must “know” (measure) what the actual room temperature is, “compare” it with the desired room temperature (set point), and adjust the output of the effectors to bring the actual temperature to the desired level. A thermosensing device in the thermostat, which monitors the magnitude of the con-

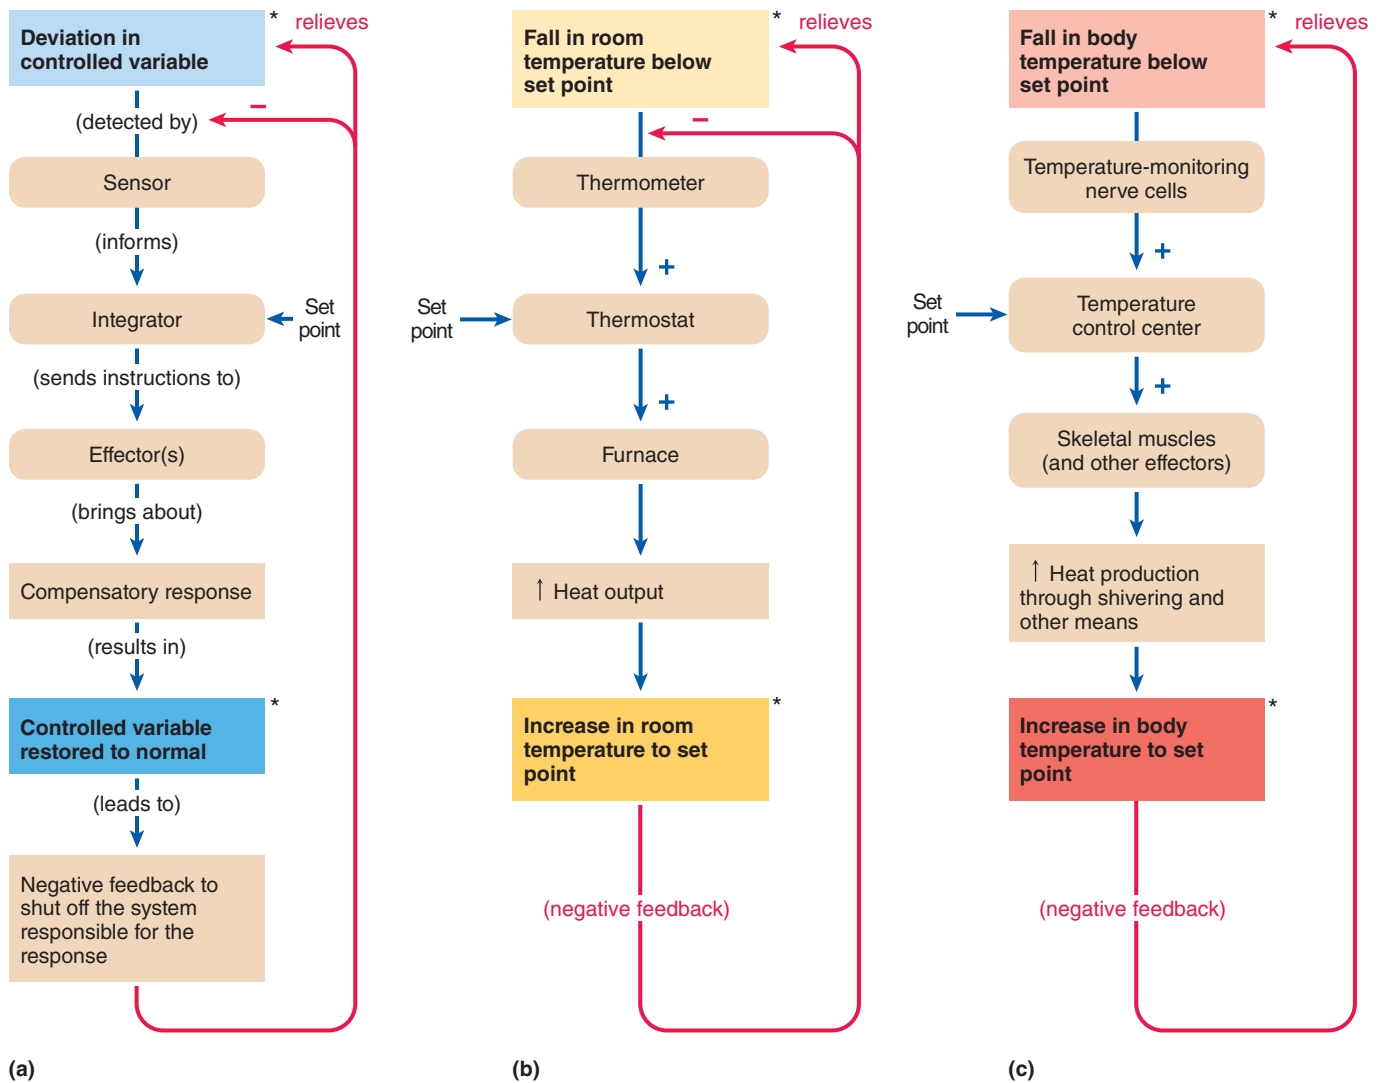

FIGURE 1-8 Negative feedback. (a) Components of a negative-feedback control system. (b) Negative-feedback control of room temperature. (c) Negative-feedback control of mammalian body temperature.

© Cengage Learning, 2013

trolled variable, provides information about the actual room temperature. The thermostat setting provides the desired temperature level, or *set point*. The thermostat acts as an integrator: It compares the sensor's input with the set point and, in this case, adjusts the heat output of the furnace to oppose the deviation from the set point.

When cold is being compensated for, the heat produced by the furnace counteracts or is “negative” to the original fall in the temperature. Note that this is still termed “negative” feedback even though heat is being added. Once the room temperature reaches the set point, the activating mechanism in the thermostat and consequently the effector is switched off. If heat production were to continue un-

abated, the room temperature would be increased above the set point. Overshooting far beyond the set point does not occur because the air temperature “feeds back” to shut off the thermostat that triggered heat output, thereby limiting its own production by altering the signal that initiated the heat production. Thus, the control system takes corrective actions to prevent the controlled variable from drifting too far below or too far above the set point.

Homeostatic systems in organisms operate very similarly with negative feedback to maintain a controlled factor in a relatively steady state. For an example, you can see the similarities between the thermostat system of Figure 1-8b and one aspect of the mammalian thermoregulatory system,

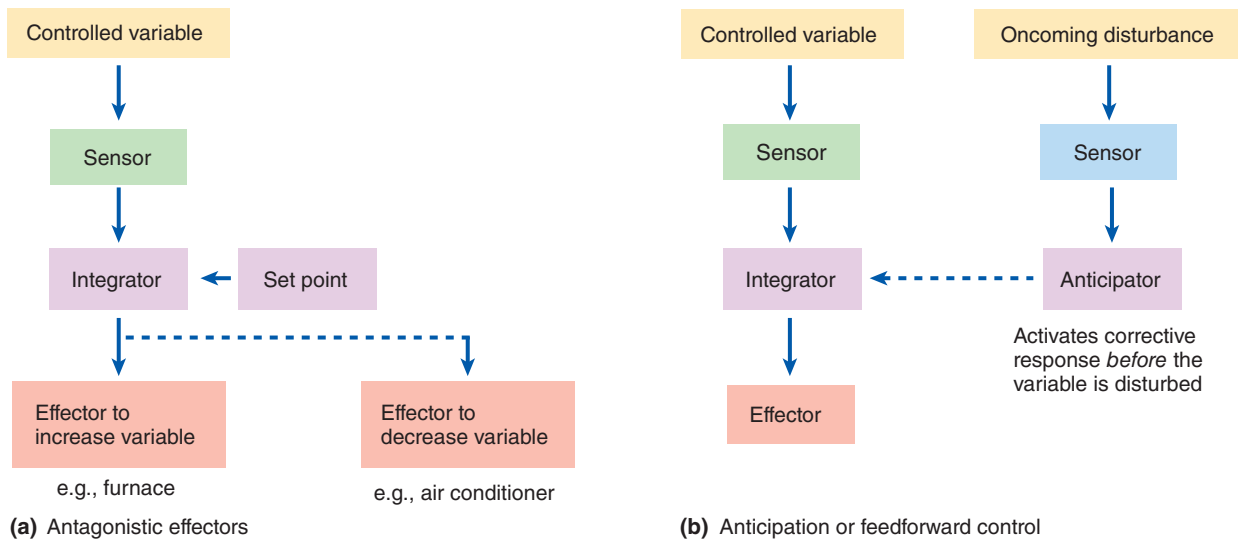

FIGURE 1-9 Expansion and enhancement of basic negative-feedback system.

© Cengage Learning, 2013

shown in Figure 1-8c. This is the system we described earlier (p. 2), in which a region of the brain, the hypothalamus, acts as an integrator for controlling body temperature.

Feedback effectors can be antagonistic and can include behaviors as well as internal organs

The basic negative-feedback mechanism we have just discussed can be expanded in several ways. For effectors, there are two alternative design features to keep in mind:

- **Antagonistic control.** If corrections can occur in either direction of change, by having two effectors with opposite effects, or by regulation that can increase or decrease a single effector's output, the system is said to have **antagonistic control** (Figure 1-9a). Note the importance of the antagonistic design in the home system just described: If the controlled variable can be regulated to oppose a change in one direction only, the variable can move in uncontrolled fashion in the opposite direction. For example, if the house is equipped only with a furnace to oppose a fall in room temperature, no mechanism is available to prevent the house from getting too hot in summer. However, the room temperature can be kept relatively constant through two opposing mechanisms, one that heats and one that cools the room (that is, an air conditioner), despite wide variations in the temperature of the external environment.
- **Behaviors as effectors.** An effector for a disturbance is typically an organ that directly adjusts some internal state (such as a muscle that shivers to produce heat). However, **behaviors** (specific animal movement patterns used in specific situations, typically requiring coordinated actions of many neural and muscular components) can also serve as corrective processes, and are thus also effectors. Recall that some animals are *avoiders*; these typically use behavioral effectors. For example, monarch butterflies (see Figure 1-7) migrate from the northern United States and Canada to California and Mexico for the winter, thus avoiding extreme cold.

(This navigational behavior is genetically programmed to an amazing degree: The monarchs that migrate south are hatched in the north and are several-generation descendants of the monarchs that migrated north.)

Let's look at another example. Killifish are remarkable intertidal bony fishes that can survive in salinities ranging from freshwater to well above seawater concentrations, while maintaining a relatively consistent internal salinity at about 35 to 45% that of normal seawater. When the fish face a change in external salinity (such as when rainfall dilutes an exposed tide pool), cells in their gills (physiological effectors) adjust the rate of salt intake into the blood to a level necessary for homeostasis. At the same time, if the tide pool has a salinity gradient, the fish actively seek a patch of water that has about 35 to 45% salinity (a behavioral effector process). Thus, killifish are both regulators and avoiders.

Inadequacies in negative-feedback systems can be improved by anticipation and acclimatization

It is important to note that, even with the added sophistication of antagonistic control, a basic referenced negative-feedback system (sensor, integrator with set points, and effectors) has two inherent flaws. First, it cannot be perfectly *homostatic* ("same state"), because it must first suffer a disturbing change before it can react and make corrections, resulting in a *delayed response*. Similarly, there is another delay in shutting off an effector, and so basic systems tend to overshoot the set point somewhat. Thus, many regulated parameters—body temperature, hormone levels, water balance, for example—fluctuate continuously (hence the prefix *homeo-*). Second, some components may not work well in a new environment or situation, such as after an animal migrates from low to high altitude. Evolution (and human engineers) have come up with two ways to enhance regulation to overcome these problems (which exist to varying degrees among systems and animals).

- **Anticipation or feedforward system.** An anticipation or feedforward system reduces the delay phenomenon by

detecting or predicting an oncoming disturbance *before* a regulated state is changed (for example, perturbed beyond the set point) (Figure 1-9b). It may also predict the results of an effector's output before reaching the set point. The anticipator then activates the appropriate response *in advance* of the change or suppresses the effector before it overshoots the set point. For example, modern electronic thermostats have anticipator circuits that shut off the furnace just before the set point is actually reached, so that the hot air already on its way from the furnace to the thermostat brings the room to the set point without overshooting. As an organismal example, temperature sensors in a mammal's skin detect external heat or cold, and can trigger corrective responses *before* the internal "core" temperature is disturbed. Similarly, when a meal is still in the digestive tract, a feedforward mechanism increases secretion of a hormone (insulin) that promotes cellular uptake and storage of ingested nutrients after they have been absorbed from the digestive tract. This anticipatory response helps limit the rise in blood nutrient concentration that follows nutrient absorption.

- **Acclimatization systems.** Acclimatization systems are mechanisms that alter existing feedback and other components, usually over many days, to work better in a new situation. Examples of new situations include migrating to high altitude or entering a different season. To continue the temperature theme, mammals may increase their hair or fat layers as winter approaches and shed them in the spring, thus augmenting the basic internal negative-feedback system.

Some processes that are technically forms of acclimatization are not always designated as such, because they do not involve habitat features. For example, the muscle mass of an animal increases over time if locomotory activity undergoes a prolonged increase, as during migration. This form of acclimatization is often called **upregulation**. The opposite effect, **downregulation**, can also occur, as when muscle mass declines during more sedentary periods.

A note on terminology: The term **acclimation** refers to acclimatization processes that take place in a controlled situation, such as a laboratory. Acclimation and acclimatization processes, as well as up- and downregulation, are often called *adaptations* by many people. For example, a mountain climber may say he or she has "adapted" to high altitude. However, this term can be misleading, because evolutionary biologists use "adaptation" to refer to genetic changes that occur over many generations through variation and natural selection (p. 1). You will encounter both terms—*acclimatization*, *adaptation*—frequently, and for the latter term, you should always note whether it is being used in the between-generations (evolutionary) or the within-organism (physiological) sense.

1.6 Regulated Change

Not everything in organisms is homeostatic by any means, not even some of those traditionally considered to be classic examples. Mammalian body temperature is again a good example: Although normally quite narrowly regulated in most mammals most of the time, body temperature varies considerably with fever, between wake and sleep, and in hibernation.

Some internal processes are not always homeostatic but may be changed by reset and positive-feedback systems

There are many nonhomeostatic outcomes of acclimatization to changing environmental stresses. For many animals, negative-feedback regulation cannot be modified to keep working at an optimum, and acclimatization involves switching to a state of **dormancy** (a state of greatly reduced metabolism), such as *hibernation* by a small mammal in which body temperature falls dramatically. Or consider the embryos of a brine shrimp (sold commercially as "sea monkeys") in the Great Salt Lake in Utah. When the embryos are washed up on a dry shoreline, they can lose over 98% of their internal water, yet remain viable by entering a resistant cyst state (which can hatch out years later if put in water). These animals maintain homeostasis only in the broadest sense of "survival." (Compare this to mammals, which die if they lose more than 10 to 15% body water!)

Furthermore, many functions such as locomotion, growth and development, and neural signaling are not homeostatic at all (though they may contribute to homeostasis in some fashion). Some regulatory systems are simply switched on when stimulated for a particular need, and are then switched off. Examples of such "on-demand" regula-

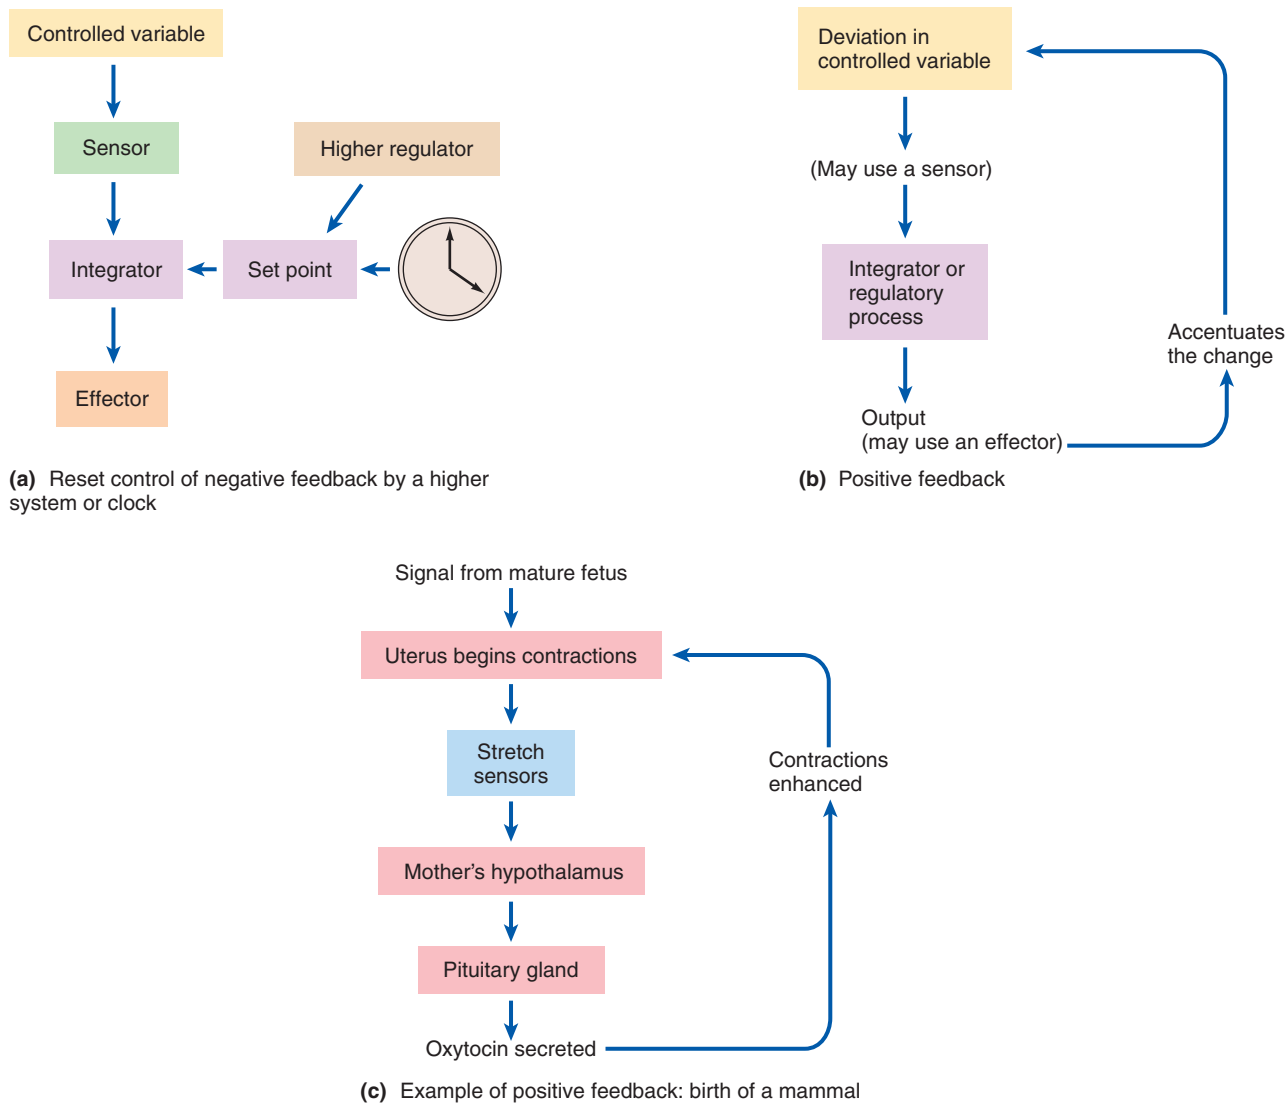

FIGURE 1-10 Mechanisms for regulated change.

© Cengage Learning, 2013

tion are muscles and glands in the digestive tract, which are locally activated to churn and digest the food when present and shut off when not. This can contribute to other homeostatic needs such as nutrient concentrations in the blood, but this regulation is not homeostatic in itself. Some physiologists have termed nonhomeostatic regulation **rheostasis** (“variable state”).

Evolution has also come up with two other mechanisms for regulating useful nonhomeostatic change, which we mention frequently in later chapters:

- **Reset system:** one that changes the set point of a negative-feedback system, in a *temporary*, *permanent*, or *cyclic* fashion (Figure 1-10a). Fever is an example of a temporary reset of body temperature. At sexual maturity in a mammal, sex hormone concentrations are permanently reset to higher levels. Annual hibernation (such as by a squirrel) and many reproductive cycles are additional examples of cyclical resets regulated by internal biological clocks (see Chapter 7). You can probably think of both temporary and cyclical mechanisms for the room thermostat system of Figure 1-8b.

- **Positive-feedback systems** create rapid change when conditions demand a rapid change from a set point. In negative feedback, a control system’s output is regulated to resist change, so that the regulated variable is maintained at a relatively steady set point. With positive feedback, however, the output is continually enhanced so that the controlled variable continues to move in the direction of the initial change (Figure 1-10b). Instead of bringing about a response that counteracts the initial change, positive feedback reinforces the change in the same direction. Such action is comparable to the heat generated by a furnace triggering the thermostat to call for even more heat output from the furnace so that the room temperature continuously rises. Because positive feedback moves the controlled variable even farther from a steady state, it does not occur purposefully very often in organisms, where the major goal is maintenance of stable, homeostatic conditions. Indeed, unintended positive feedback can lead to rapid death. For example, in congestive heart failure a weak mammalian heart re-

sults in a drop in blood pressure, triggering negative-feedback systems that retain fluid in the body in an attempt to increase blood pressure (more fluid in blood vessels increases pressure). However, more fluid increases stress on the heart, weakening it further, dropping pressure again, and so the cycle continues until the heart fails completely.

Nevertheless, positive feedback is often very useful. Examples include neuron action potentials, lactation, blood clotting, bile release, many mating behaviors and orgasms, ovulation, and some reactions of immune systems are all positive feedback. These all have one thing in common: A relatively rapid change is needed because of a new situation in which the homeostatic set point is no longer appropriate. As a detailed example, consider the birth of a mammalian infant. The hormone *oxytocin* causes powerful contractions of the uterus. As uterine contractions push the baby against the cervix (the exit from the uterus), the resultant stretching of the cervix triggers a sequence of events that releases even more oxytocin, which causes even stronger uterine contractions, triggering the release of more oxytocin, and so on (Figure 1-10c). Positive feedback here is useful to help the infant be born relatively quickly once it reaches a key stage of developmental maturity.

Except for permanent and cyclical reset systems, non-homeostatic “change” mechanisms (on-demand, temporary reset, and positive feedback) need to be shut off once they are no longer needed. The mechanisms for this vary but typically involve the loss of the initiating signal. For example, the oxytocin positive-feedback loop stops once the fetus is no longer pushing on the cervix. Like negative-feedback systems, some of these change systems can be activated in feedforward fashion and improved or adjusted up or down by acclimatization. For example, the activation of digestive muscles and glands (described earlier) can be feedforward-activated by the taste and smell of food. And the internal clock that cyclically resets a human’s body temperature each night and day can be acclimatized to a new time zone by local sunlight exposure.

Disruptions in regulation can lead to illness and death

When one or more of an animal’s systems fail to function properly, homeostasis (or the ability to regulate change) is disrupted, and all the cells may suffer because they no longer have a suitable environment in which to live and function. Various pathophysiological states ensue, depending on the type and extent of homeostatic disruption. The term *pathophysiology* refers to the abnormal functioning of organisms (altered physiology) associated with disease. When a homeostatic disruption becomes so severe that it is no longer compatible with survival, death results. An example is that of congestive heart failure, mentioned earlier.

check your understanding 1.6

Describe how reset and positive-feedback systems create useful change.

1.7 Organization of Regulatory and Organ Systems

Control of an animal’s functions is often—erroneously—portrayed as a centralized command system with the brain and endocrine systems regulating everything. In fact, such a design would be needlessly cumbersome and slow because every tiny response needed by each cell or tissue for homeostasis would require these events: a signal to a central command organ; a decision; a return signal; and finally a local response. For many simple responses, the time delay could be harmful; for example, you would not want to wait for some central endocrine gland to signal the need for a blood clot when your foot is injured and bleeding. Therefore, control in an animal is actually **hierarchical**, much like governmental systems in many countries!

Homeostasis (and other regulation) is hierarchically distributed

The United States and Canada, for example, have at least four levels in this hierarchy in order of increasing priority: city, county, state/province, and federal (or national) governments. Basic local needs are delegated to city governments because local knowledge of the situation is better, and it would be unnecessarily slow to wait for interactions with the national level (considerable delays occur if a city resident requires new federal permission for construction work on his or her home). But needs that involve the whole country (such as distributing food supplies and defending the country) often require the highest level of control. Similarly, many simple, common homeostatic responses in animals are controlled locally, at the level of individual cells, tissues, or organs. Only when more complex responses are needed is a whole-body (“federal” or “national”) system needed.

Let’s examine this hierarchy in more detail. At the most basic level, an individual cell can regulate its internal energy supplies, ion concentrations, and cell volume, at least to some extent. Beyond the cellular level, control systems that operate to maintain homeostasis are often grouped into two broad classes in this hierarchical design—intrinsic and extrinsic controls. **Intrinsic controls** are those regulated by a single tissue or organ on its own (akin to a county or state/province government). For example, as an exercising muscle rapidly uses up O_2 and produces CO_2 to generate energy to support its contractile activity, the O_2 concentration falls and the CO_2 concentration increases within the muscle. These local chemical changes are directly detected by the smooth muscle in the walls of the blood vessels that supply the exercising muscle and result in the relaxation of the smooth muscle and dilation (open widely) of the vessels, which increases blood flow into the exercising muscle. This local mechanism contributes to the maintenance of an optimal level of O_2 and CO_2 in the internal fluid environment surrounding the exercising muscle’s cells. As we discussed earlier, this response is generated at the local level, which avoids unnecessary delays and possibly avoids the reduced precision of generalized whole-body responses.

However, many factors in the internal environment are maintained by **extrinsic controls**, which are regulatory mechanisms initiated outside an organ to alter its activity

BODY SYSTEMS

Made up of cells organized according to specialization to maintain homeostasis.
See Chapter 1.

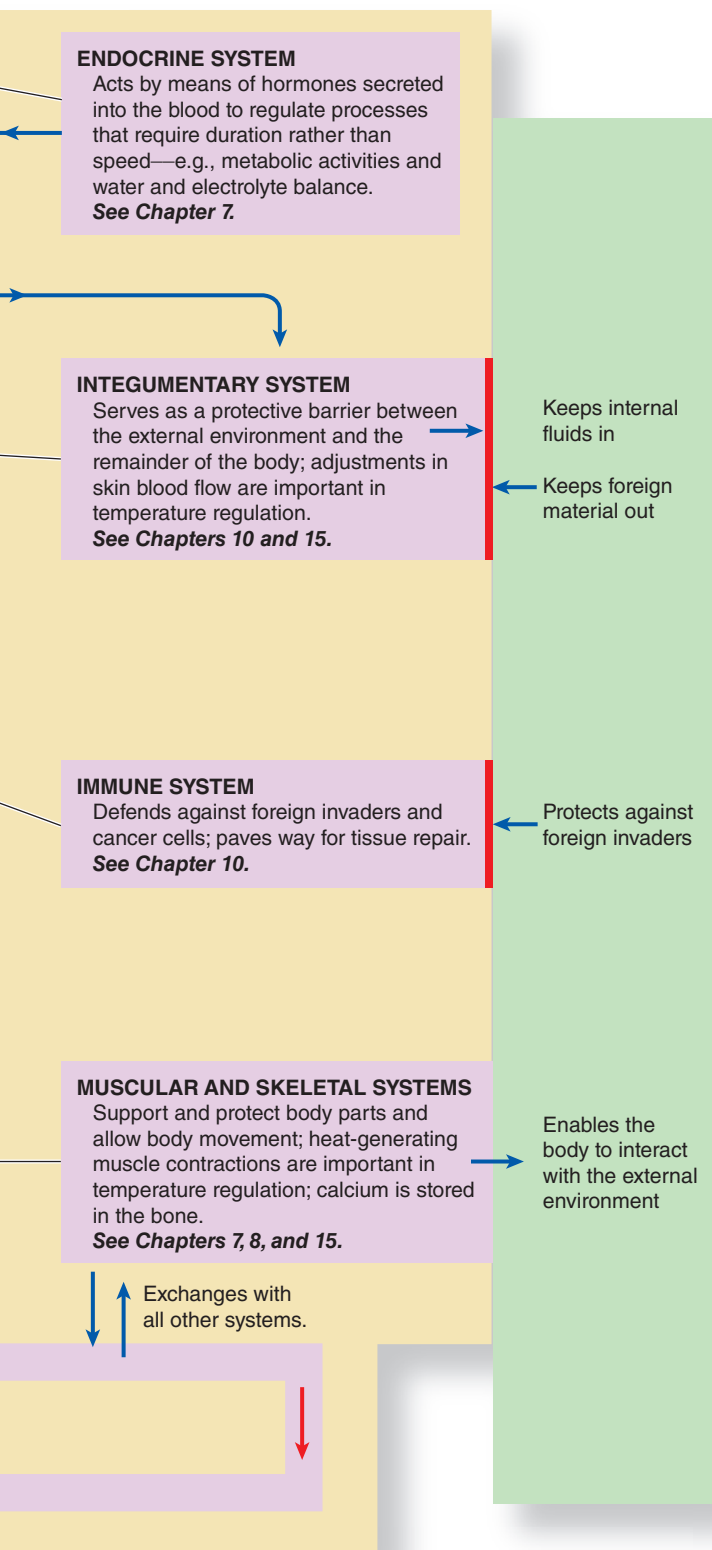

FIGURE 1-11 The major vertebrate body systems and their roles.

© Cengage Learning, 2013

(the “national government” level). Often this involves coordination of two or more organs. Extrinsic control of the various organs and systems is accomplished by the nervous, endocrine, and (to some extent) immune systems. Extrinsic control permits coordinated regulation of several organs toward a common goal; in contrast, intrinsic controls are self-serving for the organ in which they occur. Coordinated, overall regulatory mechanisms are critical for maintaining the needs of the internal environment as a whole. For example, the nervous system can take priority over an individual organ’s regulation of blood flow during exercise (diverting blood from digestive to muscular systems; just as the national government can sometimes override state/province and city governments).

Organ systems can be grouped according to whole-body contributions

Now that you have considered the basic features of living systems and the importance of homeostasis, let’s briefly examine the actual working components of animals that carry out these functions. These components govern the organization of most of this book. As we said earlier, physiologists typically categorize organs in animals into functional **systems** based on their contributions to the whole organism. In turn, these systems can be grouped into four categories based on the broad view of life itself: whole-body control systems; maintenance systems; support and movement systems; and reproductive systems. There are about 11 major body systems (see Figure 1-11 for vertebrates), as follows.

Whole-Body Control Systems Whole-body control systems regulate and coordinate homeostatic and other functions of the other systems for the good of the whole body. Keep in mind that these do not control all activities in the hierarchical control design.

1. **Nervous systems** control and coordinate bodily activities that require swift responses. They are especially important in detecting and initiating reactions to changes in the external environment. Furthermore, they are responsible for more complex “higher” functions such as consciousness, learning and memory, and creativity. In animals with central brains, this system is also hierarchical, for example, with short **reflex** responses (automatic, unlearned reactions to a stimulus) and longer more complex responses.
2. The hormone-secreting glands of **endocrine systems** regulate activities that require duration rather than speed. These systems are especially important in controlling reproductive cycles, the concentration of nutrients, and the internal environment’s volume and electrolyte composition.

Support and Movement Systems From a purely homeostatic view, support and movement are not necessarily directed toward maintaining homeostasis, although holding position (“posture”) is a type of homeostasis. And the ability to protect from harm and obtain food contributes to the broad homeostasis of body integrity and survival.

3. **Skeletal systems** provide support and protection for the soft tissues and organs. In vertebrates, the skeleton also

functions in homeostatic regulation of calcium (Ca^{2+}), an electrolyte whose plasma concentration must be maintained within very narrow limits. Together with the muscular system, the skeletal system also enables movement of animals and their parts.

4. **Muscular systems** move the skeletal components to which the skeletal muscles are attached. Furthermore, the heat generated by muscle contraction is important in temperature regulation in some animals, especially birds, mammals, and some insects and fishes.

Maintenance Systems These are organ systems that do most of the actual work of maintaining the internal environment. The systems and their most important contributions to homeostasis are as follows:

5. **Circulatory systems** are the transport systems that carry materials such as nutrients, O_2 , CO_2 , nitrogenous wastes, electrolytes, heat, and hormones from one part of an animal to another.
6. **Defense or immune systems** defend against foreign invaders (viruses, bacteria, parasites) and body cells that have become cancerous. They also pave the way for repair or replacement of injured or worn-out cells. Because some defensive responses can coordinate activities of organs throughout the body (at least in mammals), in recent years many researchers have come to regard the mammalian immune system as the third whole-body control system (along with nervous and endocrine systems). For now, we will leave it under maintenance systems.
7. **Respiratory systems** obtain O_2 from and eliminate CO_2 to the external environment. By adjusting the rate of removal of acid-forming CO_2 , a respiratory system is also important in maintaining the proper pH (acid–base balance) of the internal environment.
8. **Excretory systems** remove excess water, salt, acid, and other electrolyte from the plasma and eliminate them, along with waste products other than CO_2 .
9. **Digestive systems** break down dietary food into small nutrient molecules that can be absorbed into the circulatory system for distribution to all cells. They also transfer water and electrolytes from the external environment into the internal environment. A digestive system eliminates undigested food residues to the external environment in the feces. (The vertebrate liver also excretes some wastes—see Chapter 12.)
10. **Integumentary systems** serve as outer, protective physical barriers that prevent internal fluid from being lost from organisms and foreign microorganisms from entering them. These organs are also important for regulating body temperature in some animals.

Reproductive Systems Reproductive systems are not essential for homeostasis of the individual and therefore are not essential for survival of the individual. They are essential, however, for perpetuation of the species.

11. **Reproductive systems** consist of organs that produce gametes (eggs, sperm), organs to deliver them and, in some animals, support systems for offspring (such as yolk production, and embryo and fetal development).

As we examine each of these systems in greater detail, always keep in mind that a body is a coordinated whole even though each system provides its own special contributions. It is easy to forget that all the parts actually fit together into a functioning, interdependent whole body. Accordingly, each chapter concludes with a brief overview of the integrative, whole-body contributions of the system.

Keep another point in mind as you read through the book: The functioning whole is greater than the sum of its separate parts. Through specialization, cooperation, and interdependence, cells combine to form a coordinated, unique, single living organism with more diverse and complex capabilities than is possessed by any of the cells that make it up.

How Homeostasis and Integration Contribute to the Body as a Whole

In this chapter, you have learned that homeostasis is a dynamic steady state of the constituents in the internal fluid environment (the extracellular fluid) that surrounds and exchanges materials with the cells. You have also learned how homeostasis can be enhanced with anticipation and acclimatization, and how nonhomeostatic regulated changes are controlled by resets and positive feedback. Homeostasis and regulated changes are regulatory features essential for the survival and normal functioning of cells, and each cell, through its specialized activities, contributes as part of a body system to these regulatory features.

This integrated relationship among cells, organ systems, and the whole organism is the foundation of physiology and the central theme of this book. We have already described how cells are organized according to specialization into body systems. How the key functions of life and body systems maintain this internal consistency and necessary changes are the topics covered in the remainder of this book. Each chapter concludes with this capstone feature to facilitate your understanding of (1) how the systems and functions under discussion contribute to whole-body homeostasis and regulated change and (2) the integrated interactions and interdependency of body systems.

Chapter Summary

- Biological adaptations have two levels of explanation: the mechanistic (or proximate) and the evolutionary (or ultimate). Evolution by natural selection occurs when offspring exhibit differential survival and reproduction due to variations in their genes. Adaptations reflect evolutionary history including constraints and cost–benefit trade-offs, so are not always logically optimal.
- Physiology is an integrative discipline, using physics, genetics, ecology, and so on; and it is also comparative, using animals of all types to reveal both the diversity and the universality of processes. This often follows the Krogh principle, which states that, for every adaptation, there will be a particular species in which it is most conveniently studied.
- The hypothetico-deductive method is the most widely accepted version of “the scientific method.” Data are gathered about an aspect of nature in the “discovery” phase, then alternative hypotheses are made to explain them. Testable deductions must be made from the hypotheses, with experiments and observations designed to test them, leading to support, refinement, or rejection of hypotheses.
- Life has the properties of self-organization, self-regulation, self-support and movement, and self-reproduction. Cells are progressively organized into tissues, organs, systems, and finally the whole body. Tissues are epithelial for linings, connective for support, neural for electrical communication, and muscular for contraction.
- Size matters: Many anatomical and physiological features are scaled to (that is, are dependent on) body size. For example, the larger the organism, the smaller the surface-area-to-volume ratio; and larger animals usually live longer than smaller ones.
- Body cells are in contact with a privately maintained internal environment instead of with the external environment that surrounds organisms. Homeostasis is the maintenance of a consistent internal state and is essential for proper cell function; each cell in turn, as part of an organized system, contributes to homeostasis. Negative feedback, such as a home thermostat, is the main mechanism for homeostasis, with sensors, integrators with set points, and effectors. Some animals are good internal regulators, while others behaviorally avoid disturbances, and others do not avoid or internally regulate but conform to the environment. Some use enantiohomeostasis: varying one body parameter to achieve homeostasis in another.
- Feedback effectors can be antagonistic (e.g., shivering and sweating devices) and can include behaviors as well as internal organs. Inadequacies in negative-feedback systems can be improved by anticipation (initiating corrections before a disturbance) and acclimatization (improving response of a feedback component in a new situation).
- Some internal processes are not always homeostatic but may be changed by reset systems, which raise or lower a negative-feedback system set point, and positive-feedback systems, which rapidly enhance changes. Disruptions in regulation can lead to illness and death.
- Homeostasis (and other regulation) is hierarchically distributed, with intrinsic regulation occurring locally in cells and tissues for rapid control of basic needs, and extrinsic (mainly neural and hormonal) for coordinating multiple body parts, often overriding intrinsic controls for the good of the whole.
- Organ systems can be grouped according to whole-body contributions, following universal life properties, into regulatory (neural, hormonal), maintenance (digestive, respiratory, circulatory, immune, excretory, integumentary), support and movement (skeletal and muscular), and reproductive systems.

Review, Synthesize, and Analyze

1. Some people dismiss the concept of evolution as “just a theory.” Using the hypothetico-deductive method, explain why most scientists accept evolution as fully established.
2. Explain why the term *homeostasis* (similar state) was chosen rather than *homostasis* (same state).
3. Why is positive feedback sometimes useful, but also often dangerous, even lethal?
4. What are intrinsic and extrinsic controls, why are they analogous to the U.S. government system of city, county, state, and federal levels, and why is this hierarchy useful?
5. Why is the Krogh principle useful in the field of animal physiology?

Cellular and Molecular Physiology

2.1 Introduction

As we noted in Chapter 1, cells are distinct from their inanimate constituents because they have the ability to grow, replicate, perform complex metabolic reactions, and respond to environmental stimuli. Modern cellular physiologists are unraveling many of the broader mysteries of how cells work, both as living systems individually and in their specialized contributions to multicellular organisms. Comparative physiologists study how an individual species is adapted to a specific environment in part by analyzing the molecular structure and organization of its cells. Analyses of the structures of living cells, and of the molecular components of which they are made, show the deep interconnectedness of all life through evolution. In this chapter, we'll review those structures and molecules.

It is important to realize that, although researchers have analyzed structures and functions of most of the molecular constituents of cells, no one has thus far been able to assemble building-block chemicals artificially into a living system in a laboratory environment (although attempts are under way). Scientists have created a new bacterium with an artificial genome, but a previously living cell was still needed in

which to insert the synthesized genome. (**Genome** refers to the entire genetic code of an organism.) It is not merely the presence of various molecules that confers the unique characteristics of life; it is the complex organization and interaction of these molecules within the cell that is critical. Much remains to be learned about the molecular organization necessary for life, and tools that allow us to do so are continuously increasing in sophistication and power.

Water, other inorganic chemicals, and four types of organic molecules are the universal components of cells

Living systems are constructed from two broad classes of chemicals called *inorganic* and *organic molecules*. Scientists originally designated organic chemicals as those from living or once-living sources, but today the term *organic* refers to almost all molecules made from the element carbon (and invariably hydrogen, with the smallest organic molecule being methane or natural gas, CH₄). Based on this defini-

tion, organic material has now been confirmed on other planets and a moon (Titan) in our solar system, in nebulae in space, and even on a distant planet, Osiris, by the Hubble Space Telescope. Located 150 light-years from Earth (about 900 trillion miles), Osiris also has oxygen in its atmosphere. However, the development of life on Osiris is unlikely because its close proximity to its sun (4.3 million miles) probably makes it too hot.

All other chemicals are termed *inorganic*, even small carbon-containing molecules such as carbon dioxide (CO₂). Although cells contain a large variety of inorganic and organic components, there are some fundamental, universal types. We assume you are familiar with the basic inorganic and organic molecules of life; for those who are not, details are summarized here.

Water (H₂O) is the universal inorganic molecule of life on Earth. Its properties such as its *polarity* (unequal sharing of electrons between hydrogen and oxygen) and hydrogen-bond formation make it unique among molecules in the universe for serving as a

Photo: Thomas A. Steitz

FIGURE 2-1 The complex structures of proteins are mainly determined by weak bonds between amino-acid side groups, allowing proteins to be dynamic and flexible. Here, a model of an enzyme, hexokinase, is at work. Hexokinase catalyzes phosphorylation of glucose. (a) A glucose molecule (color-coded red) is heading toward the active site, a cleft in the enzyme (green). (b) When the glucose molecule makes contact with the site, parts of the enzyme briefly close in around it and drive the chemical reaction.

medium for the reactions of life. In particular, polarity allows water molecules to bind to any molecule that is charged or polar. Indeed, water is sometimes called “the universal solvent.” In addition, other small inorganic ions such as sodium (Na^+), potassium (K^+), chloride (Cl^-) and phosphate (PO_4^{3-}) appear to be universal solutes (dissolved molecules) in cells; we explore the roles of these and other inorganic chemicals later.

Because of the unique bonding ability of carbon, millions of different organic molecules are possible. However, it is possible to simplify this tremendous diversity into a few categories. The building blocks of organic molecules are called **monomers**, and chains of monomers linked together are called **polymers**. The largest polymers, called **macromolecules**, are the most important organic components of life. The basic categories of organic molecules are as follows:

1. **Carbohydrates** are made of carbon, hydrogen, and oxygen. The smallest building-block (monomer) units are simple sugars or **monosaccharides** such as **glucose**, the dominant energy molecule in most animals. In turn, these can form polymers called **polysaccharides**, such as **glycogen** (a branching chain of glucose molecules and an important energy storage molecule in animals). In addition to energy, carbohydrates can be used to form important structures such as **cellulose**, one of the constituents of plant cell walls, and **chitin**, a component of the exoskeleton of arthropods. Sugars are also often found attached to proteins to form **glycoproteins**, which are important components of cell membranes and signaling systems (see Chapter 3).
2. **Lipids** are made of carbon and hydrogen (and sometimes oxygen) and are **hydrophobic** (“water fearing”); that is, they do not easily dissolve in water. This arises from the fact that C–H bonds are nonpolar because they share electrons equally and cannot form hydrogen

bonds with water. You probably know that oil, a hydrophobic hydrocarbon, floats on water. This is because water molecules make hydrogen bonds with each other but not with oil molecules, which are in effect squeezed out as water molecules attract each other. (Lipids then rise to the top because they are less dense than water.) This lipid–water interaction is one of the most important chemical forces in living systems. Key examples of lipids are **fatty acid** monomers, which provide energy and serve as signal molecules; **triglycerides** (polymers of three fatty acids and glycerol), which are energy stores in animals; **phospholipids**, used to make membranes; and **cholesterol**, which is used to make membranes, steroid hormones, and bile.

3. **Amino acids** and **proteins** are made of carbon, hydrogen, oxygen, and nitrogen in a specific arrangement. Carboxylic amino acids, the most biologically common type, have an amino group (NH_2), an acid group (carboxyl, or COOH), and a side group that gives each amino acid unique properties. Amino acids may be used for energy, as **osmolytes** (see Chapter 13), or as signal molecules (Chapter 4), but their most crucial role is to form polymers called **peptides** and **proteins**. Peptides and proteins are formed from 20 different carboxylic amino acids (*glycine*, *alanine*, etc.), arranged in any order and to almost any length, providing an endless list of possible types of proteins. These polymers are the principal dynamic molecular agents of life, forming regulating compounds, such as signal molecules and receptors; transporters that move molecules through membranes; structural and functional components (such as those in muscle filaments); and enzymes, the primary catalysts of life’s chemical reactions (Figure 2-1a).

Ultimately a protein’s structure and function is as a result of the properties of its amino acid composition

and the respective chemical properties of its constituent amino acids (especially their side groups), and how they interact with each other and the surrounding medium. The highly complex three-dimensional structures that result from these molecular interactions determine a protein's function; that is, shape determines function. There are up to four levels of structure involving peptide chains and proteins.

4. **Nucleotides and nucleic acids** are made of carbon, nitrogen, oxygen, hydrogen, and phosphate in a particular arrangement. The monomers are called **nucleotides**, which have three components: a sugar (ribose or deoxyribose), phosphate, and a **base** that is one of five major types designated **A, G, C, T, and U** (adenine, guanine, cytosine, thymine, and uridine). These can form two types of polymers differing in the sugar component and one of the bases:
 - **Deoxyribonucleic acid, or DNA**, made of A, G, C, and T, is the basis for storage of genetic information and the process of inheritance.
 - **Ribonucleic acid, or RNA**, made of A, G, C, and U, helps convert that information into cell structures and working machinery.

We'll examine the functions of DNA and RNA later after reviewing basic features of cells.

All cells have two major subdivisions: the plasma membrane and the cytoplasm

Recall that life falls into three domains of *archaea*, *bacteria*, and *eukarya*, but in terms of basic cell features, biologists have traditionally designated two basic types—*prokaryotic* and *eukaryotic* (Chapter 1). Regardless of classification, all cells share many common features, having two major subdivisions—the *plasma membrane* and the *cytoplasm*—and having DNA-based genetic information systems. Eukaryotic cells have a third subdivision, the *nucleus*, to house the DNA, along with other membrane-bound structures called *organelles* in the cytoplasm.

The **plasma** or **cell membrane** is a very thin oily barrier that encloses each cell, separating the cell's contents from the surrounding environment. Its composition, further detailed in Chapter 3, is primarily composed of phospholipids, proteins and glycoproteins, and often cholesterol. The fluid contained within all the cells of the body is known collectively as **intracellular fluid (ICF)**, and the fluid outside the cells is referred to as **extracellular fluid (ECF)**. The plasma membrane does not merely serve as a mechanical barrier to hold in the contents of the cells; it also can selectively control movement of many molecules between the ICF and ECF. The plasma membrane can be likened to the gated walls that enclosed ancient cities. Through this structure, the cell can regulate the entry of nutrients and other needed supplies and the export of products manufactured within, while at the same time guarding against unwanted traffic into or out of the cell. However, not all molecules are selectively regulated; for example, water and CO₂ molecules (because they are so small) and hydrophobic molecules (except very large ones) can typically diffuse through most membranes.

The **cytoplasm** is that portion of the cell interior not occupied by the nucleus. It contains a number of discrete, specialized *organelles* (the cell's "little organs") and the *cyto-*

skeleton (a scaffolding of proteins that serve as the cell's "bone and muscle") dispersed within the *cytosol* (a complex, gel-like liquid). **Organelles** are distinct, highly organized structures that perform specialized functions within the cell.

Many macromolecular structures need to be flexible to function and to be regulated, and protecting those structures is the basis for many forms of homeostasis

Large molecular complexes, the framework of living cells, can be very vulnerable because their higher-level structures are often held together with weak bonds such as hydrogen bonds, as opposed to the strong or covalent bonds that join atoms within single molecules. Reliance on weak bonds is important because they give macromolecular structures dynamic features that could not occur with stronger, more rigid covalent bonds. Membranes, for example, are held together primarily by the result of hydrophobic interactions (Chapter 3) and thus can be flexible. Flexibility is necessary for cell shape changes and for many transport proteins to move molecules through membranes. The DNA double helix relies on hydrogen bonding so it can be readily disassembled for RNA formation and DNA replication. In addition, the complex three-dimensional structures of proteins are mainly determined by weak bonds between amino-acid side groups, allowing many proteins to be dynamic and flexible. Dynamic changes in proteins are crucial for everything from transport to enzyme catalysis. An example of the latter is shown in Figure 2-1b.

Another reason why many protein molecules are inherently flexible is that this characteristic allows their shapes to alter in order to regulate their activities, that is, be activated or inhibited. Useful conformational changes are induced in at least four ways: (1) from the binding of a regulatory molecule to a special binding site, a process called **allosteric** ("other site") **modulation**; (2) from a change in an electric field; (3) from physical deformation; and (4) by **phosphorylation**—the addition of a phosphate group by an enzyme called a **kinase** or by removal of phosphate by a **phosphatase**. We present examples of all four in later chapters.

But there is a price to be paid for having flexible macromolecules. The cost is that the shapes of such molecules can be disturbed by changes in common environmental factors. Temperature, for example, can disrupt weak bonds so that proteins lose their three-dimensional conformation, which is essential for their function. Similarly, inorganic ions can bind to charged side chains of amino acids, disrupting their weak bond interactions. *Thus, one of the major forces in the evolution of homeostasis*—the process of maintaining a consistent interior environment (for example, in pH level or salt content)—*has been the provision of an optimal environment for the functioning of macromolecules.*

Archaeal and bacterial cells have a simpler organization than eukaryotic cells

The two prokaryotic cell types, Archaea and Bacteria, have an outer plasma membrane but do not contain a separate nucleus or (for the most part) other organelles per se. The prokaryotic cytoplasm is the site where the cell converts energy and synthesizes the molecules necessary for cell

TABLE 2-1 Summary of Cytoplasm Components

Cytoplasm Component	Structure	Function
MEMBRANOUS ORGANELLES		
Endoplasmic Reticulum	Extensive, continuous membranous network of fluid-filled tubules and flattened sacs, partially studded with ribosomes	Forms new cell membrane and other cell components and manufactures products for secretion
Golgi Complex	Sets of stacked, flattened membranous sacs	Modifies, packages, and distributes newly synthesized proteins
Lysosomes	Membranous sacs containing hydrolytic enzymes	Serve as cell's digestive system, destroying foreign substances and cellular debris
Peroxisomes	Membranous sacs containing oxidative enzymes	Perform detoxification activities
Mitochondria	Rod- or oval-shaped bodies enclosed by two membranes, with the inner membrane folded into cristae that project into an interior matrix	Act as energy organelles; major site of ATP production; contain enzymes for citric acid cycle, proteins of electron transport system, and ATP synthase
NONMEMBRANOUS ORGANELLES		
Ribosomes	Granules of RNA and proteins—some attached to rough ER, some free in cytosol	Serve as workbenches for protein synthesis
Proteasomes	Tunnel-like protein complexes	Serve to break down unwanted proteins
Vaults	Shaped like hollow octagonal barrels	Serve as cellular trucks for transport from nucleus to cytoplasm
Centrosome/ Centrioles	A pair of cylindrical structures at right angles to each other (centrioles) surrounded by an amorphous mass	Form and organize the microtubule cytoskeleton
CYTOSOL		
Intermediary Metabolism Enzymes	Dispersed within the cytosol	Facilitate intracellular reactions involving degradation, synthesis, and transformation of small organic molecules
Transport, Secretory, and Endocytic Vesicles	Transiently formed, membrane-enclosed products synthesized within or engulfed by the cell	Transport and/or store products being moved within, out of, or into the cell, respectively
Inclusions	Glycogen granules, fat droplets	Store excess nutrients
Cytoskeleton		As an integrated whole, serves as the cell's "bone and muscle"
Microtubules	Long, slender, hollow tubes composed of tubulin molecules	Maintain asymmetric cell shapes and coordinate complex cell movements, specifically serving as highways for transport of secretory vesicles within cell, serving as main structural and functional component of cilia and flagella, and forming mitotic spindle during cell division
Microfilaments	Intertwined helical chains of actin molecules; microfilaments composed of myosin molecules also present in muscle cells	Play a vital role in various cellular contractile systems, including muscle contraction and amoeboid movement; serve as a mechanical stiffener for microvilli
Intermediate Filaments	Irregular, threadlike proteins	Help resist mechanical stress

growth and function. Even though there is no distinct nucleus, prokaryotes have a distinct nuclear area with a single, circular chromosome. Given these similarities, why are Archaea and Bacteria now separated into their own domains,

with some biologists even calling for the abolishment of the term *prokaryote*?

In fact, though looking similar in the microscope, Archaea and Bacteria differ significantly in many fundamental

FIGURE 2-2 Diagram of cell structures visible under an electron microscope.

© Cengage Learning, 2013

ways, such as in their genetic sequences, mechanisms of gene regulation, and cell-wall components, with some archaeal features being more closely related to eukaryotic ones than to bacterial ones. In terms of importance for animal physiology, true bacteria include many of the familiar pathogens that cause animal diseases (but note there are even more species that are not pathogenic). Archaea, though they have now been found in most habitats on Earth, were originally noted for their ability to colonize extreme environments, such as hot springs and highly saline lakes, and to exhibit unusual metabolisms as well. Though Archaea are not known to cause animal diseases, one group of particular importance is the *methanogens*, methane-producing Archaea that populate digestive tracts of many animals (see Chapter 14) as well as low-oxygen sediments of aquatic habitats.

Interestingly, some bacteria (not Archaea) do possess one membrane-bound organelle—called the *acidocalcisome*—that resembles a lysosome (p. 44) and plays an important role in osmoregulation, and which has been found in many eukaryotes as well. Its ancestral role is believed to be linked to its ability to store cations and phosphate, with cation and pH homeostasis derived following the divergence of prokaryotes and eukaryotes.

Eukaryotic cells are subdivided into the plasma membrane, nucleus, and cytoplasm

Eukaryotes are all based on a complex cell type with a plasma membrane and a distinct *nucleus* and other organelles in the cytoplasm's **cytosol**, a complex, semigelatinous watery mass filling the cell interior. Table 2-1 summarizes the main division of a eukaryotic cell and the functions of the major components. Nearly all eukaryotic cells contain five main types of **membranous organelles**—the *endoplasmic reticulum*, *Golgi complex*, *lysosomes*, *peroxisomes*, and *mitochondria* (Figure 2-2; Table 2-1). These organelles are similar in all eukaryotic cells, although there are some variations depending on the specialized capabilities of each cell type. Organelles increase the efficiency of metabolism (especially in cells larger than bacteria) by acting as scaffolds for macromolecules (such as enzymes) participating together in a series of reactions, and by serving as intracellular “specialty shops.” Each contains a specific set of chemicals for carrying out a particular cell function. This compartmentalization is evolutionarily advantageous because it permits chemical activities that would not be compatible with each other to occur simultaneously within the cell. For example,

the enzymes that destroy unwanted proteins in the cell do so within the protective confines of the lysosomes without the risk of destroying essential cell proteins. About half of the total cell volume is occupied by organelles.

The cytosol also contains many small molecules, proteins such as enzymes, and critical large **nonmembranous organelles**: *ribosomes*, *proteasomes*, *vaults*, and several types of *cytoskeleton*—filamentous proteins that control cell shape and movements (Figure 2-2; Table 2-1). We discuss these later. Many fundamental metabolic chemical reactions take place in the cytosol. The cytoskeletal network, which elaborately laces the cytosol, gives the eukaryotic cell its shape, provides for its internal organization, and regulates its movements (as you'll see).

The nucleus, which is typically the largest single organized cell component, can be seen under magnification as a distinct spherical or oval structure, usually located near the center of the cell. Surrounding it is a double-layered membrane with many pores, which separates the nucleus from the remainder of the cell. Sequestered within the nucleus is the cell's genetic material, which we discuss in the next section.

Evidence shows that the eukaryotic cell evolved from a *symbiosis* (two different species living intimately together) between two or more prokaryotic cell types. Mitochondria and chloroplasts (organelles for photosynthesis in plants and algae) are descended from free-living bacterial ancestors that took up residence in a larger host cell, possibly an archaeal cell. This idea was first hypothesized by the Russian biologist Konstantin Mereschowsky in 1905, but it was the American biologist Lynn Margulis who assembled the overwhelmingly convincing evidence in the 1960s. Among the most telling pieces of evidence are the occurrence of bacterial-type ribosomes (complexes that synthesize proteins that we examine later) and genes (the units of inheritance to which we turn our attention next) in bacterial-like chromosomes (strands of genetic material) inside chloroplasts and mitochondria.

Let's now examine each of the eukaryotic components in more detail.

check your understanding 2.1

What are a eukaryotic cell's three major subdivisions?

Why is it important for macromolecular cellular structures to be flexible? Provide an example.

2.2 Nucleus, Chromosomes, and Genes

The **nucleus** of eukaryotic cells (as well as the cytosol of prokaryotic cells) contains the materials for genetic instructions and inheritance. The key molecule is the double helix formed by DNA, which is packaged with proteins called *histones* in the nucleus to form complexes called **chromosomes**. DNA has two important functions: providing a code of information for RNA and protein synthesis and serving as a genetic blueprint during cell replication (for genetic inheritance). By coding for the kinds and amounts of various enzymes and other proteins that are produced, the nucleus indirectly governs most cell activities and serves as the cell's

control center. Information critical to animal physiology is summarized here (Figure 2-3).

DNA contains codes in the form of genes for making RNAs and proteins through the processes of transcription and translation

Recall that DNA is constructed from the four nucleotide bases A, G, T, and C. Because these bases exhibit complementary binding—that is, they bind to each other in pairs of A to T, G to C—the double helix of DNA serves as a genetic blueprint during cell replication to ensure that the cell produces additional cells just like itself, thus continuing the identical type of cell line within the body. Furthermore, in the reproductive cells, the DNA blueprint passes on genetic characteristics to future generations.

As with amino acids in proteins, the sequence of A, G, T, and C can vary to form countless codes, or “instructions.” An individual coding sequence, along with regulatory codes that we discuss shortly, is called a *gene*. Within any single species, there may be tens of thousands of genes; and the variations that occur among all species on Earth are limitless. This is analogous to using the relatively few letters of an alphabet to make unlimited numbers of sentences. Gene codes ultimately direct the synthesis of specific RNA and proteins within the cell. First, in the process of **transcription**, the gene (DNA strand that codes for a particular protein) is *transcribed* (copied) into a **pre-messenger RNA** molecule (pre-mRNA) by an enzyme called *RNA polymerase*. This pre-mRNA is a complementary copy of the gene that contains the coding sequences (called *exons*) and noncoding sequences (*introns*). The pre-messenger RNA in turn is processed into a final **messenger RNA** (mRNA) by removal of the dispersed introns and ligation of the exons, a process called **mRNA splicing**. This step is followed by the addition of noncoding signal sequences to the leading and trailing ends of the molecule. The mature mRNA can now exit the nucleus through its membrane pores. Within the cytoplasm in the process called **translation**, mRNA delivers the coded message to a *ribosome* (a “factory” made of protein and **ribosomal RNA**, or **rRNA**; p. 38), which “reads” the mRNA code in order to translate it into the appropriate amino acid sequence for the designated protein being synthesized. Finally, **transfer RNA** (tRNA) transfers the appropriate amino acids from the cytoplasm to the ribosome to be added to the protein under construction (Figure 2-3). (Note that rRNA and tRNA are themselves the products of gene transcription; thus, not all genes code for mRNAs.)

Different genes are expressed in different tissues and organs

Because each cell in a multicellular eukaryote usually has identical DNA sequences, you might assume that all cells would produce the same proteins. This is not the case, however, because—in addition to common or “housekeeping” functions that all cells require—different cell types transcribe different sets of genes and thus synthesize different proteins for their specialized roles. For example, all mammalian cells contain the genes for hemoglobin proteins—which serve to bind and carry oxygen—but these genes are only *expressed* (that is, transcribed and translated to produce proteins) in erythrocytes (red blood cells). In addition,

FIGURE 2-3 Summary of the flow of genetic information from DNA to proteins in eukaryotic cells. The DNA is transcribed into RNA in the nucleus; RNA is translated in the cytoplasm. Prokaryotic cells do not have a nucleus; transcription and translation proceed in their cytoplasm.

© Cengage Learning, 2013

many genes are active only under certain conditions or life stages. For example, many genes involved in animal sexual maturation are inactive in pre-adults.

How is this **differential gene expression** accomplished? There appear to be two levels of control:

1. *Regulation of individual genes with promoters and transcription factors.* A complete gene does not just consist of a code for an RNA strand (also known as the open reading frame), but also has regulatory DNA sequences called **promoters** that help regulate the gene's expression (Figure 2-4a). Special regulatory proteins—themselves the products of other genes—control the process by regulating the packaging of the DNA and the action of RNA polymerase. One DNA sequence, the *TATA box* (so called because it contains the nucleotide sequence TATAA), must be bound by proteins forming a *basal transcription complex* (Figure 2-4b), which recognizes the promoter code and then activates RNA polymerase to make the pre-mRNA copy of the nearby protein-coding sequences. However, this does not provide specificity for different cell types, because these general factors are often the same for numerous genes in numerous cell types. Other promoter sequences, often called **enhancers**, typically must be activated first. In one
2. *Regulation of transcription factors in different tissues and at different stages.* Through the process of cell differentiation in embryonic development, each specialized cell type expresses its own set of genes for specific transcription factors. The transcription factors in turn activate genes for organ-specific proteins and thus yield specialized cell functions. However, this process does not work just in embryos. Gene expression is constantly being altered in adult animals by various metabolic factors and signaling molecules. Enhancers are also called **response elements** if they respond (via specific transcription factors) to metabolic factors and signal molecules such as hormones. As we discuss later, many hormones exert their effects by controlling specific transcription factors that control gene expression through response elements (Figure 2-4b).

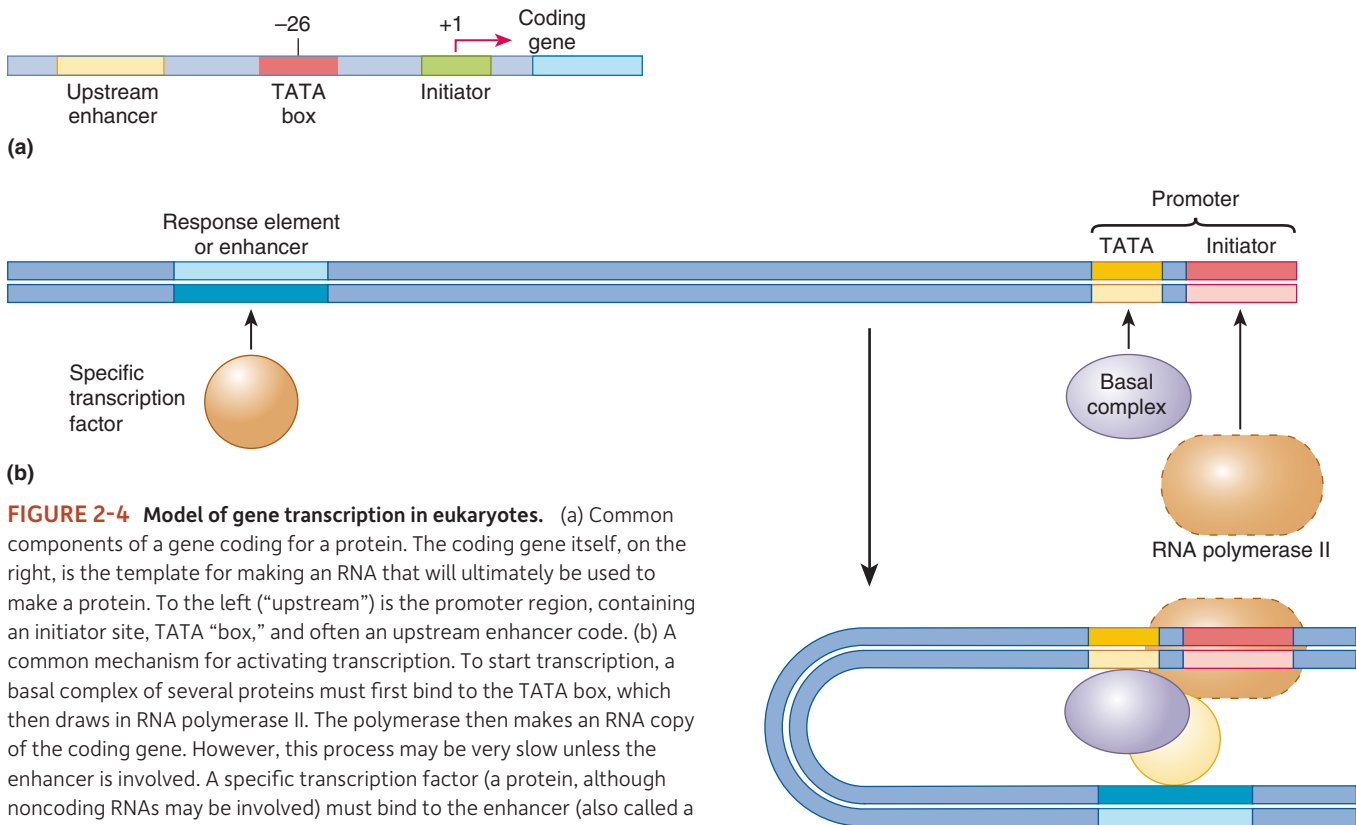

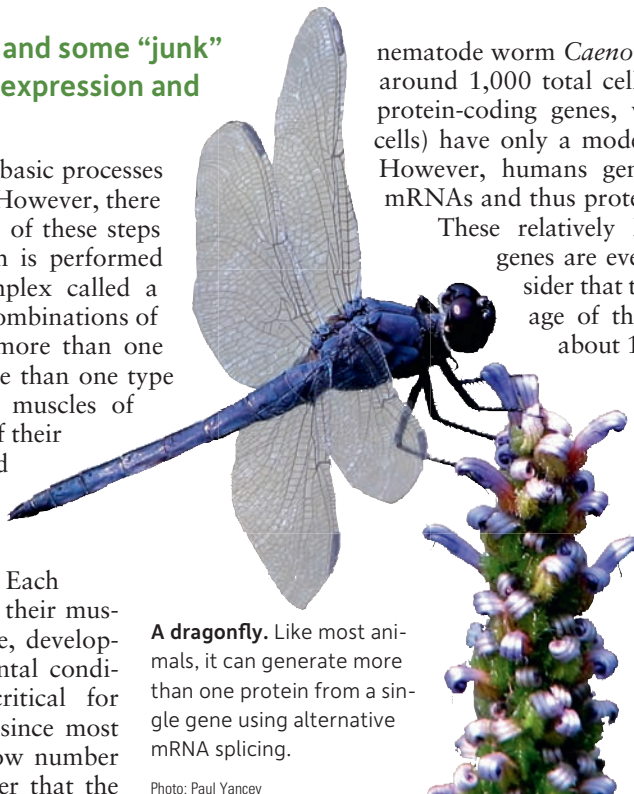

FIGURE 2-4 Model of gene transcription in eukaryotes. (a) Common components of a gene coding for a protein. The coding gene itself, on the right, is the template for making an RNA that will ultimately be used to make a protein. To the left (“upstream”) is the promoter region, containing an initiator site, TATA “box,” and often an upstream enhancer code. (b) A common mechanism for activating transcription. To start transcription, a basal complex of several proteins must first bind to the TATA box, which then draws in RNA polymerase II. The polymerase then makes an RNA copy of the coding gene. However, this process may be very slow unless the enhancer is involved. A specific transcription factor (a protein, although noncoding RNAs may be involved) must bind to the enhancer (also called a response element if the transcription factor is activated by metabolic or hormonal signals). This causes looping of the DNA to bring the specific factor-enhancer complex in alignment with the basal promoter complex. This can greatly enhance the rate of transcription.

© Cengage Learning, 2013

Alternative splicing of RNA and some “junk” DNA are important in gene expression and evolution

These steps above constitute the basic processes of transcription and translation. However, there is a very important modification of these steps called **alternative splicing**, which is performed by a special RNA–protein complex called a **spliceosome**. By using different combinations of exons, spliceosomes can make more than one mRNA code and so lead to more than one type of protein. For example, flight muscles of dragonflies (which spend much of their lives flying to hunt, fight, and mate) can make six different forms from one gene of a contraction-regulating protein called *troponin* (Chapter 8). Each form may help them acclimatize their muscles to a different behavioral use, developmental stage, and/or environmental condition. Alternative splicing is critical for generating many protein forms since most organisms have a surprisingly low number of protein-coding genes. Consider that the

A dragonfly. Like most animals, it can generate more than one protein from a single gene using alternative mRNA splicing.

Photo: Paul Yancey

nematode worm *Caenorhabditis elegans* (which has only around 1,000 total cells in its body) has about 19,000 protein-coding genes, while humans (with trillions of cells) have only a modest amount more, about 25,000. However, humans generate a far greater number of mRNAs and thus proteins than do the worms.

These relatively low numbers of protein-coding genes are even more surprising when we consider that they make up only a small percentage of the total DNA, for example, only about 1.5% in humans. The rest has long been called “junk” DNA because it had been thought to be largely useless. Some probably is; however, unlike protein-coding genes, the amount of non-protein-coding DNA does roughly correlate with organismal complexity, suggesting important roles that are now being discovered. As an example, consider two species of North American voles that differ dramatically in their behaviors in part due to “junk” DNA differences. Prairie voles are socially monogamous

while meadow voles are promiscuous. The former have many more *receptors* (cell membrane proteins that bind external signal molecules, p. 93) for a major hormone in brain areas regulating social interactions than do the latter. Remarkably, the difference is in part due to a longer stretch of noncoding DNA in the promoter region of the prairie vole's gene, which somehow increases the gene's expression. The "junk" DNA's role was tested by engineering (p. 34) prairie voles with a shorter stretch; they behaved monogamously like meadow voles! This suggests major behavioral differences could evolve from very simple genetic changes.

In addition, some introns and other noncoding RNAs become *microRNAs* (miRNAs) and *small interfering RNAs* (siRNA), classes of RNAs that regulate gene expression by guiding mRNA splicing, or—in a process called **RNA interference** or **RNAi**—by binding to mRNAs to inhibit their translation (e.g., during development or viral invasion). As an example, researchers have found that one particular miRNA decreases rapidly when a zebra finch learns a new song. Presumably, this reduction allows certain genes involved in song memory to be expressed.

Finally, a striking study in 2010 of "junk" DNA usefulness reported that *pseudogenes* (nonfunctioning protein-coding genes that were probably active in an organism's ancestors) can make untranslated mRNAs that bind with interfering miRNAs, which would otherwise have inhibited translation of mRNA from a "good" gene similar to the pseudogene. This may be a new type of gene regulation, though its importance is not yet known.

Telomeres protect chromosome ends, and their loss is associated with aging

Eukaryotic chromosomes are linear, and researchers have found that the ends lose segments of DNA every time a chromosome is replicated during cell division. To prevent loss of coding genes, the chromosomes have stretches of repeated, noncoding DNA sequences called *telomeres*. Each time a cell divides, a piece of telomere is lost, but presumably no harm is done because the lost DNA nucleotide sequences contain no genes. However, that changes once the telomeres are gone. At that point, useful genes begin to be lost during cell replication, causing cell malfunctions, and in fact, most cells cease dividing. Scientists have found that this feature of chromosome structure, which sets an upper limit on the number of times a cell can divide, correlates with the aging of individuals. Indeed, researchers have found a linear correlation between the length of telomere lost per year and the lifespan of five species of birds and eight species of mammals. For example, zebra finches lose about 500 nucleotides of telomere each year and live for about 5 years. Common terns, in contrast, lose only about 50 nucleotides per year and live for about 26 years. These rates vary among individuals within a species, and another study on tree swallows found that 1-year-olds with short telomeres had lower survival than 1-year-olds with longer telomeres.

The rate of telomere loss is not random or uncontrollable: Telomeres can be repaired by an enzyme called *telomerase*. For reasons not fully understood, the rate of telomere repair, and thus presumably the longevity of species, varies widely among organisms and is subject to natural selection. One possibility that limits the evolution of higher repair rates in short-lived species is cancer. Researchers have found that

high telomerase activity does increase the number of times a cell can divide but also correlates with a greater chance of that cell becoming cancerous, that is, repeatedly dividing without stopping and thus forming a tumor.

check your understanding 2.2

What are the basic processes of transcription?

How is differential gene expression accomplished?

How is gene expression regulated?

2.3 Methodology

Many molecular processes we have just discussed are used throughout this text. Because this is the most rapidly growing area of biology, it is useful to understand how molecular knowledge is acquired. Here we introduce some of the major molecular techniques mentioned later in the text.

Driving much of the growth in knowledge about molecular biology are the *genome projects*. In the last years of the 20th century, scientists undertook an international effort to decipher the complete human genetic sequence—the arrangement of the A, G, T, and C nucleotides. Dubbed the Human Genome Project, its goal was to yield insight into the codes responsible for human genetics, development, physiological functions, evolution, and diseases. At about the same time, researchers initiated genome projects for various microbes (some of which were the first to be completed), some plants, and several other animal species. Since then, many species including protistan and fungal ones have been added to the list. The deciphering of genomes is often an example of the discovery phase of science (p. 6). For example, recently the first amphibian genome (in the Western clawed frog) was deciphered, and a large (150 million nucleotide) sequence was found that is virtually identical in chickens and humans. Genome analysis also can result in, and be used to test, new hypotheses about evolution and genes. See the box, *Molecular Biology and Genomics: Genomics and Evolution*.

Although the wealth of genome data available is enormous and growing daily, that does not mean we are close to achieving a genetic understanding of physiology. The role of any individual gene in an organism's physiology is sometimes readily apparent—think of hemoglobin genes, for example, which code for the proteins that carry oxygen in blood—but often it is not. Many genes being discovered by genome analysis have functions that are either speculative or fully unknown, and many proteins have been found that are similarly mysterious. Because of the enormous complexity and intricacy of cellular pathways, it clearly will be many decades before scientists know what each and every gene does, how each evolved, how each is regulated throughout an organism's life cycle, and how each and its products interact with other genes. Uncovering gene functions is the goal of the new field of *genomics*, which uses a variety of new technologies to reveal the connections between genes and cell (or organismal) function. A companion field, *proteomics* (also called *proteonomics*), is focused on discovering the functions of proteins.

In later chapters, we describe some of the recent findings of genomics and proteomics. Next we briefly describe some of the key methods being used.

Molecular Biology and Genomics

Genomics and Evolution

Genomic data have yielded many exciting findings important for understanding animal physiology and its evolution. Evolutionary change is primarily based on changes—mutations—in the DNA code that increase the fitness of the organism. Mutations have been the subject of genetic analysis for more than 100 years, yielding many important discoveries about the evolution of new features via changes in genetic codes. The new technologies have enormously increased the pace of discovery. For example, the traditional view holds that DNA mutates randomly. But genome analysis is revealing that some organisms have stretches of DNA that mutate at extraordinarily high rates, resulting in apparently useful evolutionary diversity. One example has been found in an interesting group of tropical mollusks, the predatory cone snails. Not only do these snails have colorful shells prized by collectors around the world, they also possess venomous proteins—*conotoxins*—that are used to paralyze prey fish, shrimp, and other mollusks (the venom blocks ion channels, described in Chapter 4). A conotoxin is being used medically, for example, to deaden

nerves in people suffering from chronic pain. Each of the 500 species of cone snails has a unique set of genes coding for unique conotoxins. Analysis reveals that sections of the venom genes have mutated at rates far faster than the rest of the snail genome. The causes of this rapid mutation are uncertain but have played a role in the evolutionary diversity of cone snail species and their predatory physiologies.

This type of “deliberate” rapid mutation in a selective section of DNA is called **focused variation**. It may be a widespread phenomenon, thought to occur in the evolution of snake and scorpion venom, for example. It probably occurs in the evolution of parasite antigens (proteins on the surface that an animal’s immune system recognizes as foreign), allowing some parasites to evade host immune defenses previously induced against them.

Genomics is also revealing the importance of **horizontal gene transfer** in evolution. This so-called *jumping gene* phenomenon—which can result from viral infection and other mechanisms we’ll not describe—is the permanent insertion of a gene from one species into the genome of another.

The cone shell, *Conus textile*.

This occurs frequently in microbes; for example, some bacteria can gain antibiotic-resistance genes from other bacteria (even other species) that evolved them. But evidence for this phenomenon has also been found in eukaryotic genomes as well (as you will see later for mitochondrial genes). Perhaps the most dramatic is an animal genome with photosynthetic genes! Many cells of the seaslug *Elysia chlorotica* have photosynthetic organelles called *chloroplasts*, which the slug obtains from eating algae and which produce sugars for the animal using solar energy. Recently, researchers found that the slug’s genome has permanently obtained the genes for synthesizing *chlorophyll*, the algal and plant compound responsible for capturing the sun’s energy.

Immunofluorescence An important technique that predates modern genomics and proteomics, but that is used widely in conjunction with them, is **immunofluorescence**. This method relies on the ability of mammals and birds to generate specific antibodies (immune proteins; Chapter 10) that bind to foreign proteins entering their bodies. A target protein of interest in species A is purified and injected into species B, typically a laboratory rabbit. The rabbit’s immune system makes antibodies to the protein. The antibodies are purified, and a fluorescent molecule is covalently bound to each. The new fluorescent antibody is then injected into species A, or added to a solution bathing a tissue slice from species A. The antibody binds only to places where the target protein occurs, and the fluorescent molecule allows the researchers to visualize its locations through a microscope (Figure 2-5). In this way, proteins of known functions, and “new” proteins discovered by proteomics, can be located in specific tissues and at specific developmental stages of a particular species.

Gene Knockout, Knock-In, and RNA Interference One way to elucidate gene functions is to block the function of a gene and then study resulting defects (if any) in the animal’s structures and/or physiology to gain clues about gene (and protein) function. A commonly used approach is the **knock-out method**, in which a laboratory animal is raised from a

FIGURE 2-5 Immunofluorescence. Immunofluorescent light micrograph of a section through a kangaroo rat kidney epithelial cell during mitosis (cell division). Antibodies have been used to attach fluorescent dyes to specific cell structures. The nuclear membrane (not seen) that encloses the chromosomes (blue) is breaking down. The actin microfilaments (red) and tubulin microtubules (green) of the cytoskeleton maintain the structure of the cell. The two centrioles (pink dots, upper left and lower right) are microtubule-organizing centers.

(a)

FIGURE 2-6 DNA Microarrays. (a) A microarray chip. Thousands of DNA samples are placed on a 1-cm-square slide by robotics. These slides are then bound by complementary DNA or RNA and visualized using fluorescent markers. The location and intensity of the fluorescent signal is analyzed by computer to establish which genes are currently being transcribed and to what extent. (b) A DNA microarray from DNA of a carp, hybridized with liver cDNAs from control animals (labeled green) and from animals subjected to cold temperatures (red). Yellow spots indicate genes with expressions equal in the two groups; green spots are genes expressed more strongly in control animals; and red spots are those expressed more strongly in cooled animals.

(b)

fertilized egg that has had a specific gene disrupted. In the opposite approach, **knock-in**, genes are inserted into specific locations. Results of such experiments can be surprising. For example, researchers in Korea knocked out in mice the gene for an enzyme that adds the sugar fucose (a hexose sugar) to proteins. The result was female mice that act like males! Apparently a key protein that regulates masculinizing hormones in fetuses could not work without fucose attached. These methods are not always useful, however, if a knock-out yields aborted development or widespread aberrations. An analogy is studying an automobile's internal workings by selectively removing instructions in a robotic factory for assembling key components—components you know little about as you begin. If you mutate an unknown instruction yielding a car that will not start and leaks fuel from a loose tube between fuel tank and engine, you would conclude the instructions were for attaching the tube. But if another mutated instruction leads to no car but just a pile of its parts, conclusions would be trickier. Was the instruction a master command to activate the assembly robots? Or just for setting up the initial framework of the car? Or perhaps for how to use bolts, rivets, and welds? Similarly, knockout changes in cells that are lethal in early development can be hard to interpret. Nevertheless, there have been other useful knock-outs that you will see in later chapters.

Another gene-suppression method uses RNA interference (p. 33). Artificially synthesized interfering RNAs are used as a tool to inhibit specific mRNA translation in cells,

both to investigate the roles of that messenger and its protein and to inhibit disease processes.

DNA Microarrays Another powerful new technology is called the **DNA microarray**, or colloquially, the “gene chip.” In its basic form, a gene chip is a small plate (membrane or glass slide) onto which thousands of different genes from an organism are bound. This technique takes advantage of the fact that DNA and RNA sequences can bind in complementary fashion to one another. RNA from a particular organ is isolated and converted into corresponding *complementary DNA* (called *cDNAs*). The cDNA is labeled with a fluorescent molecule or radioactive atoms and used as a “probe”: The cDNAs are exposed to the chip, and any genes active in that organ are revealed by the binding of the cDNA to the genes bound to the plate. Different levels of fluorescent intensities indicate the relative activities (or expression) of these genes. In this way, researchers can determine what genes are active at any given time in a life cycle, and during stress conditions and disease (Figure 2-6). Much of microarray research is “discovery science” (p. 6) in that gene

FIGURE 2-7 Gene therapy and transgenics. (a) Gene therapy in bone marrow cells. A cloned gene that directs the synthesis of a missing protein is introduced into bone marrow cells from the mouse. The transformed cells are replaced in the mouse's body, where they produce the desired protein. (b) The procedure for producing transgenic mammals. The two mice on the bottom have not received new genes. The mouse on the top has received a new gene, which it can pass on to its offspring. The mouse on the top is a transgenic organism, and the altered gene is a transgene.

expression patterns are often conducted without a detailed hypothesis, but data for devising new hypotheses can arise from this exploration.

Databases Genomics also relies heavily on the fact that all life is related via evolution. Thus, the nucleotide sequences of related genes in different organisms are similar. Analysis based on this principle makes extensive use of computers and the Internet, which provide access to databases containing most sequenced genes to date. There are at least two important ways to use these data. First, if a gene is discovered that has an unknown function, its sequence can be compared to all related genes in all analyzed species. This

should give a clue to the “new” gene’s function because some of the related genes in the database are likely to have known functions. Second, the sequence of a gene with a known function can be used to look for similar (undiscovered) genes in the genome databases. In this way, previously unsuspected genes (and possibly proteins) can be found in other tissues in the same organisms, or in other species.

Gene Therapy and Transgenics The ultimate goal of genomics is to understand genes so that they can be used in practical ways. An increasingly important application is that of **gene therapy**, in which a defect arising from a mutated gene is corrected by inserting a normal gene (Figure 2-7a). This can

be done in a fertilized egg, or in an adult tissue. For example, researchers found that one form of canine blindness—*Leber congenital amaurosis*—can arise from a single defective gene that codes for a protein called RPE65. This protein helps synthesize a pigment used by the retina to receive light. Researchers created a modified nonpathological virus carrying a normal RPE65 gene and injected it into the right retina of blind dogs (the left retina received a control injection). Amazingly, the dogs regained some visual function and could navigate around obstacles that they had formerly bumped into repeatedly in a dimly lit room. Testing of this gene therapy on blind humans began in 2008, with some success. In 2010, the vision of mice with *retinitis pigmentosa* blindness was improved with a new nonviral form of DNA delivery called *compacted DNA nanoparticles*, in which a single gene of therapeutic value is compacted into a small polymer rod small enough to enter nuclear pores.

The technology used in gene therapy can also be used to create **transgenic** animals (Figure 2-7b). Here, a gene from one species is inserted into a fertilized egg or adult tissue of another (though unlike the knock-in method, insertion is not designed to be at a specific site). This may confer commercially useful properties into an agricultural animal; for example, sheep have been created that carry genes for human proteins with medical uses. The sheep produce milk containing these human proteins. Also, mosquitoes have been engineered to make proteins that block malarial parasites from entering their circulatory fluids, which may help slow the spread of malaria to humans. The process may also be used to create markers or tracers of gene activity for basic research. In 2000, the first transgenic primate—a rhesus monkey named ANDi—was created, with a jellyfish gene that produces *green fluorescent protein (GFP)*, a protein for bioluminescence. This gene, when attached to a host species' gene, provides a visual marker of that gene's activity in different organs and stages (see Immunofluorescence, p. 34).

Cloning Finally, another technology based on the nucleus is that of **whole-animal cloning**. Because most adult cells contain the same DNA sequences on chromosomes throughout an organism's life cycle, the adult DNA, in theory, can code for a genetically identical offspring—a clone. In one common method of cloning called *nuclear transplantation*, the nucleus of a fertilized egg is removed or destroyed, and a carefully selected nucleus from an adult cell is injected in its place. Poorly understood factors synthesized within the egg somehow rewind the internal clock of the adult genetic material and restore it to the *pluripotent* state. When the adult DNA is exposed to the proper signals (such as specific transcription factors), the genetic program initiates the development of a new animal (Figure 2-8). Frogs were cloned in this manner in the 1960s, but only in the late 1990s was a mammal—a sheep named Dolly, in Scotland—produced by cloning. Since then, many other mammals have been cloned, including rodents, cows, goats, cats, a mule, and a horse. Strains of medically and agriculturally useful animals might be maintained by cloning. In addition, this technology might be used to save endangered species. However, it is not clear how successful the process will be in the long run. Many of the cloned mammals have shown signs of premature aging, probably because they developed from adult DNA that had suffered damage (e.g., to telomeres) during the parent's life. In addition to the physiological problems, the use of this and

FIGURE 2-8 Nuclear-transplantation techniques in mammals. The genetic material is removed from the recipient cell (an egg), and then replaced by a nucleus from a donor cell. The resulting embryo is then transferred to a surrogate mother. The clones are genetically identical to the donor.

other genetic technologies remains fraught with ethical dilemmas. See *Unanswered Questions: Are cloning and genetic engineering ethical?*

Note that cloning is not simply an artificial technique. Basic cell division is a form of cloning. Many multicellular organisms, including many "primitive" animals, reproduce by cloning (although not by nuclear transplantation). Adult sea anemones and corals (Cnidarians), for example, can split in two to produce two genetically identical individuals (see Chapter 16, Reproduction).

Cloning is not the only procedure that is capable of reprogramming the DNA of an adult animal into an embryonic

state. Let's look at another procedure that likewise can generate embryonic cells.

unanswered Questions | Are cloning and genetic engineering ethical?

As we have noted, the fields of genomics and proteomics have far more questions than answers. In addition, the techniques involved raise serious bioethical questions for human society. What are the ethical pros and cons in cloning animals or creating transgenic animals? <<

Reprogramming Differentiated Cells into Pluripotent Cells Certainly we think of cellular aging as irreversible: Tissue aging can be accelerated by diabetes and dramatically slowed by severe caloric restriction, but reversal of aging is a concept more suitable for science fiction. Or is it? In 2006, Shinya Yamanaka of the University of Kyoto created what are now termed **induced pluripotent stem cells (iPSCs)**. Normally mammalian development is a one-way street; embryonic stem cells become progressively more *differentiated* or specialized with time. There is only a comparatively brief window during development where every cell possesses the ability to differentiate into any adult cell. **Pluripotency** describes the ability of an embryonic stem cell to become any cell type found in the adult animal. In the adult, all that remains of these precursor cells are the stem cells that continuously replenish the mature cells within a tissue. For example, skin stem cells develop into an animal's hair and skin while blood stem cells continuously regenerate the various blood cell types. The novelty of Yamanaka's research arises from the observation that adult cells can be rejuvenated by introducing various genes that are normally active during the embryonic stage of development. It remains to be determined why the expression of embryonic genes in an adult cell reprograms that adult cell into an embryo-like state, including restoration of the telomere caps that protect the ends of the chromosomes. By using *retroviruses* as delivery vehicles, the embryonic "reprogramming" genes can be transferred into the host cell genome. More recent studies have demonstrated that the production of iPSCs requires the retrovirus carrier to transport genetic material from as few as two of the original two dozen reprogramming embryonic genes or more simply by introducing the proteins encoded by four of the reprogramming genes directly into the cell.

At the present time, about a dozen different adult cell types from four different species (mouse, rat, monkey, and human) have been successfully reprogrammed into iPSCs. Ultimately, the objective of researchers is to produce iPSCs without using viruses as carriers, which reduces the cancer risk, and instead expose adult cells to a cocktail of drugs that mimic the effect of the reprogramming genes. Consider the remarkable implications of this research: employing a comparatively simple procedure to use an animal's own iPSCs to produce replacement parts for cells and organs damaged by disease. In 2011, Roberto Bolli reported the ability of heart stem cells to repair heart tissue damaged after a heart attack. Within seven days after the infarct, the stem cells had infiltrated the entire region of the infarct resulting in a gradual improvement in cardiovascular function.

Now that we have examined some key techniques of molecular investigation, we will turn our attention to organelles, other molecular complexes, and metabolism. Recall that in addition to the nucleus, eukaryotic cells contain several other large structures, including other membrane-bound structures or organelles.

What are the potential uses of gene therapy?

How has the old dogma that the specialty of cells is irreversibly set once they have differentiated been challenged by the discovery of iPSCs?

How are the technological approaches of cloning and iPSCs similar to each other?

2.4 Ribosomes and Endoplasmic Reticulum

Ribosomes are ribosomal RNA-protein complexes that synthesize proteins, indirectly under the direction of nuclear DNA. Recall that mRNA carries the genetic message from the nucleus to the ribosome "workbench," where protein synthesis takes place (see Figure 2-2). Note that prokaryotes also have ribosomes, with a slightly different structure.

Ribosomes are found in two locations. Unattached or "free" ribosomes are dispersed throughout the cytosol. Bound ribosomes are found on membranes of a major organelle, the **endoplasmic reticulum (ER)**—an elaborate, fluid-filled membranous system distributed extensively throughout the cytosol, where it is primarily a protein-manufacturing factory. Two distinct types of ER—rough and smooth—can be distinguished. The **rough ER** consists of stacks of relatively flattened interconnected sacs, whereas the **smooth ER** is a meshwork of tiny interconnected tubules (Figure 2-9). Even though these two regions differ considerably in appearance and function, the ER is thought to be one continuous organelle with many interconnected channels. The relative amount of smooth and rough ER varies between cells, depending on the activity of the cell.

The rough endoplasmic reticulum and its ribosomes synthesize proteins for secretion and membrane construction

The outer surface of the rough ER is studded with ribosomes, giving it a "rough" or granular appearance. These ribosomes synthesize and release a variety of new proteins into the **ER lumen**, the fluid-filled space enclosed by the ER membrane. These proteins serve one of two purposes: (1) Some are destined for export to the cell's exterior as secretory products, such as proteinaceous hormones or enzymes. (2) Others are transported to sites within the cell for use in constructing new cell membrane (either new plasma or organelle membrane) or other protein components of organelles. Cell membranes consist mostly of lipids (fats) and proteins. The membranous wall of the ER also contains enzymes essential for the synthesis of nearly all the lipids

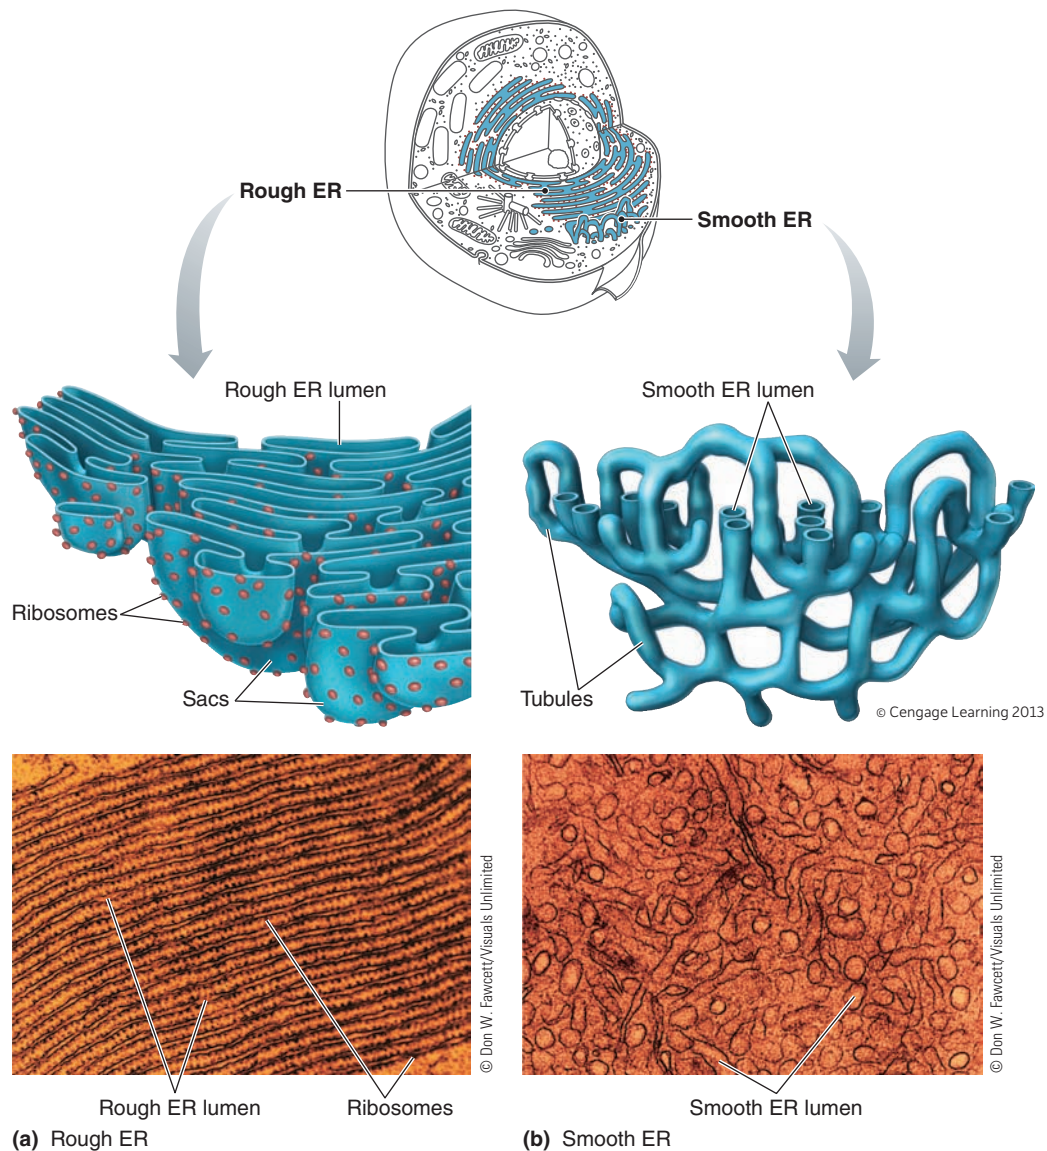

FIGURE 2-9 Endoplasmic reticulum (ER). (a) Diagram and electron micrograph of the rough ER, which consists of stacks of relatively flattened interconnected sacs studded with ribosomes. (b) Diagram and electron micrograph of the smooth ER, which is a meshwork of tiny interconnected tubules. The rough ER and smooth ER are connected, making one continuous organelle.

needed to produce new membranes. These newly synthesized lipids enter the ER lumen along with the proteins. Predictably, the rough ER is most abundant in cells specialized for protein secretion (for example, cells that secrete digestive enzymes) or in cells that require extensive membrane synthesis (for example, rapidly growing cells such as immature egg cells).

Within the ER lumen, a newly synthesized protein is folded into its final conformation and may also be modified in other ways, such as being pruned or having sugar molecules attached to it (*glycosylation*). After this processing, a new protein cannot pass out through the lumen of the ER membrane and therefore becomes permanently separated from the cytosol as soon as it has been synthesized. In contrast to the rough ER ribosomes, free ribosomes synthesize proteins that are used within the cytosol. In this way, newly

produced molecules that are destined for export out of the cell or for synthesis of new cell components (those synthesized by the ER) are physically separated from those that belong in the cytosol (those produced by the free ribosomes).

How do the newly synthesized molecules within the ER lumen get to their destinations at other sites inside the cell or to the outside of the cell? They do so through the action of the smooth endoplasmic reticulum.

The smooth endoplasmic reticulum packages new proteins in transport vesicles

The smooth ER does not synthesize proteins because it does not contain ribosomes; hence it is “smooth.” Instead, it serves a variety of other purposes that vary among cell types.

FIGURE 2-10 Overview of the secretion process for proteins synthesized by the endoplasmic reticulum.

Note that the secretory product never comes into contact with the cytosol.

© Cengage Learning, 2013

In most cells, the smooth ER is rather sparse and serves primarily as a central packaging and discharge site for molecules that are to be transported from the ER. Newly synthesized proteins and lipids pass from the rough ER to gather in the smooth ER. Portions of the smooth ER then “bud off” (that is, balloon outward, then are pinched off), forming **transport vesicles** that enclose the new molecules in a spherical capsule derived from the smooth ER membrane (Figure 2-10). (A **vesicle** is a fluid-filled, membrane-enclosed intracellular cargo container.) Newly synthesized membrane components are rapidly incorporated into the ER membrane itself to replace the membrane that was used to “wrap” the transport vesicle. Transport vesicles move to the Golgi complex for further processing of their cargo (discussed shortly).

In contrast to the sparseness of the smooth ER in most cells, some specialized types of cells have an extensive smooth ER, which confers additional cell functions as follows:

- The smooth ER is abundant in cells that specialize in lipid metabolism—for example, cells that secrete *steroid hormones* in arthropods and vertebrates (see Chapter 7). (A steroid is a special type of lipid derived from cholesterol.) The membranous wall of the smooth ER contains enzymes for synthesis of lipids. By themselves, lipid-producing enzymes in the rough ER membrane cannot carry out enough lipid synthesis to maintain adequate steroid-hormone secretion levels, so these cells have an expanded smooth-ER compartment to house the addi-

tional enzymes necessary to keep pace with demands for hormone secretion.

- In vertebrate liver cells, the smooth ER contains enzymes specialized for detoxifying toxic compounds produced within the body by the metabolism of substances that enter from the outside (such as drugs and plant toxins). These detoxification enzymes alter toxic substances so that the latter can be eliminated more readily via excretory organs. The amount of smooth ER available in liver cells for the task of detoxification can vary dramatically, depending on the need. For example, if phenobarbital (a barbiturate drug used as a sedative) is administered in large quantities to a mammal, the amount of smooth ER with its associated detoxification enzymes doubles within a few days (a form of *acclimatization* or *upregulation*, p. 17), only to return to normal within five days after drug administration ceases. The mechanisms involved in regulating these changes are not well understood.
- Muscle cells have evolved another specialized use for the smooth ER. They have an elaborate, modified smooth ER known as the *sarcoplasmic reticulum*, which stores calcium and plays an important role in muscle contraction (see Chapter 8).

check your understanding 2.4

Describe the structure of the endoplasmic reticulum, distinguishing between the rough and the smooth ER. What is the function of each?

2.5 Golgi Complex

Closely associated with the endoplasmic reticulum is the **Golgi complex**, which consists of sets of flattened, slightly curved, membrane-enclosed sacs, or *cisternae*, stacked in layers (see Figure 2-10). The sacs within each Golgi stack do not come into physical contact with one another. Note that the flattened sacs are thin in the middle but have dilated, or bulging, edges. The number of Golgi stacks varies, depending on the cell type. Some cells have only one stack, whereas cells highly specialized for protein secretion may have hundreds of stacks.

Transport vesicles carry their cargo to the Golgi complex for further processing

The majority of the newly synthesized molecules that have just budded off from the smooth ER enter a Golgi stack. When a transport vesicle carrying its newly synthesized cargo reaches a Golgi stack, the vesicle membrane fuses with the membrane of the sac closest to the center of the cell. The vesicle membrane opens up and becomes integrated into the Golgi membrane, and the contents of the vesicle are released to the interior of the sac (see Figure 2-10). (Note that vesicles are typically associated with cytoskeletal filaments, which are discussed later in this chapter.)

These newly synthesized raw materials continue to travel via vesicles through the layers of the Golgi stack, from the innermost sac closest to the ER to the outermost sac near the

plasma membrane. During this transit, two important inter-related functions take place:

1. *Processing the raw materials into finished products.* Within the Golgi complex, the “raw” proteins from the ER are modified into their final form, such as attaching carbohydrates. The biochemical pathways that the proteins undergo during their passage through the Golgi complex are elaborate, precisely programmed, and specific for each final product.
2. *Sorting and directing the finished products to their final destinations.* The Golgi complex is responsible for sorting and segregating different types of products according to their function and destination, namely, products (1) to be secreted to the cell’s exterior, (2) to be used for construction of new plasma membrane, or (3) to be incorporated into other organelles, especially lysosomes.

The Golgi complex packages secretory vesicles for release by exocytosis

How does the Golgi complex sort and direct finished proteins to the proper destinations inside and outside the cell? Finished products collect within the dilated edges of the Golgi complex’s sacs. The dilated edge of the outermost sac then pinches off to form a membrane-enclosed vesicle containing a selected product. For each type of product to read its appropriate site of function, each distinct type of vesicle takes up a specific product before budding off. Vesicles with their selected cargo destined for different sites are wrapped in membranes containing distinctly different surface proteins. Each type of surface protein serves as a specific **docking marker** (like an address on an envelope). A vesicle can “dock” and “unload” its selected cargo only at the appropriate **docking-marker acceptor**, a protein located only at the proper destination within the cell (like a house address). Thus, Golgi products reach their appropriate site of function because they are sorted and delivered like addressed envelopes containing particular pieces of mail being delivered only to the appropriate house addresses.

Specialized secretory cells include endocrine cells that secrete protein hormones and digestive gland cells that secrete digestive enzymes. In secretory cells, numerous large **secretory vesicles** (or granules), which contain proteins to be secreted, bud off from the Golgi stacks. Secretory vesicles, which are about 200 times larger than transport vesicles, store the secretory proteins until the cell is stimulated by a specific signal that indicates a need for release of that particular secretory product. On the appropriate signal, a vesicle moves to the cell’s periphery, fuses with the plasma membrane, and empties its contents to the outside (Figures 2-10 and 2-12a). This mechanism—releasing substances originating within the cell to the exterior—is called **exocytosis** (*exo*, “out of”; *cyto*, “cell”). Exocytosis is the primary mechanism for accomplishing secretion. Secretory vesicles fuse only with the plasma membrane and not with any of the internal membranes that enclose organelles, thereby preventing fruitless or even dangerous discharge of secretory products into the organelles.

Exocytosis can be an explosive event because vesicle contents are often ejected. The most extreme example may be in Cnidaria (anemones, coral, hydras, jellies, and so on). All Cnidaria sting prey by using epithelial cells with special

FIGURE 2-11 Nematocyst formation in Cnidaria. “C” indicates the capsule of the forming nematocyst, “G” is the Golgi complex, “rER” is the rough ER, “N” is the nucleus, “t” is tubule, “s” are stylets. © Cengage Learning, 2013

Golgi-derived vesicles called **nematocysts**, capsules each having a double-layered wall and an inverted tube studded with barbs (often with a toxin). On contact with prey, the capsule exocytoses the barbed tube, which inverts, exposing the spines and jabbing the prey (Figure 2-11). This exocytosis is one of the fastest biological actions known. It appears driven in part by *osmosis*, which we cover in the next chapter. (Briefly, water tends to move from dilute to concentrated solutions.) The capsule is full of cations and long amino-acid chains called *polyglutamate*, serving as *osmolytes* (see Chapter 13) that create a solution much more concentrated than the external environment. The rigid capsule prevents premature discharge. Prey contact triggers a lid on the capsule to open, and water rushes in by osmosis, inverting the tube.

Let's now look in more detail at how secretory vesicles take up specific products in the Golgi stacks for release into the ECF and why they are able to dock only at the plasma membrane (Figure 2-13).

- The newly finished proteins destined for secretion contain a unique sequence of amino acids known as a *sorting signal*, and the interior surface of the Golgi membrane contains *recognition markers*, proteins that

recognize and attract specific sorting signals. Recognition of the right protein's sorting signal by the complementary membrane marker ensures that the proper cargo is captured and packaged into the secretory vesicle.

- Coat proteins* called *coatomer* from the cytosol bind with another specific protein facing the outer surface of the membrane. The linking of these coat proteins causes the surface membrane of the Golgi sac to curve and form a dome-shaped bud around the captured cargo. Eventually, the surface membrane closes and pinches off the vesicle.
- After budding off, the vesicle sheds its coat proteins and exposes the docking markers, known as *v-SNAREs*, which face the outer surface of the vesicle membrane.
- A v-SNARE can only bind lock-and-key fashion with its docking marker acceptor, called a *t-SNARE*, on the targeted membrane. In the case of secretory vesicles, the targeted membrane is the plasma membrane, the designated site for secretion to take place. Thus, the v-SNAREs of secretory vesicles fuse only with the t-SNAREs of the plasma membrane. Once a vesicle has

docked at the appropriate membrane by means of matching SNAREs, the two membranes completely fuse; then the vesicle empties its contents at the targeted site.

By manufacturing its particular secretory protein ahead of time and storing this product in secretory vesicles, a secretory cell has a readily available reserve from which to secrete large amounts of this product on demand. If a secretory cell had to synthesize all its product on the spot as needed for export, the cell would be more limited in its ability to meet varying levels of demand.

Secretory vesicles are formed only by secretory cells. However, the Golgi complex of these and other cell types sorts and packages newly synthesized products for different destinations within the cell. In each case, a particular vesicle captures a specific kind of cargo from among the many proteins in the Golgi lumen, and then addresses each shipping container for a distinct destination.

check your understanding 2.5

How does the Golgi complex sort and direct finished proteins to the proper destinations inside and outside the cell?

How are the coat proteins different from docking markers?

2.6 Lysosomes and Proteasomes

Two major structures in the cytosol are important for breaking down unwanted materials: the *lysosome* organelle and the *proteasome* complex.

Lysosomes digest extracellular material brought into the cell by phagocytosis

Lysosomes are small organelles that break down organic molecules (*lys* means “breakdown”; *some* means “body”). Instead of having a uniform structure, as is characteristic of all other organelles, lysosomes vary in size and shape, depending on the contents they are digesting. Most commonly, lysosomes are small (0.2 to 0.5 μm in diameter) oval or spherical membrane-bound bodies. On average, a cell contains about 300 lysosomes. They were first described in 1955 by Christian De Duve, who noted that lysosomes were acidic organelles containing an array of powerful **hydrolytic enzymes** or **hydrolases**, which catalyze **hydrolysis**, reactions that break down organic molecules by the addition of water at a bond site (*hydrolysis* means “splitting with water”). In lysosomes the organic molecules are cell debris and foreign material, such as bacteria, that have been brought into the cell. Each lysosome contains more than 30 different hydrolases synthesized in the ER and transported to the Golgi complex for packaging into the budding lysosome. Lysosomal enzymes are similar to the hydrolytic enzymes that the digestive system secretes to digest food. Thus, lysosomes serve as the intracellular “digestive system.”

Extracellular material to be attacked by lysosomal enzymes is brought into the cell through the process of phagocytosis, a type of endocytosis. **Endocytosis** (Figure 2-12b), the reverse of exocytosis, refers to the internalization of extracellular material within a cell (*endo* means “within”). Endocytosis

can be accomplished in three ways—*pinocytosis*, *receptor-mediated endocytosis*, and *phagocytosis*—depending on the contents of the internalized material and the cell type.

Pinocytosis With **pinocytosis** (“cell drinking”), a droplet of extracellular fluid is taken up nonselectively. First, the plasma membrane dips inward (or invaginates), forming a pouch that contains a small bit of ECF (Figure 2-14a). The plasma membrane then seals at the surface of the pouch, trapping the contents in a small, intracellular **endocytic vesicle**. *Dynamin*, the protein responsible for pinching off an endocytic vesicle, forms rings that wrap around and “wring the neck” of the pouch, severing the vesicle from the surface membrane. Besides bringing ECF into a cell, pinocytosis provides a means to retrieve extra plasma membrane that has been added to the cell surface during exocytosis.

Receptor-Mediated Endocytosis Unlike pinocytosis, which involves the nonselective uptake of the surrounding fluid, **receptor-mediated endocytosis** is a highly selective process that enables cells to import specific large molecules that the cell needs from its environment. Receptor-mediated endocytosis is triggered by the binding of a molecule such as a protein to a specific surface membrane receptor site. This binding causes the plasma membrane at that site to invaginate, and then seal at the surface where it now contains the protein/receptor complex (Figure 2-14b). The pouch is formed by the linkage of *clathrin* molecules, which are membrane-deforming coat proteins on the inner surface of the plasma membrane. Clathrin is a different coat protein than the one used for exocytosis, and the resulting clathrin-containing pouch is known as a *coated pit* because it is coated with clathrin. Cholesterol complexes, vitamin B₁₂, the hormone insulin, and iron are examples of substances selectively taken into cells by receptor-mediated endocytosis.

Unfortunately, some viruses can sneak into cells by exploiting this mechanism. For instance, flu viruses and HIV/FIV, the viruses that cause human and feline AIDS (see p. 482), respectively, gain entry to cells via receptor-mediated endocytosis. They do so by binding with membrane receptor sites normally designed to trigger internalization of a needed molecule.

Phagocytosis During **phagocytosis** (“cell eating”), large multimolecular particles are internalized. Most body cells perform pinocytosis, many carry out receptor-mediated endocytosis, but only a few specialized cells are capable of phagocytosis. The latter are the “professional” phagocytes, the most notable being certain types of protists and immune cells that are crucial defense mechanisms in all animals (see Chapter 10). When an immune cell encounters a large multimolecular particle, such as a bacterium or tissue debris, it extends surface projections known as *pseudopodia* (“false feet”), or *pseudopods*, that completely surround or engulf the particle and trap it within an internalized vesicle (see Figure 2-14c). A lysosome fuses with the membrane of the internalized vesicle and releases its hydrolytic enzymes into the vesicle, where they attack the trapped material without damaging the rest of the cell. The enzymes largely break down the material into reusable raw ingredients, such as amino acids, glucose, and fatty acids. These small products pass through the lysosomal membrane and enter the cytosol.

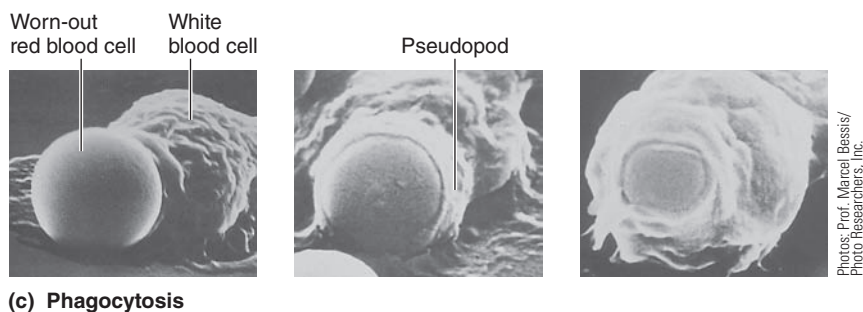

FIGURE 2-14 Forms of endocytosis. (a) Diagram of pinocytosis. The surface membrane dips inward to form a pouch, then seals the surface, forming an intracellular endocytic vesicle that nonselectively internalizes a bit of ECF. (b) Diagram of receptor-mediated endocytosis. When a large molecule such as a protein attaches to a specific surface receptor, the membrane pockets inward with the aid of a coat protein, forming a coated pit, then pinches off to selectively internalize the molecule in an endocytic vesicle. (c) Scanning electron micrograph series of a white blood cell phagocytizing an old, worn-out red blood cell by extending surface projections known as pseudopods that wrap around and seal in the targeted material.

Lysosomes remove worn out organelles

Lysosomes can also fuse with aged or damaged organelles to remove parts of the cell. This selective self-digestion makes way for new replacement parts. All organelles are renewable. If the whole cell is severely damaged or dies, the lysosomes rupture and release their destructive enzymes into the cytosol so that the cell digests itself entirely. In most tissues, elimination of a nonfunctional cell clears the way for its replacement with a healthy new one through cell division. However, in tissues in which cell reproduction rarely occurs,

such as mammalian heart and brain tissue, scar tissue replaces the self-destructed dead cells.

In specific instances, lysosomes cause intentional self-destruction of healthy cells. This happens as a normal part of embryonic development when certain unwanted tissues that form are programmed for destruction. For example, embryonic ducts in mammals that are capable of forming a male reproductive tract are deliberately destroyed during the development of a female fetus. Similarly, many larval (caterpillar) tissues must be destroyed in a butterfly's pupal stage. Lysosomes also play an important role in tissue regression,

FIGURE 2-15 Process for targeting a protein to a proteasome for degradation. This process requires three enzymes working in concert to tag the ill-fated protein with a chain of ubiquitin molecules. The first enzyme (E1) binds to and activates a ubiquitin molecule and then hands it off to the second enzyme (E2), which in turn joins to a third enzyme (E3). E3 enzymes are like socket wrenches that fit various target proteins using “sockets” called F-box proteins. When an E3 binds to a protein, the ubiquitin molecule carried by the E2 is broken off and transferred to the protein. The cycle repeats until the protein is tagged with a chain of ubiquitins. This chain binds to the proteasome, which allows enzymes near the opening of the proteasome to unfold the protein and push it into the proteasome’s chamber, where other enzymes chop it to pieces.

such as during the normal reduction in the uterine lining following pregnancy. Such *programmed* cell death is termed **apoptosis**. (Other cellular enzymes and organelles, especially mitochondria, are also involved in apoptosis; see Chapter 3.)

Proteasomes destroy internal proteins

The other important intracellular digestive apparatus is the **proteasome**, a large tunnel-like structure made of numerous proteins (Figure 2-15). The proteasome, of which there are many thousands per cell, has the job of taking in internal cell proteins (rather than external ones) and chopping them up into reusable amino acids. Why would a cell want to destroy its own proteins? Although cell proteins are made for specific purposes, they outlive their usefulness if that purpose is only needed temporarily. For example, during cell division, many regulatory proteins have to be made, then destroyed, for the cell to move through the various stages of mitosis. Also, in extreme starvation proteins must be broken down to provide emergency energy supplies. Some cell proteins are not useful at all due to errors in their production (such as misfolding) or even genetic mutations. Without proteasomes, unneeded proteins could accumulate in cells to harmful levels.

Proteins are not randomly destroyed by proteasomes. Instead, special enzymes recognize unwanted proteins (in ways not completely understood) and “tag” them with a tiny protein called *ubiquitin*. The ubiquitin-tagged protein is then recognized by the proteasome and drawn in to its disassembly tunnel. However, as in the case of lysosomes, this destruction process can go awry and cause harm. For example, some viruses have evolved their own proteins that can tag useful cellular defense proteins for proteasome destruction.

2.7 Peroxisomes

Typically, several hundred small **peroxisomes** that are about one third to one half the average size of lysosomes are present in a cell. Peroxisomes, like lysosomes, are membrane-enclosed sacs containing enzymes, but unlike lysosomes, which contain hydrolytic enzymes, peroxisomes house several powerful *oxidative enzymes* and contain most of the cell’s *catalase*.

Oxidative enzymes, as the name implies, use oxygen (O_2), to strip hydrogen from certain organic molecules. This reaction helps detoxify various wastes produced within the cell or foreign toxic compounds that have entered the cell, such as ethanol that is consumed in alcoholic beverages.

The major product generated in the peroxisome, *hydrogen peroxide* (H_2O_2), is formed by molecular oxygen and the hydrogen atoms stripped from the toxic molecule. Hydrogen peroxide is potentially destructive if allowed to accumulate or escape from the confines of the peroxisome. However, peroxisomes also contain an abundance of **catalase**, an enzyme that decomposes potent H_2O_2 into harmless H_2O and O_2 . This latter reaction is an important safety mechanism that destroys the potentially deadly peroxide at the site of its production, thereby preventing its possible devastating escape into the cytosol.

Compare the function of lysosomes, proteasomes, and peroxisomes.

Why is it important that a cell have a source of antioxidants?

2.8 Mitochondria and Energy Metabolism

Mitochondria are the energy organelles or “power plants” of the cell; they extract energy from the nutrients in food and transform it into a usable form to support cell activities. As you will see in Chapter 8, mitochondria can also take up Ca^{2+} under physiological conditions, often at sufficient magnitude to influence cytoplasmic Ca^{2+} homeostasis. About 90% of the energy that cells—and, accordingly, that tissues, organs, and the whole body—need to survive and function is generated by mitochondria. The mammalian organ most dependent on mitochondrial energy production is the brain, followed by the heart and some forms of skeletal muscle, and the kidneys and hormone-synthesizing tissues.

Mitochondria are generally rod- or oval-shaped structures about the size of a bacterium. However, they can vary in size and shape depending on the tissue type, even within a given animal. The mitochondria of arthropod motor neurons are rodlike, with branches extending 1 μm or more. The similarity in basic size of mitochondria and bacteria is not a coincidence; as we noted earlier, there is considerable evidence that mitochondria are descendants of bacteria that invaded or were engulfed by primitive cells early in evolutionary history. Mitochondrial DNA (*mtDNA*), exclusively inherited from the maternal side, contains genes for producing many of the molecules mitochondria need to transduce energy. (Mitochondrial ancestors probably had all the necessary genes, but some have transferred horizontally [p. 34] into nuclear DNA.) Recent research suggests that flaws gradually accumulate in mitochondrial DNA over an animal's lifetime, and the resultant progressive impairment in mitochondrial energy transduction has been implicated in a wide variety of disorders, including muscle weakness, seizures, blindness, and degenerative illnesses associated with aging. In addition, *mtDNA* can be used to date ancient biological samples. By measuring the mutations that accumulate in the mitochondrial DNA, researchers can assign an approximate age to the sequence. In this fashion *mtDNA* acts like a molecular clock. *mtDNA* is used because the cell has only two copies of the nuclear DNA, whereas thousands of copies of *mtDNA* are found in each cell.

Mitochondria are enclosed by two membranes

Like nuclei, mitochondria are enclosed by a double membrane—a smooth outer membrane that surrounds the mitochondrion itself and an inner membrane that forms a series of infoldings or shelves called **cristae**, which project into an inner cavity filled with a gel-like solution known as the **matrix** (Figure 2-16). Cristae contain crucial proteins that ultimately are responsible for converting much of the energy in food into a usable form (the electron transport proteins, described shortly). The generous folds of the inner membrane greatly increase the surface area available for housing these important proteins. (This is a common theme in physiology: Increasing the surface area of various body structures by means of surface projections or infoldings makes more surface area available to participate in the structure's functions.) The matrix consists of a concentrated mixture of hundreds of different dissolved enzymes (the cit-

FIGURE 2-16 Mitochondrion. Diagram and electron micrograph of a mitochondrion. Note that the outer membrane is smooth while the inner membrane forms folds known as cristae that extend into the matrix. An intermembrane space separates the outer and inner membranes. The electron transport proteins embedded in the cristae are ultimately responsible for converting much of the energy of food into a usable form.

ric acid cycle enzymes, soon to be described) that are important in preparing nutrient molecules for the final extraction of usable energy by the cristae proteins.

Aerobic metabolism in mitochondria relies on O_2 to convert energy in food into ATP

Every cell of an animal relies on specific biochemical pathways to generate energy from the food it consumes. One unifying principle of biochemistry is the similarity in the major pathways of metabolism that organisms use. Some of these pathways are termed **aerobic** (“with air” or “with O_2 ”) and require the consumption of O_2 , whereas others are

called **anaerobic** (“without air” or “without O₂”), and can proceed in the absence of O₂. Most cell types can switch from one pathway to the other depending on the physiological state of the organism and availability of O₂. Aerobic metabolism in eukaryotes requires mitochondria; anaerobic may or may not.

For most organisms, the ultimate source of energy is the sun (exceptions are noted in Chapter 14). Solar energy is trapped by photosynthetic organisms and used to convert CO₂ into carbohydrates, which pass through food chains to herbivores (plant-eating animals) and ultimately to carnivores (meat-eating animals). Animal cells (with rare exceptions such as the photosynthetic seaslug, p. 690) cannot use solar energy directly. Instead, they must extract energy from the chemical energy stored in the energy-rich carbon-hydrogen bonds of ingested food. Note that energy is released when electrons are transferred from high-energy bonds to *electron acceptors* like oxygen in *oxidation-reduction* reactions. (Recall from your chemistry class that **oxidation** is the removal of electrons from a substance, which becomes **oxidized**, whereas the addition of electrons to a substance is termed a **reduction** and the substance that receives the electrons is said to be **reduced**.)

Let’s look at energy usage in detail. First, animal cells must convert food energy into intermediate forms that they can use to run other cell reactions. These forms are primarily:

- The high-energy phosphate bonds of **adenosine triphosphate (ATP)**, which consists of adenosine with three phosphate groups attached, and is made by adding a phosphate (with an electron) to **ADP (adenosine diphosphate)**.
- The electrons (with hydrogen) in reduced **nicotinamide adenine dinucleotide (NADH)**, made by transferring two electrons and a hydrogen to the oxidized form **NAD⁺**, an electron acceptor derived from the B vitamin *niacin*.

ATP and NADH are universal energy carriers—the common “currency” of life on Earth—because these energized biomolecules contain chemically useful forms of stored energy. NADH carries energy-rich electrons that can be used to reduce other organic molecules. Each NADH molecule is actually worth almost three ATPs! As you will see, the hydrogen and electrons of NADH may be transferred ultimately to *oxygen*, the final electron acceptor, in order to make more ATP. Similarly, ATP carries a high-energy bond in the terminal phosphate; when this is split, a substantial amount of energy is released. The energy released can drive the energy-requiring activities within the cell, such as contraction of a muscle, transport of ions across a membrane, or synthesis of a new protein. To “cash in” the energy currency of ATP, enzymes split the terminal phosphate bond of ATP, which yields ADP plus inorganic phosphate (P_i) plus energy:

In this energy scheme, food might be thought of as the “crude fuel,” whereas ATP is the “refined fuel” for operating the cell’s machinery. ATP is constantly being used by cell processes and must constantly be replenished.

Let’s elaborate on this fuel conversion process (Figure 2-17). In the vast majority of animals, the cell has several

options available to it when its supply of ATP molecules becomes depleted:

- Energy-rich nutrients stored within the cell can be broken down to generate ATP.
- Similar nutrients can be mobilized from specialized storage cells in the animal and transferred, via a circulatory system or diffusion, to energy-depleted cells.
- Dietary energy nutrients (i.e., food) can be digested, or broken down, by the digestive system into smaller absorbable units that can be transferred (again, by circulation or diffusion) from the lumen of the digestive tract to cells whose energy supplies are depleted (see Chapter 14).

The main endogenous fuels stored by most animal cells are *glycogen* and *triglycerides* (defined earlier, p. 26), and—in some marine animals—**waxes** (a fatty acid linked to a fatty alcohol). Vertebrates store glycogen in the liver, muscles, and glia, whereas triglycerides are stored in *adipose* (fat) tissue. Insects store huge reserves of carbohydrate and triglycerides in their *fat body*, the insect equivalent of a liver. Generally, periods of short-term strenuous activity rely on the combustion of glycogen whereas during prolonged activity there is a transition to the combustion of fat. For example, during foraging flight, locusts rely on carbohydrate sources, but during long-distance migratory flight, they rely on the combustion of fat. Dragonflies use fats to power their prolonged hovering behaviors. In salmon (fish that migrate between rivers and the ocean), so-called expendable proteins can be converted into amino acids and used as fuel during migration. Similarly, amino acids can be used to fuel energy needs in some species of marine nonvertebrates as well as in insects. In many vertebrates, the use of protein stores as a fuel to generate ATP represents a “last ditch” effort for survival. For example, Emperor penguins, who fast for prolonged periods in Antarctica during the winter months when near-shore seas are frozen over, rely on stored triglycerides for fuel generation. When these supplies are exhausted and the body is forced to burn its protein stores, the penguin returns to the sea to replenish its fuel.

Glycolysis The most common energy pathway begins with glucose, which can be derived from most dietary carbohydrates (such as starch, a plant storage polymer composed of glucose units). Stored carbohydrates and some amino acids can also be converted into glucose. When delivered to the cells by a circulatory system, the nutrient molecules are transported across the plasma membrane into the cytosol. Among the thousands of enzymes within the cytosol are those responsible for **glycolysis**, a chemical process that breaks down the simple 6-carbon sugar molecule, glucose, into two **pyruvate** molecules, each of which contains three carbons. There are actually 10 separate sequential reactions in glycolysis, each catalyzed by a separate enzyme. Glycolysis is common to almost every cell (prokaryotic and eukaryotic) and is believed to be the most ancient of the metabolic pathways, having arisen before oxygen accumulated in the atmosphere. During this process, two hydrogens and two electrons are released and (except for one H⁺) transferred to NAD⁺ molecules (becoming NADH) for later use. In addition, some of the energy stored in the chemical bonds of glucose is used to convert ADP into ATP (Figure 2-18). Importantly, although glycolysis is widespread, it is not very

FIGURE 2-17 Summary of ATP production from the complete oxidation of one molecule of glucose.

The total of 32 ATP assumes that electrons carried by each NADH yield 2.5 ATP and those carried by each FADH_2 yield 1.5 ATP during oxidative phosphorylation.

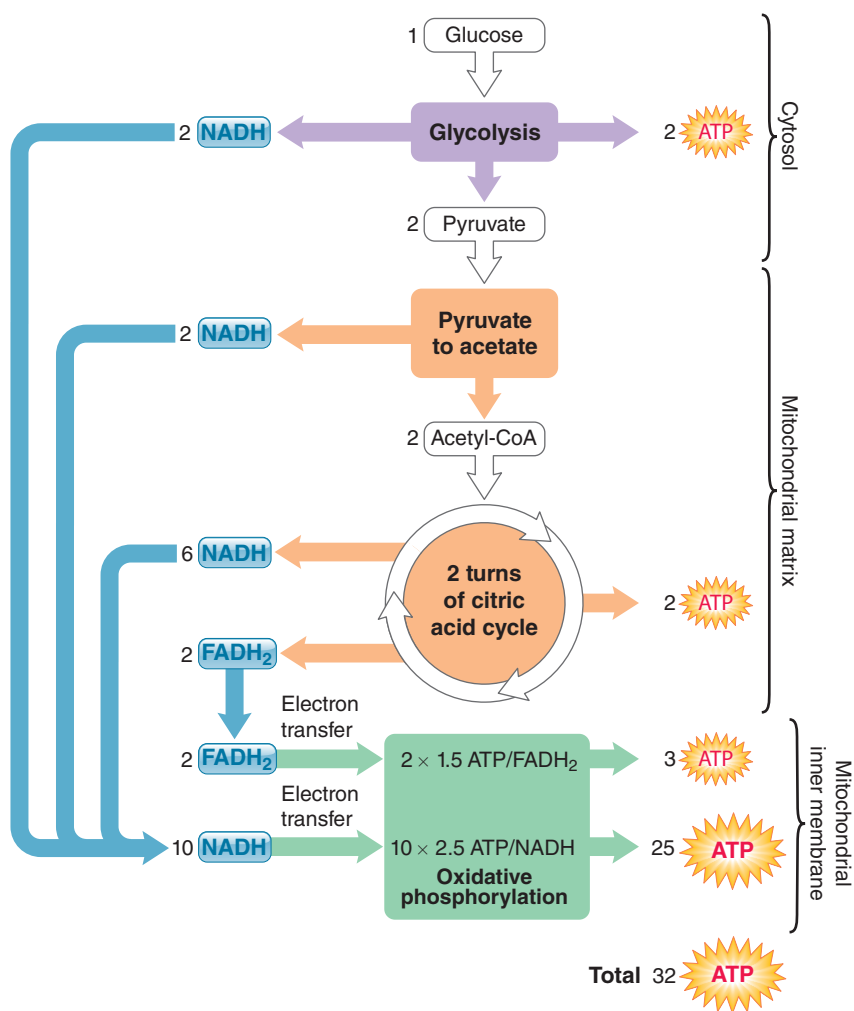

FIGURE 2-18 Glycolysis in the cytosol. Glycolysis splits glucose (six carbons) into two pyruvate molecules (three carbons each), with a net yield of 2 ATP plus 2 NADH (available for further energy extraction by the electron transport system).

© Cengage Learning, 2013

efficient in terms of energy extraction: *One molecule of glucose yields only two molecules of ATP in glycolysis.* Much of the energy originally contained in the glucose molecule is still locked in the chemical bonds of the pyruvate molecules. The low-energy yield of glycolysis is sufficient to sustain the needs of many single-celled anaerobic organisms and temporarily supports some aerobic cells through periods of reduced oxygen supply, but is grossly insufficient to sustain the long-term energy requirements of large, active animals. This is where the mitochondria come into play.

Citric Acid Cycle The pyruvate produced by glycolysis in the cytosol can be selectively transported into the mitochondrial matrix. Here it is further broken down into a 2-carbon molecule, acetic acid, by enzymatic removal of one of the carbons in the form of carbon dioxide (CO_2), which eventually is eliminated from the body as an end product, or waste (Figure 2-19). During this breakdown process, a carbon-hydrogen bond is disrupted, so a hydrogen atom and two electrons are also released and transferred to make another NADH from NAD^+ . The acetic acid thus formed combines with *coenzyme A*, a derivative of pantothenic acid (a B vitamin), producing the compound acetyl coenzyme A or *acetyl-CoA*.

Acetyl-CoA then enters the **citric acid cycle**, a cyclical series of eight biochemical reactions catalyzed by the enzymes of the mitochondrial matrix. This cycle is also known as the *Krebs cycle*, in honor of its principal discoverer, or the *tricarboxylic acid (TCA) cycle*, because citric acid contains three carboxylic acid groups. Notably, the pyruvate formed in glycolysis can be further oxidized to generate more ATP *only* when oxygen is available to the animal. This cycle of reactions can be compared to one revolution around a Ferris wheel. (Keep in mind that Figure 2-19 is highly schematic. It depicts a cyclical series of biochemical reactions. The molecules themselves are not physically moved around in a cycle.) On the top of the Ferris wheel, acetyl-CoA, a 2-carbon molecule, enters a seat already occupied by *oxaloacetic acid*, a 4-carbon molecule. These two molecules link together to form a 6-carbon *citric acid* molecule and the trip around the citric acid cycle begins. As the seat moves around the cycle, at each new position, matrix enzymes modify the passenger molecule to form a slightly different molecule. These molecular alterations have the following important consequences:

1. Two carbons are “kicked off the ride”—released one at a time from 6-carbon citrate, converting it back into 4-carbon oxaloacetate, which is now available at the

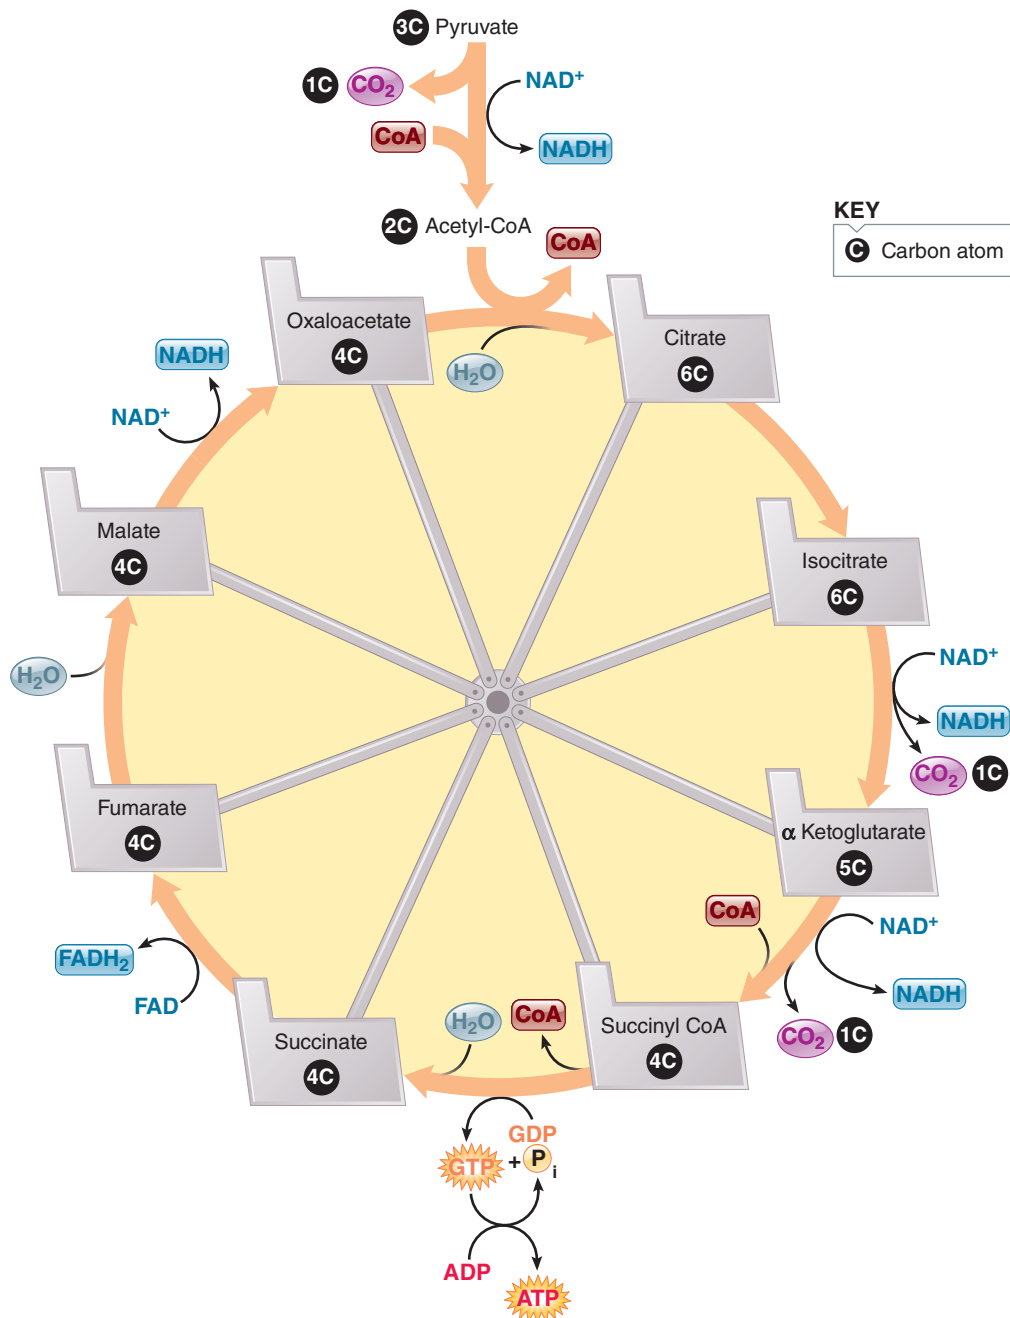

FIGURE 2-19 Citric acid cycle in the mitochondrial matrix. The two carbons entering the cycle by means of acetyl-CoA are eventually converted to CO_2 , with oxaloacetate, which accepts acetyl-CoA, being regenerated at the end of the cyclical pathway. The hydrogens released at specific points along the pathway bind to the hydrogen carrier molecules NAD^+ and FAD for further processing by the electron transport system. One molecule of ATP is generated for each molecule of acetyl-CoA that enters the citric acid cycle, for a total of two molecules of ATP for each molecule of processed glucose.

© Cengage Learning, 2013

top of the cycle to pick up another acetyl-CoA for another revolution through the cycle. CoA is recycled too; it is released at the end, making it available to bind with a new acetate to form another acetyl-CoA.

2. The released carbon atoms become two molecules of CO_2 . This CO_2 , as well as the CO_2 produced during the formation of acetic acid from pyruvate, diffuses out of the

mitochondrial matrix and subsequently out of the cell to enter the ECF. In animals with circulatory systems such as blood, the gas (and its derivative, bicarbonate; p. 540) is carried to the lungs or gills, where it is eliminated. (Note that the oxygen in the CO_2 molecule is derived from the molecules that were involved in the reactions, not from free molecular oxygen supplied by breathing.)

3. Hydrogen atoms and their electrons are also “bumped off” during the cycle at four of the chemical conversion steps. The key purpose of the citric acid cycle is to produce these hydrogens for entry into the electron transport system in the inner mitochondrial membrane. These hydrogens and electrons are “captured” by two acceptors—NAD⁺ and **flavine adenine dinucleotide (FAD)**, a derivative of the B vitamin *riboflavin*, which becomes FADH₂. Three NADH and one FADH₂ are produced for each turn of the citric acid cycle.
4. One more molecule of ATP is produced for each molecule of acetyl-CoA processed. Actually, ATP is not directly produced by the citric acid cycle. The released energy is used to directly link inorganic phosphate to **guanosine diphosphate (GDP)** to form **guanosine triphosphate (GTP)**, a high-energy molecule similar to ATP. The energy from GTP can then be transferred to ATP as follows:

Because each glucose molecule is converted into two acetic acid molecules, fueling two turns of the citric acid cycle, two more ATP molecules are produced from each glucose molecule.

These two additional ATPs are still not much of an energy profit. However, the citric acid cycle is important in preparing the hydrogen carrier molecules for their entry into the final stage, *oxidative phosphorylation*, which produces far more energy than the sparse amount of ATP produced by the cycle itself.

Electron Transport Chain and Oxidative Phosphorylation

Considerable untapped energy is still stored in the released hydrogen atoms, which contain electrons at high-energy levels. So far we have not mentioned any role for free oxygen in these reactions. That is because free (or molecular) oxygen—O₂—is not a reactant in the pathways of either glycolysis or the citric acid cycle. However, oxygen is essential as the final electron acceptor, as you will see, in the disposition of the reduced intermediate acceptors, NADH and FADH₂. The “big payoff” comes when NADH and FADH₂ enter the electron transport chain (step 1), which consists of electron carrier molecules located in the inner mitochondrial membrane lining the cristae (Figure 2-20). The high-energy electrons are extracted from the hydrogens held in NADH and FADH₂ and transferred sequentially to the electron carrier molecules, freeing NAD and FAD to pick up more hydrogen atoms (step 2). The electron transport molecules are arranged in a specific order on the inner membrane so that the high-energy electrons are progressively transferred through a chain of reactions, with the electrons falling to successively lower energy levels at each step (step 3).

This electron transport chain is also called the **respiratory chain** because it relates to use of O₂. A fundamental question now arises: Why is oxygen essential for the survival of most organisms? Ultimately, it is the passage of these electrons generated from foodstuffs to available O₂ derived from the environment (air or water) that ensures survival. Electrons that become bound to O₂ are in their lowest energy state. Oxygen thus enters the mitochondria to serve as the final electron acceptor of the electron transport chain. This negatively charged oxygen (negative because it has acquired

additional electrons) then combines with the positively charged hydrogen ions (positive because they have donated the electrons at the beginning of the electron transport chain) to form two waters (H₂O) (step 4).

As the electrons move through this chain of reactions to ever-lower energy levels, they release energy. Part of the released energy is lost as heat, but some is harnessed by the mitochondrion to synthesize ATP through the following steps. At three sites in the electron transport system (Complexes I, III, and IV), the *energy released during the transfer of electrons is used to transport hydrogen ions (H⁺)* across the inner mitochondrial membrane from the matrix to the space between the inner and outer mitochondrial membranes, the *intermembrane space* (step 5). As a result, hydrogen ions are more heavily concentrated in the intermembrane space than in the matrix. Consider the amazing fact that the mitochondrion has created a powerful force, that is, a gradient available to do work. This H⁺ gradient generated by the electron transport system (step 6) can now supply the energy that drives ATP synthesis by the membrane-bound mitochondrial enzyme ATP synthase.

ATP synthase consists of a *basal unit* embedded in the inner membrane, connected by a stalk to a *headpiece* located in the matrix, with the *stator* bridging the basal unit and headpiece. Because H⁺ ions are more heavily concentrated in the intermembrane space than in the matrix, they have a strong tendency to flow back into the matrix through the inner membrane via channels formed between the basal units and stators of the ATP synthase complexes (step 7). This flow of H⁺ ions activates ATP synthase and powers ATP synthesis by the headpiece, a process called **chemiosmosis**. Passage of H⁺ ions through the channel makes the headpiece and stalk spin like a top (step 8), similar to the flow of water making a waterwheel turn. As a result of the changes in its shape and position as it turns, the headpiece is able to sequentially pick up ADP and P_i, combine them, and release the ATP product (step 9).

Oxidative phosphorylation encompasses the entire process by which ATP synthase synthesizes ATP by phosphorylating (adding a phosphate to) ADP using the energy released by electrons as they are transferred to O₂ by the electron transport system. The harnessing of energy into a useful form as the electrons tumble from a high-energy state to a low-energy state can be likened to a power plant converting the energy of water tumbling down a waterfall (while turning a turbine) into electricity.

The series of steps that lead to oxidative phosphorylation may at first seem unnecessarily complicated. Why not just directly oxidize, or “burn,” food molecules to release their energy? Oxidation was originally used to describe the reaction that occurs when fuel substances are burned in air, in which oxygen directly accepts the electrons derived from the fuels and all the energy stored in the food molecule is released explosively as heat (Figure 2-21). However, in the animal, oxidation of food molecules actually occurs in many small, controlled steps so that the food molecule’s chemical energy is gradually made available for convenient packaging in a storage form useful to the cell. (Analogously, the fuel in an automobile’s tank is not normally burned all at once—that would produce an explosion. Rather, fuel is fed a little at a time into the engine combustion chambers.) Approximately 70% of the chemical energy released in the oxidation of glucose to CO₂ and H₂O is recovered as energy in the form

- 1** The high-energy electrons extracted from the hydrogens in NADH and FADH_2 are transferred from one electron-carrier molecule to another.
- 2** The NADH and FADH_2 are converted to NAD^+ and FAD, which frees them to pick up more hydrogen atoms released during glycolysis and the citric acid cycle.
- 3** The high-energy electrons fall to successively lower energy levels as they are transferred from carrier to carrier through the electron transport system.
- 4** The electrons are passed to O_2 , the final electron acceptor of the electron transport system. This oxygen, now negatively charged because it has acquired additional electrons, combines with H^+ ions, which are positively charged because they donated electrons at the beginning of the electron transport system, to form H_2O .

- 5** As electrons move through the electron transport system, they release free energy. Part of the released energy is lost as heat, but some is harnessed by the mitochondrion to transport H^+ across the inner mitochondrial membrane from the matrix to the intermembrane space at Complexes I, III, and IV.
- 6** As a result, H^+ ions are more heavily concentrated in the intermembrane space than in the matrix. This H^+ gradient supplies the energy that drives ATP synthesis by ATP synthase.
- 7** Because of this gradient, H^+ ions have a strong tendency to flow into the matrix across the inner membrane via channels between the basal units and stators of the ATP synthase complexes.
- 8** This flow of H^+ ions activates ATP synthase and powers ATP synthesis by the headpiece, a process called **chemiosmosis**. Passage of H^+ ions through the channel makes the headpiece and stalk spin like a top.
- 9** As a result of changes in its shape and position as it turns, the headpiece picks up ADP and P_i , combines them, and releases the ATP product.

of ATP, and much less is converted to heat. The heat produced is not completely wasted energy in endotherms such as birds and mammals; it is used to help maintain body temperature, with any excess heat being lost to the environment. (Endotherms are organisms that generate internal heat for thermoregulation; see Chapter 15.)

When enough O₂ is present, mitochondrial processing (both the citric acid cycle in the matrix and the electron transport chain on the cristae) harnesses sufficient energy to generate 26 more molecules of ATP, for a total net yield of 30 ATPs per molecule of glucose processed after glycolysis. The overall reaction for oxidation of food molecules to yield energy is as follows:

Glucose, the principal nutrient derived from dietary carbohydrates, is the fuel preference of most cells. The overall equation for glucose including the ATP of glycolysis is

However, nutrient molecules derived from fats (fatty acids) and, if necessary, from protein (amino acids) can also participate at specific points in this overall chemical reaction to eventually produce energy. Amino acids are usually used for protein synthesis instead of energy production, but they can be used as fuel if insufficient glucose and fat are available.

Mitochondrial metabolism can create oxidative stress

Unfortunately, leakage of some of the electrons associated with mitochondrial metabolism can potentially damage the tissues of the host animal and contribute to the aging process. This requires cellular strategies to detoxify and limit the production of certain metabolites of molecular oxygen known as *reactive oxygen species (ROS)*. ROS encompass a variety of diverse chemicals, which includes superoxide anions, hydroxyl radicals, peroxynitrite, and hydrogen peroxide (Figure 2-22). Some ROS are **free radicals** (molecules containing one or more unpaired electrons and thus react readily with other molecules, acquiring or giving up an electron to achieve stability). Radicals, such as hydroxyl radicals and superoxide, are extremely unstable. In contrast, other forms such as hydrogen peroxide are comparatively long-lived. ROS production is countered by an elaborate antioxidant system that includes the enzymatic scavengers *superoxide dismutase (SOD)*, *catalase*, and *glutathione peroxidase*. SOD increases the conversion of superoxide to hydrogen peroxide, while catalase and glutathione peroxidase convert hydrogen peroxide to water. Levels of catalase tend to correlate positively with lifespan in mammals. A variety of other nonenzymatic, low-molecular-weight molecules are also important in scavenging ROS and include *ascorbate* (vitamin C), tocopherols (vitamin E derivatives), *flavonoids*, *carotenoids* (vitamin A derivatives), and perhaps most important in long-lived species, *uric acid*, which is present in high concentrations within cells. Dietary intake of carotenoids, which vary seasonally, are also suggested to increase antioxidant protection in some species (see Chapter 10, p. 458).

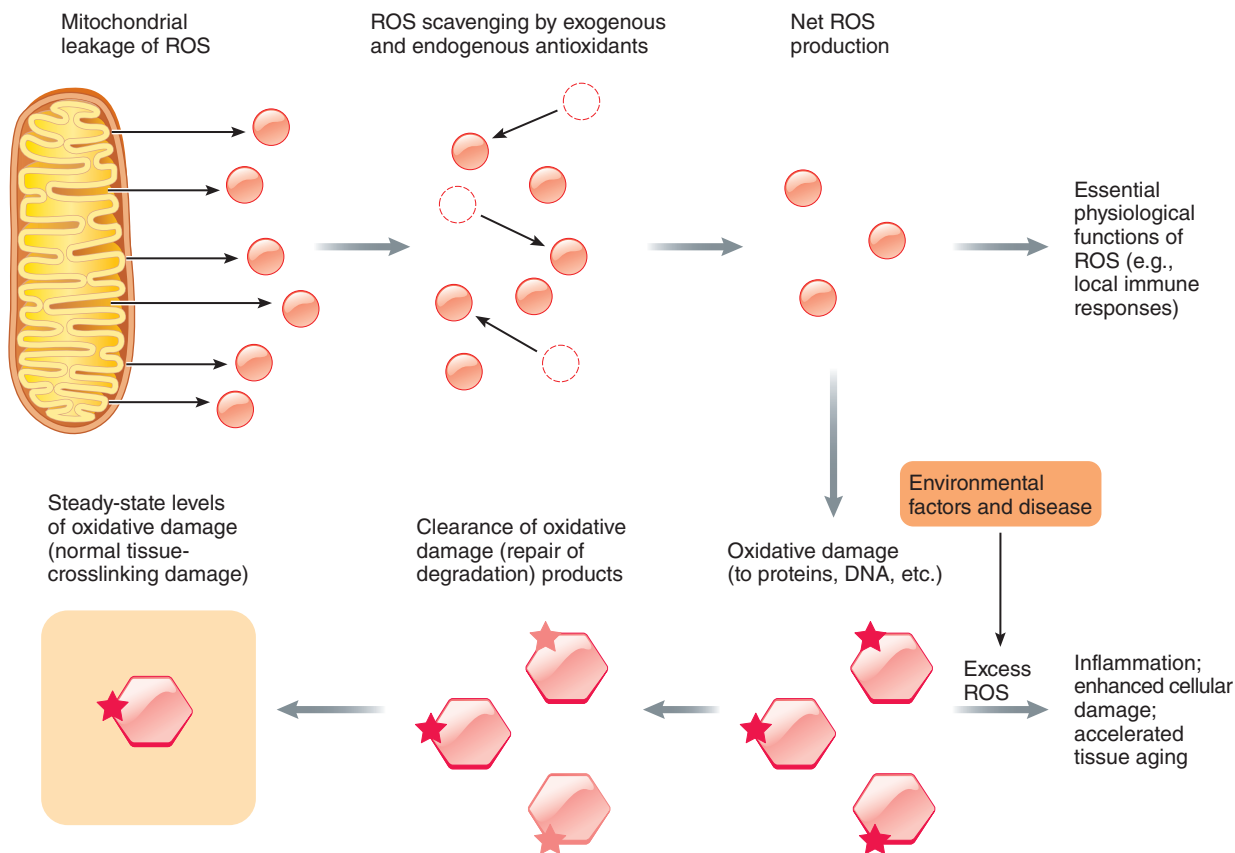

FIGURE 2-22 Production and fate of reactive oxygen species (ROS). Mitochondrial production of ROS is counteracted by both endogenous and exogenous antioxidants. Net ROS production can be harnessed by the immune system for local immune responses. Excess leakage of ROS leads to oxidative damage of cells and their constituents. Under normal physiological conditions, some damage to cellular components is reversible; however, there is also a steady-state accumulation of tissue crosslinks in a species-specific pattern of aging. Excessive ROS production results from inflammation associated with disease as well as environmental factors such as dietary toxins and radiation, which can lead to accelerated tissue aging and/or enhanced cellular damage leading to specific complications.

© Cengage Learning, 2013

Oxidative stress occurs when reactive oxygen species production overwhelms the antioxidant defenses, as with inflammation. In such coupled oxidation-reduction reactions, also termed **redox reactions**, electrons release some of their energy as they pass from a donor to an acceptor molecule. An organism is in redox balance if the electrons that are generated through metabolism are removed at an equivalent rate. Problems arise when these reactive species are not scavenged by antioxidants but instead react with other components of the cell, generating an imbalance in the redox reaction favoring oxidation, which results in oxidative stress. Longevity of a species as well as the ability of individual organisms to withstand oxidative stress and inflammation can thus be critically linked to the efficacy of its antioxidant system.

ROS are not always useless by-products. ROS generation by phagocytic cells is a critical host defense mechanism used to combat infection (see Chapter 10). Further, cytosolic ROS production under conditions of metabolic stress may trigger specific signaling pathways within the cell, activating mechanisms to cope with stress.

Mitochondrial densities vary among tissue and organ types such as muscles

Concentrations of ATP normally remain fairly constant in any particular tissue, even during high metabolic activity. How, then, can cells maintain ATP supplies during the transition from rest to work, particularly in skeletal muscles? Consider the different rates of ATP use in muscles at maximum energy output. For example, the flight muscle of the locust uses ATP at about 5,400 mole/g/min. In comparison, ATP use is about 600 mole/g/min in hummingbird flight muscle and only 30 mole/g/min in an exercising human's limb muscles. One solution is to alter the total number of mitochondria per unit volume—that is, the *density* of mitochondria—within each cell. Indeed, muscle cells generally have mitochondrial densities corresponding to their energy loads (see Chapter 8). Skeletal muscles of terrestrial vertebrates have 1 to 10% of their volume as mitochondria (in comparison to 30 to 50% in vertebrate hearts). As befits its enormous energy demand, locust and dragonfly flight muscle has up to 50% of their volume as mitochondria. As

Photo: © John M. Coffman

A Carolina locust. The flight muscles of this animal are densely packed with mitochondria, which in turn have an unusually high packing density of cristae for ATP production.

an extreme example, specialized modified muscles called *heater cells*, located at the base of the brain in billfish (such as swordfish), keep temperatures in the brain and eye above ambient temperature (see Chapter 15). These cells contain one of the highest mitochondrial densities of any animal cell, ranging from 55 to 70% of total cell volume. Mitochondrial density is not necessarily fixed; it can be upregulated in many skeletal muscles after a prolonged increase in muscular activity (see Chapter 8). Acclimation to cold temperatures (see Chapter 15) also involves change in mitochondrial numbers. For example, the mitochondrial cell volume increases from 2.9 to 4.5% in the aerobic (red) muscle fibers in striped bass following acclimation from 25 to 5°C.

The second solution to high energy demands is to increase the *packing of cristae* within mitochondria. In particular, the packing is two to three times denser in mitochondria of insect flight muscle, hummingbird flight muscle, skipjack tuna swimming (red) muscle, and leg muscles of mammalian endurance “athletes” such as pronghorn antelopes.

Phosphagens provide a rapid source for ATP production

A third solution to meeting the cells’ ATP requirements involves the mobilization of tissue-specific *phosphagens* (see Chapter 8). Phosphagens are organic phosphate compounds present in high concentrations in the muscle cell that can transfer a high-energy phosphate group to ADP in order to regenerate ATP. They are made from ATP in times of plenty (when the cell is resting and has plenty of energy intake). In

mammals, phosphagens are in sufficient supply to produce ATP for only a short time, such as up to about 10 seconds in humans. Thereafter the concentration of phosphagens must also be replenished by oxidation of sugars and fatty acids. The highest concentrations of phosphagens are in white skeletal muscle fibers, cells that rely heavily on anaerobic energy processes (see Chapter 8). There are somewhat lower concentrations in red skeletal muscle fibers (those that rely on aerobic metabolism), the heart, and the brain. The phosphagen of vertebrates is *creatine phosphate*, whereas nonvertebrates use a variety of organic phosphate compounds, the best investigated being *arginine phosphate*. Insect flight muscle contains a surprisingly low amount of arginine phosphate, suggesting that the efficiency of oxygen delivery to the muscle tissue is adequate to meet the requirements of aerobic metabolism.

Oxygen deficiency forces cells to rely on glycolysis and other anaerobic reactions, producing lactate, propionic acid, octopine, or other end products

Phosphagens can produce ATP in the absence of oxygen, but for a very limited time. How can animals meet their metabolic requirements in the absence of molecular oxygen for prolonged periods? Consider that in the absence of O₂, the electron transport chain cannot accept electrons from NADH and FADH₂ and so “shuts down.” This occurs during bursts of high activity (such as a cheetah running) and when animals must cease breathing (as in an oyster closing its shell tightly during low tide). In such cases, glycolysis is usually the primary pathway for ATP replenishment. Recall that glycolysis takes place in the cytosol and involves the breakdown of glucose into pyruvate, producing a low yield of two molecules of ATP per molecule of glucose. Oxidative phosphorylation, the source of 26 out of every 30 ATP molecules, ceases, and the untapped energy of the glucose molecule may remain locked in the bonds of the pyruvate molecules. In some groups such as most vertebrates, pyruvate is converted into lactate (Figure 2-23) by an enzyme called *lactate dehydrogenase (LDH)*, in a reaction that regenerates NAD⁺, the hydrogen-electron acceptor needed for earlier steps in glycolysis to proceed (p. 48):

Lactate thus steadily accumulates in the tissues and gradually reduces the pH. Lactate production is necessary because the electron transport chain can no longer regenerate the acceptors NAD⁺. We will encounter this reaction and LDH in later chapters.

Significant modifications to anaerobic end products have evolved at two points in the glycolytic pathway.

1. **Higher ATP yield.** The first modification is at the *phosphoenolpyruvate (PEP)* step, the net ATP-yielding step just before pyruvate formation in glycolysis:

Many animals (bivalve mollusks such as oysters, nematodes, parasitic helminths, and the swamp-dwelling annelid *Alma emeni*) gain more than two ATPs per glucose by channeling PEP into a partial set of reactions in the

FIGURE 2-23 Comparison of energy yield and products under anaerobic and aerobic conditions. In anaerobic conditions, only 2 ATP are produced for every glucose molecule processed, but in aerobic conditions a total of 32 ATP are produced per glucose molecule.

© Cengage Learning, 2013

citric acid cycle, in reverse direction. The end product is usually either succinic acid, yielding four ATPs per glucose, or propionic acid, yielding six ATPs per glucose (compare the following with Figure 2-18):

Some nonvertebrates (such as bivalve mollusks) can use **aspartate** (an amino acid) as an anaerobic fuel. Aspartate is particularly high in oyster and mussel hearts. It is converted to oxaloacetate (by removal of ammonia), which enters the pathway just described.

2. **Alternative end products.** The second modification point is the conversion of pyruvate for the purposes of regenerating NAD⁺. The acid problem created by lactate production is avoided in some organisms, in which pyruvate is converted to a variety of nonacidic organic products, including

- *Strombine*, *tauropine*, *lysopine*, *octopine*, *alanine*, and *alanopine* in mollusks. The first four compounds are produced by joining pyruvate to an amino acid: glycine, taurine, lysine, and arginine, respectively.
- *Ethanol* (alcohol) and *acetate*. Yeasts metabolize glucose anaerobically to two ethanol and two CO₂ molecules, a process used in manufacturing beer, for example. Goldfish wintering at the bottom of ice-covered ponds and lakes produce ethanol as the oxygen levels drop. This is the only vertebrate known to use this pathway.

Ultimately, end products such as lactate that accumulate in body fluids are converted back to pyruvate using NAD⁺ as

the electron acceptor. Pyruvate can then either enter into the citric acid cycle or be reconverted back into glucose or glycogen. Regardless of the disposition of pyruvate, oxygen is required. A functional electron transport system is essential to capture the energy from the NADH and FADH₂ during these reactions. The conversion of lactate to glucose is an example of *gluconeogenesis* (“new formation of glucose”). Basically, it is a reversal of glycolysis, because the principal intermediates of the pathway are the same. However, the gluconeogenic pathway involves several different enzymes and requires the expenditure of six molecules of ATP for each molecule of glucose generated. The ATP is necessary because glucose synthesis is energetically “uphill,” that is, an energy-requiring process (in contrast to glycolysis, which is “downhill,” in terms of energy expenditure).

Tolerance of oxygen deficiency varies widely among organisms

Many animals require oxygen continuously as the final electron acceptor for survival, and are classified as **obligate aerobes**. In mammals, most cells cannot survive more than a few minutes without oxygen. Anaerobic pathways are, however, important during intense bursts of activity. Skeletal muscle cells in particular take advantage of this ability during short bursts of strenuous exercise, when energy demands for contractile activity outstrip the animal’s ability to bring adequate O₂ to the exercising muscles to support oxidative phosphorylation. For example, cheetahs are noted for their remarkable sprint speeds. However, the metabolic costs incurred to the animal include an enormous *oxygen debt* and a reduction in blood and tissue pH (acidosis; see Chapter 13) caused by the accumulation of lactate. Cheetahs can sustain this intense activity for only brief periods of time and must rest for lengthy periods before resuming any activity.

A Closer Look at Adaptation Anoxic Animals

Three species of *loriciferans*, tiny sediment-dwelling marine animals that belong to their own phylum first described in 1983, have recently been found in sediment cores obtained from the bottom of a briny (hyper-salty), acidic and sulfurous basin of anoxic (oxygen-starved) water 3.5 kilometers below the Mediterranean Sea's surface. These creatures are almost a millimeter long and appear like jellyfish sprouting from a conical shell. They may be the first known animal example of an obligate anaerobe. Adaptations to their anoxic environment include a lack of mitochondria and

the presence of **hydrogenosomes**, respiratory organelles that generate ATP and molecular hydrogen found previously only in some obligate anaerobic fungi and protists. Similar to mitochondria in structure but lacking a genome, they are bounded by a double membrane, the inner one with some cristaelike projections. Discoveries such as these offer the possibility of identifying additional metazoan life in other anoxic regions of the planet.

A loriciferan.

In some species of fish, anaerobic pathways can fuel intermediate swimming speeds (between cruising and sprint), for sustained periods of time (tens of minutes). Lactate accumulates in large quantities in their white muscle fibers, and, unlike in mammals, removing these end products requires many hours of recovery. Because of the depletion of glucose stores and the poor return in energy yield on glucose, animals can rely on anaerobic metabolism for only relatively brief periods. When energy stores become depleted, vertebrate muscles fatigue and lose their ability to contract.

Some species of organisms—the **facultative anaerobes**—can adapt to anaerobic conditions for periods ranging from days to months by substituting other electron acceptors for oxygen, or by entering dormant states. The latter include embryos of brine shrimp (p. 17) and cysts of tardigrades (p. 614), which can survive inactive without oxygen indefinitely. Active facultative anaerobes include some parasitic worms such as tapeworms that can survive without oxygen indefinitely, and bivalve mollusks that live in the intertidal zone. For extended periods of time each day, these animals close their shells when exposed to air. Limiting desiccation by the sun in this way also renders them unable to exchange respiratory gases. Thus, they rely on the alternative pathways described earlier. Snapping turtles, the longest hibernating reptile in North America, bury themselves in the mud for up to eight months each year. Anaerobic glycolysis supplies the energy needs of these animals, at the expense of a buildup of lactate (particularly in the shell; see Chapter 13). However, in these and most vertebrates the brain and the heart normally continue their reliance on oxygen, albeit at a reduced rate.

A third group of organisms, called **obligate anaerobes**, are inhibited or killed in the presence of oxygen and thrive in anaerobic environments. These are primarily some archaea, bacteria (such as *Clostridium*, the source of botulism in improperly canned foods), and protozoa such as *Entamoeba*, which causes intestinal diseases such as dysentery in many mammals. Until recently, no animal was thought to be an obligate anaerobe, but that changed in 2010: see the box, *A Closer Look at Adaptation: Anoxic Animals*.

Animal cells that rely on anaerobic metabolism must have available to them an immediately available reservoir of

stored energy supplies. For example, in vertebrate white skeletal muscle fibers, fuel is stored within the cell in the form of glycogen. Tissue glycogen can then be readily mobilized to glucose in times of energy expenditure. In many nonvertebrates, glycogen stores can form a significant proportion of the actual muscle tissue weight (see Chapter 8), and some have alternative fuels such as aspartate (p. 56). Phosphagens (p. 55) can also be used anaerobically, though generally for only a short time before they are exhausted.

2.9 Vaults

Vaults, which are three times as large as ribosomes, are shaped like octagonal barrels (Figure 2-24). They have been found in many (but not all) animal groups and some protists. Their name comes from their multiple arches, which reminded their discoverers of vaulted or cathedral ceilings. A cell may contain thousands of vaults, but they have been elusive until recently because they do not show up with ordinary staining techniques. Two clues to the function of vaults may be their octagonal shape and their hollow interior. Intriguingly, the nuclear pores are also octagonal and the same size as vaults, leading to speculation that vaults may be cellular “trucks.” According to this proposal, vaults would dock at nuclear pores, pick up molecules such as mRNAs or ribosome subunits synthesized in the nucleus, and deliver their cargo elsewhere in the cell such as the

FIGURE 2-24 Vaults. Diagram of closed and open vaults and electron micrograph of vaults, which are octagonal barrel-shaped nonmembranous organelles believed to transport either messenger RNA or the ribosomal subunits from the nucleus to cytoplasmic ribosomes.

© Dr. Leonard H. Rome/UCLA School of Medicine

rough ER. Ongoing research supports vaults' role in nucleus-to-cytoplasm transport, but what cargo they are carrying is uncertain.

2.10 Cytosol

Recall that the cytosol is the semiliquid portion of the cytoplasm that surrounds the organelles. It occupies about 55% of the total cell volume. Its amorphous appearance under an electron microscope belies the fact that the cytosol is not a uniform liquid mixture but is actually more like a highly organized, gelatinous mass with differences in composition and gelatinous consistency between various regions and states of the cell.

The cytosol is important in intermediary metabolism, ribosomal protein synthesis, and storage of fat and glycogen

Four general categories of activities are associated with the cytosol: (1) enzymatic regulation of intermediary metabolism; (2) ribosomal protein synthesis; (3) storage of fat and

carbohydrate; and (4) temporary storage of vesicles. Dispersed throughout the cytosol is a *cytoskeleton* that gives shape to the cell, provides an intracellular organizational framework, and is responsible for various cell movements.

Enzymatic Regulation of Intermediary Metabolism The term *intermediary metabolism* refers collectively to the large set of intracellular chemical reactions that involve the degradation, synthesis, and transformation of small organic molecules such as simple sugars, amino acids, and fatty acids. These reactions, regulated by feedback loops, are critical for ultimately capturing energy to be used for cellular activities and for providing the raw materials needed for maintaining cell structure and function and for cell growth. All intermediary metabolism occurs in the cytoplasm and mostly in the cytosol. Thousands of enzymes involved in glycolysis and other intermediary biochemical reactions are found in the cytosol.

Ribosome Protein Synthesis Also dispersed throughout the cytosol are the free ribosomes, as we noted earlier. Often, cytosolic ribosomes that are synthesizing identical proteins are clustered together in “assembly lines” known as polyribosomes.

Storage of Fat and Glycogen Excess nutrients not immediately used for ATP production are converted in the cytosol into storage forms that are readily visible even under a light microscope. Such nonpermanent masses of stored material are known as *inclusions*. The main forms, as we noted earlier, are glycogen and triglycerides. Storage of energy in the form of triglyceride lipids represents the largest and most important form of storing extra energy because lipids have almost twice the energy density of carbohydrates and proteins. Intermediates of lipid metabolism are channeled directly into the tricarboxylic acid cycle of mitochondria, yielding proportionately greater amounts of ATP. (Curiously, mitochondria of cartilaginous fishes cannot use fatty acids, but those of all other vertebrates can.) Through a microscope, small fat droplets can be seen within the cytosol in various cells. In insect fat bodies and vertebrate adipose tissue, the stored triglycerides can occupy almost the entire cytosol, coalescing to form one large fat droplet (Figure 2-25a). The other visible storage product is glycogen, which appears as aggregates or clusters dispersed throughout the cell (Figure 2-25b). Cells vary in their ability to store glycogen, with liver and muscle cells having the greatest stores. When food is not available to provide fuel for the citric acid cycle and electron transport chain, stored glycogen and fat are broken down to release glucose and fatty acids, respectively, which can feed into the mitochondrial energy-producing machinery.

Storage of Vesicles Secretory vesicles that have been processed and packaged by the endoplasmic reticulum and Golgi complex also remain in the cytosol, where they are stored until signaled to empty their contents extracellularly. In addition, transport vesicles are transiently present in the cytosol as they carry their selected cargo from one membrane-enclosed organelle compartment to another or to the plasma membrane. Likewise, endocytotic vesicles can be found transiently in the cytosol until the cell disposes of these packages it has internalized.

cell division, the centrioles form a mitotic spindle out of microtubules to direct movement of chromosomes. You will learn about the microtubules in the next section.

2.12 Cytoskeleton: Cell “Bone and Muscle”

Permeating the cytosol is the **cytoskeleton**, a complex protein network that acts as the “bone and muscle” of the cell. The distinct shape, size, complexity, and intracellular specialization of the various body cells necessitate intracellular scaffolding to support and organize the cell components into an appropriate arrangement and to control their movements. These functions are performed by the cytoskeleton. This elaborate network has at least three distinct elements (Figure 2-26): (1) *microtubules*, (2) *microfilaments*, and (3) *intermediate filaments* (Table 2-1). The different parts of the cytoskeleton are structurally linked and functionally coordinated to provide certain integrated functions for the cell. Because of the complexity of this network and the variety of functions it serves, we discuss its elements separately.

Microtubules are essential for maintaining asymmetric cell shapes and are important in complex cell movements

The **microtubules** are the largest of the cytoskeletal elements. They are very slender (22 nanometer, or nm, in diameter; 1 nm = 1 billionth of a meter), long, hollow, unbranched tubes composed primarily of **tubulin**, a small, globular protein molecule (6 nm in diameter) (Figure 2-26a).

Microtubules position many of the cytoplasmic organelles, such as the ER, Golgi complex, lysosomes, and mitochondria. They are also essential for maintaining an asymmetric cell shape, such as that of a nerve cell, whose elongated *axon* may extend a meter in length or more in a large vertebrate, from the origin of the cell body in the spinal cord to the termination of the axon at a muscle (see Chapter 4). Microtubules, along with specialized intermediate filaments, stabilize this asymmetric axonal extension.

Microtubules also play an important role in coordinating numerous complex cell movements, including (1) transport of secretory vesicles from one region of the cell to another, (2) movement of specialized cell projections such as cilia and flagella, and (3) distribution of chromosomes during cell division through formation of a mitotic spindle. Let's examine each of these roles.

Transport of Secretory Vesicles Secretory vesicles produced by the Golgi complex are too big to move quickly by simple diffusion, particularly in large and long cells like neurons (Chapter 4) and tall thin epithelial cells. Microtubules solve this problem by providing a “highway” for vesicular traffic (and for mitochondria as well), with the driving force dependent on ATP. **Molecular motors** are the transporters. A molecular motor is a protein that attaches to the particle to be transported, then uses energy harnessed from ATP to “walk” along the microtubule with the particle riding in “piggyback” fashion (*motor* means “movement”). **Kinesin**, one such motor protein, consists of two “feet,” a stalk, and

check your understanding 2.9, 2.10

How does the shape of a vault provide a clue as to one of its possible functions?

How is the relative fat content of an adipose cell different from that of other cells? In what biological form are fats and sugars stored?

2.11 Centrosome, Centrioles, and Microtubule Organization

The **centrosome**, or **cell center**, located near the nucleus, consists of the centrioles surrounded by an amorphous mass of proteins. The **centrioles** are a pair of short cylindrical structures that lie at right angles to each other at the centrosome's center. The centrosome is the cell's main **microtubule organizing center (MTOC)**. Microtubules are one of the components of the cytoskeleton. When a cell is not dividing, microtubules are formed from the amorphous mass and radiate outward in all directions from the centrosome (Figure 2-2). These microtubules anchor many of the membranous organelles and also serve as “highways” along which vesicles are transported within the cell by “molecular motors.” In some cells, the centrioles form cilia and flagella, which are elongated, slender motile structures made up of bundles of microtubules. During

FIGURE 2-26 Components of the cytoskeleton. (a) Microtubules, the largest of the cytoskeletal elements, are long, hollow tubes formed by two slightly different variants of globular-shaped tubulin molecules. (b) Most microfilaments, the smallest of the cytoskeletal elements, consist of two chains of actin molecules wrapped around each other. (c) The intermediate filament keratin, found in skin, is made of three polypeptide strands wound around one another. The composition of intermediate filaments, which are intermediate in size between the microtubules and microfilaments, varies among different cell types.

© Cengage Learning, 2013

a fanlike tail (Figure 2-27). The tail binds to the secretory vesicle to be moved, and the feet move one at a time, as if walking. They alternately attach to one tubulin molecule on the microtubule, bend and push forward, then let go. During this process, the back foot swings ahead of what was the front foot and then attaches to the next tubulin molecule farther down the microtubule. The process is repeated over and over as kinesin moves its cargo to the plasma membrane by using each of the tubulin molecules as a stepping-stone. You'll see a detailed example for neurons in Chapter 4.

Movement of Cilia and Flagella Microtubules are also the dominant structural and functional components of cilia and flagella. These specialized protrusions from the cell surface allow a cell to move materials across its surface (in the case of a stationary cell) or to propel itself through its environment (in the case of a motile cell or animal). **Cilia** (meaning “eyelashes”; singular, *cilium*) are numerous tiny, hairlike protrusions found in large numbers on the surface of a ciliated cell. **Flagella** (meaning “whips”; singular, *flagellum*) are whiplike appendages; typically, a cell has one or a few flagella at most. Even though they project from the surface of the cell, cilia and flagella are both intracellular structures covered by the plasma membrane.

FIGURE 2-27 How a kinesin molecule “walks.” A kinesin molecule walks along the surface of a microtubule by alternately attaching and releasing its “feet” as it cyclically swings the rear foot ahead of the front foot.

© Cengage Learning, 2013

Cilia beat or stroke in unison, much like the coordinated efforts of a rowing team. Each cilium exerts a rapid active stroke, which moves material on the cell surface forward. This stroke is followed by a recovery phase in which the cilium more slowly returns to its original position with a kind of unrolling, backward movement that does not exert much force, so there is little pushing in the reverse direction. On a ciliated swimming animal like a ctenophore (comb jelly), hundreds of coordinated cilia push on the external seawater to create propulsion. Mammals have ciliated cells that line the respiratory tract (to help remove foreign particles from the lungs, Figure 2-28) and the oviduct of the female repro-

FIGURE 2-28 Cilia in the respiratory tract. Scanning electron micrograph of cilia on cells lining the human respiratory tract. The respiratory airways are lined by goblet cells, which secrete a sticky mucus that traps inspired particles, and epithelial cells that bear numerous hairlike cilia. The cilia all beat in the same direction to sweep inspired particles up and out of the airways.

ductive tract. You’ll learn more about these in Chapter 11 and about the reproductive tract in Chapter 16.

In addition to the multiple motile cilia found in cells in these specific locations, almost all vertebrate cells possess a single nonmotile *primary cilium*. Until recently, primary cilia were considered useless vestiges, but growing evidence suggests that they act as microscopic sensory organs that sample the extracellular environment. For example, the primary cilium of olfactory neurons contains receptors that detect odors, while the primary cilium of the epithelial cells lining the kidney tubules extends from the apical surface to monitor flow rate through the tubule. They may also be critical for receiving regulatory signals involved in controlling growth, cell differentiation, and cell proliferation (expansion of a given cell type).

The only vertebrate cells that bear flagella are sperm. The whiplike motion of the flagellum or “tail” enables a sperm to move through its environment. This ability is particularly useful when the sperm maneuvers for final penetration of the ovum during fertilization. Flagella are found in a few other animal cell types, such as the *choanocytes* (cells that create feeding current) of sponges that we discuss in Chapter 9.

Cilia and flagella arise from centrioles and consequently have the same basic internal structure. During cellular division they form after a duplicated centriole moves to a position just under the plasma membrane, where microtubules grow outward from the centriole in an orderly pattern to form the motile appendage. The centriole remains at the base of the developed cilium or flagellum and becomes the so-called **basal body**, a short cylinder composed of a parallel microtubular symmetry similar to that of the cilium or flagellum. Those consist of nine fused pairs of microtubules (doublets) arranged in an outer ring around two single unfused microtubules in the center (Figure 2-29). This characteristic

“9 + 2” array of microtubules extends throughout the length of the motile appendage. (In contrast, a primary cilium lacks the central pair of microtubules giving rise to a “9 + 0” array, which does not beat.)

Associated with these microtubules are accessory proteins that maintain the microtubules' organization and play an essential part in the microtubular movement that causes the entire structure to bend. The most important of these accessory proteins is **dynein**, which forms a set of armlike projections from each doublet of microtubules (see Figure 2-29b). The sliding of adjacent microtubule doublets past each other produces the bending movements of cilia and flagella. Sliding is accomplished by the dynein arms, which are motor proteins such as kinesin. The dynein arms have the capability of splitting ATP and then using the released energy to “crawl” along the neighboring microtubule doublet (similar to kinesin movement) to cause relative displacement of the doublets. Groups of cilia working together are oriented to beat in the same direction and contract in a synchronized manner through controlling mechanisms that are poorly understood. These mechanisms appear to involve the single microtubules at the cilium's center and their surrounding accessory proteins, the inner sheath (see Figure 2-29).

Formation of the Mitotic Spindle Cell division involves two discrete but related activities: **mitosis** (nuclear division) and **cytokinesis** (cytoplasmic division). Mitosis involves replication of the DNA-containing chromosomes, which are then evenly distributed in the two halves of the cell. In cytokinesis, the plasma membrane is constricted in the middle of the cell, and the two halves separate into two new daughter cells, each with a full complement of chromosomes.

The replicated chromosomes are pulled apart by a cellular apparatus called the **mitotic spindle**, which is transiently assembled from microtubules only during cell division and which uses kinesin motors. The microtubules of the mitotic spindle are formed by the centrioles. During cell division, the centrioles replicate; then, the new centriole pairs move to opposite ends of the cell and form the spindle apparatus. The spindle apparatus is responsible for the organized assemblage of microtubules. Some anticancer drugs interfere with microtubule assembly that ordinarily pulls the chromosomes to opposite poles during cell division.

Besides their role in mitotic-spindle formation, the centrioles and surrounding complex of densely staining proteinaceous material together assemble the many microtubules that normally radiate throughout the cytoskeleton. The centrioles are identical in structure to basal bodies. In fact, under some circumstances, the centrioles and basal bodies are interconvertible.

Microfilaments are important to cellular contractile systems and as mechanical stiffeners

The **microfilaments** are the smallest (6 nm diameter) elements of the cytoskeleton visible with a conventional electron microscope. The most obvious microfilaments in most cells are those composed of **actin**, a protein molecule that has a globular shape similar to tubulin. Unlike tubulin, which forms a hollow tube, actin is assembled into two twisted strands, much like two strings of pearls twisted into a helix (spiral) to form a microfilament (see Figure 2-26b).

FIGURE 2-30 Cytokinesis. Diagram and micrograph of a cell undergoing cytokinesis, in which a contractile ring composed of actin filaments tightens, squeezing apart the two duplicate cell halves formed by mitosis.

In muscle cells, another protein called **myosin** forms a different kind of microfilament (see Chapter 8). In most cells, myosin is not as abundant and does not form such distinct filaments.

Microfilaments serve at least two functions: (1) They play a vital role in various cellular contractile systems, and (2) they act as mechanical stiffeners for several specific cellular projections.

Microfilaments in Cellular Contractile Systems Actin-based assemblies are involved in muscle contraction, cell division, and cell locomotion. The most obvious, best organized, and most clearly understood cell contractile system is that found in muscle. As you will see in detail in Chapter 8, muscle contains an abundance of actin and myosin filaments. **Myosin** is a kinesin-like molecular motor that has heads that walk along the actin microfilaments, pulling them inward in a way that causes a muscle cell to contract.

Nonmuscle cells can also contain “musclelike” assemblies. Some of these microfilament contractile systems are transiently assembled to perform a specific function when needed. A good example is the contractile ring that forms during **cytokinesis**, the process by which the two halves of a dividing cell separate into two new daughter cells, each with a full complement of chromosomes. The ring consists of a beltlike bundle of actin filaments located just beneath the plasma membrane in the middle of the dividing cell. When this ring of fibers contracts and tightens with its myosin motors, it pinches the cell in two (Figure 2-30).

FIGURE 2-31 An amoeba undergoing amoeboid movement.

Complex actin-based assemblies are also responsible for most cell locomotion. Four types of adult mammalian cells are capable of moving on their own—sperm, white blood cells, fibroblasts, and skin cells. In nonvertebrates, amoebocytes—immune cells—crawl similarly. Sperm move by the flagellar mechanism already described. Motility for the other cells is accomplished by **amoeboid movement**, a cell-crawling process that depends on the activity of their actin filaments, in a mechanism similar to that used by amoebae to maneuver through their environment. When crawling, the motile cell forms *pseudopods* at the “front” or leading edge of the cell in the direction of the target (Figure 2-31). For example, the target that triggers amoeboid movement might be the proximity of food in the case of an amoeba, or a bacterium in the case of a white blood cell or amoebocyte. Pseudopods are formed as a result of the organized assembly and disassembly of branching actin networks. During amoeboid movement, actin filaments continuously grow at the cell’s leading edge through the addition of actin molecules at the front of the actin chain. This filament growth protrudes that portion of the cell forward as a pseudopod. Simultaneously, actin molecules at the rear of the filament are being disassembled and transferred to the front of the line. Thus, the filament does not get any longer; it stays the same length but moves forward through the continuous transfer of actin molecules from the rear to the front of the filament in what is termed *treadmilling* fashion. The cell attaches the pseudopod to the surrounding connective tissue and at the same time detaches from its older adhesion site at the rear. The cell uses the new adhesion site at the leading edge as an anchor, then pulls the bulk of its body forward through cytoskeletal contraction using myosin motors.

Microfilaments as Mechanical Stiffeners Besides their role in cell contractile systems, the actin filaments’ second major function is to serve as mechanical supports or stiffeners for several cellular extensions, of which the most common are microvilli. **Microvilli** are microscopic, nonmotile, hairlike projections from the surface of many epithelial cells linings, such as the vertebrate small intestine and kidney tubules. Within each microvillus, a core consisting of parallel actin filaments linked together forms a rigid mechanical stiffener that keeps these valuable surface projections intact. A single small-intestinal cell may have several thousand microvilli, which are packed together like the bristles of a brush, pro-

FIGURE 2-32 Microvilli in the small intestine. Scanning electron micrograph showing microvilli on the surface of a small-intestine epithelial cell.

jecting from the cell’s free surface (Figure 2-32). Their presence greatly increases the surface area available for transferring material across the plasma membrane, such as for absorbing digested nutrients in an intestine or recovering useful substances passing through the kidney. You will see more important examples in the sensory systems of fish and the mammalian inner ear in Chapter 6.

Both microtubules and microfilaments form both stable structures, such as microvilli, and transient structures, such as mitotic spindles and contractile rings, as the need arises. Pools of unassembled tubulin and actin subunits in the cytosol can be rapidly assembled into organized structures to perform specific activities, then disassembled when they are no longer needed.

Intermediate filaments are important in regions of the cell subject to mechanical stress

The **intermediate filaments** are intermediate in size between the microtubules and the microfilaments (7 to 11 nm in diameter)—hence their name. The proteins that compose the intermediate filaments vary between cell types, but in general they appear as irregular, threadlike molecules. These proteins form tough, durable fibers that play a central role in maintaining the structural integrity of a cell and in resisting mechanical stresses externally applied to a cell. In contrast to the other cytoskeletal elements, the intermediate filaments are highly stable structures. No evidence exists for a reversible pool between unassembled and assembled intermediate-filament proteins. The different types of intermediate filaments are tailored to suit their structural or tension-bearing role in specific cell types. In general, only one class of intermediate filament is found in a particular cell type. Several important examples follow:

- Neurofilaments are intermediate filaments in nerve cell axons (see Chapter 4). Together with microtubules, neurofilaments strengthen and stabilize these elongated cellular extensions.

By Tim Vickers

FIGURE 2-33 The crowded cytosol. Diagram of cell interior with microtubules (*light blue*), actin filaments (*dark blue*), ribosomes (*orange and purple*), soluble proteins (*light blue*), kinesin (*red*), small molecules (*white*) and RNA (*pink*).

- Intermediate filaments in skeletal muscle cells hold the actin–myosin contractile units in proper alignment (Chapter 8).
- Skin cells contain irregular networks of intermediate filaments made of the protein **keratin** (see Figure 2-26c). These intracellular filaments interconnect with extracellular filaments that tie adjacent cells together, creating a continuous filamentous network that extends throughout the skin and gives it strength. When the surface skin cells die, their tough keratin skeletons persist to form a protective waterproof outer layer. Hair and nails are also keratin-based structures.

Emphasizing the importance of intermediate filaments in some specialized cell types, intermediate filaments account for up to 85% of the total protein in nerve cells and keratin-producing skin cells, whereas these filaments constitute only about 1% of other cells' total protein on average.

The cytoskeleton functions as an integrated whole, links other parts of the cell, and contributes to cytosolic “crowding”

Collectively, the cytoskeletal elements and their interconnections support the plasma membrane and are responsible for the particular shape, rigidity, and spatial geometry of each

different cell type. Furthermore, growing evidence suggests that the cytoskeleton serves as a lattice to organize groups of enzymes for many cellular activities. This internal framework thus acts as the cell's “skeleton” (Figure 2-33; see also Figure 2-5). New studies hint that the cytoskeleton as a whole is not merely a supporting structure that maintains the tensional integrity of the cell but may serve as a mechanical communications system as well. Various components of the cytoskeleton behave as if they were structurally connected or “hard-wired” to each other as well as to the surface plasma membrane and to the nucleus. This force-carrying network may serve as a mechanism by which mechanical forces acting on the cell surface reach all the way from the plasma membrane through the cytoskeleton to ultimately influence gene regulation in the nucleus. Furthermore, as you have learned, the coordinated action of the cytoskeletal elements directs intracellular transport and regulates numerous cellular movements and thereby also serves as the cell's “muscle.”

As we finish this look at the major components of eukaryotic cells, you may wonder how all these structures fit within a cell. In fact, the total number of organelles along with macromolecular complexes do fit, but they create a crowded cytosol. These structures are estimated to take up to 40% of the physical space inside a cell (Figure 2-33). Such crowding is predicted to slow down diffusion rates consider-

ably, much as a person will take longer to move through a crowd than across an empty field. Conversely, crowding is predicted to increase the rates of chemical reactions between large macromolecules in the same region, such as transcription regulating proteins binding to DNA in the nucleus. The overall importance of these effects is currently being investigated and is likely to be of even greater importance in dehydration stresses, such as the cells of an animal losing too much water would suffer.

Which of these is responsible for maintaining the cell in an asymmetric shape, such as that of a nerve cell?

2.13 Cell-to-Cell Adhesions

In multicellular organisms, plasma membranes not only serve as the outer boundaries of all cells but also participate in cell-to-cell adhesions, allowing groups of cells to bind together into tissues and to be packaged further into organs. Organization of cells into appropriate groupings may be at least partially attributable to the carbohydrate chains on the membrane surface. Once arranged, cells are held together by three different means: (1) *cell adhesion molecules* (CAMs) in the cells' plasma membranes, (2) the *extracellular matrix*, and (3) specialized *cell junctions*.

The extracellular matrix serves as the biological “glue”

Many cells within a tissue are not in direct physical contact with neighboring cells. Instead, they are held together by the **extracellular matrix** (ECM), an intricate meshwork of fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates. The watery gel, an ECF component usually called the interstitial fluid, provides a pathway for diffusion of nutrients, wastes, and other water-soluble traffic between the blood and tissue cells. Interwoven within this gel are three major types of protein fibers:

1. **Collagen** forms cablelike fibers or sheets that provide tensile strength (resistance to longitudinal stress). Collagen is the most abundant protein in mammals, making up nearly half of the total body protein by weight. In *scurvy*, a human condition caused by vitamin C deficiency (due to a human pseudogene, p. 33), these fibers are not properly formed. As a result, the tissues, especially those of the skin and blood vessels, become very fragile. This leads to bleeding in the skin and mucous membranes, which is especially noticeable in the gums.
2. **Elastin** is a rubberlike protein fiber most abundant in tissues that must be capable of easily stretching and then recoiling after the stretching force is removed. It is found, for example, in mammalian lungs, which stretch and recoil as air moves in and out.
3. **Fibronectin** promotes cell adhesion and holds cells in position. Researchers have found reduced amounts of

this protein within certain types of cancerous tissue, possibly explaining why cancer cells do not adhere well to each other but tend to break loose and metastasize (spread elsewhere in the body).

Local cells, most commonly **fibroblasts** (“fiber formers”) present in the matrix, secrete the extracellular matrix. Often the matrix and the cells within it are known collectively as **connective tissue** because they connect cells together into tissues and tissues into organs. The exact composition of extracellular matrix components varies for different tissues, providing distinct local environments for the various cell types in the body. In some tissues, the matrix becomes highly specialized to form such structures as cartilage or tendons or, on appropriate calcification, the hardened structures of bones and teeth.

Contrary to long-held belief, the ECM is not just a passive scaffolding for cellular attachment but also helps regulate the behavior and functions of the cells with which it interacts. Cells are able to function normally and indeed even to survive only when associated with their normal matrix components. The matrix is especially influential in cell growth and differentiation. In a vertebrate's body, only circulating blood cells are designed to survive and function without attaching to the ECM.

Some cells are directly linked together by specialized cell junctions

In tissues where the cells lie in close proximity to each other, CAMs provide some tissue cohesion as they “Velcro” adjacent cells to each other. In addition, some cells within given types of tissues are directly linked by one of three types of specialized cell junctions: (1) *desmosomes* (adhering junctions), (2) *tight junctions* (impermeable junctions), or (3) *gap junctions* (communicating junctions).

Desmosomes Acting like “spot welds” that anchor together two closely adjacent but nontouching cells, **desmosomes** consists of two components: (1) a pair of dense, buttonlike cytoplasmic thickenings known as *plaque* located on the inner surface of each of the two adjacent cells; and (2) strong glycoprotein filaments containing *cadherins* (a type of CAM) that extend across the space between the two cells and attach to the plaque on both sides (Figure 2-34). These intercellular filaments bind adjacent plasma membranes together so they resist being pulled apart. Thus, desmosomes are adhering junctions. They are the strongest cell-to-cell connections.

Desmosomes are distributed widely throughout animal bodies. Desmosomes are most abundant in tissues that are subject to considerable stretching, such as the skin, heart, and the uterus. In these tissues, functional groups of cells are riveted together by desmosomes. Furthermore, intermediate cytoskeletal filaments, such as tough keratin filaments in the skin, stretch across the interior of these cells and attach to the desmosome plaques located on opposite sides of the cell's inner surface. This arrangement forms a continuous network of strong fibers throughout the tissue, both through and between the cells, much like a continuous line of people firmly holding hands. This interlinking fibrous network provides tensile strength, reducing the chances of the tissue being torn when stretched.

FIGURE 2-34 Desmosome. Desmosomes are adhering junctions that spot-ribose cells, anchoring them together in tissues subject to considerable stretching.

Tight Junctions Tight junctions join sheets of epithelial tissue. Epithelial tissue covers or produces the surface of animal bodies and lines all their internal cavities. Usually these sheets serve as highly selective barriers between two compartments that have considerably different chemical compositions. For example, the epithelial sheet lining a digestive tract separates the food and potent digestive juices within the inner cavity (lumen) from the ECF that lies on the other side. To accomplish this, the lateral (side) edges of the adjacent cells in the epithelial sheet are joined together in a tight seal near their luminal border by “kiss sites,” which are sites at which membrane *junctional proteins* from two adjacent cells fuse directly (Figure 2-35). These tight junctions are impermeable and thus prevent materials from passing between the cells. Passage across the epithelial barrier, therefore, must take place through the cells, not between them. This *transcellular* (“through the cell”) traffic is regulated by means of the channels and carrier proteins present in the plasma membrane. If the cells were not joined by tight junctions, uncontrolled exchange of molecules could take place between the compartments by unregulated traffic through the spaces between adjacent cells (*paracellular* pathway). Thus, tight junctions prevent undesirable leaks within epithelial sheets. (See Chapters 12 and 14 for specific details on epithelial transport in kidneys and digestive tracts.)

Gap Junctions At a gap junction, a gap exists between adjacent cells that are linked by small connecting tunnels known as *connexons* made of *connexin* proteins in vertebrates and

FIGURE 2-35 Tight junction. Tight junctions are impermeable junctions that join the lateral edges of epithelial cells near their luminal borders, thus preventing movement of materials between the cells. Only regulated passage of materials can occur through these cells, which form highly selective barriers that separate two compartments of highly different chemical composition.

innexin proteins in other animals (e.g., arthropods, nematodes). A **connexon** is made up of six protein subunits arranged in a hollow tubelike structure. Two connexons, one from each of the plasma membranes of two adjacent cells, extend outward and join end-to-end to form a connecting tunnel between the two cells (Figure 2-36). The small diameter of the tunnels permits small water-soluble particles such as ions (electrically charged particles) to pass between the connected cells but precludes passage of large molecules such as proteins. Gap junctions are found in most organs, but are perhaps best studied in heart muscle and smooth muscle. Movement of ions between cells through gap junctions plays an important role in transmitting electrical activity throughout an entire muscle mass. Because this electrical activity brings about contraction, the presence of gap junctions enables synchronized contraction of a whole muscle mass, such as the heart (see Chapter 9). Some nerve cells are also connected in this way. For example, crayfish escape attack by rapidly flipping their tails. Gap junctions allow for rapid conduction of the electrical signal (see Chapter 4).

Many tissues that are not electrically active also are connected by gap junctions, where they permit unrestricted passage of small nutrient molecules between cells. For example,

glucose, amino acids, and other nutrients pass through gap junctions to a developing egg cell from surrounding cells within the mammalian ovary, thus helping the egg stockpile these essential nutrients. Furthermore, these gap junctions also serve as avenues for the direct transfer of small signaling molecules from one cell to the next. Such transfer permits the cells connected by gap junctions to directly communicate with each other. This communication provides one possible mechanism by which cooperative cell activity may be coordinated. In the next chapter, we'll describe another recently discovered tunnel-like communication device called a *nanotube*.

The cytosol's surrounding barrier, the plasma membrane, is intimately involved in desmosome, tight and gap junctions, and nanotubes. The properties of this major structure are explored in the next chapter, including other ways by which cells "talk to each other."

How Cellular and Molecular Physiology Contribute to the Body as a Whole

The ability of cells to perform functions essential for their own survival as well as specialized tasks that contribute to homeostasis and regulated changes within an animal ultimately depends on the successful and cooperative operation of the intracellular components. For example, genes must be regulated at the right time and place to construct cell structures. Also, to support life-sustaining activities, all cells must convert energy into a usable form from nutrient molecules. Energy is converted intracellularly by chemical reactions that take place within the cytosol and mitochondria.

In addition to being essential for basic cell survival, the organelles and cytoskeleton also participate in many cells' specialized tasks that contribute to homeostasis. Here are several examples:

- Nerve and endocrine cells both release chemical messengers that are important in regulatory activities aimed at maintaining homeostasis—for example, chemical messengers released from nerve cells stimulate the respiratory muscles, which accomplish life-sustaining exchanges of O_2 and CO_2 between the body and environment through breathing. These chemical messengers (neurotransmitters in nerve cells and hormones in endocrine cells) are all produced by the endoplasmic reticulum and Golgi complex and released by exocytosis from cells when needed.
- The ability of muscle cells to contract depends on their highly developed cytoskeletal microfilaments sliding past each other. Muscle contraction is responsible for many homeostatic activities, including (1) contraction of heart muscle; (2) contraction of the muscles attached to

skeletal elements, which enables behaviors, such as procuring food, fleeing predators, and mating; and (3) contraction of the muscle in the walls of digestive tracts, which moves the food along the tracts.

- White blood cells and amoebocytes help animal bodies resist infection by making extensive use of lysosomal destruction of engulfed particles as they police the body for microbial invaders. These cells are able to roam the

body fluids by means of amoeboid movement, a cell-crawling process accomplished by alternate assembly and disassembly of actin, one of their cytoskeletal components.

As we begin to examine the various organs and systems, keep in mind that proper cell functioning is the foundation of all organ activities.

Chapter Summary

- Water, other inorganic chemicals, carbohydrates, lipids, proteins, and nucleic acids are the universal components of cells.
- Many macromolecular structures need to be flexible to function and to be regulated, and protecting those structures is the basis for many forms of homeostasis.
- Prokaryotic (archaeal, bacterial) cells have a simpler organization than eukaryotes as exemplified by the lack of a separate nucleus and most organelles. Eukaryotic cells are subdivided into the plasma membrane, nucleus, and cytoplasm with organelles.
- DNA contains codes in the form of genes for making proteins through the processes of transcription and translation with different genes expressed in different tissues and organs. Individual genes are regulated by promoters and transcription factors, whereas in different tissues transcription is regulated by transcription factors expressed at different stages of development. Driving much of the growth in knowledge about molecular biology are the genome projects, which utilize a variety of experimental procedures to elucidate the connections between the gene and the cell.
- The rough endoplasmic reticulum synthesizes proteins for secretion and membrane construction, whereas the smooth endoplasmic reticulum packages new proteins in transport vesicles. Transport vesicles carry their cargo to the Golgi complex for further processing. Once there, the Golgi complex packages secretory vesicles for release by exocytosis.
- Lysosomes digest extracellular material brought into the cell by phagocytosis, whereas proteasomes destroy internal proteins, that is, intracellular proteins that have outlived their usefulness.
- Mitochondria are the energy organelles or “power plants” of the cell; using oxygen, they extract energy from the nutrients in food and transform it into a usable form—primarily ATP—to support cell activities. However, leakage of some of the electrons associated with mitochondrial metabolism can potentially damage the tissues of the host animal and contribute to the aging process.
- Oxygen deficiency forces cells to rely on glycolysis and other anaerobic reactions, producing lactate, propionic acid, octopine, or other end products. However, tolerance of oxygen deficiency varies widely among tissues as well as different organisms.
- The cytosol is important in intermediary metabolism, ribosomal protein synthesis, and storage of fat and glycogen.
- Permeating the cytosol is the cytoskeleton, a complex protein network that acts as the “bone and muscle” of the cell. The distinct shape, size, complexity, and intracellular specialization of the various body cells necessitate intracellular scaffolding to support and organize the cell components into an appropriate arrangement and to control their movements.
- The microtubules, the largest of the cytoskeletal elements, are important for intracellular transport and cilia and flagella. Microfilaments are the smallest element of the cytoskeleton and are important to cellular contractile systems and as mechanical stiffeners. Intermediate filaments are important in regions of the cell subject to mechanical stress. The cytoskeleton functions as an integrated whole and links other parts of the cell, possibly as a lattice to organize groups of enzymes for many cellular activities.
- The extracellular matrix serves as the biological “glue.” It is an intricate meshwork of fibrous proteins embedded in the interstitial fluid. Interwoven within this gel are three major types of protein fibers: collagen, elastin, and fibronectin.
- Some cells are directly linked together by specialized cell junctions. Desmosomes act like “spot welds” that anchor together two closely adjacent but nontouching cells; tight junctions join sheets of epithelial tissue and prevent undesirable leaks from one compartment to another; and gap junctions allow small molecules to pass from one cell to another.

Review, Synthesize, and Analyze

1. What organelles serve as the intracellular digestive system? What type of enzymes do they contain? What functions do these organelles serve?
2. How are free radicals important in the aging process? For species with comparative longevity, what is the mechanism by which they are able to overcome the degenerative processes associated with free radicals?
3. Distinguish among *cellular respiration*, *oxidative phosphorylation*, and *chemiosmosis*.
4. On an expedition to survey life in deep ocean waters in the Mediterranean Sea, you recover a Loriciferan from 350 km below the surface in the hostile L'Atalante basin. As a biologist onboard the vessel, how would you determine if the animals were really surviving in such an anaerobic environment rather than simply drifting down from elsewhere and dying?
5. Is iPSC technology the long sought after “fountain of youth”? Speculate on a mechanism by which the expression of embryonic genes can reprogram a differentiated cell.

6. You have been provided a strand of hair from a woolly mammoth. How would you determine its approximate age? How might you try to resurrect a living mammoth?
7. Oxygen can be considered a double-edged sword. Although essential for life, it also generates free radicals that contribute to the aging process. What other elements could alternatively be substituted for oxygen as a final electron acceptor? Specify any advantages/disadvantages associated with its use.

Membrane Physiology

3.1 Membrane Structure and Composition

The survival of every animal cell depends on the maintenance of an intracellular content unique for that cell type despite the remarkably different composition of the extracellular fluid surrounding it. This difference in fluid composition inside and outside a cell is maintained by the **plasma membrane**, an extremely thin layer of lipids and proteins that forms the outer boundary of every cell and encloses the intracellular contents. In addition to serving as a mechanical barrier that traps needed molecules within the cell, the plasma membrane plays an active role in determining the composition of the cell by selectively permitting specific substances to pass between the cell and its environment. Besides controlling the entry of nutrient molecules and the exit of waste products, the plasma membrane maintains differences in ion concentrations between the cell's interior and exterior. These ionic differences, as you will learn, are important in the electrical

activity of cells. Also, the plasma membrane plays a key role in the ability of a cell to respond to changes, or signals, in the cell's environment. No matter what the cell type, these common functions accomplished by the plasma membrane are crucial to the cell's survival and to the cell's ability to perform specialized homeostatic activities.

In this chapter, we examine the common structural and functional patterns shared by plasma membranes of all cells. We also explore how many of the functional differences between cell types are due to subtle variations in the composition of their plasma membranes. For example, modifications in specific protein components of the plasma membranes of various cell types enable different cells to interact in different ways with essentially the same extracellular fluid environment. To illustrate, thyroid gland cells are the only cells in a vertebrate to use iodine. Appropriately, a membrane protein unique to the plasma membranes of thyroid gland cells permits these cells (and no others) to take up iodine from the blood.

The plasma membrane is a fluid lipid bilayer embedded with proteins

The plasma membrane is too thin to be seen under an ordinary light microscope, but with an electron microscope it appears as a **trilaminar structure** (three-layered; *lamina* means “layer”) consisting of two dark layers separated by a light middle layer (Figure 3-1). The specific arrangement of the molecules that make up the plasma membrane is responsible for this “sandwich” appearance.

All plasma membranes consist mostly of lipids (fats) and proteins plus small amounts of carbohydrates. The most abundant membrane lipids are phospholipids, with lesser amounts of cholesterol. **Phospholipids** have a **polar** (electrically charged) head containing a negatively charged phosphate group and two **nonpolar** (electrically neutral) fatty acid tails (Figure 3-2a). The polar end is *hydrophilic* (“water loving”)

FIGURE 3-1 Trilaminar appearance of a plasma membrane in an electron micrograph. Depicted are the plasma membranes of two adjacent cells. Note that each membrane appears as two dark layers separated by a light middle layer.

© Don W. Fawcett/Visuals Unlimited

because it can interact with water molecules, which are also polar; the nonpolar end is *hydrophobic* (“water fearing”) and will not mix with water. Such two-sided molecules self-assemble into a **lipid bilayer**, a double layer of lipid molecules, when in contact with water (Figure 3-2b). The hydrophobic tails bury themselves in the center away from the water, whereas the hydrophilic heads line up on both sides in contact with the water. The outer surface of the bilayer is exposed to extracellular fluid (ECF), whereas the inner surface is in contact with the intracellular fluid (ICF) (Figure 3-2c). (Do not confuse the bilayer with the trilaminar appearance it gives!)

This lipid bilayer is not a rigid structure at normal body temperatures but instead is fluid, with a consistency more like liquid cooking oil than like solid shortening. The phospholipids, which are not held together by chemical bonds, are constantly moving. They can twirl, vibrate, and move around within their own half of the bilayer, exchanging places millions of times a second. This phospholipid movement accounts in large part for membrane *fluidity*. A certain degree of fluidity is required, for example, for the proper action of transport and channel proteins (p. 73), and for cell shape changes. Conversely, an overly fluid membrane is too leaky and can harm or kill cells. We’ll explore fluidity in more detail shortly.

Cholesterol contributes to both the fluidity and the stability of the membrane (Figure 3-3). By being tucked in between the phospholipid molecules, cholesterol molecules prevent the fatty acid chains from packing together and crystallizing, a process that would drastically reduce membrane fluidity. Through their spatial relationship with phospholipid molecules, cholesterol molecules also help stabilize the phospholipids’ position. Cholesterol also affects the functional attributes of cell membranes such as the activities of various membrane proteins. In animals exposed to varied environmental temperatures, cholesterol provides some rigidity to the membrane and can counter some of the temperature-induced perturbations in membrane fluidity (which can be detrimental at high temperatures). For example, concentrations of cholesterol in the plasma membranes of rainbow

trout (*Oncorhynchus mykiss*) increase with increasing environmental temperature. Cholesterol also reduces the permeability of the gill membrane to water and the flow of ions. For this reason, the concentration of cholesterol is approximately twice as great in the gill plasma membranes of bony fish as in other tissues. Cholesterol content is even higher in gill membranes of sharks, in order to prevent the loss of *urea* from their blood (see Chapter 13).

Also contributing to membrane fluidity are differences in membrane composition. For example, fish, as well as other *poikilotherms* (organisms whose body temperatures vary with the environment; Chapter 15), can alter the composition of their lipids to synthesize membranes with physical properties that let them adapt and function at low ambient temperatures. Cold temperatures cause the membrane lipids to become more rigid (like butter placed in a refrigerator). For this reason, membrane lipids of animals adapted to cold environments are enriched in **polyunsaturated fatty acids (PUFAs)** at the expense of a reduction in **saturated fatty acids (SFAs)**. The addition of double bonds (points of unsaturation) into the fatty acid molecule results in chains that do not stack together well and so do not become too rigid in the cold, thus offsetting the effects of low temperatures on fluidity. There are two distinctly different groups of PUFAs: the omega-6 series, in which the first double bond is

found between the sixth and seventh carbon atoms in the fatty acid chain, and the omega-3 series, in which the first double bond is located between the third and fourth carbon atoms. For every 20°C decrease in ambient temperature, there is a 1.3- to 1.4-fold increase in the ratio of UFAs to SFAs. Characteristics of lipids containing PUFAs include a reduction in membrane order because of their more expanded conformation. Under frigid conditions these lipids pack less efficiently. For example, brain fatty acids of Antarctic fish are enriched in 24-carbon PUFAs. The proportion of PUFAs in membranes of cold-adapted marine fish may be as high as 42%, compared to 33% in species inhabiting more temperate waters. (See Chapter 15 for more on temperature and membranes.)

The most prominent long-chain omega-3 PUFAs in fish oils are **eicosapentaenoic acid (EPA)**, which is 22 carbons long, with five double bonds (20:5, omega-3) and **docosahexaenoic acid (DHA)**, which is 22 carbons long, with six double bonds (22:6, omega-3). DHA is also important for mammalian brain development, perhaps because it increases membrane fluidity at *synapses* (neural junctions), aiding neurotransmitter release (see pp. 131–132). The highest amounts of EPA and DHA are in fatty fish such as mackerel, herring, and salmon; white fish such as cod and flounder contain only small amounts of omega-3 PUFAs.

Attached to or inserted within the lipid bilayer are the **membrane proteins** (Figure 3-3). **Integral proteins** are embedded in the lipid bilayer; if they extend through the entire thickness of the membrane, they are called **transmembrane proteins** (*trans* means “across”). Like phospholipids, integral proteins also have hydrophilic and hydrophobic regions. **Peripheral proteins** are usually polar molecules that do not penetrate the membrane. They stud only the outer or inner surface, anchored by relatively weak chemical bonds with the

polar parts of integral membrane proteins or membrane lipids. The plasma membrane has about 50 times more lipid molecules than protein molecules. However, proteins account for nearly half of the membrane's mass because they are much larger than the lipids. The fluidity of the lipid bilayer enables many membrane proteins to float freely like "icebergs" in a moving "sea" of lipid, although the cytoskeleton restricts the mobility of proteins that perform a specialized function in a specific area of the cell. This view of membrane structure is known as the **fluid mosaic model**, in reference to the membrane fluidity and the ever-changing mosaic pattern of the proteins embedded within the lipid bilayer.

A small amount of **membrane carbohydrate** is located only at the outer surface. Short-chain carbohydrates protrude like tiny antennas from the outer surface, bound primarily to membrane proteins and to a lesser extent to lipids. These sugary combinations are known as *glycoproteins* and *glycolipids*, respectively (Figure 3-3), and the "sugar coating" they form is called the *glycocalyx* (*glyco* means "sweet"; *calyx* means "husk").

The different components of the plasma membrane carry out a variety of functions. As a quick preview, the lipid bilayer forms the primary barrier to diffusion, the proteins perform most of the specific membrane functions, and the carbohydrates play an important role in "self"-recognition processes and cell-to-cell interactions.

The mosaic model and membrane-skeleton fence model describe membrane structure and function

The fluid mosaic model can account for the trilaminar appearance of the plasma membrane. When researchers use stains to help them visualize the plasma membrane under an electron microscope, the two dark lines represent the hydrophilic polar regions of the lipid and protein molecules that have taken up the stain. The light space between corresponds to the poorly stained hydrophobic core formed by the nonpolar regions of these molecules.

Even though the outer and inner layers have the same appearance when viewed with an electron microscope, our description makes clear that the plasma membrane actually is asymmetric; that is, the surface of the membrane facing the extracellular fluid is strikingly different from the surface facing the cytoplasm. Carbohydrate is located only on the outer surface; the outer and inner surfaces bear different amounts and types of protein; and even the lipid composition of the outer half of the bilayer varies somewhat from the inner half. This distinct sidedness of the membrane is related to the different functions carried out at the outer and inner surfaces.

Furthermore, considerable heterogeneity exists within each half of the membrane. For example, recent information suggests that not all membrane proteins are as freely mobile and uniformly distributed as proposed by the fluid mosaic model. To explain this phenomenon, researchers proposed the **membrane-skeleton fence model**, in which the mobility of proteins that perform a specialized function in a specific area of the membrane is restricted by several means. Whereas some proteins can drift randomly within the membrane (similar to a dog that freely roams the neighborhood), scientists think other proteins are tethered to the cytoskeleton (see p. 64) (much like a dog restricted by a leash). These

so-called *nondiffusing* or *immobile* proteins constitute a sizable proportion of the total membrane fraction. Still other proteins appear restricted to **confinement zones** by fine cytoskeletal *meshwork fences* within the membrane (similar to a dog confined by a fence to its own backyard). Sometimes these barriers to mobility temporarily open so that proteins can move between confinement zones. Finally, a few proteins undergo rapid, highly directed transport toward a specific region of the membrane, perhaps being carried by motor proteins similar to kinesin (see p. 60). (This is analogous to a dog being carried by its owner to a particular destination.) Thus, the emerging view is that the plasma membrane is a highly complex, dynamic, regionally differentiated structure.

The lipid bilayer forms the basic structural barrier that encloses the cell

In addition to providing fluidity, the lipid bilayer serves at least two other important functions:

1. It forms the basic structure of the membrane. The phospholipids can be visualized as the "pickets" that form the "fence" around the cell.
2. Its hydrophobic interior serves as a barrier to passage of water-soluble substances between the ICF and ECF. Most water-soluble substances cannot dissolve in and pass through the lipid bilayer. (However, water molecules themselves and some other small uncharged molecules such as CO₂ are small enough to pass between the molecules that form this barrier.) By means of this barrier, the cell can maintain different mixtures and concentrations of solutes (dissolved substances) inside and outside the cell.

The membrane proteins perform a variety of specific membrane functions

A variety of different proteins within the plasma membrane serve the following specialized functions (see Figure 3-3), some of which we will discuss in detail later:

1. **Channels.** Some transmembrane proteins form water-filled pathways, or channels, across the lipid bilayer. Their presence enables water-soluble ions that are small enough to enter a channel to pass through the membrane without coming into direct contact with the hydrophobic lipid interior.
2. **Carriers.** Another group of proteins that span the membrane serve as **carrier proteins**, which transfer larger, specific substances across the membrane that cannot cross on their own. Both channels and carriers help determine what substances are transferred between the ICF and ECF.
3. **Receptors.** Many proteins on the outer surface serve as **receptors**, proteins with sites that "recognize" and bind with specific molecules in the cell's environment. This binding initiates a series of membrane and intracellular events (to be described later) that alter the activity of the particular cell. In this way, chemical messengers in the blood, such as hormones, can influence only the specific cells that have receptors for the messenger while having no effect on other cells, even though every cell is exposed

to the same messenger via its widespread distribution by the blood. To illustrate, the mammalian anterior pituitary gland secretes into the blood thyroid-stimulating hormone (TSH), which can attach to the surface receptors of thyroid gland cells to stimulate secretion of thyroid hormone.

4. **Docking-marker acceptors.** Still other proteins on the inner surface serve as **docking-marker acceptors** that bind lock-and-key fashion with the docking markers of secretory vesicles (see p. 41). Secretion is initiated as stimulatory signals trigger the fusion of the secretory vesicle membrane with the inner surface of the plasma membrane through interactions between their SNARE proteins (see Chapter 2, p. 43). The secretory vesicle subsequently opens up and empties its contents to the outside by exocytosis.
5. **Enzymes.** Another group of proteins function as **membrane-bound enzymes** that control specific chemical reactions at either the inner or the outer cell surface. These also vary among cell types. For example, the outer layer of the plasma membrane of skeletal muscle cells contains an enzyme that destroys the neurotransmitter that triggers muscle contraction, enabling the muscle to relax.
6. **CAMs.** Still other proteins serve as **cell adhesion molecules (CAMs)**. Many CAMs protrude from the outer membrane surface and form loops or other appendages that the cells use to grip each other or grasp the connective tissue fibers between cells. For example, *cadherins*, a type of CAM found on the surface of adjacent cells, interlock in zipper fashion to help hold the cells within tissues and organs together. Other CAMs, such as the *integrins*, span the plasma membrane where they serve as a structural link between the outer membrane and its extracellular surroundings and also connect the inner membrane surface to the intracellular cytoskeletal scaffolding. Besides mechanically linking the cell's external environment and intracellular components, integrins also relay regulatory signals through the plasma membrane in either direction. Some CAMs also function as "signaling molecules" in cell growth and in inflammatory responses, among other things.
7. **Self-identity markers.** Finally, still other proteins on the outer membrane surface, especially in conjunction with carbohydrates, are important in cells' ability to recognize "self" (that is, cells of the same type) and in cell-to-cell interactions, as described next.

The membrane carbohydrates serve as self-identity markers

The short sugar chains on the outer-membrane surface serve as self-identity markers that enable cells to identify and interact with each other in the following ways.

1. Different cell types have different markers. The unique combination of sugar chains projecting from the surface membrane serves as the "trademark" of a particular cell type, enabling a cell to recognize others of its own kind. These carbohydrate chains play an important role in recognition of "self" and in cell-to-cell interactions. Cells can recognize other cells of the same type and join together to form tissues. This is especially important

during embryonic development. If cultures of embryonic cells of two different types such as nerve cells and muscle cells, are mixed, the cells sort themselves into separate aggregates of nerve cells and muscle cells. "Self"-recognition is also crucial in all animal immune responses (e.g., *major histocompatibility complex* in mammals, Chapter 10, p. 483).

2. Carbohydrate-containing surface markers are also involved in tissue growth, which is normally held within certain limits of cell density. Cells do not "trespass" across the boundaries of neighboring tissues; that is, they do not overgrow their own territory. The exception is the uncontrolled spread of cancer cells, which have been shown to bear abnormal surface carbohydrate markers.

We now turn our attention to the topic of membrane transport, focusing on how the plasma membrane selectively controls what enters and exits the cell.

check your understanding 3.1

How do lipids organize themselves to form a plasma membrane, and what purpose does the membrane's hydrophobic interior serve?

What are the functions of and ways of altering membrane fluidity? What structural changes in membrane composition help maintain fluidity at elevated environmental temperatures? At low environmental temperatures?

What functions do membrane proteins have?

What functions do membrane carbohydrates have?

3.2 Unassisted Membrane Transport

Anything that passes between a cell and the surrounding extracellular fluid must be able to penetrate the plasma membrane. If a substance can cross the membrane, the membrane is said to be **permeable** to that substance; if a substance cannot pass, the membrane is **impermeable** to it. The plasma membrane is **selectively permeable** in that it lets some particles pass through while excluding others. In some instances permeability can be controlled, as exemplified by the opening or closing of specific channels.

Lipid-soluble substances and small polar molecules can passively diffuse through the plasma membrane down their electrochemical gradient

Two properties of particles influence whether they can permeate the plasma membrane without any assistance: (1) the relative solubility of the particle in lipid and (2) the size of the particle. Highly lipid-soluble particles can dissolve in the lipid bilayer and pass through the membrane. Uncharged or nonpolar molecules (such as O₂, CO₂, alcohol, steroids, and fatty acids) are very lipid-soluble and readily permeate the membrane. Charged particles (ions such as Na⁺ and K⁺) and polar molecules (such as glucose and proteins) have low

FIGURE 3-4 Diffusion.

- (a) Diffusion down a concentration gradient.
 (b) Dynamic equilibrium, with no net diffusion occurring.

© Cengage Learning, 2013

lipid solubility but are very soluble in water. The lipid bi-layer serves as an impermeable barrier to such particles.

Yet some of these particles, for example glucose and Na^+ and K^+ , must cross the membrane for the cell to survive and function. (Most cells use glucose as their fuel of choice to produce ATP.) Cells have several means of assisted transport—the channels and carriers noted earlier—to move particles across the membrane that must enter or leave the cell but cannot do so unaided. We will look at these in more detail later.

Even though a particle might be capable of permeating the membrane by virtue of its lipid solubility or its ability to fit through a channel, some force is needed to produce its movement across the membrane. Two general types of forces are involved: (1) **passive forces**, which do not require the cell to expend energy to produce movement; and (2) **active forces**, which require cellular energy (ATP) to be expended to transport a substance across the membrane. Let's now examine the various methods of passive and active membrane transport.

In unassisted membrane transport, particles that can permeate the membrane diffuse passively down their concentration gradient

Molecules that can penetrate the plasma membrane on their own—that is, unassisted—are passively driven across the membrane by two forces: *diffusion* down a concentration gradient and/or *conduction* along an electrical gradient. We will first examine diffusion.

All molecules are in continuous random motion at temperatures above absolute zero as a result of heat (thermal) energy. Because of this Brownian motion (named after the Scottish botanist Robert Brown, who in 1827 described random motions of floating pollen), each molecule moves separately and randomly in any direction. This motion is most evident in liquids and gases, where the individual molecules

have more room to move before colliding with another molecule, bouncing off each other in different directions like billiard balls striking each other. However, the greater the molecular concentration of a substance in a solution, the greater the likelihood of collisions. As a result, if a substance can move between regions with different concentrations, a nonrandom net movement called **diffusion** (from *diffusus*, spread out) occurs. To see how, note the example in Figure 3-4a where the concentration differs between area A and area B in a solution. Such a difference in between two adjacent areas is called a **concentration** (or **chemical**) **gradient**. Random molecular collisions occur more frequently in area A than in B. As a result, more molecules bounce from area A into area B than in the opposite direction. In both areas, the *individual molecules move randomly and in all directions*, but the *net movement of molecules by diffusion is not random*, but rather from the area of higher concentration to the area of lower concentration.

The term **net diffusion** refers to the difference between two opposing movements. If 10 molecules move from A to B while 2 molecules simultaneously move from B to A, the net diffusion is 8 molecules moving from A to B. Molecules spread in this way until the substance is uniformly distributed between the two areas and a concentration gradient no longer exists (Figure 3-4b). At this point, even though movement is still taking place, no *net* diffusion is occurring, because the opposing movements exactly counterbalance each other. Movement of molecules from A to B is exactly matched by movement of molecules from B to A. This situation is known as a **steady state** or **equilibrium**.

What happens if a plasma membrane separates different concentrations of a substance? If the substance can permeate the membrane, net diffusion of the substance occurs through the membrane down its concentration gradient from the area of high concentration to the area of low concentration (Figure 3-5a). No energy is required for this movement, so it is a passive mechanism of membrane transport. For example, O_2 is

KEY

= Penetrating solute

 = Nonpenetrating solute

transferred across the lung membrane by this means. The blood carried to the lungs is low in O₂, having given up O₂ to the body tissues for cellular metabolism. The air in the lungs, in contrast, is high in O₂ because it is continuously exchanged with fresh air by the process of breathing. Because of this concentration gradient, net diffusion of O₂ occurs from the lungs into the blood as blood flows through the lungs. Thus, as blood leaves the lungs for delivery to the tissues, it is high in O₂. (Recall from Chapter 1 that August and Marie Krogh were the first to demonstrate that oxygen moves by diffusion in lungs.) Let’s look at membrane diffusion more closely.

Fick’s Law of Diffusion Several factors in addition to the concentration gradient influence the rate of net diffusion across a membrane. In 1855 Adolf Fick in Germany derived an expression that gives the rate, termed *Q*, at which molecules diffuse from one area to another (**Fick’s law of diffusion**, Table 3-1), with the following factors:

1. *The magnitude (or steepness) of the concentration gradient.* The greater the difference in concentration, the greater the rate of diffusion. For example, let’s follow CO₂ in a running lizard. The working muscles produce CO₂ more rapidly as a result of burning additional fuel to produce the extra ATP they need to power the stepped-up, energy-demanding contractile activity. The resultant increase in CO₂ level in the muscles creates a greater-than-normal CO₂ difference between the muscles and the blood. Because of this larger gradient, more CO₂ than usual enters the blood. As this blood reaches the lizard’s lungs, a greater-than-normal CO₂ difference exists between the blood and air in the lungs. Accordingly, more CO₂ than normal diffuses from the blood into the air before equilibrium is achieved. This extra CO₂ is subsequently breathed out to the environment. Thus, any additional CO₂ produced by exercising muscles is eliminated from the body simply as a result of the increase in CO₂ concentration gradient.
2. *The permeability of the membrane to the substance.* The more permeable the membrane is to a substance, the

TABLE 3-1 Factors Influencing the Rate of Net Diffusion of a Substance across a Membrane (Fick’s Law of Diffusion)

Factor	Effect on Rate of Net Diffusion
↑ Concentration gradient of substance (ΔC)	↑
↑ Surface area of membrane (A)	↑
↑ Lipid solubility (β)	↑
↑ Molecular weight of substance (MW)	↓
↑ Distance (thickness) (ΔX)	↓

Modified Fick’s equation:

$$\begin{aligned} \text{Net rate of diffusion (Q)} &= \frac{\Delta C \cdot A \cdot \beta}{\sqrt{MW} \cdot \Delta X} \\ \left[\text{diffusion coefficient (D)} \propto \frac{1}{\sqrt{MW}} \right] \\ \left[\text{permeability (P)} = \frac{D\beta}{\Delta X} \right] \\ \text{Restated } Q &\propto \Delta C \cdot A \cdot P \end{aligned}$$

© Cengage Learning, 2013

more rapidly the substance can diffuse down its concentration gradient. Note that if the membrane is impermeable to the substance, no diffusion can take place across the membrane, even though a concentration gradient may exist (Figure 3-5b). For example, because the plasma membrane is impermeable to the vital intracellular proteins, they cannot escape from the cell, even though they are in much greater concentration in the ICF than in the ECF.

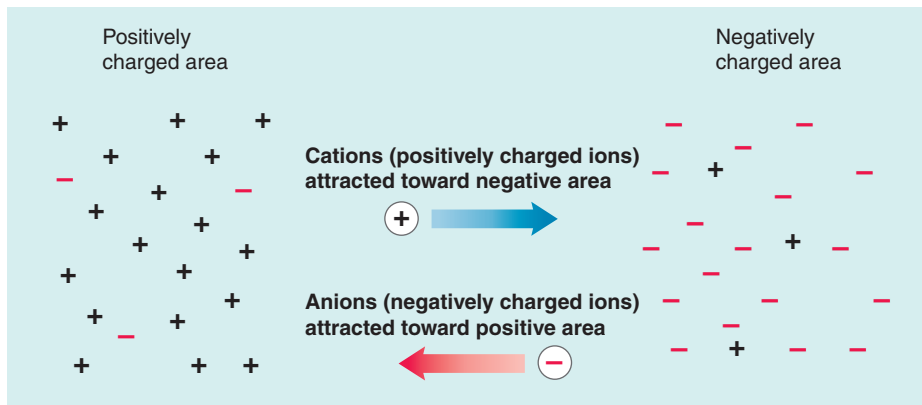

FIGURE 3-6 Movement along an electrical gradient.

© Cengage Learning, 2013

3. *The surface area of the membrane across which diffusion is taking place.* Obviously, the larger the surface area available, the greater the rate of diffusion it can accommodate. For example, absorption of nutrients across the membranes in the small intestine is enhanced by surface foldings (*villi*) and projections (*microvilli*) that greatly increase the available absorptive surface area (Chapter 14).
4. *The molecular weight of the substance.* Lighter molecules such as O_2 and CO_2 bounce farther on collision than do heavier molecules. Consequently, O_2 and CO_2 diffuse rapidly, permitting rapid exchanges of these gases across the respiratory membranes.
5. *The distance through which diffusion must take place.* The greater the diffusion barrier thickness, the slower the rate of diffusion. Accordingly, membranes across which diffusing particles must travel are normally relatively thin, such as the membranes separating the air and blood in vertebrate lungs.
6. *Temperature.* Generally, as temperatures increase, the higher kinetic energy of molecules will increase diffusion rates. Permeability may also be affected, generally increasing as temperature rises.

One of the most important aspects of diffusion to keep in mind is how extraordinarily *slow* the process is because of its inherent randomness and molecular scale. For example, oxygen moving only by diffusion through a nostril would take many years to reach equilibrium within a large air-breathing animal. Thus, an animal that needs to transport molecules such as oxygen and hormones over large distances cannot rely on diffusion. As you will see, evolution resulted in alternative transport systems, termed *bulk transport* mechanisms, that move the entire medium carrying molecules of interest. *The slowness of diffusion, and thus its inadequacy for movement over large distances, has been the primary force in the evolution of circulatory systems* and other bulk transport processes in multicellular animals (Chapter 9).

Ions that can permeate the membrane also conduct passively along their electrical gradient

Movement of **ions** (electrically charged particles that have either lost or gained an electron) is also affected by their electrical charge. Like charges (those with the same kind of charge) repel each other, whereas opposite charges attract each other. If a relative difference in charge exists between two adjacent areas (Figure 3-6), the positively charged ions

(**cations**) tend to move toward the more negatively charged area, whereas the negatively charged ions (**anions**) tend to move toward the more positively charged area. A difference in charge between two adjacent areas thus produces an **electrical gradient** that passively induces ion movement—a process called *conduction*. When an electrical gradient exists between the ICF and ECF, only ions that can permeate the plasma membrane can conduct down this gradient. The simultaneous existence of an electrical gradient and concentration (chemical) gradient for a particular ion is called an **electrochemical gradient**. Later in this chapter, you will learn how electrochemical gradients contribute to the electrical properties of the plasma membrane.

You will frequently find that ion movement is called “diffusion,” but this is improper terminology when charge differences are causing movement. Recall that diffusion is based on random molecular motions, and is very slow. Ion conduction, in contrast, is much faster because of charge interaction, which is a strong directional force (think about how fast two magnets can move toward each other, an analogous situation). If the electrical systems in your house relied on diffusion (rather than conductance) of electrons, it would take many decades for the electrons to reach your house from a power plant!

Osmosis is the net movement of water through a membrane

Water molecules can readily permeate most plasma membranes. Even though water molecules are strongly polar, they are small enough to slip through momentary spaces created between the phospholipid molecules’ tails as they sway and move within the lipid bilayer. This simple fact has enormous implications for cell physiology and evolution. At some early point in the evolution of the first cells, there would have been an unequal distribution of molecules: a high concentration of organic molecules on the inside and a low concentration on the outside. Why might such differences be a potential problem for cells? The answer lies with the difference in total **solute** (dissolved substance) concentrations on either side of the membrane, coupled with water’s ability to penetrate most membranes. As a membrane-enclosed system, a cell must contend with a powerful force, **osmosis**—the result of movement of water down its own concentration gradient through a membrane (note that diffusion of water in an open system without a membrane is

not osmosis, but simply diffusion). Osmosis occurs if the total concentration of solutes is not equal inside and outside the cell. Osmotic imbalances can be inward (leading to cell swelling) or outward (leading to cell shrinkage). Left unchecked, osmotic movement of water can impair cellular function and, if extreme, result in cell destruction.

Osmosis across membranes results between solutions with different concentrations of a nonpenetrating solute

In simplest terms, the driving force for diffusion of water across the membrane is the same as for any other diffusing molecule, namely, its concentration gradient. Usually, the term **concentration** refers to the density of the solute in a given volume of water. It is important to recognize, however, that the addition of a solute to pure water in essence decreases the water concentration.

Compare the water and solute concentrations in two compartments separated by a membrane in Figure 3-7. The container labeled side 1 has a low solute concentration and thus a high water concentration. In side 2, more of the water molecules have been replaced by solute, and the water concentration decreases correspondingly. In this situation, the solution in side 2 with higher solute concentration is said to be **hyperosmotic** with respect to the other. Conversely, side 1, with higher water concentration, is **hypo-osmotic**. Note that in Figure 3-7, the solutions are separated by a membrane that permits passage of water but not solute. Thus, water will move down its own concentration gradient from side 1 (lower solute/higher water concentrations) to side 2 (higher solute/lower water concentrations). Because solutions are always referred to in terms of concentration of solute, *water moves by osmosis to the area of higher solute concentration*. The solute can be thought of as “drawing,” or attracting, water, but osmosis is almost always portrayed as a special case of diffusion, in which water molecules move by this inherently random process. But when we actually measure the rate of osmosis across membranes, we find that for many solutes the rate is much faster than that predicted by Fick’s law. In fact, the physical chemistry of osmosis is not fully understood (see *Unanswered Questions: Is osmosis really the simple diffusion of water down its concentration gradient?* on p. 80). However, we will treat it as a form of diffusion.

As a result of water movement alone, side 2’s volume increases while the volume of side 1 correspondingly decreases. Loss of water from side 1 increases the solute concentration on side 1, whereas addition of water to side 2 reduces the solute concentration on that side. Eventually, the concentrations of water and solute on the two sides of the membrane become equal, and net diffusion of water ceases. The side originally containing the greater solute concentration has a larger volume, having gained water. With all concentration gradients abolished, an **isosmotic** state (*isos*, “equal”), net osmosis ceases.

What happens if a nonpenetrating solute is present on side 2 and pure water is present on side 1 (Figure 3-8)? Osmosis again occurs from side 1 to side 2, but the concentrations between the two compartments can never become equal. No matter how dilute side 2 becomes because of water diffusing into it, it can never become pure water, nor can side 1 ever acquire any solute. Because equilibrium is impossible

FIGURE 3-7 Relationship between solute and water concentration in a solution.

© Cengage Learning, 2013

to achieve, does net diffusion of water (osmosis) continue unabated until all the water has left side 1? No. As the volume expands in compartment 2, a difference in **hydrostatic** (*hydro*, “fluid;” *static*, “standing”) pressure between the two compartments is created, and it opposes osmosis. (Hydrostatic pressure is the pressure exerted by a standing, or stationary, fluid on an object—in this case the plasma membrane.) The hydrostatic pressure exerted by the larger volume of fluid on side 2 is greater than the pressure exerted by water moving from side 1. This hydrostatic pressure difference tends to push fluid from side 2 to side 1. The magnitude of opposing pressure necessary to completely stop osmosis is defined as the **osmotic pressure** of the solution on side 2. The osmotic pressure can be related directly to the concentration of nonpenetrating solute. The greater the concentration of nonpenetrating solute → the lower the concentration of water → the greater the drive for water to move by osmosis from pure water into the solution → the greater the opposing

FIGURE 3-8 Osmosis when pure water is separated from a solution containing a nonpenetrating solute.

© Cengage Learning, 2013

pressure required to stop the osmotic flow → the greater the osmotic pressure of the solution. Therefore, *a solution with a high solute concentration exerts greater osmotic pressure than does a solution with a lower solute concentration.*

Colligative properties of solutions are dependent solely on the number of dissolved particles

Osmotic pressure is one of the so-called **colligative properties** of solutes, which are those that depend solely on the number of dissolved particles in a given volume of solution, not on the chemical properties of the solute. There are four such properties for an idealized solute (one that fits this description) at 1 mole in 1 kg of water (defined as 1 *molal*): (1) it has an osmotic pressure of 22.4 atmospheres (atm), (2) it raises the boiling point by 0.54°C, (3) it depresses

freezing point by 1.86°C, and (4) it reduces vapor pressure. The effect on freezing point is important in the context of animals adapting to freezing temperatures (Chapter 15).

Osmotic pressure can be measured in atmospheres, but is more conveniently expressed as **osmolality**, as osmoles/kg water (osmol/kg) or milliosmoles/kg water (mosmol/kg), because for an ideal solute this osmotic value is equal to its *molal* concentration. Note that a 1-molal solution (1 mole/kg water) is not quite equal to a 1-molar solution (1 mole/liter solution), but in the range of concentrations for most biological fluids, the two are nearly equal. Since biologists tend to use molar (M) rather than molal because it is easier to measure a liter than to weigh a kg of water, **osmolality** with corresponding abbreviations **Osm** (osmoles/liter) and **mOsm** (milliosmoles/liter) are commonly used. An ideal solute dissolved at a concentration of 1 M yields about 1 Osm or 1,000 mOsm. For example, because a molecule of glucose remains as an intact molecule when in solution, 1 M glucose equals 1 Osm. By contrast, because a molecule of NaCl dissociates (separates) into 2 ions—Na⁺ and Cl[−]—when in solution, 1 M NaCl equals about 2 Osm (actually 1.86 Osm, because Na⁺ and Cl[−] ions in solution occasionally bind together temporarily to act as one particle). Because osmolality depends on the number, not the nature, of particles, any mixture of particles can contribute to the osmolality of a solution. Two useful examples of osmotic pressures in the biological world are about 1,000 mOsm for average seawater, and 300 mOsm (approximately) for most mammalian internal fluids. In fact, the basic dissolved constituents of cells—inorganic ions plus metabolites, proteins, and so forth—typically yield an osmotic pressure of roughly 250–400 mOsm in most organisms.

Tonicity refers to the effect the concentration of nonpenetrating solutes in a solution has on cell volume

Whereas the osmotic pressure of a solution refers to a colligative property, the **tonicity** of a solution refers to the effect on cell volume of the concentration of nonpenetrating solutes in the solution surrounding the cell. Solutes that can penetrate the plasma membrane quickly become equally distributed between the ECF and ICF (intracellular fluid) and thus do not contribute to long-term osmotic or tonicity differences. An **isotonic solution** (*iso* means “equal”) has the same concentration of nonpenetrating solutes as do normal body cells. When a cell is bathed in an isotonic solution, no water enters or leaves the cell by osmosis, so cell volume remains constant. Thus, the ECF in animals is normally isotonic to cells so that no net diffusion of water occurs across the plasma membranes. This is important because cells, especially neural cells, do not function properly if they are swollen or shrunk. Any change in the concentration of nonpenetrating solutes in the ECF produces a corresponding change in the water concentration difference across the plasma membrane. The resultant osmotic movement of water brings about changes in cell volume.

The easiest way to demonstrate this phenomenon is to place mammalian red blood cells in solutions with varying concentrations of nonpenetrating solutes (Figure 3-9). Normally the plasma in which red blood cells are suspended has the same osmotic activity as the fluid inside these cells, en-

FIGURE 3-9 Tonicity and osmotic water movement.

© Cengage Learning, 2013

abling the cells to maintain a constant volume. If red blood cells are placed in a hypo-osmotic solution, water enters the cells by osmosis. Net gain of water by the cells causes them to swell, perhaps to the point of rupturing, or lysing. In this situation causing swelling, the solution is called **hypotonic** (*hypo* means “below”). If, in contrast, red blood cells are placed in a concentrated or hyperosmotic solution, the cells shrink as they lose water by osmosis. In this situation, the solution is called **hypertonic** (*hyper* means “above”). When a red blood cell decreases in volume, its surface area does not decrease correspondingly, so the cell assumes a *crenated*, or spiky, shape. Thus, it is critical that the concentration of nonpenetrating solutes in the ECF quickly be restored to normal should the ECF become hypotonic (as with ingesting too much water) or hypertonic (as with losing too much water through severe diarrhea). (See Chapters 12 and 13 for further details about the important homeostatic mechanisms that regulate ECF osmolarity.)

Given that water penetrates membranes readily, whereas many solutes do not, a top priority of every animal cell is **osmotic homeostasis**, or **cell volume regulation**. This is the ability of a cell to adapt to an inequality of total solutes between its internal composition and the surrounding fluid. Inequalities can readily arise because a cell has a minimal requirement for internal solutes necessary for life, but the total concentration of these solutes may not match that of the external environment. Imbalances can occur from selective transport of solutes in and out of the cell as well (see next section). And imbalances may change in magnitude and direction within an animal’s life cycle. For example, in the ocean the epithelial cells covering the gills of a salmon are

responsible for limiting water loss from their body fluids, whereas during migration into the spawning grounds in fresh water, the cells are involved with the net movement of water into the body fluids. How cells and whole animals cope with these demands is covered in Chapter 13.

unanswered Questions | Is osmosis really the simple diffusion of water down its concentration gradient?

Although osmosis is generally characterized as water diffusing down its concentration gradient, created by differences in dissolved solutes that reduce water concentration, considerable evidence shows this is an oversimplification. In particular, some dissolved salts actually *increase* the effective concentration of water, and yet water in a lower-salt solution always osmoses through a membrane into a higher-salt solution. G. Hulett in 1902 first proposed an alternative explanation for osmosis. He hypothesized that the *pressure of the dissolved molecules colliding with the membrane causes water molecules to move*. The solution with the higher concentration has more collisions and thus exerts more pressure. This appears to alter the bonding forces between water molecules such that these molecules are pulled through the membrane into the side with higher salt. In recent decades, H. T. Hammel has provided considerable evidence that Hulett was correct. For this reason, the phenomenon of osmosis still remains incompletely understood. <<

check your understanding 3.2

Distinguish between diffusion and osmosis.

Why is the movement of ions down an electrical gradient not an example of diffusion?

What happens to the concentration of water inside a cell if ECF solute concentrations increase? Decrease? Explain why for both cases.

3.3 Assisted Membrane Transport

All kinds of transport we have discussed thus far—diffusion down concentration gradients, conduction along electrical gradients, and osmosis—produce net movement of molecules capable of permeating the plasma membrane by virtue of their lipid solubility or small size. Large, poorly lipid-soluble molecules such as proteins, glucose, and amino acids cannot cross the plasma membrane on their own no matter what forces are acting on them. Most small, charged molecules (*ions*) have the same property. This impermeability ensures that the large intracellular proteins and critical ions cannot escape from the cell. It is important that these molecules remain in the cell where they belong and can carry out their functions.

However, because of this impermeability, the cell must provide mechanisms for deliberately transporting some of these types of molecules into or out of the cell when it is necessary. For example, the cell must usher into the cell essential nutrients, such as glucose for energy and amino acids for the synthesis of proteins, and transport out of the cell metabolic wastes and secretory products, such as water-soluble protein hormones and digestive enzymes. Some ions must enter or leave the cell in, for example, signaling processes such as those of neurons. Cells use two classes of mechanisms to accomplish selective transport processes for poorly permeable molecules: (1) *channel and carrier-mediated transport* for transfer of small water-soluble substances across the membrane, and (2) *vesicular transport* for movement of large molecules and even multimolecular particles. Let's now examine these processes.

Channel transport is accomplished by protein pores, while carrier-mediated transport generally requires proteins that “flip-flop”

As you saw earlier, both channels and carriers are transmembrane proteins that serve as selective avenues for the movement of water-soluble substances across the membrane, but there are notable differences between them. (1) Only ions (and water, in the case of *aquaporins*; see next column) fit through the narrow channels, whereas moderately sized polar molecules such as glucose and amino acids are transported across the membrane by carriers. (2) Channels called **gated channels** can be open or closed as a result of changes in channel shape in response to a controlling

mechanism; others called **leak channels** are open all the time, thus permitting unregulated leakage of their chosen ion across the membrane through the channels down their gradients. Similar to leak channels, carriers are almost always “open for business,” but they work by very different mechanisms. (3) Movement through channels is considerably faster than carrier-mediated transport. When open for traffic, channels are open at both sides of the membrane at the same time, permitting continuous, rapid movement of ions between the ECF and ICF through these nonstop passageways. By contrast, carriers are never open to both the ECF and ICF simultaneously. They must change shape to alternately pick up passenger molecules on one side of the membrane and then drop them off on the other side, a time-consuming process. Whereas a carrier may move up to 5,000 particles per second across the membrane, 5 million ions may pass through a channel in a second.

Channels are highly selective. Not only does their small diameter preclude passage of particles greater than 0.8 nanometer (nm) in diameter (1 nm = 1 billionth of a meter), but a given channel can also selectively attract or repel particular ions. For example, sodium (Na^+) channels can accommodate the passage of only Na^+ , whereas only K^+ can pass through potassium (K^+) channels. This selectivity is due to specific arrangements of various chemical groups on the interior surfaces of the proteins that form the channel walls. Cells vary in the number, kind, and activity of channels they have. As an example of a channel, we will examine water channels, leaving additional details on ion channels for the next chapter.

Aquaporins Osmotic water movement across a basic lipid bilayer membrane is relatively slow. For many membranes, the rate of osmosis is far too great to be explained by this process. Investigation of membrane proteins led to the discovery of special water channels called **aquaporins** (Figure 3-10). They are found in all membranes where rapid water movement is necessary: 1 to 10 billion water molecules per second can pass through an aquaporin in single file. Their discovery began with bovine lens in the 1980s: Michael Gorin, Barbara Yancey, and colleagues analyzed the gene for a major lens protein whose function was not known and deduced from the amino acid code that it was likely to be an aqueous channel. The name “aquaporin” was subsequently coined in the 1990s following elucidation of the complete structure and function of the aquaporin in mammalian red blood cells by Peter Agre's research team (resulting in a 2003 Nobel Prize in Chemistry for Agre). Since those discoveries, aquaporins in all kingdoms of life have been found; in mammals alone, there are at least 13 different aquaporin-type proteins, designated (in order of discovery) AQP0 (lens) to AQP12 (pancreas). Different cell types vary in their density of aquaporins and thus in their water permeability. You'll see a major role for aquaporins in water regulation by the mammalian kidney in Chapter 12.

Carrier-Mediated Transport Carrier proteins span the thickness of the plasma membrane and can undergo reversible changes in shape so that specific binding sites can alternately be exposed at either side of the membrane. That is, the carrier “flip-flops” so that binding sites located in the interior of the carrier are alternately exposed to the ECF and the ICF. Figure 3-11 is a schematic representation of how

FIGURE 3-10 Aquaporins. (a) Structure of an aquaporin forming a channel in a membrane. The channel is lined with hydrophilic amino acids that attract water molecules in single file. (b) One of the Nobel Prize-winning experiments from Peter Agre's laboratory. Incubation in hypotonic buffer fails to cause swelling of a control frog oocyte (*left*), due to low water permeability. In contrast, an oocyte injected with mammalian aquaporin RNA (*right*) exhibits high water permeability due to production of aquaporin proteins, and the cell has exploded.

FIGURE 3-11 Model for facilitated diffusion, a passive form of carrier-mediated transport.

© Cengage Learning, 2013

this **carrier-mediated transport** process takes place. As the molecule to be transported attaches to a binding site on the carrier on one side of the membrane (step 1), it triggers a change in the carrier's shape that causes the same site to be exposed to the other side of the membrane (step 2). Then, having been moved in this way from one side of the membrane to the other, the bound molecule detaches from the carrier (step 3). After the passenger detaches, the carrier reverts back to its original shape (step 4).

Carrier-mediated transport systems display three important characteristics that determine the kind and amount of material that can be transferred across the membrane: *specificity*, *saturation*, and *competition*.

1. **Specificity.** As with channels, each carrier protein is specialized to transport a specific substance, or at most a few closely related chemical compounds. For example, amino acids cannot bind to glucose carriers, although several structurally similar amino acids may be able to use the same carrier. Cells vary in the types of carriers they have, thus permitting transport selectivity among cells. For example, as we noted earlier, the plasma membranes of vertebrate thyroid gland cells uniquely have carriers for iodine. A number of inherited diseases involve defects in transport systems for a particular substance. *Cystinuria* (cysteine in the urine) is such a disease, involving defective cysteine carriers in human and dog kidney membranes. This transport system normally removes cysteine from the fluid destined to become urine and returns this essential amino acid to the blood. When this carrier is malfunctioning, large quantities of cysteine remain in the urine, where it is relatively insoluble and tends to precipitate. This is one cause of urinary or kidney stones.
2. **Saturation.** A limited number of carrier binding sites are available within a particular plasma membrane for a specific substance. Therefore, there is a limit to the amount of a substance that a carrier can transport across the membrane in a given time. This limit is known as the **transport maximum** (T_m). Until the T_m is reached, the number of carrier binding sites occupied by a substance and, accordingly, the substance's rate of transport across the membrane are directly related to its concentration. The more of a substance available to be transported, the more will be transported. When the T_m is reached, the carrier is saturated (all binding sites are occupied), and the rate of the substance's transport across the membrane is maximal. Further increases in the substance's concentration are not accompanied by corresponding increases in the rate of transport (Figure 3-12).

As an analogy, consider a ferry boat that can maximally carry 100 people across a river during one trip in an hour. If 25 people are on hand to board the ferry, 25 will be transported that hour. Doubling the number of people on hand to 50 doubles the rate of transport to 50 people that hour. Such a direct relationship exists between the number of people waiting to board (the concentration) and the rate of transport until the ferry is fully occupied (its T_m is reached). The ferry can maximally transport 100 people per hour. Even if 150 people are waiting to board, still only 100 will be transported per hour.

FIGURE 3-12 Comparison of carrier-mediated transport and simple diffusion down a concentration gradient. With simple diffusion of a molecule down its concentration gradient, the rate of transport of the molecule into the cell is directly proportional to the extracellular concentration of the molecule. With carrier-mediated transport of a molecule down its concentration gradient, the rate of transport of the molecule into the cell is directly proportional to the extracellular concentration of the molecule until the carrier is saturated, at which time the rate of transport reaches the transport maximum (T_m). After T_m is reached, the rate of transport levels off despite further increases in the ECF concentration of the molecule.

Saturation of carriers is a critical rate-limiting factor in the transport of selected substances across vertebrate kidney membranes during urine formation and across the intestinal membranes during absorption of digested foods. Furthermore, it is sometimes possible to regulate (for example, by hormones) the rate of carrier-mediated transport by varying the affinity (attraction) of the binding site for its passenger or by varying the number of carriers ("ferry boats"). For example, the hormone insulin in vertebrates greatly increases the carrier-mediated transport of glucose into most cells by promoting an increase in the number of glucose carriers in the cell's plasma membranes. Deficiency of insulin secretion (diabetes mellitus) drastically impairs a cell's ability to take up and use glucose as the primary energy source.

3. **Competition.** Several closely related compounds may compete for a ride across the membrane on the same carrier. If a given binding site can be occupied by more than one type of molecule, the rate of transport of each substance is lower when both molecules are present than when either is present by itself. To illustrate, assume the ferry has 100 seats (binding sites) that can be occupied by either men or women. If only men are waiting to board, up to 100 men can be transported during each trip; the same holds true if only women are waiting to board. If, however, both men and women are waiting to board, they will compete for the available seats so

that fewer men and fewer women will be transported than when either group is present alone. Fifty of each might make the trip, although the total number of people transported will still be the same, 100 people. In other words, when a carrier can transport two closely related substances, such as the amino acids glycine and alanine, the presence of both diminishes the rate of transfer of either.

Facilitated diffusion is passive carrier-mediated transport

Carrier-mediated transport takes two forms, depending on whether energy must be supplied to complete the process. (1) **Facilitated diffusion** uses a carrier to facilitate (assist) the transfer of a particular substance across the membrane “downhill” from high to low concentration. This process is passive and does not require energy because movement occurs naturally down a concentration gradient. (2) **Active transport**, in contrast, requires the carrier to expend energy to transfer its passenger “uphill” *against* a concentration gradient, from an area of lower concentration to an area of higher concentration. An analogous situation is a ball on a hill with a barrier in front of it. If a way is provided to move through the barrier—for example, a partition that folds down when the ball bumps it—no energy is required to move the ball downhill (once rolling because of gravity, the ball will penetrate the barrier and continue to the bottom of the hill). Getting the ball uphill, however, requires the use of energy; for example, the barrier may have a powered catapult to flip the ball to the top.

The most notable example of facilitated diffusion is the transport of glucose into cells. Glucose can be at a higher concentration in the blood than in the tissues. Fresh supplies of this nutrient are regularly added to the blood by eating and from reserve energy stores in the body. Simultaneously, the cells may metabolize glucose almost as rapidly as it enters the cells from the blood. As a result, there can be a continuous gradient for net diffusion of glucose into the cells. Being a polar molecule, however, glucose cannot cross cell membranes on its own and is too large to fit through a channel. Without glucose carrier molecules (called *glucose transporters*, or *GLUT*) to facilitate membrane transport of glucose, the cells would be deprived of their preferred source of fuel.

The binding sites on facilitated diffusion carriers can bind with their passenger molecules when exposed to either side of the membrane (see Figure 3-11). As a result of thermal energy, these carriers undergo spontaneous changes in shape, alternately exposing their binding sites to the ECF or ICF. Passenger binding triggers the carrier to flip its conformation and drop off the passenger on the opposite side of the membrane. Because passengers are more likely to bind with the carrier on the high-concentration side than on the low-concentration side, the net movement always proceeds down the concentration gradient from higher to lower concentration. As is characteristic of mediated transport, the rate of facilitated diffusion is limited by saturation of the carrier binding sites, unlike the rate of simple diffusion, which is always directly proportional to the concentration gradient (Figure 3-12).

Active transport is carrier-mediated transport that uses energy and moves a substance against its concentration gradient

Active transport also involves the use of a protein transporter (channel or carrier) to transfer a specific substance across the membrane, but in this case the transporter moves the substance uphill against its concentration gradient. Active transport comes in two forms. In **primary active transport**, energy is *directly* required to move a substance against its concentration gradient; the transporter (a modified channel in the case of ions) splits ATP to power the transport process. In **secondary active transport**, energy is required in the entire process, but it is *not directly* used to produce uphill movement. That is, the carrier does not split ATP; instead, it moves a molecule uphill by using “secondhand” energy stored in the form of an **ion concentration gradient** (most commonly an Na^+ gradient). This ion gradient is built up by primary active transport of the ion by a different transporter. Let’s examine each process in more detail.

Primary Active Transport With active transport, the binding site has a greater affinity for its passenger on the low-concentration side as a result of *phosphorylation* (p. 27) of the transporter on this side (Figure 3-13, step 1). The transporter acts as an enzyme that has ATPase activity, which means it splits the terminal phosphate from an ATP molecule to yield ADP and inorganic phosphate plus free energy (step 1) (Do not confuse *ATPase*, which splits ATP, with *ATP synthase*, which synthesizes ATP.) The phosphate group then attaches to the transporter, increasing the affinity of its binding site for the ion. As a result the ion to be transported binds to the transporter on the low-concentration side (step 2). In response to this binding, the transporter changes its conformation so that the ion is now exposed to the high-concentration side of the membrane (step 3). The change in transporter shape reduces the affinity of the binding site for the passenger, so the ion is released on the high-concentration side. Simultaneously the change in shape is also accompanied by *dephosphorylation* (step 4). The transporter then returns to its original conformation (step 5). Thus, ATP energy is used in the phosphorylation–dephosphorylation cycle of the transporter. It alters the affinity of the transporter’s binding sites on opposite sides of the membrane so that transported ions are moved uphill from an area of low concentration to an area of higher concentration.

Primary active-transport transporters all move charged ions, namely Na^+ , K^+ , H^+ , Cl^- or Ca^{2+} , across the membrane. Analysis of the structures of these transporters has been difficult, but recent studies on the Na^+/K^+ *ATPase* transporter (which we will describe shortly) show that it is probably a modified channel, not a carrier. This was discovered when a coral toxin was applied to the transporter, resulting in it being locked “open” so that the slow pump became a fast leak channel for Na^+ . Rather than calling them channels, however, these active transporters are usually called “*pumps*,” analogous to water pumps that require energy to lift water against the downward pull of gravity. There are numerous pump proteins, especially those that move protons and other ions essential to life.

FIGURE 3-13 Model for active transport. The energy of ATP is required in the phosphorylation–dephosphorylation cycle of the carrier to transport the molecule uphill from a region of low concentration to a region of high concentration.

© Cengage Learning, 2013

The simplest active-transport systems pump a single type of passenger. An example is the **hydrogen-ion** (proton or H^+) **pump**. One type of this pump—the **F-ATPase**—may have been the first ATPase pump to evolve; as we saw in Chapter 2, they are used to generate energy by creating a hydrogen gradient. Another widespread type, the **V-ATPase** pump, is used to remove H^+ from body fluids, such as by the mammalian kidney, insect Malpighian tubules, and crustacean gills for excretion (see Chapter 12).

Other more complicated active transport mechanisms involve the transfer of two different passengers, either simultaneously in the same direction (called **symporting**) or sequentially in opposite directions (**antiporting**). For example, specialized vertebrate stomach cells use another type of proton pump to transport H^+ into the stomach lumen in exchange for a K^+ ion. This pump moves H^+ against a tremendous gradient: The concentration of H^+ in the stomach lumen is three to four million times greater than in the blood.

Primary Active Transport: The Na^+/K^+ ATPase Pump The most important example of an antiport pump is undoubtedly the **Na^+/K^+ ATPase pump** (**Na^+/K^+ pump** for short), found in the plasma membrane of all cells. This transporter transports Na^+ out of the cell, concentrating it in the ECF of multicellular organisms, and picks up K^+ from the outside, concentrating it in the ICF (Figure 3-14). The pump has high affinity for Na^+ on the ICF side. Binding of Na^+ to the transporter triggers the splitting of ATP through ATPase activity and subsequent phosphorylation of the transporter on the intracellular side, inducing a change in transporter shape, which moves Na^+ to the exterior. Simultaneously the change in shape increases the transporter's affinity for K^+ on the ECF side. Binding of K^+ leads to dephosphorylation of the transporter, inducing a second change in transporter shape, which transfers K^+ into the cytoplasm. There is not a direct exchange of Na^+ for K^+ , however. The Na^+/K^+ pump moves three Na^+ out of the cell for every two K^+ it pumps in. (To appreciate the magnitude of active Na^+/K^+ pumping that

FIGURE 3-14 Na⁺/K⁺ pump. The plasma membrane of all cells contains an active-transport carrier, the Na⁺/K⁺ pump, which uses energy in the carrier's phosphorylation–dephosphorylation cycle to sequentially transport Na⁺ out of the cell and K⁺ into the cell against these ions' concentration gradient. This pump moves three Na⁺ out and two K⁺ in for each ATP split.

© Cengage Learning, 2013

takes place, consider that a single nerve cell membrane contains approximately 1 million Na⁺/K⁺ pumps capable of transporting about 200 million ions per second.)

The Na⁺/K⁺ pump (Figure 3-14) plays two important roles:

1. It maintains Na⁺ and K⁺ concentration gradients across the plasma membrane of all cells. These gradients are

critically important for secondary active transport (discussed in detail shortly) as well as for the ability of nerve and muscle cells to generate electrical signals essential to their functioning (a topic discussed in the next chapter).

2. It helps regulate cell volume by controlling the concentrations of solutes inside the cell and thus minimizing osmotic effects that would induce swelling or shrinking of the cell.

The activity of the Na^+/K^+ pump is inhibited by the highly toxic metabolic inhibitor **ouabain**. Ouabain is isolated from the bark and root of the ouabaio tree and has been used by tribes in Africa since antiquity as an arrow poison. Oxygen deprivation can also reduce activity of the Na^+/K^+ pump because of the decline in ATP production. In vertebrates the number of Na^+/K^+ pump units in the cell membrane is regulated, in part, by thyroid hormone (see p. 301). Salt water acclimation in trout and salmonids (such as chum and pink salmon) involves an increase in gill basolateral Na^+/K^+ pump units as the freshwater acclimated epithelial cells transition to a salt secreting epithelium. The activity of these pump units in maintaining the electrochemical gradients across the plasma membrane accounts for approximately 25% of the standard metabolic rate in these animals (see Chapter 15).

Secondary Active Transport With primary active transport, energy is *directly* required to move a substance uphill. In addition, many cells can also actively transport certain solutes by moving them uphill from low to high concentration using *symporters*—also called **cotransport carriers**—that have two binding sites, one for an ion and one for the nutrient molecule. This secondary active transport may at first seem confusing because it uses “secondhand” energy stored in the form of an established **ion electrochemical gradient** (for example, an Na^+ gradient) to move the cotransported molecule uphill. This is a very efficient interaction. The cotransported molecule is essentially getting a free ride because Na^+ must be pumped out anyway to maintain the electrical and osmotic integrity of the cell. Cell energy (in the form of ATP) is not directly used by the carrier protein, but rather the energy stored in the Na^+ gradient (maintained with ATP) is used. Let us examine this more closely in mammals, in which (unlike most cells of the body) the intestinal and kidney cells transport glucose and amino acids by cotransport. Intestinal cells transport these nutrients from inside the intestinal lumen into the blood, concentrating them in the blood until none of these molecules are left in the lumen to be lost in the feces. The kidney cells save these nutrient molecules for the body by transporting them out of the fluid that is to become urine, moving them against a concentration gradient into the blood. These carriers that transport glucose against its concentration gradient from the lumen in the intestine and kidneys are distinct from the glucose facilitated-diffusion carriers found in all cells.

Here we focus specifically on symport in intestinal epithelial cells. This carrier, known as the **sodium and glucose cotransporter** or SGLT, is located in the luminal membrane (the membrane facing the intestinal lumen). The Na^+/K^+ pumps lie in the basolateral membrane (the membrane at the base of the cell opposite the lumen and along the lateral edge of the cell below the tight junction; see Figure 2-35). More Na^+ is present in the lumen than inside the cells because the basolateral energy-requiring Na^+/K^+ pump keeps the intracellular Na^+ concentration low. Because of this Na^+ concentration difference, more Na^+ binds to the SGLT when it is exposed to the lumen than when it is exposed to the ICF (Figure 3-15, step 1). Binding of Na^+ to SGLT then increases the carrier’s affinity for its other passenger (for example, glucose), so the carrier has a high affinity for glucose when exposed to the outside (step 2a). When both Na^+ and glu-

cose are bound to the carrier, it undergoes a conformational change and opens to the inside of the cell (step 2b). Both Na^+ and glucose are released to the interior, Na^+ because of the lower intracellular Na^+ concentration, and glucose because of the reduced affinity of the binding site on release of Na^+ (step 2c).

Note that the movement of Na^+ into the cell by SGLT carrier is downhill, but the movement of glucose is uphill, because glucose becomes concentrated in the cell. The released Na^+ is quickly pumped out by the Na^+/K^+ pumps, keeping the level of intracellular Na^+ low. The glucose that is carried into the cell by this process then passively moves out of the cell across the basolateral border down its concentration gradient and enters the blood (step 3). This movement is accomplished by facilitated diffusion, mediated by another carrier in the plasma membrane. This passive carrier is GLUT (p. 84), identical to the one that transports glucose into other cells, but in intestinal and mammalian kidney cells it transports glucose out of the cell. The difference depends on the direction of the glucose concentration gradient. In the case of intestinal and kidney cells, because of secondary active transport, glucose is in higher concentration inside the cells.

In the previous example, the symporter is responsible for the inward movement of both Na^+ and the substrate molecule. Molecules can also be moved in *opposing* directions by transport carriers as long as there is an established concentration or electrical (or electrochemical) gradient for one of the molecules. In this *antiport* (also known as *countertransport*) exchange, the solute and Na^+ move through the membrane in opposite directions, as you saw for the Na^+/K^+ pump, but here powered by the Na^+ gradient rather than ATP. For example, the uptake of Na^+ through the skin of frogs uses a carrier that extrudes H^+ . This carrier plays an important role in maintaining the appropriate pH inside the cells (a fluid becomes more acidic as its H^+ concentration rises). Adding *amiloride* to the water inhibits both the uptake of Na^+ and the excretion of H^+ . Similarly, the Na^+/H^+ and $\text{Cl}^-/\text{HCO}_3^-$ antiporters in the gill epithelium of freshwater teleosts (higher bony fishes) are responsible for the uptake of Na^+ and Cl^- from the environment in exchange for the loss of hydrogen and bicarbonate (HCO_3^-) ions. Chloride ion can be pumped from solutions as low as 0.02 mM in fresh water (FW) across the gill surface to approximately 100 mM in the ECF. In these examples, the source of energy for the transport of Na^+ and Cl^- is derived from gradients of H^+ and HCO_3^- produced as by-products of metabolism in the animal’s body. This mechanism permits these animals to restore valuable solute lost from the body through the gills and urine in exchange for removing these waste by-products.

Before leaving the topic of pump- and carrier-mediated transport, think about all the activities that rely on carrier assistance. All cells depend on carriers for the uptake of glucose and amino acids, which serve as the major source of energy and structural building blocks, respectively. Na^+/K^+ pumps are essential for generating cellular electrical activity and for ensuring that cells have an appropriate intracellular concentration of osmotically active ions. Active transport, both primary or secondary, is used extensively to accomplish the specialized functions of the nervous and digestive systems as well as excretory organs and all types of muscle.

FIGURE 3-15 Symport of glucose. Glucose is transported across intestinal and kidney cells against its concentration gradient by means of secondary active transport mediated by the sodium and glucose cotransporter (SGLT) at the cells' luminal membrane.

With vesicular transport, material is moved into or out of the cell wrapped in membrane

The special carrier-mediated transport systems embedded in the plasma membrane can selectively transport ions and small polar molecules. But how do large polar molecules, such as the protein hormones secreted by endocrine cells, or even multimolecular materials, such as the bacteria ingested by white blood cells, leave or enter the cell? These materials cannot cross the plasma membrane, even with assistance of single membrane proteins. These large particles are transferred between the ICF and ECF by being wrapped in a membrane-enclosed vesicle, a process known as **vesicular transport**. Vesicular transport requires energy expenditure by the cell, so this is an *active* method of membrane transport. Energy is needed to accomplish vesicle formation and vesicle movement within the cell. Recall from Chapter 2 that transport into the cell in this manner is termed *endocytosis*, while transport out of the cell is *exocytosis*. An important feature of vesicular transport is that the materials sequestered within the vesicles do not mix with the cytosol. The vesicles are designed to recognize and fuse only with a targeted membrane, ensuring a directed transfer of designated large polar molecules or multimolecular materials between the cell's interior and exterior.

Endocytosis In endocytosis, the plasma membrane surrounds the substance to be ingested, then fuses over the surface, pinching off a membrane-enclosed vesicle so that the engulfed material is trapped within the cell (see Figure 2-12b). Recall that there are three forms of endocytosis (p. 44), depending on the nature of the material internalized: *pinocytosis* (nonselective uptake of ECF), *receptor-mediated endocytosis* (selective uptake of a large molecule), and *phagocytosis* (selective uptake of a multimolecular particle or cell). Once inside the cell, an engulfed vesicle has two possible destinies:

1. In many instances, lysosomes fuse with the vesicle to degrade and release its contents into the intracellular fluid (p. 45).
2. In some cells, the endocytotic vesicle bypasses the lysosomes and travels to the opposite side of the cell, where it releases its contents by exocytosis. This provides a pathway to shuttle intact particles through the cell. Such vesicular traffic is one means by which materials are transferred through the thin cells lining the capillaries of vertebrates, across which exchanges are made between the blood and surrounding tissues.

Exocytosis In exocytosis, almost the reverse of endocytosis occurs: A membrane-enclosed vesicle formed within the cell fuses with the plasma membrane, then opens up and releases its contents to the exterior (p. 41). This serves two different purposes:

1. It provides a mechanism for secreting large polar molecules, such as proteins that cannot cross the plasma membrane. In this case, the vesicular contents are highly specific and are released only on receipt of appropriate signals.
2. It enables the cell to add specific components to the membrane, such as selected carriers, channels, or receptors, depending on the cell's needs.

Balance between Endocytosis and Exocytosis The rate of endocytosis and exocytosis must be kept in balance to maintain a constant membrane surface area and cell volume. More than 100% of the plasma membrane may be used in an hour to wrap internalized vesicles in a cell actively involved in endocytosis, necessitating rapid replacement of surface membrane by exocytosis. In contrast, when a secretory cell is stimulated to secrete, it may temporarily insert up to 30 times its surface membrane through exocytosis. This added membrane must be specifically retrieved by an equivalent level of endocytotic activity.

Caveolae There may be a fourth vesicular mechanism by which cells can exchange materials with their environment, called *caveolae* ("tiny caves"). These are tiny, flask-shaped indentations dimpling the plasma membrane of many epithelial and smooth muscle cells. Researchers have observed these small, flask-shaped pits for more than 45 years through electron microscopy. However, it was not until the mid-1990s that evidence accumulated indicating that caveolae may have two functions:

1. *Another route for transport into cells:* An abundance of receptors cluster in these tiny chambers, some of which appear to play a role in cellular uptake of small molecules and ions. The best-studied example is the transport of the B vitamin *folic acid* into the cell. When folic acid binds with its receptors, which are concentrated in the portions of the plasma membrane that form the caveolae, the extracellular openings of these tiny caves close off. The high concentration of folic acid within a closed caveolar compartment encourages the movement of this vitamin across the caveolar membrane into the cytoplasm. Cellular uptake through the cyclic opening and closing of caveolae has been termed **potocytosis**.
2. *A "switchboard" for relaying signals from many extracellular chemical messengers into the cell's interior:* Many membrane receptors important in signal mechanisms are concentrated in the caveolae, leading one investigator to call these tiny caves "signaling organelles." Signaling is a critical topic we cover in detail in the next section.

Our discussion of membrane transport is now complete; Table 3-2 summarizes the established pathways by which materials can pass between the ECF and ICF.

check your understanding 3.3

Are aquaporins channels or carriers? Explain.

How is symporting by facilitated diffusion similar to and yet different from symporting by secondary active transport? Illustrate with examples.

How does the Na^+/K^+ ATPase antiport pump work, and why is it so important?

Does the process of exocytosis require energy to work? Explain.

TABLE 3-2 Methods of Membrane Transport and Their Characteristics

Method of Transport	Substances Involved	Energy Requirements and Force-Producing Movement	Limit to Transport
SIMPLE DIFFUSION			
Diffusion through Lipid Bilayer	Nonpolar molecules of any size (e.g., O ₂ , CO ₂ , fatty acids)	Passive; molecules move down concentration gradient (from high to low concentration)	Continues until gradient is abolished (dynamic equilibrium with no net diffusion)
Diffusion through Protein Channel	Specific small ions (e.g., Na ⁺ , K ⁺ , Ca ²⁺ , Cl ⁻)	Passive; ions move down electrochemical gradient through open channels (from high to low concentration and by attraction of ion to area of opposite charge)	Continues until there is no net movement and dynamic equilibrium is established
Osmosis	Water only	Passive; water moves down its own concentration gradient (to area of lower water concentration, i.e., higher solute concentration)	Continues until concentration difference is abolished or until stopped by opposing hydrostatic pressure or until cell is destroyed
CARRIER-MEDIATED TRANSPORT			
Facilitated Diffusion	Specific polar molecules for which carrier is available (e.g., glucose)	Passive; molecules move down concentration gradient (from high to low concentration)	Displays a transport maximum (T _m); carrier can become saturated
Primary Active Transport	Specific cations for which carriers are available (e.g., Na ⁺ , K ⁺ , H ⁺ , Ca ²⁺)	Active; ions move against concentration gradient (from low to high concentration); requires ATP	Displays a transport maximum; carrier can become saturated
Secondary Active Transport (Symport or Antiport)	Specific polar molecules and ions for which coupled transport carriers are available (e.g., glucose, amino acids for symport; some ions for antiport)	Active; substance moves against concentration gradient (from low to high concentration); driven directly by ion gradient (usually Na ⁺) established by ATP-requiring primary pump. In symport, cotransported molecule and driving ion move in same direction; in antiport, transported solute and driving ion move in opposite directions	Displays a transport maximum; coupled transport carrier can become saturated
VESICULAR TRANSPORT			
Endocytosis			
Pinocytosis	Small volume of ECF fluid; also important in membrane recycling	Active; plasma membrane dips inward and pinches off at surface, forming internalized vesicle	Control poorly understood
Receptor-Mediated Endocytosis	Specific large polar molecule (e.g., protein)	Active; plasma membrane dips inward and pinches off at surface, forming internalized vesicle	Necessitates binding to specific receptor on membrane surface
Phagocytosis	Multimolecular particles (e.g., bacteria and cellular debris)	Active; cell extends pseudopods that surround particle, forming internalized vesicle	Necessitates binding to specific receptor on membrane surface
Exocytosis	Secretory products (e.g., hormones and enzymes) as well as large molecules that pass through cell intact; also important in membrane recycling	Active; increase in cytosolic Ca ²⁺ induces fusion of secretory vesicle with plasma membrane; vesicle opens up and releases contents to outside	Secretion triggered by specific neural or hormonal stimuli; other controls involved in transcellular traffic and membrane recycling not known

3.4 Intercellular Communication and Signal Transduction

Communication is critical for the survival of the society of cells that collectively compose the animal. The ability of cells to communicate with each other is essential for coordination of their diverse activities to maintain homeostasis as well as to control growth and development of the animal as a whole.

Communication between cells is orchestrated by direct contact and by extracellular chemical messengers

Intercellular communication can take place either directly or indirectly (Figure 3-16).

Direct Intercellular Communication This involves physical contact between the interacting cells by three mechanisms (Figure 3-16 a to c):

1. **Through gap junctions** (Figure 3-16a): The most intimate means of intercellular communication is through gap junctions, the minute tunnels that bridge the cytoplasm of neighboring cells in some types of tissues. Through these specialized anatomic arrangements (see Figure 2-34), small molecules and ions are directly exchanged between interacting cells without ever entering the ECF. Gap junctions are especially important in permitting electrical signals to spread from one cell to the next in cardiac and smooth muscle. However, in response to an increase in intracellular Ca^{2+} or H^+ ion concentrations, gap junctions rapidly close.
2. **Through transient direct linkup of surface markers** (Figure 3-16b): Some cells, such as those of the immune system, have specialized markers on the surface membrane that allow them to directly link up transiently and interact with certain other cells that have compatible markers for transient interactions. This is the means by which the phagocytes of the body's defense system specifically recognize and selectively destroy only undesirable cells, such as microbial invaders, while leaving the body's own healthy cells alone (Chapter 10).
3. **Through nanotubes** (Figure 3-16c): These are recently discovered long tubes with an internal actin-filament support surrounded by a plasma membrane that permits contiguous contact between two cells. They allow transfer of not only signal molecules but also whole organelles such as mitochondria. They have been identified between some developing insect and mammalian cells and between some mammalian immune cells.

Indirect Intercellular Communication The most common means by which cells communicate with each other is through intercellular chemical messengers, of which there are six categories based on modes of action: *paracrine*s, *neurotransmitters*, *hormones*, *neurohormones*, *pheromones*, and *cytokines*. In each case, a specific chemical messenger is synthesized by specialized cells to serve a designated purpose. On being released into the ECF by appropriate stimulation, these signaling agents act on other particular cells, the messenger's **target cells**, in a prescribed manner. To exert

its effect, an intercellular messenger, also known as a **ligand**, must bind with target-cell receptors specific for it. Receptors are typically transmembrane glycoproteins, that is, integral proteins that extend through the thickness of the plasma membrane and have carbohydrate chains attached on their outer surface (see Figure 3-3). A given cell may have thousands to as many as a few million receptors, of which hundreds to as many as 100,000 may be for the same chemical messenger. Different cell types have distinct combinations of receptors, allowing them to react individually to various regulatory extracellular chemical messengers. The modes of action of the six categories of chemical messenger are as follows (Figure 3-16 d to h):

- **Paracrine**s (Figure 3-16d) are local chemical messengers whose effect is exerted only on neighboring cells in the immediate environment of their site of secretion. (If their action affects the same cell that secreted them, they are called **autocrine**s.) Because paracrine are distributed by simple diffusion, their action is restricted to short distances. They do not gain entry to the blood in any significant quantity, because they are rapidly inactivated by locally existing enzymes. One example of a paracrine is *histamine*, which is released from a specific type of mammalian connective tissue cell during an inflammatory response within an invaded or injured tissue. Among other things, histamine dilates (opens more widely) the blood vessels in the vicinity to increase blood flow to the tissue. This action brings additional blood-borne immune-response supplies into the affected area (Chapter 10). Paracrine must be distinguished from chemicals that influence neighboring cells after being released nonspecifically. For example, an increased local concentration of CO_2 in an exercising muscle promotes local dilation of the blood vessels supplying the muscle. The resultant increased blood flow helps meet the more active tissue's increased metabolic demands. However, CO_2 is produced by all cells and is not specifically released to accomplish this particular response, so it and similar molecules are not paracrine.
- **Neurotransmitters** (Figure 3-16e) are used by neurons (nerve cells), which communicate directly with the cells they innervate (their target cells) by releasing these signal molecules in response to electrical signals (see p. 132). Like paracrine, neurotransmitters are very short-range chemical messengers, which diffuse from their site of release across a narrow extracellular space to act locally on only an adjoining target cell, which is usually another neuron, a muscle, or a gland. (Note that neurons may also release true paracrine, called *neuro-modulators*, as discussed in Chapter 4).
- **Hormones** (Figure 3-16f) are long-range chemical messengers that are specifically secreted into the circulation by endocrine (ductless) glands (see p. 9) in response to an appropriate signal. Circulatory fluid (blood or lymph) carries the messengers to other sites in the body, where they exert their effects on their target cells some distance away from their site of release. Only the target cells of a particular hormone bear receptors to bind with this hormone. Nontarget cells are not influenced by any blood-borne hormones that reach them.
- **Neurohormones** (Figure 3-16g) are hormones released by **neurosecretory neurons**. These respond to and con-

DIRECT INTERCELLULAR COMMUNICATION

INDIRECT INTERCELLULAR COMMUNICATION VIA EXTRACELLULAR CHEMICAL MESSENGERS

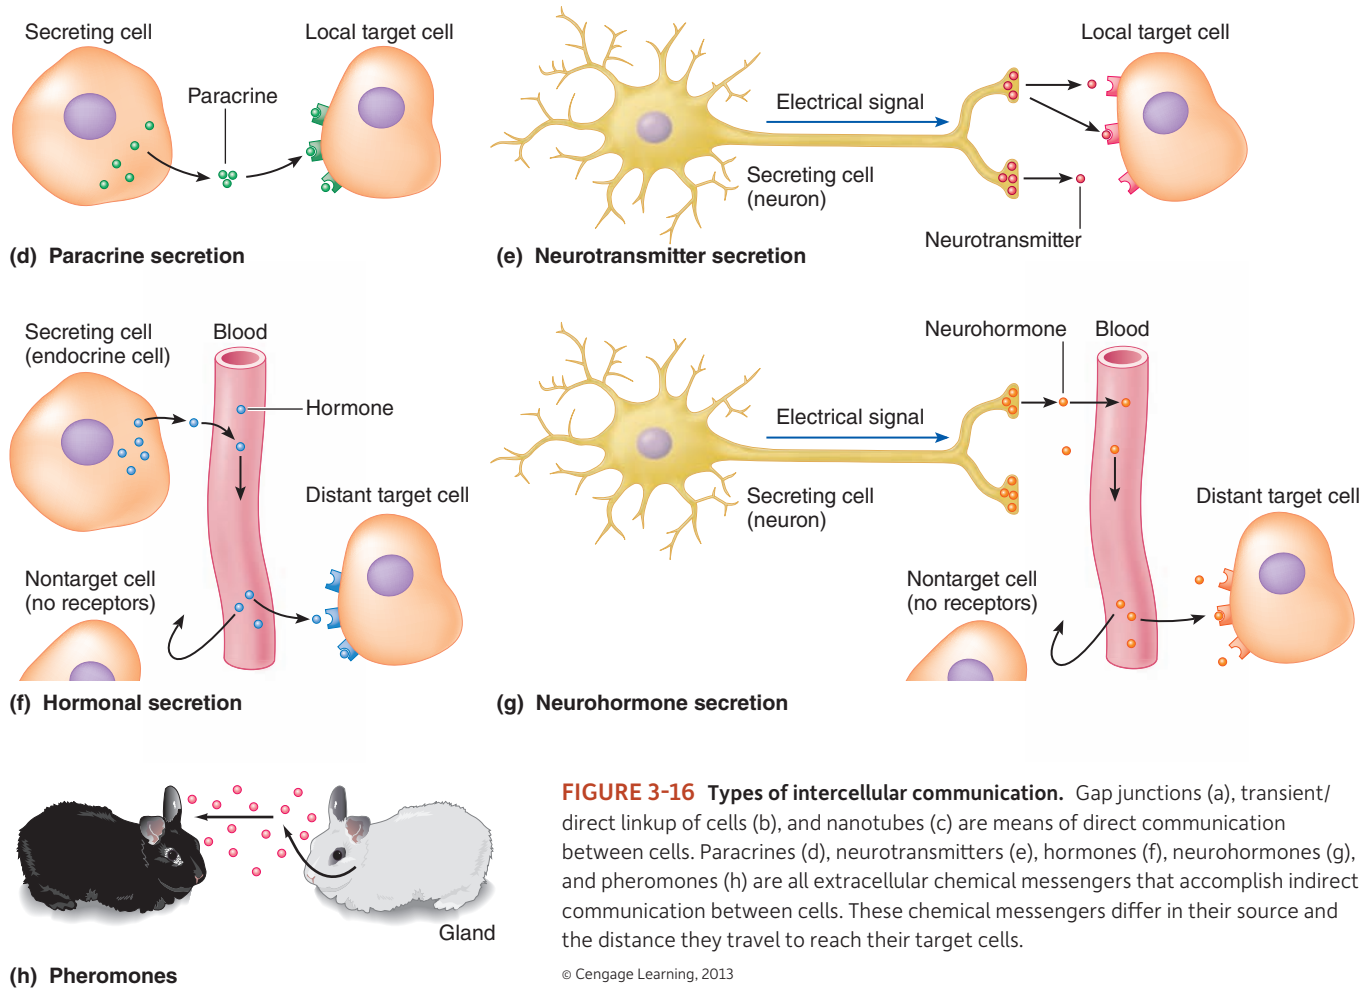

FIGURE 3-16 Types of intercellular communication. Gap junctions (a), transient/direct linkup of cells (b), and nanotubes (c) are means of direct communication between cells. Paracrine (d), neurotransmitters (e), hormones (f), neurohormones (g), and pheromones (h) are all extracellular chemical messengers that accomplish indirect communication between cells. These chemical messengers differ in their source and the distance they travel to reach their target cells.

© Cengage Learning, 2013

duct electrical signals like neurons, but instead of directly innervating target cells, they release neurohormones into the circulatory fluid. The neurohormone is then distributed to the target cells. Thus, like endocrine cells, neurosecretory neurons release blood- or hemolymph-borne chemical messengers, whereas ordinary neurons secrete short-range neurotransmitters into a confined space.

- **Pheromones** (Figure 3-16h) are chemical signals released into the environment, usually by glands, and travel through the air or water to sensory cells in another animal. Such signals are used for sexual activity (such as signaling of readiness to mate), marking of territories,

and other behaviors related to interactions among individuals of a species.

- **Cytokines** (not shown in Figure 3-16) are another class of signal molecules, which scientists historically discovered in the mammalian immune system and initially studied outside the framework of the traditional chemical messengers. Cytokines are regulatory peptides with a variety of effects that can be local, like paracrine, or at a distance, like hormones. But they are not produced by specialized gland or paracrine cells. Instead, they can be made by almost any body cell with another (non-signaling) primary function, and are generally involved in development and immunity.

Structures of Signal Molecules Molecules used as messengers make up a long list that is still growing. The list can be simplified into categories of chemical structures, as follows:

- **Eicosanoids:** Derivatives of fatty acids, **eicosanoids** are used primarily as paracrine. Examples include **prostaglandins**, which regulate vertebrate smooth-muscle action among other effects (Chapter 16), and **anandimide** (also spelled *anandamide*), a paracrine neuromodulator in the mammalian brain involved in appetite and memory (p. 196).
- **Gases:** Three inorganic gases, though normally considered toxic pollutants, have now been found to be produced in animals as natural messengers. **Nitric oxide (NO)**, a small, highly reactive, short-lived gas molecule once known primarily as a toxic air pollutant, has been found as a paracrine in many animal phyla. Also, researchers have found evidence that both **carbon monoxide (CO)** and **hydrogen sulfide (H₂S)** are paracrine. We'll examine NO and H₂S functions later.
- **Purines:** The primary messengers in this chemical group are **adenosine** and **ATP**. They are used as paracrine and neurotransmitters in addition to their roles in nucleic acids and cellular energy. Adenosine is one major target of **caffeine** (see later discussion).
- **Amines:** This large category consists of a few amino acids and numerous derivatives. It includes many paracrine, such as histamine and serotonin, and many hormones, such as epinephrine (Chapter 7).
- **Peptides and proteins:** Numerous amino-acid sequences are produced as messengers, as paracrine, cytokines, neurohormones, and hormones (Chapter 7).
- **Steroids:** These hydrophobic molecules are derived from cholesterol. They are primarily hormones and sometimes pheromones (Chapter 7). Their lipid nature permits them to diffuse directly through cell membranes.
- **Retinoids:** These messengers are derived from vitamin A and are mainly paracrine involved in development and differentiation. These will not be considered further.

Chemical messengers can have multiple, unrelated effects because of the “same key, different locks” principle

As we have noted, chemical messengers generally exert their effects by binding to receptor proteins. (We discuss the details of this shortly.) It is important to realize that one cannot deduce what the cellular response to any particular messenger will be from the messenger's chemical structure. This is because the *response is determined by the receptor*. Thus, a particular hormone or other signaling molecule can bind to a receptor on target cell A and trigger response 1, and also (at the same time or different time) bind to a receptor on target cell B and trigger a different response 2. Responses 1 and 2 may be completely unrelated. This may be called the “*same key, different locks*” principle. Think of a messenger as something like a key that can fit a variety of locks (receptors). Lock A may start your car, whereas lock B may open your house, and in principle, you could have one key that does both. (We don't usually have single keys that do both, but then again, evolution is often more economical than we are.)

TABLE 3-3 Some Functions of Nitric Oxide (NO)

- Causes relaxation of vertebrate arteriolar smooth muscle, helping to control blood flow through the tissues and in maintaining mean arterial blood pressure (Chapter 9).
- Dilates the arterioles of the mammalian penis and clitoris, thus serving as the direct mediator of erection of these reproductive organs. Erection is accomplished by rapid engorgement of these organs with blood (Chapter 16).
- Used as chemical warfare against bacteria and cancer cells by phagocytic cells of various animal immune systems (Chapter 10).
- Interferes with mammalian platelet function and blood clotting at sites of vessel damage.
- Serves as a novel type of neurotransmitter in brains and elsewhere (Chapter 5).
- Plays a role in the changes underlying memory (Chapter 5).
- By promoting relaxation of vertebrate digestive-tract smooth muscle, helps regulate peristalsis, a type of contraction that pushes digestive tract contents forward.
- Relaxes the smooth muscle cells in the airways of mammalian lungs, helping keep these passages open to facilitate movement of air in and out of the lungs (Chapter 11).
- Modulates the filtering process involved in mammalian urine formation.
- Directs blood flow to O₂-starved tissues in vertebrates.
- May play a role in relaxation of vertebrate skeletal muscle.
- In concert with CO, is involved in the cellular resistance to stress.
- Modulates light production in fireflies.

© Cengage Learning, 2013

Nitric oxide (NO) illustrates this principle nicely. Studies have revealed an astonishing number of biological roles for NO, many unrelated (Table 3-3). NO is derived from the amino acid arginine in an oxidative reaction that consumes oxygen and NADPH (an electron-hydrogen donor similar to NADH, p. 48). Because NO is a gas, and so cannot be stored and released as needed, the synthesis of NO is tightly regulated. Three nitric oxide synthase (NOS) isoenzymes, each the product of a unique gene, have been characterized. Nitric oxide has a variety of paracrine actions in almost all animal phyla that have been studied, ranging from memory in neurons to control of blood flow (for an example, see the box, *A Closer Look at Adaptation: Lighting Up the Night* on p. 96). In 1998, the Nobel Prize was awarded to Robert Furchgott, Louis Ignarro, and Ferid Murad for their pioneering work in this complex field.

This principle explains why so many drugs have so-called *side effects*: For example, the paracrine histamine has multiple unrelated roles. When released by certain immune cells (Chapter 10), it binds to H1 receptors, triggering parts of the inflammation process. In the stomach, histamine binds

to H₂ receptors that regulate acid production; and in the brain, it binds to H₃ receptors that induce alertness. These functions appear to be independent. They explain why many antihistamine drugs, designed to block inflammation, also make you drowsy: Those drugs bind to and block histamine from binding both H₁ and H₃ receptors.

Extracellular chemical messengers bring about cell responses primarily by signal transduction

Extracellular chemical messengers, such as hormones delivered by the blood or neurotransmitters released from nerve endings, usually do not trigger changes in target cells directly. Some cannot even enter their target cells to bring about the desired intracellular response. Instead, most of these messengers issue their orders by binding with receptors (with specific binding sites for one type of messenger) that trigger a biochemical chain of events inside the target cell. This process is called **signal transduction**, in which incoming signals (instructions from extracellular chemical messengers) are conveyed to the target cell's interior for execution. (A *transducer* is a device that receives energy or information from one system and transmits it in a different form to another system. For example, your radio receives radio waves sent out from the broadcast station and transmits these signals in the form of sound waves that can be detected by your ears.) The combination of extracellular messenger with receptor triggers a sequence of intracellular events that ultimately controls a particular cellular activity important in maintaining homeostasis or activating a regulated change, such as membrane transport, secretion, metabolism, contraction, or division and differentiation.

Signal transduction occurs by two broad types of mechanisms, depending on the messenger and receptor type. (1) **Lipophilic** (lipid-soluble) extracellular messengers gain entry into the cell by dissolving in and passing through the lipid bilayer of the target cell's plasma membrane. Small gases also penetrate the membrane. These messengers usually bind to receptors inside the target cell to initiate the desired intracellular response themselves, usually by changing gene activity. (2) In contrast, most **lipophobic** (water-soluble) extracellular messengers cannot gain entry to the target cell because they are poorly soluble in lipid and cannot dissolve in the plasma membrane. These messengers signal the cell to perform a given response by first binding with surface membrane receptors specific for that given messenger. Let's examine these two types in more depth.

Internal receptors bind lipophilic and gaseous external messengers that enter the cell

Dispersed within the cytoplasm and nucleus of most cells are special protein receptors that bind small and hydrophobic chemical messengers that can penetrate the cell membrane. These messengers include steroid hormones, eicosanoids, the hydrophobic amine hormones of the thyroid gland, and gases. (In recent years, some lipophilic messengers have been found to act on receptors within the same cell that produced them, a process called **intracrine** signaling.) Following the binding of messenger to the receptor, at least two different events can ensue, depending on the system:

- **Nitric oxide:** The internal receptor for NO is also an enzyme, *guanylyl cyclase*, which produces a second messenger, *cyclic GMP*. This in turn activates other cell proteins.
- **Thyroid and steroid hormones:** These have what might be viewed as more profound effects, because they alter gene transcription. Here the internal receptor is a **transcription factor**, a protein that, when bound with its messenger, can recognize a particular promoter sequence of genes (the *enhancer* or *response element* sequence, p. 31). The adjoining coding gene is then transcribed, an mRNA is translated, and new proteins are produced in the cell. Details of this mode of action are covered at the gene level in Chapter 2, and at the hormonal level in Chapter 7.

Some lipophobic external messengers bind to plasma membrane receptors, which alter ion channels or trigger phosphorylating enzymes (kinases)

The second broad mechanism of transduction involves the lipophobic messengers that bind to membrane receptors. Despite the wide range of possible responses, binding of the receptor with the extracellular messenger (the **first messenger**) brings about the desired intracellular response by only three general means: (1) by opening or closing specific channels in the membrane to regulate the movement of particular ions into or out of the cell, (2) by activating an enzyme that phosphorylates a cell protein, or (3) by transferring the signal to an intracellular chemical messenger (the **second messenger**), which in turn triggers a preprogrammed series of biochemical events within the cell. Because of the universal nature of these events, let's examine each more closely.

Chemically Gated Receptor-Channels Some first messengers bind to receptors that open or close *gated*-receptor-channels that regulate movement of particular ions across the membrane. In many cases, the *receptor itself serves as an ion channel* (Figure 3-17a). When the appropriate extracellular messenger binds to the **receptor-channel**, the channel opens or closes, depending on the signal. There are three different types of gated channels, depending on which of the following mechanisms bring about channel opening and closing: (1) **chemically gated** or **ligand gated**, by binding of an extracellular chemical messenger to a specific membrane receptor that is in close association with, or an integral part of, the channel; (2) **voltage gated**, by changes in electrical current in the plasma membrane; and (3) **mechanically gated**, by stretching or other mechanical deformation of the channel. For now, we will concentrate on chemical gating and defer the other two methods of controlling channels until later (for example, see p. 117).

For other channels, the receptor is a separate protein located near the channel. In this case, binding of the extracellular messenger with its receptor activates membrane-bound intermediaries known as **G proteins**, which in turn open (or in some instances close) the appropriate adjacent channel. (The mechanism of action of G proteins is discussed shortly.)

By opening or closing specific channels, extracellular messengers can regulate the flow of particular ions across

FIGURE 3-17 Types of receptors according to mode of action. (a) A receptor-channel opens when an extracellular messenger binds to it. The resultant ion entry ultimately leads to the cellular response. (b) An enzyme site on the cytoplasmic side of a receptor-enzyme is activated when an extracellular messenger binds to the side facing outside the cell. The activated receptor-bound enzyme ultimately leads to the cellular response. (c) Binding of an extracellular (first) messenger to the extracellular side of a G-protein coupled receptor activates a membrane-bound effector protein by means of a G-protein intermediary. The effector protein produces an intracellular second messenger, which ultimately leads to the cellular response.

the membrane. This ionic movement can be responsible for two different cellular events:

1. A small, short-lived movement of Na^+ , K^+ , or both across the membrane alters the electrical activity of cells that are capable of generating electrical signals (or impulses), such as nerve and muscle cells.
2. A transient flow of calcium (Ca^{2+}) into the cell through opened Ca^{2+} channels triggers an alteration in shape and function of specific intracellular proteins, which leads to the cell's response. Illustrative is the increase in cytosolic Ca^{2+} responsible for triggering the release of secretory product from many gland cells.

On completion of the response, the extracellular messenger is removed from the receptor site, and the chemically gated channels close once again. The ions that moved across the membrane through opened channels to trigger the response are returned to their original location by spe-

cial membrane carriers. Cytosolic Ca^{2+} may be increased in another way besides entry from the ECF through opened membrane channels: Intracellular Ca^{2+} stores can be released in a second-messenger pathway, as described in the next section.

Phosphorylating Enzymes and the Tyrosine Kinase Pathway

Some receptors have an associated enzyme, called a **protein kinase**, that phosphorylates a target cell protein (Figure 3-17b). This activity is activated when a first messenger binds to the receptor. Recall that *phosphorylation* refers to the transfer of a phosphate group from ATP to the protein at the expense of degrading ATP to ADP. Attachment of a phosphate group to a protein induces the protein to change its shape and function (either activating or inhibiting it) to bring about the desired response.

In response to phosphorylation, these proteins alter their shape and function, that is, are activated, to ultimately

A Closer Look at Adaptation

Lighting Up the Night

One of the most memorable natural displays that humans encounter are the summertime light shows of lightning bugs or fireflies. Male fireflies (actually a type of beetle) produce yellowish light in their abdomens as a way to attract mates; the longer and brighter a male produces light, the more likely he will attract females. Light is produced when an enzyme called *luciferase* catalyses a reaction between oxygen and a molecule called *luciferin*. This takes place in organelles called *peroxisomes* (p. 46) in light-organ cells. Scientists have long known that the beetle's brain triggers light by neurons that extend to the light organ in the abdomen. But the nerves attach to the air tubes (trachea) leading into the organ rather than on the light-producing cells. How does the signal actually get to those cells? Light production re-

quires oxygen, which is normally too low for light production in the light organs because mitochondria consume oxygen in the course of normal aerobic metabolism (pp. 51–53). The secret to light regulation is to let the oxygen get to the light cells. New studies show that the nerve signal triggers an enzyme to produce *nitric oxide* (NO), a paracrine signal researchers discovered in mammals as a local regulator of blood flow. In fireflies, NO appears to inhibit mitochondrial processes, allowing oxygen from the trachea to diffuse to the light cells. A crucial experiment consisted of exposing a dissected light organ to NO in the lab. It lit up!

The control of light production illustrates two major mechanisms of intercellular communication. First, a neuron carrying a signal from a central regulator (the

Photo: © Michael Jeffords

brain) releases a neurotransmitter molecule; second, a local or paracrine signal (NO) is triggered to affect the target system (in this case, mitochondria in the light cells). We'll mention many examples of such long-distance and local signaling mechanisms throughout our study of animal physiology.

accomplish the cellular response dictated by the first messenger. Transduction may occur in a single step, as in the common **tyrosine kinase pathway** (Figure 3-18), where the *receptor itself functions as an enzyme*, a so-called **receptor-enzyme**, which has a protein kinase site on its portion that faces the cytoplasm. In actuality, there is a lack of complete understanding of tyrosine kinases because of their complexity and multiplicity. To activate the protein kinase, appropriate extracellular messengers must bind with two of these receptors, which assemble into a pair. On activation, the receptor's protein kinase adds phosphate groups to tyrosine residues incorporated in the receptor itself (**autophosphorylation**) (Figure 3-18). Designated proteins inside the cell recognize and bind to the phosphorylated receptor. Then the receptor's protein kinase adds phosphate groups to the bound proteins. As a result of phosphorylation, the proteins change shape and function (are activated), enabling them to bring about the desired cellular response. In this pathway, the portions of the proteins that are specifically phosphorylated in both the receptor and designated proteins contain the amino acid tyrosine. Because of this specificity, such receptor-enzymes are called **tyrosine kinases**.

The hormone insulin, which plays a major role in maintaining glucose homeostasis, exerts its effects via tyrosine kinases. Also, many growth factors that help regulate cell growth and division, such as *nerve growth factor* and *epidermal growth factor*, act via this pathway. Receptor tyrosine kinases also play crucial roles in normal physiological processes including embryogenesis, cell proliferation and cell death. This network can also detect, amplify, filter, and process a variety of environmental and intercellular cues.

1 Two extracellular messengers bind to two receptors and receptors pair, activating receptor's protein kinase site.

2 Protein kinase site self-phosphorylates receptor's tyrosines.

3 Inactive designated protein binds to receptor, which phosphorylates protein, activating it.

4 Active designated protein brings about desired response.

FIGURE 3-18 Tyrosine kinase pathway.

© Cengage Learning, 2013

Other lipophobic external messengers bind to plasma membrane receptors, which stimulate second-messenger production, often via G proteins

Most lipophobic hormones work more indirectly than the mechanisms we've just described by binding to **G-protein-coupled membrane receptors (GPCRs)**, which in turn exert effects in target cells by acting through a **second-messenger system** to alter the activity of preexisting proteins. There are two major second-messenger pathways: One uses **cyclic adenosine monophosphate (cyclic AMP, or cAMP)** as a second messenger, while the other employs **diacylglycerol-inositol triphosphate** and Ca^{2+} in this role.

The G-protein system is found on the inner surface of the plasma membrane, as an intermediary between the receptor and effector protein (Figure 3-17c). G proteins are so named because they are bound to guanine nucleotides—**guanosine triphosphate (GTP)** when active or **guanosine diphosphate (GDP)** when inactive. An inactive G protein consists of a complex of alpha (α), beta (β), and gamma (γ) subunits, with a GDP molecule bound to the α subunit. A number of different G proteins with varying α subunits have been identified. The different G proteins are activated in response to binding of various first messengers to surface receptors. When an appropriate extracellular messenger (a first messenger) binds with its receptor, the receptor attaches to the appropriate G protein, resulting in release of GDP from the G-protein complex. GTP then attaches to the α subunit, an action that activates the G protein. Once activated, the G protein breaks away from the G-protein complex and moves along the inner surface of the plasma membrane until it reaches an effector protein. An effector protein is either an enzyme or an ion channel within the membrane. The α subunit links up with the effector protein and alters its activity. Researchers have identified more than 300 different receptors that convey instructions of extracellular messengers through the membrane to effector proteins by means of G proteins.

FIGURE 3-19 Mechanism of action of hydrophilic hormones via activation of the cyclic AMP second-messenger pathway.

© Cengage Learning, 2013

Cyclic AMP Second-Messenger GPCR Pathway Cyclic AMP is the most widely used second messenger. In the following description of the cAMP pathway, the numbered steps correlate to the numbered steps in Figure 3-19.

Binding of the first messenger to its surface membrane receptor (GPCR) activates the associated G protein, which in turn activates the effector protein, in this case the enzyme **adenylyl cyclase** (step 1), located on the cytoplasmic side of the plasma membrane. Adenylyl cyclase induces the conversion of intracellular ATP to cAMP by cleaving off two of the phosphates (step 2). (This is the same ATP used as the common energy currency in the body.) Acting as the intracellular second messenger, cAMP triggers a preprogrammed series of biochemical steps within the cell to bring about the response

dictated by the first messenger. To begin, cyclic AMP activates a specific intracellular enzyme, **protein kinase A** (step 3). Protein kinase A, in turn, phosphorylates a designated preexisting intracellular protein, such as an enzyme important in a particular metabolic pathway. Phosphorylation causes the protein to change its shape and function, thereby activating it (step 4). This activated protein brings about the target cell's ultimate response to the first messenger (step 5). For example, the activity of a particular enzymatic protein that regulates a specific metabolic event may be increased or decreased. After the response is completed, the subunit cleaves off a phosphate, converting GTP to GDP, in essence shutting itself off, then rejoins the β and γ subunits to restore the inactive G-protein complex. Cyclic AMP and the other

participating chemicals are inactivated so that the intracellular message is “erased” and the response can be terminated. For example, cAMP is quickly degraded by **phosphodiesterase**, a cytosolic enzyme that is continuously active. This action provides another highly effective means of turning off the response when it is no longer needed. Other complementary means of terminating the response are removal of the added phosphates by protein phosphatase or removal of the first messenger.

Note that in this signal transduction pathway, the steps involving the extracellular first messenger, the receptor, the G-protein complex, and the effector protein occur *in the plasma membrane* and lead to activation of the second messenger. The extracellular messenger cannot enter the cell to “personally” deliver its message to the proteins that carry out the desired response. Instead, it initiates membrane events that activate an intracellular second messenger, cAMP. The second messenger then triggers a chain reaction of biochemical events *inside the cell* that leads to the cellular response.

Different types of cells have different proteins available for phosphorylation and modification by protein kinase A. Therefore, a *common second messenger such as cAMP can induce widely differing responses in different cells*, depending on what proteins are modified. Cyclic AMP can be thought of as a molecular “switch” that can “turn on” (or “turn off”) different cell events, depending on the kinds of protein activity ultimately modified in the various target cells. The type of proteins altered by a second messenger depends on the unique specialization of a particular cell type. This can be likened to being able to either illuminate or cool off a room depending on whether the wall switch you flip on is wired to a device specialized to light up (a chandelier) or one specialized to create air movement (a ceiling fan). In the body, the variable responsiveness once the switch is turned on results from genetically programmed differences in the sets of proteins within different cells. For example, depending on its cellular location, activating the cAMP pathway can modify heart rate in the heart, stimulate the formation of female sex hormones in the ovaries, break down stored glucose in the liver, control water conservation during urine formation in the kidneys, create simple memory traces in the brain, or cause “perception” of a sweet taste by a taste bud.

Diacylglycerol-Inositol Trisphosphate- Ca^{2+} Second-Messenger Pathway Some cells use Ca^{2+} instead of cAMP as a second messenger. In such cases, binding of the first messenger to a GPCR eventually leads by means of G proteins to activation of the enzyme **phospholipase C**, an effector protein bound to the inner side of the membrane (step 1 in Figure 3-20). This enzyme breaks down **phosphatidylinositol bisphosphate** (abbreviated **PIP₂**), a component of the tails of the phospholipid molecules within the membrane itself. The products of PIP₂ breakdown are **diacylglycerol (DAG)** and **inositol trisphosphate (IP₃)** (step 1). Lipid-soluble DAG remains in the lipid bilayer of the plasma membrane, but water-soluble IP₃ diffuses into the cytosol. IP₃ mobilizes intracellular Ca^{2+} stored in the endoplasmic reticulum to increase cytosolic Ca^{2+} by binding with IP₃-gated receptor-channels in the ER membrane (step 3a). Calcium then takes on the role of second messenger, ultimately bringing about the response commanded by the first messenger. Many of the Ca^{2+} -dependent cellular events are triggered by activation of **calmodulin**, an intracellular Ca^{2+} -binding protein

(step 4a). Activation of calmodulin by Ca^{2+} is similar to activation of protein kinase A by cAMP. From here, the patterns of the two pathways are similar. The activated calmodulin phosphorylates the designated proteins (perhaps through multiple steps), thereby causing these proteins to change their shape and function, activating them (step 5a). The active designated proteins bring about the ultimate desired cellular response (step 6a). For example, this pathway is the means by which chemical messengers can activate smooth muscle contraction. Note that in this pathway, calmodulin, not protein kinase, brings about the necessary change in form and function of the designated proteins to get the job done.

Simultaneous to the IP₃ pathway, the other PIP₂ breakdown product, DAG, sets off another second-messenger pathway. (IP₃ and DAG themselves are sometimes considered to be second messengers.) DAG activates **protein kinase C (PKC)** (step 3b), which phosphorylates designated proteins, different from those phosphorylated by calmodulin (step 4b). The resultant change in shape and function of these proteins activates them. These active proteins produce another cellular response (step 5b). Although currently the subject of considerable investigation, the DAG pathway is not yet understood as well as the other signaling pathways. IP₃ and DAG typically trigger complementary actions inside a target cell to accomplish a common goal because both of these products are formed at the same time in response to the same first messenger. For example, extracellular chemical messengers promote increased contractile activity of blood-vessel smooth muscle via the IP₃/intracellular Ca^{2+} /calmodulin pathway, and the DAG pathway enhances the sensitivity of the contractile apparatus to Ca^{2+} .

The IP₃ pathway is not the only means of increasing intracellular Ca^{2+} . Intracellular Ca^{2+} can be increased by entry from the ECF or by release from Ca^{2+} stores inside the cell via means other than the IP₃ pathway. Calcium channels in both the surface membrane and in the ER may be opened by either electrical or chemical means. In later chapters, you will see examples of voltage changes regulating Ca^{2+} channels in synaptic transmission (Chapter 4) and muscle contraction (Chapter 8). The pathways can get even more complex than this. Calcium entering from the ECF can serve as a second messenger to trigger an even larger release of Ca^{2+} from intracellular stores, as it does to bring about contraction in cardiac muscle (Chapter 9). This all sounds confusing, but these examples are meant to illustrate the complexity of signaling, not to overwhelm.

Furthermore, the cAMP and Ca^{2+} pathways frequently overlap in bringing about a particular cellular activity. For example, cAMP and Ca^{2+} can influence each other. Calcium-activated calmodulin can regulate adenylyl cyclase and thus influence cAMP, whereas protein kinase A may phosphorylate and thereby change the activity of Ca^{2+} channels or carriers. Therefore, the cell-signaling pathways may communicate with one another to integrate their responses. This interpathway interaction is called **cross talk**.

Although the cAMP and Ca^{2+} pathways are the most prevalent second-messenger systems, they are not the only ones. For example, in a few cells **cyclic guanosine monophosphate (cyclic GMP)** serves as a second messenger in a system analogous to the cAMP system. In other cells, the second messenger is still unknown. Remember that activation of second messengers is a universal mechanism employed by a

FIGURE 3-20 Mechanism of action of hydrophilic hormones via concurrent activation of the IP₃/Ca²⁺ second-messenger pathway and the DAG pathway.

variety of extracellular messengers in addition to hydrophilic hormones. (See the box, *Molecular Biology and Genomics: Programmed Cell Suicide* on p. 101, for a surprising signal-transduction pathway—one that causes a cell to kill itself.)

Amplification by a Second-Messenger Pathway Several remaining points about receptor activation and the ensuing events merit attention. First, considering the number of steps in a second-messenger relay chain, you might wonder why so many cell types use the same complex system to

accomplish such a wide range of functions. The multiple steps of a second-messenger pathway are actually advantageous because the cascading (multiplying) effect of these pathways greatly amplifies the initial signal (Figure 3-21). *Amplification* means that the output of a system is much greater than the input. Using the cAMP pathway as an example, binding of one extracellular messenger molecule to a receptor activates a number of adenylyl cyclase molecules (let's arbitrarily say 10), each of which activates many (in our hypothetical example, let's say 100) cAMP molecules.

FIGURE 3-21 Amplification of the initial signal by a second-messenger pathway. Through amplification, very low concentrations of extracellular chemical messengers, such as hormones, can trigger pronounced cellular responses.

© Cengage Learning, 2013

Each cAMP molecule then acts on a single protein kinase A, which phosphorylates and thereby influences many (again, let’s say 100) specific proteins, such as enzymes. Each enzyme, in turn, is responsible for producing many (perhaps 100) molecules of a particular product, such as a secretory product. The result of this cascade, with one event triggering the next in sequence, is a tremendous amplification of the initial signal. In our hypothetical example, one extracellular messenger molecule has been responsible for inducing a yield of 10 million molecules of a secretory product. In this way, very low concentrations of hormones and other chemical messengers can trigger pronounced cell responses.

Regulation of Receptors Although membrane receptors serve as links between extracellular first messengers and intracellular second messengers in the regulation of specific cellular activities, the receptors themselves are also frequently subject to regulation. In many instances, receptor number and affinity (attraction of a receptor for its chemical messenger) can be altered, depending on the circumstances. For example, the number of receptors for the hormone insulin can be decreased in response to a chronic elevation of insulin in mammalian blood. This is usually called *downregulation* if receptors are decreased in number, or *upregulation* if increased (akin to acclimatization, p. 16).

Pharmacological agents and toxins are often agonists or antagonists affecting communication mechanisms

As we have seen, cell communication mechanisms involve a wide variety of small organic signal molecules and large proteins such as receptors and G-protein transducers. The steps involving these molecules are vulnerable to external chemicals entering the animal body. In particular, signaling steps are major targets of chemicals that have evolved for defending against predators and for capturing prey. Plants in particular, because they cannot actively fight or run away, have evolved an enormous variety of defensive chemicals that interfere with animal communication systems. Many animals (such as the curare frog of South America) also have evolved such defensive toxins, and also “offensive” toxins such as snake venom that are used to capture prey. Chemicals that affect a communication mechanism fall into two broad categories:

- **Antagonists** block a step in a communication pathway. Often these are chemicals that are similar in molecular structure to a signal molecule, but different enough to cause interference. Frequently, an antagonist binds to a receptor without activating that receptor, while at the same time blocking the binding of the normal signal molecule. For example, the active agent of the curare frog, *D-tubocurarine*, binds to and blocks the acetylcholine receptor at nerve–muscle synapses. As we shall see later (p. 134), acetylcholine normally triggers receptors that initiate muscle contraction; by blocking the receptor, the toxin causes paralysis. Another example is *anti-histamine*, discussed earlier (p. 94).

Molecular Biology and Genomics

Programmed Cell Suicide

In the vast majority of cases, the signal transduction pathways triggered by the binding of an extracellular first messenger to a membrane receptor are aimed at promoting useful functions, growth, survival, or reproduction of the cell. By contrast, most animal cells have a built-in pathway that, if triggered, causes the cell to commit suicide by activating intracellular protein-snipping enzymes, which slice the cell into small, disposable pieces. Such deliberate programmed cell death is termed **apoptosis** (meaning “dropping off” of cells that are no longer useful, much as autumn leaves drop off trees; pronounced “app-oh-TOE-sis” with a silent “p” as in “pterodactyl”). Apoptosis differs from the other form of cell death, **necrosis** (meaning “make dead”). Necrosis is uncontrolled, accidental, messy murder of useful cells that have been severely injured by, for example, a physical blow, O₂ deprivation, or disease.

Apoptosis is a normal part of life: Individual cells that have become superfluous or disordered are triggered to self-destruct for the greater good of maintaining the whole body’s health or to aid development. Genomic analysis shows that even the most primitive animals, sponges, have apoptosis genes, but protists do not. Scientists believe that cell suicide, along with cell–cell adhesion and growth-control mechanisms, were key innovations in the evolution of multicellularity. Here are some examples of apoptotic functions:

1. **Development.** Certain unwanted cells produced during development are programmed to kill themselves as a body is sculpted into its final form. For example, apoptosis deliberately prunes the embryonic ducts capable of form-

ing a mammalian male reproductive tract during the development of a female. Likewise, apoptosis destroys many larval tissues when a caterpillar pupates and becomes a butterfly.

2. **Turnover.** Optimal functioning of most tissues depends on a balance between controlled production of new cells and regulated cellular self-destruction. This balance maintains the proper number of cells in a given tissue while ensuring a controlled supply of fresh cells that are at their peak of performance.
3. **Defense.** Apoptosis provides a means to remove cells infected with harmful viruses. Furthermore, infection-fighting white blood cells (in vertebrates) that have finished their prescribed function and are no longer needed, execute themselves. Also, apoptosis often removes cells that have suffered irreparable damage by exposure to radiation or other poisons, and cells that are becoming cancerous.

A cell signaled to commit suicide detaches itself from its neighbors, then shrinks instead of swelling and bursting. As its lethal weapon, the suicidal cell activates a cascade of normally inactive intracellular protein-cutting enzymes, the **caspases**, which kill the cell from within. When a cell has been signaled to undergo apoptosis, the mitochondria become leaky, permitting *cytochrome c* to leak out into the cytosol, where it activates the caspase cascade. (Cytochrome c, a component of the electron transport chain, usually participates in oxidative phosphorylation to produce ATP; see Figure 2-20, p. 52). Once unleashed, the caspases act like molecular scissors to systematically dismantle the cell. Snipping

A normal cell (left) and a cell undergoing apoptosis (right).

Dr. Gopal Murti/Visuals Unlimited, Inc.

protein after protein, they chop up the nucleus, then break down the internal shape-holding cytoskeleton, and finally fragment the cell itself into disposable membrane-enclosed packets (see accompanying photo). Importantly, the contents of the dying cell remain wrapped by plasma membrane throughout the entire self-execution process, thus avoiding the spewing of potentially harmful intracellular contents characteristic of necrosis. Cells in the vicinity swiftly engulf and destroy the apoptotic cell fragments by phagocytosis. The breakdown products are then recycled for other purposes as needed.

Evolutionary differences in apoptosis genes may explain a curious difference between humans and chimpanzees: The former are subjected to a variety of deadly cancers while the latter very rarely get cancer. Genomic analysis shows that, while human–chimp genes differ by an average of two amino acid mutations per protein, genes for apoptotic and DNA-repair proteins differ by eight amino acid mutations. This has resulted in cancerous cells avoiding apoptosis more often in humans than in chimps. Why did these differences evolve? One hint is that the same genes that reduce apoptosis in humans allow for sperm—which undergo apoptosis as they age—to survive longer and thus increase human fertility.

- **Agonists** activate a step in a communication pathway. Again, often these are chemicals that are similar in molecular structure to a signal molecule, but in this case they cause the same general effect; for example, an agonist may bind to a receptor and activate it, just as the normal signal molecule would. However, the agonist is often structurally somewhat different so that it may bind for an abnormally long time, or it may not be broken down effectively to shut off the stimulus. For example, *nicotine* (found in tobacco) is a long-lasting agonist

of one class of acetylcholine receptors (“nicotinic receptors”; see p. 164).

A common class of antagonistic molecule is the **methylxanthines**, *caffeine* and *theophylline*, molecules that have structures similar to those of cAMP and adenosine. Caffeine is found in coffee and cacao beans (chocolate). In tea leaves, the concentration of theophylline can be as high as 3.5%. The activity of PDE (phosphodiesterase, which shuts off the cAMP cascade) is decreased by these antagonistic chemicals,

which bind to the enzyme. These compounds also block the receptors for **adenosine**, a paracrine that usually dampens neural activity by opening potassium channels (Chapter 4). Methyl xanthines are noted for their powerful stimulatory effects on the central nervous system and (in vertebrates) heart function. These compounds probably evolved to disrupt the feeding behavior of herbivorous insects. When administered artificially to animals, methyl xanthines exert unpredictable effects on their behavior. For example, caffeine administration prevents spiders from spinning a functional web. In many cases, scientists do not know whether inhibition of PDE or adenosine receptors or both are the basis of these effects.

Much medical and physiological research is based on using natural agonists and antagonists (or laboratory-designed ones) as pharmacologic agents (or drugs). Medicine, of course, uses these for treating various diseases, whereas physiologists use them as probes of signal functions.

By what process does a cell commit suicide? What cellular organelles are utilized in the process?

3.5 Membrane Potential

Earlier we noted that solutes are unequally distributed between the interior and exterior of cells. We have also discussed how some cells can exploit these differences in solute concentration on either side of the membrane and can selectively change the permeability of the membrane to particular solutes. In most cells, inorganic solutes are unevenly distributed as well as organic ones, with **sodium** (Na^+) and chloride (Cl^-) dominating outside and potassium (K^+) (along with organic molecules) dominating inside. Put another way, Na^+ and Cl^- are usually the major **osmolytes** (solutes involved in osmotic pressure regulation) in the **ECF** (**extracellular fluid**) in animals, whereas K^+ is the dominant inorganic osmolyte in the **ICF** (**intracellular fluid**). Indeed, the occurrence of K^+ as the dominant intracellular cation appears universal from prokaryotes on up and suggests that this feature originated with the earliest life forms. (In Chapter 13, we'll consider why higher K^+ than Na^+ in cells is adaptive for all life.) **Excitable cells** such as neurons regulate permeability of these ions (especially Na^+ and K^+) as a signaling mechanism, as we discuss in the next chapter.

Membrane potential is a separation of opposite charges across the plasma membrane

All plasma membranes have a membrane potential, or are polarized electrically. The term **membrane potential** refers to a separation of charges across the membrane, or to a difference in the relative number of cations and anions in the ICF and ECF. Recall that opposite charges tend to attract each

other and like charges tend to repel each other. Work must be performed (energy expended) to separate opposite charges after they have come together. Conversely, when oppositely charged particles have been separated, the electrical force of attraction between them can be harnessed to perform work when the charges are permitted to come together again. This is the basic principle underlying electrically powered devices. We use the term *membrane potential* because separated charges now have the potential to do work. Potential is measured in units of volts (the same unit used for the voltage in electrical devices), but because the membrane potential is relatively low the unit used is **millivolts** (mV) ($1 \text{ mV} = 1/1,000 \text{ volt}$).

Because the concept of potential is fundamental to understanding nerve and muscle physiology, it is important to understand clearly what this term means. The membrane in Figure 3-22a is electrically neutral. An equal number of positive (+) and negative (−) charges are on each side of the membrane, so no membrane potential exists. In Figure 3-22b, some of the + charges from the right side have been moved to the left. Now the left has an excess of + charges, leaving an excess of − charges on the right. In other words, there is a separation of opposite charges across the membrane, or a difference in the relative number of + and − charges between the two sides (that is, a membrane potential exists). The attractive force between these separated charges causes them to accumulate in a thin layer along the outer and inner surfaces of the plasma membrane (Figure 3-22c). It is important to realize that these separated charges represent only a small fraction of the total number of charged particles (ions) present in the ICF and ECF. The vast majority of the fluid inside and outside the cells is electrically neutral (Figure 3-22d). The electrically balanced ions can be ignored because they do not contribute to membrane potential. Thus, an almost insignificant fraction of the total number of charged particles present in the body fluids is responsible for the membrane potential.

Note that the membrane itself is not charged. The term *membrane potential* refers to the difference in charge between the wafer-thin regions of ICF and ECF lying next to the inside and outside of the membrane, respectively. The magnitude of the potential depends on the degree of separation of the opposite charges: The greater the number of charges separated, the larger the potential.

Membrane potential is primarily due to differences in the distribution and permeability of key ions

All living cells have a membrane potential characterized by a slight excess of positive charges outside and a corresponding slight excess of negative charges on the inside. The cells of *excitable tissues*—namely nerve cells and muscle cells—have the ability to exploit this relationship and produce rapid, transient changes in their membrane potential when excited. These brief fluctuations in potential serve as electrical signals. The constant membrane potential present in nonexcitable tissues and in excitable tissues when they are at rest—that is, when they are not producing electrical signals—is known as the **resting membrane potential**. We concentrate now on the generation and maintenance of the resting potential, and in later chap-

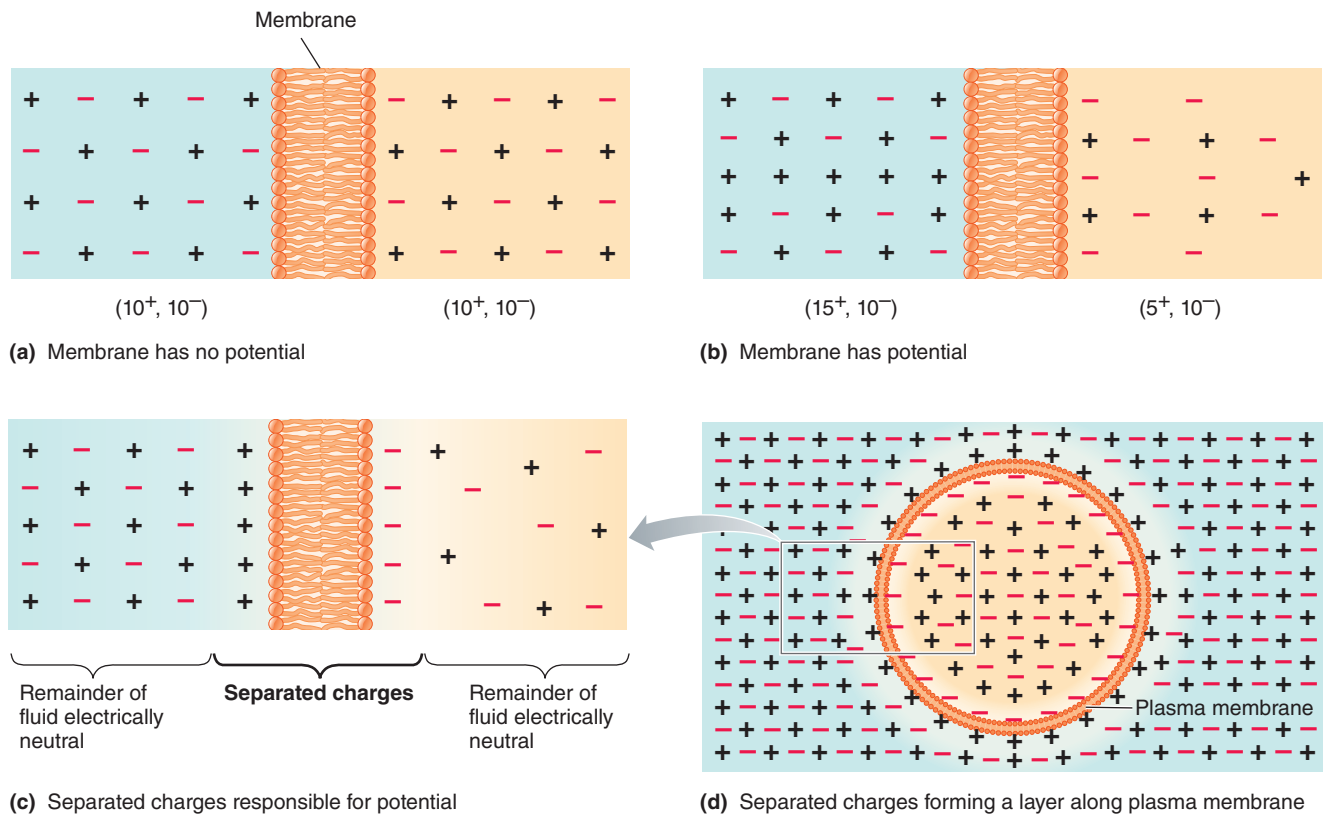

FIGURE 3-22 Determination of membrane potential by unequal distribution of positive and negative charges across the membrane. (a) When the positive and negative charges are equally balanced on each side of the membrane, no membrane potential exists. (b) When opposite charges are separated across the membrane, membrane potential exists. (c) The unbalanced charges responsible for the potential accumulate in a thin layer along opposite surfaces of the membrane. (d) The vast majority of the fluid in the ECF and ICF is electrically neutral. The unbalanced charges accumulate along the plasma membrane.

© Cengage Learning, 2013

ters, we examine the changes that take place in excitable tissues during signaling.

The unequal distribution of a few key ions between the ICF and ECF and their selective movement through the plasma membrane govern the electrical properties of the membrane. In an animal body, electrical charges are carried by ions. The ions primarily responsible for generating the resting membrane potential are Na^+ , K^+ , and A^- . The last refers to the large, negatively charged (anionic) intracellular proteins. Other ions (calcium, magnesium, chloride, bicarbonate, and phosphate, to name a few) do not make a direct contribution to the electrical properties of the plasma membrane in most cells, even though they play other important roles in the body. The concentrations of these ions differ from one animal to another, but the factors that regulate their distribution are the same.

The concentrations and relative permeabilities of the ions critical to membrane electrical activity are compared in Table 3-4. Note that Na^+ is in greater concentration in the extracellular fluid and K^+ is in much higher concentration in the intracellular fluid. These concentration differences are maintained in two very distinct ways:

1. *The Na^+/K^+ pump* (Figure 3-14) *at the expense of energy (ATP).*

TABLE 3-4 Concentration and Permeability of Ions Responsible for Membrane Potential in a Resting Nerve Cell

Ion	Concentration (millimoles/liter)		Permeability Relative
	Extracellular	Intracellular	
Na^+	150	15	1
K^+	5	150	25–30
A^-	0	65	0

© Cengage Learning, 2013

2. *Different solubilities in cell water and affinity for cell proteins.* Due to attraction of water molecules by proteins, water inside cells appears to form a hydrogen-bonded network that is different from the network of water by itself. Experimentally, researchers have found that K^+ is more soluble in this internal water than is Na^+ and that this leads to K^+ preferentially entering a cell. Also, the negative charges of proteins attract K^+ more

strongly than Na^+ because K^+ has a smaller **hydration shell** (a sphere of water molecules attracted by the ion's positive charge). The ion must lose its hydration shell before it can bind to a protein, and it is easier for K^+ to do this than for Na^+ . This effect also reinforces the accumulation of K^+ over Na^+ .

Because the plasma membrane is virtually impermeable to A^- , these large, negatively charged proteins are found *only inside* the cell. After they have been synthesized from amino acids transported into the cell, they remain trapped within the cell.

In addition to the active carrier mechanism, Na^+ and K^+ can passively cross the membrane through protein channels specific for them. It is usually much easier for K^+ than for Na^+ to get through the membrane because typically the membrane has many more K^+ leak channels than it has Na^+ leak channels. Thus, more channels are open for passive K^+ traffic across the membrane. In a nerve cell at rest (that is, when it is not conducting a nerve impulse), the membrane is about 25 to 30 times more permeable to K^+ than to Na^+ .

Armed with knowledge of the relative concentrations and permeabilities of these ions, we can now analyze the forces acting across the plasma membrane. This analysis is broken down as follows: First we consider the direct contributions of the Na^+/K^+ pump to membrane potential; second, the effect the movement of K^+ alone has on membrane potential; third, the effect of Na^+ alone; and finally, the situation that exists in the cells when both K^+ and Na^+ effects are taking place concurrently. Table 3-5 summarizes the concentration and electrical gradients that exist for K^+ and for Na^+ under various conditions. Remember throughout this discussion that the concentration gradient for K^+ is always outward and the concentration gradient for Na^+ is always inward because the Na^+/K^+ pump maintains a higher concentration of K^+ inside the cell and a higher concentration of Na^+ outside the cell. Also, note that because K^+ and Na^+ are both cations (positively charged), *the electrical gradient for both is always toward the negatively charged side of the membrane.*

Effect of Sodium/Potassium Pump on Membrane Potential

Recall that Na^+/K^+ pump transports three Na^+ out for every two K^+ it transports in. Because this unequal transport moves positive ions only, it generates a membrane potential, with the outside becoming relatively more positive than the inside as more ions are transported out than in. However, this active transport mechanism separates only enough charges to generate an almost negligible membrane potential of 1 mV to 3 mV, with the interior negative to the exterior of the cell. The vast majority of the membrane potential results from the passive diffusion of K^+ (and to a lesser extent, Na^+) down concentration gradients. Thus, most of the Na^+/K^+ pump's role in producing membrane potential is indirect, through its critical contribution to maintaining the concentration gradients directly responsible for the ion movements that generate most of the potential.

Effect of the Movement of Potassium Alone on Membrane Potential: Equilibrium Potential for K^+

Let's consider a hypothetical situation characterized by (1) the concentrations that exist for K^+ and A^- across the plasma membrane, (2) free permeability of the membrane to K^+ but not to A^- ,

TABLE 3-5 Concentration and Electrical Gradients for K^+ and Na^+ at Equilibrium Potential (E) and Resting Potential

Ion	Condition	Gradient	Direction of Gradient
K^+	E_{K^+} (−90 mV)	Concentration gradient Electrical gradient	Outward Inward
Na^+	E_{Na^+} (+60 mV)	Concentration gradient Electrical gradient	Inward Outward
K^+	Resting potential (−70 mV)	Concentration gradient Electrical gradient	Outward Inward
Na^+	Resting potential (−70 mV)	Concentration gradient Electrical gradient	Inward Inward

© Cengage Learning, 2013

and (3) no potential as yet present. The concentration gradient for K^+ would tend to move this ion out of the cell (Figure 3-23). Because the membrane is permeable to K^+ , this ion would readily pass through. As potassium ions moved to the outside, they would carry their positive charge with them, so more positive charges (K^+ along with Na^+ already on the outside) would be on the outside, whereas negative charges in the form of A^- would be left behind on the inside, similar to the situation shown in Figure 3-22b. (Remember that the large protein anions cannot diffuse out, despite a tremendous concentration gradient.) A membrane potential would now exist. Because an electrical gradient would also be present, K^+ , being a positively charged ion, would be attracted toward the negatively charged interior and repelled by the positively charged exterior. Thus, two opposing forces would now be acting on K^+ : the concentration gradient tending to move K^+ out of the cell and the electrical conduction gradient tending to move the ions into the cell.

Initially, the concentration gradient would be stronger than the electrical gradient, so net diffusion of K^+ out of the cell would continue and the membrane potential would increase. As more and more K^+ moved down its concentration gradient and out of the cell, however, the opposing electrical gradient would also become greater as the outside became increasingly more positive and the inside more negative. You might think that the outward concentration gradient for K^+ would gradually decrease as K^+ leaves the cell down this gradient. Surprisingly, however, the K^+ concentration gradient would remain essentially constant despite the outward movement of K^+ . The reason is that only infinitesimal movement of K^+ out of the cell would bring about rather large changes in membrane potential. Accordingly, such an extremely small number of K^+ ions present in the cell would have to leave the cell to establish an opposing electrical gradient, that the K^+ concentration inside and outside the cell would remain essentially unaltered. As K^+ continued to move out down its unchanging concentration gradient, the inward electrical gradient would continue to increase in strength. Net outward movement would gradually be reduced as the strength of the electrical gradient approached that of the concentration gradient. Finally, when these two forces exactly balanced each other (that is, when they were in equilibrium), no further net movement of K^+ would occur. The po-

FIGURE 3-23 Equilibrium potential for K^+ .

© Cengage Learning, 2013

- 1 The concentration gradient for K^+ tends to move this ion out of the cell.
- 2 The outside of the cell becomes more positive as K^+ ions move to the outside down their concentration gradient.
- 3 The membrane is impermeable to the large intracellular protein anion (A^-). The inside of the cell becomes more negative as K^+ ions move out, leaving behind A^- .
- 4 The resulting electrical gradient tends to move K^+ into the cell.
- 5 No further net movement of K^+ occurs when the inward electrical gradient exactly counterbalances the outward concentration gradient. The membrane potential at this equilibrium point is the equilibrium potential for K^+ (E_{K^+}) at -90 mV.

tential that would exist at this equilibrium is known as the **equilibrium potential for K^+ (E_{K^+})**. At this point, a large concentration gradient for K^+ would still exist, but no more net movement of K^+ would occur out of the cell down this concentration gradient because of the exactly equal opposing electrical gradient (Figure 3-23).

The membrane potential at E_{K^+} is -90 mV. It is not really a negative potential. By convention, *the sign always designates the polarity of the excess charge on the inside of the membrane*. A membrane potential of -90 mV means that the potential is of a magnitude of 90 mV, with the inside being negative relative to the outside. A potential of $+90$ mV would have the same strength, but in this case the inside would be more positive than the outside.

The equilibrium potential for a given ion of differing concentrations across a membrane can be calculated by means of the **Nernst equation** as follows:

$$E_{\text{ion}} = \frac{61}{z} \log \frac{C_o}{C_i}$$

where

E_{ion} = equilibrium potential for ion in mV

61 = a constant that incorporates the universal gas constant (R), absolute temperature (T), and an electrical constant known as Faraday (F), along with the conversion of the natural logarithm (\ln) to the logarithm to base 10 (\log); $61 = RT/F$.

z = the ion's valence; $z = 1$ for K^+ and Na^+ , the ions that contribute to membrane potential (for divalent ions such as Ca^{2+} , $z = 2$)

C_o = concentration of the ion outside the cell (ECF) in millimoles/liter (millimolar, mM)

C_i = concentration of the ion inside the cell (ICF) in mM

Given the mammalian ECF concentration of K^+ at 5 mM and the ICF concentration at 150 mM:

$$\begin{aligned} E_{K^+} &= 61 \log \frac{5 \text{ mM}}{150 \text{ mM}} \\ &= 61 \log \frac{1}{30} \end{aligned}$$

Because the \log of $1/30 = -1.477$,

$$E_{K^+} = 61(-1.477) = -90 \text{ mV}$$

Because 61 is a constant (for a mammal with a 37°C body temperature), the equilibrium potential is essentially a measure of the membrane potential (that is, the magnitude of the electrical gradient) that exactly counterbalances the concentration gradient that exists for the ion (that is, the ratio between the ion's concentration outside and inside the cell). For a poikilotherm with a lower body temperature of 18°C , the constant is reduced to 58. Note that the larger the concentration gradient for an ion, the greater the ion's equilibrium potential. A comparably greater opposing electrical gradient would be required to counterbalance the larger concentration gradient.

Effect of Movement of Sodium Alone on Membrane Potential: Equilibrium Potential for Na^+ A similar hypothetical situation could be developed for Na^+ alone (Figure 3-24). The concentration gradient for Na^+ would move this ion into the cell, building up positive charges on the interior of the membrane and leaving negative charges unbalanced outside (primarily in the form of chloride, Cl^- ; Na^+ and Cl^- —that is, salt—are the predominant ECF ions). Net diffusion inward would continue until equilibrium was established by the development of an opposing electrical gradient that exactly counterbalanced the concentration gradient. At this point, given the concentrations for Na^+ , the **Na^+ equilibrium potential (E_{Na^+})** would be $+61$ mV. Given that the ECF

- 1 The concentration gradient for Na^+ tends to move this ion into the cell.
- 2 The inside of the cell becomes more positive as Na^+ ions move to the inside down their concentration gradient.
- 3 The outside becomes more negative as Na^+ ions move in, leaving behind in the ECF unbalanced negatively charged ions, mostly Cl^- .
- 4 The resulting electrical gradient tends to move Na^+ out of the cell.
- 5 No further net movement of Na^+ occurs when the outward electrical gradient exactly counterbalances the inward concentration gradient. The membrane potential at this equilibrium point is the equilibrium potential for Na^+ (E_{Na^+}) at +60 mV.

FIGURE 3-24 Equilibrium potential for Na^+ .

© Cengage Learning, 2013

concentration of Na^+ is 150 mM and the ICF concentration is 15 mM,

$$E_{\text{Na}^+} = 61 \log \frac{150 \text{ mM}}{15 \text{ mM}}$$

$$= 61 \log 10$$

Because the log of 10 = 1,

$$E_{\text{Na}^+} = 61(1) = 61 \text{ mV}$$

In this case, the inside of the cell would be positive, in contrast to the equilibrium potential for K^+ . The magnitude of E_{Na^+} is somewhat less than for E_{K^+} (60 mV compared to 90 mV) because the concentration gradient for Na^+ is not as large (Table 3-4); thus, the opposing electrical gradient (membrane potential) is not as great at equilibrium.

Concurrent Potassium and Sodium Effects on Membrane Potential Neither K^+ nor Na^+ are alone in the body fluids, so equilibrium potentials exist only in hypothetical or experimental conditions. In a living cell, the effects of both K^+ and Na^+ must be taken into account. *The greater the permeability of the plasma membrane for a given ion, the greater the tendency for that ion to drive the membrane potential toward the ion's own equilibrium potential.* Because the membrane at rest is 25 to 30 times more permeable to K^+ than to Na^+ , K^+ passes through more readily than Na^+ ; thus, K^+ influences the resting membrane potential to a much greater extent than does Na^+ . Recall that K^+ acting alone would establish an equilibrium potential of -90 mV. The membrane is somewhat permeable to Na^+ , however, so some Na^+ enters the cell in a limited attempt to reach its equilibrium potential. This Na^+ influx neutralizes, or cancels, some of the potential produced by K^+ alone if Na^+ were not present.

To facilitate an understanding of this concept, assume that each separated pair of charges in Figure 3-25 represents 10 mV of potential. (This is not technically correct, because in reality, many separated charges must be present to account

for a potential of 10 mV.) In this simplified example, nine separated pluses and minuses, with the minuses on the inside, would represent the E_{K^+} of -90 mV. Superimposing the slight influence of Na^+ on this K^+ -dominated membrane, assume that two sodium ions enter the cell down the Na^+ concentration and electrical gradients. (Note that the electrical gradient for Na^+ is now inward in contrast to the outward electrical gradient for Na^+ at E_{Na^+} . At E_{Na^+} , the inside of the cell is positive as a result of the inward movement of Na^+ down its concentration and electrical gradients. In a resting nerve cell, however, the inside is negative because of the dominant influence of K^+ on membrane potential. Thus, both the concentration and electrical gradients now favor the inward movement of Na^+). The inward movement of these two positively charged sodium ions neutralizes some of the potential established by K^+ , so now only seven pairs of charges are separated, and the potential is -70 mV. This is the **resting membrane potential** of a typical nerve cell. All cells have a negative resting membrane potential with values that range from -30 to -100 mV. The resting potential of a cell is much closer to E_{K^+} than to E_{Na^+} because of the greater permeability of the membrane to K^+ , but it is slightly less than E_{K^+} (-70 mV is a lower potential than -90 mV) because of the weak influence of Na^+ .

Membrane potential can be measured directly in experimental conditions by recording the voltage difference between the inside and outside of the cell, or it can be calculated using the **Goldman-Hodgkin-Katz equation (GHK equation)**, which takes into account the relative permeabilities and concentration gradients of all permeable ions. The stable, resting membrane is permeable to K^+ , Na^+ , and Cl^- , but for reasons to be described later, Cl^- does not directly contribute to potential in most cells. Therefore, we can ignore it when calculating membrane potential, making the simplified GHK equation:

$$V_m = 61 \log \frac{P_{\text{K}^+}[\text{K}^+]_o + P_{\text{Na}^+}[\text{Na}^+]_o}{P_{\text{K}^+}[\text{K}^+]_i + P_{\text{Na}^+}[\text{Na}^+]_i}$$

1 The Na⁺/K⁺ pump actively transports Na⁺ out of and K⁺ into the cell, keeping the concentration of Na⁺ high in the ECF and the concentration of K⁺ high in the ICF.

2 Given the concentration gradients that exist across the plasma membrane, K⁺ tends to drive membrane potential to the equilibrium potential for K⁺ (−90 mV), whereas Na⁺ tends to drive membrane potential to the equilibrium potential for Na⁺ (+60 mV).

3 However, K⁺ exerts the dominant effect on resting membrane potential because the membrane is more permeable to K⁺. As a result, resting potential (−70 mV) is much closer to E_{K^+} than to E_{Na^+} .

4 During the establishment of resting potential, the relatively large net diffusion of K⁺ outward does not produce a potential of −90 mV because the resting membrane is slightly permeable to Na⁺ and the relatively small net diffusion of Na⁺ inward neutralizes (in gray shading) some of the potential that would be created by K⁺ alone, bringing resting potential to 70 mV, slightly less than E_{K^+} .

5 The negatively charged intracellular proteins (A[−]) that cannot cross the membrane remain unbalanced inside the cell during the net outward movement of the positively charged ions, so the inside of the cell is more negative than the outside.

FIGURE 3-25 Effect of concurrent K⁺ and Na⁺ movement on establishing the resting membrane potential.

© Cengage Learning, 2013

where

V_m = membrane potential in mV

61 = a constant representing RT/zF ,
when $z = 1$, as it does for K⁺ and Na⁺

P_{K^+} , P_{Na^+} = permeabilities for K⁺ and Na⁺, respectively

$[K^+]_o$, $[Na^+]_o$ = concentration of K⁺ and Na⁺ outside the cell in mM, respectively

$[K^+]_i$, $[Na^+]_i$ = concentration of K⁺ and Na⁺ inside the cell in mM, respectively.

The GHK equation is basically an expanded version of the Nernst equation. The Nernst equation can only be used to calculate the potential generated by a specific ion, but the GHK equation takes into account the combined contributions to potential of all ions moving across the membrane. Assuming the resting membrane is 25 times more permeable to K⁺ than to Na⁺, then the relative permeabilities are $P_{K^+} = 1.0$ and $P_{Na^+} = 0.04$ (1/25 of 1.0). Given these permeabilities and the concentrations for K⁺ and Na⁺ in the ECF and ICF listed in Table 3-4,

$$\begin{aligned} V_m &= 61 \log \frac{(1)(5) + (0.04)(150)}{(1)(150) + (0.04)(5)} \\ &= \log \frac{5 + 6}{150 + 0.6} \\ &= 61 \log 0.073 \end{aligned}$$

Because the log of 0.073 is −1.137,

$$V_m = 61 (-1.137) = -69 \text{ mV}$$

Adding −1 mV of potential generated directly by the Na⁺/K⁺ pump to this value totals −70 mV for the resting membrane potential.

Balance of Passive Leaks and Active Pumping at Resting Membrane Potential At resting potential, neither K⁺ nor Na⁺ is at equilibrium. A potential of −70 mV does not exactly counterbalance the concentration gradient for K⁺; it takes a potential of −90 mV to do that. Thus, there is a continual tendency for K⁺ to passively *leak* out through its channels. In the case of Na⁺, the concentration and electrical gradients do not even oppose each other; they both favor the inward movement of Na⁺. Therefore, Na⁺ continually leaks inward down its electrochemical gradient, but only slowly because of its low permeability; that is, because of the scarcity of Na⁺ leak channels.

Because such leaking goes on all the time, why does the intracellular concentration of K⁺ not continue to fall and the concentration of Na⁺ inside the cell progressively increase? This does not happen, because of the Na⁺/K⁺ pump. This active transport mechanism counterbalances the rate of leakage (Figure 3-26). At resting potential, the pump transports back into the cell essentially the same number of potassium ions that have leaked out and simultaneously transports to the outside the sodium ions that have leaked in. At this point, a steady state exists: No net movement of any ions takes place, because all passive leaks are exactly balanced by active pumping. No net change takes place in either a steady state or a dynamic equilibrium, but in a *steady state* energy must be used to maintain the constancy, whereas in a *dynamic equilibrium* no energy is needed to maintain the constancy. That is, opposing passive and active forces counterbalance each other in a steady state and opposing passive forces

FIGURE 3-26 Counterbalance between passive Na^+ and K^+ leaks and the active Na^+/K^+ pump. At resting membrane potential, the passive leaks of Na^+ and K^+ down their electrochemical gradients are counterbalanced by the active Na^+/K^+ pump, so that there is no net movement of Na^+ and K^+ , and the membrane potential remains constant.

© Cengage Learning, 2013

counterbalance each other in a dynamic equilibrium. Because in the steady state across the membrane the active pump offsets the passive leaks, the concentration gradients for K^+ and Na^+ remain constant across the membrane. Thus, not only is the Na^+/K^+ pump initially responsible for the Na^+ and K^+ concentration differences across the membrane, but it also maintains these differences.

As just discussed, it is the presence of these concentration gradients, together with the difference in permeability of the membrane to these ions, that accounts for the magnitude of the resting membrane potential. In this resting state, the potential remains constant. There is no net movement of any ions. All passive forces are exactly balanced by active forces. A steady state exists, even though there is still a strong concentration gradient for both K^+ and Na^+ in opposite directions, as well as a slight excess of positive charges in the ECF accompanied by a corresponding slight excess of negative charges in the ICF (enough to account for a potential of the magnitude of 70 mV).

Chloride Movement at Resting Membrane Potential Thus far, we have largely ignored one other ion present in high concentration in the ECF: Cl^- . Chloride is the principal ECF anion. Its equilibrium potential is -70 mV to -80 mV, similar to the resting membrane potential. Movement alone of negatively charged Cl^- into the cell down its concentration gradient would produce an opposing electrical gradient, with the inside negative compared to the outside. When physiologists were first examining the ionic effects that could account for the membrane potential, it was tempting to think that Cl^- movements and establishment of the Cl^- equilibrium potential could be solely responsible for producing the identical resting membrane potential. Actually, the reverse is true. The membrane potential is responsible for driving the distribution of Cl^- across the membrane.

Most cells are highly permeable to Cl^- but have no active transport mechanisms for Cl^- . With no active forces acting on it, Cl^- passively distributes itself to achieve an individual state of equilibrium. In this case, Cl^- is driven out of the cell, establishing an inward concentration gradient that exactly counterbalances the outward electrical gradient (that is, the resting membrane potential) produced by K^+ and Na^+ movement. Thus, the concentration difference for Cl^- between the ECF and ICF is brought about passively by the presence of the membrane potential, rather than being maintained by an active pump, as is the case for K^+ and Na^+ . Therefore, in most cells Cl^- does not influence membrane potential; instead,

membrane potential passively influences the Cl^- distribution. (Some specialized cells have an active Cl^- pump, with subsequent movement of Cl^- accounting for part of the potential.)

Specialized Use of Membrane Potential in Nerve and Muscle Cells

Nerve and muscle and cells have developed a specialized use for membrane potential. They can rapidly and transiently alter their membrane permeabilities to the involved ions in response to appropriate stimulation, thereby bringing about fluctuations in membrane potential. The rapid fluctuations in potential are responsible for producing nerve impulses in sensory and nerve cells and for triggering contraction in muscle cells. These activities are the focus of most of the next chapters. Even though all cells display a membrane potential, its significance in other cells is uncertain.

How Membrane Physiology Contributes to the Body as a Whole

All cells of an animal's body must obtain vital materials, such as nutrients and O_2 , from the surrounding ECF; they must also eliminate wastes to the ECF and release secretory products, such as chemical messengers and digestive enzymes. Thus, transport of materials across the plasma membrane between the ECF and ICF is essential for cell survival, and the constituents of the ECF must be homeostatically maintained to support these life-sustaining exchanges.

Many cell types use membrane transport to carry out their specialized activities geared toward maintaining homeostasis. Here are several examples:

1. Absorption of nutrients from the digestive tract lumen involves the transport of these energy-giving molecules across the membranes of the cells lining the tract.

2. Exchange of O_2 and CO_2 between the air and blood in the lungs involves the diffusion across the membranes of the cells lining the air sacs and blood vessels of the lungs.
3. Urine is formed by the selective transfer of materials between the blood and the fluid within the kidney tubules across the membranes of the cells lining the tubules.
4. The beating of the heart is triggered by cyclic changes in the transport of Na^+ , K^+ , and Ca^{2+} across the heart cells' membranes.
5. Secretion of chemical messengers such as neurotransmitters from nerve cells and hormones from endocrine cells involves the transport of these regulatory products to the ECF on appropriate stimulation.

In addition to providing selective transport of materials between the ECF and ICF, the plasma membrane contains receptors for binding with specific chemical messengers that

regulate various cell activities, many of which are specialized activities aimed toward maintaining homeostasis. For example, the hormone vasopressin, which is secreted in response to a water deficit in the body, binds with receptors in the plasma membrane of a specific type of kidney cell. This binding triggers the cells to conserve water during urine formation by promoting the insertion of additional aquaporins (water channels) in the plasma membrane of these cells, thus helping alleviate the water deficit that initiated the response.

All living cells have a membrane potential; the specialized activities of nerve and muscle cells depend on these cells' ability to change their membrane potential rapidly on appropriate stimulation. The transient, rapid changes in potential in nerve cells serve as electrical signals, which provide a means to transmit information along nerve pathways. This information is used to accomplish regulatory adjustments, such as restoring blood pressure to normal when signaled that it has fallen too low. Rapid changes in membrane potential also trigger muscle contraction.

Chapter Summary

- The lipid bilayer forms the basic structural barrier that encloses the cell. The membrane proteins perform a variety of specific membrane functions, which include the transport of substances in and out of the cell. Membrane carbohydrates serve as self-identity markers.
- The fluid mosaic and membrane-skeleton fence models describe membrane structure and function.
- Lipid-soluble substances and small polar molecules that can permeate the membrane diffuse passively down their concentration gradient. Ions that can permeate the membrane also move passively along their electrical (conduction) gradient.
- The slowness of diffusion, and thus its inadequacy for movement over large distances, has been the primary force in the evolution of circulatory systems and other bulk transport processes in multicellular animals. Fick's law of diffusion states that concentration gradient, temperature, molecular weight of the diffusing substance, thickness, and surface area of the membrane affect the net rate of diffusion across a membrane.
- Osmosis is the net movement of water through a membrane. Because solutions are always referred to in terms of concentration of solute, water moves by osmosis to the area of higher solute concentration. Osmotic pressure is one of the so-called colligative properties of solutes. These properties depend solely on the number of dissolved particles in a given volume of solution, not on the chemical properties of the solute. Tonicity refers to the effect the concentration of nonpenetrating solutes in a solution has on cell volume.
- Special mechanisms are used to transport selected molecules unable to cross the plasma membrane on their own. Channel proteins form selective pores for specific ions or, in the case of aquaporins, for water. Carrier- and pump-mediated transport systems display three important characteristics that determine the kind and amount of material that can be transferred across the membrane: specificity, saturation, and competition. Active transport is carrier-mediated transport that uses energy and moves a substance against its concentration gradient. For example, the Na^+/K^+ pump moves three Na^+ out of the cell for every two K^+ it pumps in. With secondary active transport, energy is required in the entire process, but it is not directly required to run the pump; rather it uses the energy of an Na^+ gradient to move substances such as glucose against a gradient.
- Large particles are transferred between the ICF and ECF not by crossing the membrane but by being wrapped in a membrane-enclosed vesicle, a process known as vesicular transport. Caveolae may play roles in membrane transport and signal transduction.
- Communication between cells is largely orchestrated by extracellular chemical messengers, of which there are six types: paracrine, neurotransmitters, hormones, neurohormones, pheromones, and cytokines.
- Binding of the membrane receptor with the extracellular chemical messenger (the first messenger) brings about the desired intracellular response by only three general means: (1) by opening or closing specific ion channels in the membrane to regulate the movement of particular ions into or out of the cell, (2) by activating an enzyme that phosphorylates a cell protein, or (3) by transferring the signal to an intracellular chemical messenger (the second messenger), which in turn triggers a preprogrammed series of biochemical events within the cell.

- Some extracellular chemical messengers activate receptor-enzymes via a tyrosine kinase receptor, an enzyme that transfers a phosphate group from ATP to a particular intracellular protein.
- Some extracellular messengers bind with receptors that activate membrane-bound intermediaries known as G proteins, which in turn open (or in some instances close) the appropriate adjacent channel or amplify enzymes that activate second messengers such as cyclic AMP, which in turn activates additional steps. Each step in the signal transduction pathway amplifies the initial signal.
- Membrane potential is a separation of opposite charges across the plasma membrane, due primarily to differences in the distribution and permeability of key ions, with K^+ and large anions dominating in the ICF and Na^+ and Cl^- dominating in the ECF. The Na^+/K^+ pump's role in producing membrane potential is indirect, through its critical contribution to maintaining the concentration gradients directly responsible for the ion movements that generate most of the potential. The resting membrane potential is near the equilibrium for K^+ , whose outward diffusion gradient is opposed by negative charges in the cell. Membrane potential can be measured directly by recording the voltage difference between the inside and outside of the cell, or it can be calculated using the Goldman-Hodgkin-Katz equation, which takes into account the relative permeabilities and concentration gradients of all permeable ions.

Review, Synthesize, and Analyze

1. What advantages are there to using diffusion as a transport mechanism versus active transport of a substance?
2. A trout exposed to acid mine drainage experiences an increase in mucus production along the gills. According to Fick's law of diffusion, how would that affect the movement of oxygen through the gill capillaries?
3. Why would hyponatremia (low plasma sodium concentrations) in an animal be better treated with an Na^+ /glucose solution rather than the ingestion of salt tablets alone? Normal plasma sodium concentrations are between 135 and 145 mEq/L, while severe diarrhea or vomiting can lower concentrations to less than 125 mEq/L.
4. What advantages are there for cells to use different second messenger systems?
5. How does the Na^+/K^+ pump contribute to the development of a membrane potential? How does the movement of ICF K^+ ions down its concentration gradient affect membrane potential?
6. How is primary active transport different from that of secondary active transport? Which form of transport does the Na^+/K^+ pump use? Explain.
7. Explain how the cascading effect of hormonal pathways amplifies the response.
8. Consider the effect of a twofold increase in the ECF concentration of Na^+ or K^+ ions. Which increase in ion concentration is the more deadly and why? Hint: Consider if the calculated decrease in E_{K^+} or the increase in E_{Na^+} bring the resting membrane potential of the nerve or muscle cell closer to threshold potential? Why would this change in ion concentration stop the heart from beating?

Neuronal Physiology

4.1 Introduction

Every cell displays a membrane potential, which refers to a separation of positive and negative charges across the membrane, as discussed in the preceding chapter. This negative potential is related to the uneven distribution of Na^+ , K^+ , and large intracellular protein anions between the intracellular fluid (ICF) and extracellular fluid (ECF), and to the differential permeability of the plasma membrane to these ions (see pp. 102–104).

Excitable cells such as neurons and muscles evolved for rapid signaling, coordination, and movement

A number of cell types in eukaryotes have evolved a specialized use for this membrane potential. They can undergo transient, rapid changes in their membrane potentials that serve as either rapid electrical signals or stimulators of rapid cellular action. These cells, called **excitable cells**, are best known in animals. Here we explore the two main types of excitable animal cells, *neurons* (or *nerve cells*) and *muscle cells*. (Some

endocrine cells and ova are also excitable.) In Chapter 3, you learned that the membrane potential that exists when a neuron or muscle cell is not excited is called the *resting potential* (although the membrane is far from “resting” because of the balanced leak-pump activity constantly going on). In contrast, when these cells are excited, a rapid, self-propagating electrical signal along the membrane called an *action potential* is produced. Evolution of neurons and muscles enabled rapid long-distance communication, coordination of activities between cells, and rapid movement. These abilities are especially important for survival in organisms that require quick responses often involving more than one organ.

We can see the evolutionary roots of these abilities in the protozoan *Paramecium* (see photo p. 25). When a *Paramecium* bumps into an obstacle, an action potential is initiated that rapidly and without decay sweeps around the entire cell. This triggers a nearly simultaneous reversal in the direction of beating of its cilia, and the cell quickly backs away. This response may

have evolved because these unicellular protists are large, and movement of signals by simple diffusion would be much too slow (a topic we will explore in Chapters 9 and 11).

Neurons use similar electrical signals to receive, process, initiate, and transmit messages. In this chapter, we consider how neurons undergo changes in potential to accomplish their function. In muscle cells, these electrical signals initiate contraction, which will be discussed later (Chapters 8 and 9).

Terminology and Methodology Before understanding what these electrical signals are and how they are created, you must become familiar with the following terms used to describe changes in potential, as pictured in Figure 4-1:

1. **Polarization:** Charges are separated across the plasma membrane, so that the membrane has potential to do work. Any time the value of the membrane potential is not 0 mV, in either the positive or negative direction, the membrane

FIGURE 4-1 Types of changes in membrane potential.

© Cengage Learning, 2013

is in a state of polarization. Recall that the magnitude of the potential is directly proportional to the number of positive and negative charges separated by the membrane and that the sign of the potential (+ or -) always designates whether excess positive or excess negative charges are present, respectively, on the inside of the membrane.

2. **Depolarization:** A change in potential that makes the membrane less polarized than at resting potential. Since excitable cells have negative resting potentials (at about -70 mV in a typical neuron, p. 106), depolarization decreases membrane potential in the positive direction. A cell's potential can become positive as it does during an action potential when the membrane potential reverses itself (for example, becoming $+30$ mV).
3. **Repolarization:** The membrane returns to resting potential after having been depolarized.
4. **Hyperpolarization:** A change in potential that makes the membrane more polarized (more negative) than at resting potential. Hyperpolarization increases membrane potential, moving it even farther from 0 mV (for instance, a change from -70 mV to -80 mV); more charges are separated than at resting potential.

One possibly confusing point should be clarified. On the device used for recording rapid changes in potential, during a depolarization when the inside becomes *less* negative than at resting, this *decrease* in the magnitude of the potential is represented as an *upward* deflection. By contrast, during a hyperpolarization when the inside becomes *more* negative than at resting, this *increase* in the magnitude of the potential is represented by a *downward* deflection.

It is also important to understand how researchers obtained much of the information in this chapter (and the end of Chapter 3). There are two major types of techniques. The first involves the use of various **microelectrodes** that can be inserted into a neuron with little damage. With these electrodes (in conjunction with electrodes outside the cell), local potentials across membranes can be measured accurately (see the caption to the chapter opening photograph). In addition, such electrodes can be used to produce a **voltage clamp**, in which the potential across a membrane is held at a constant value by an electronic circuit. This allows the researcher to determine, for example, what kinds of ions

move across the membrane at any given voltage. The second group of methodologies involves **patch clamping**, in which a tiny pipette is attached to a plasma membrane with gentle suction. This forms a tight seal around one patch of a membrane. With a fine-enough pipette, a researcher can isolate a *single* ion channel or receptor protein and measure its properties. Through the pipette, various substances can be added (such as signal molecules to bind to receptors); and electrodes within and external to the pipette can be used to measure or control (for example, clamp) potentials.

In addition, much research on neuron function, including all the pioneering work, has been done on nonvertebrate preparations (see the opening photograph of the chapter). Over the years, researchers have found that neurons work by nearly identical membrane and molecular mechanisms in all animal phyla that have been studied. Thus, there has been a high degree of conservation since the first animal neurons evolved.

Electrical signals are produced by changes in ion movement through ion channels across the plasma membrane

Changes in membrane potential (depolarization or hyperpolarization) are brought about by changes in ion movement across the membrane. Changes in ion movement in turn are brought about by changes in membrane permeability in response to *triggering events*. Depending on the type of electrical signal, a triggering event might be (1) a stimulus, such as sound waves stimulating specialized neural endings in an animal's ear; (2) a change in the electrical field in the vicinity of an ion channel within the membrane of an excitable cell; (3) an interaction of a chemical messenger with a surface receptor on a neuron or muscle cell membrane; or (4) a spontaneous change of potential caused by inherent imbalances in the leak-pump cycle. (You will learn more about the nature of these various triggering events as our discussion of electrical signals continues.)

Because ions responsible for carrying charge cannot penetrate the plasma membrane's lipid bilayer, these charges can cross the membrane only through channels specific for them. As described in Chapter 3, there are two types of channels: **leak channels** or nongated channels, which are open all the time, and **gated channels**, which can be opened or closed in response to specific triggering events. It is the "gates" guarding particular ionic channels that triggering events open or close to alter membrane permeability. The subsequent ionic movements redistribute charge across the membrane and thus change membrane potential.

Like many proteins, gated channels are inherently flexible proteins whose conformations can be altered in response to external factors (Chapter 3). In this case, the "gates" alternately permit or block ion passage through the channel. There are at least four kinds of gated channels, depending on the factor that induces the change in channel conformation; we'll explore the first two in this chapter:

1. **Voltage-gated ion channels**, which open or close in response to changes in membrane potential; these are crucial to action potentials.
2. **Chemically gated channels** (also called **ligand gated**), which change conformation *allosterically* (p. 27) in

response to the binding of a specific chemical messenger with a membrane receptor that is in close association with the channel. You have seen such channels in signal transduction (Figure 3-17) and will see them in *synapses* in this chapter.

3. **Mechanically gated channels**, which respond to stretching or other mechanical deformation such as touch; these are important in sensory transduction (Chapter 6).
4. **Thermally gated channels** respond to local changes in temperature (heat or cold), also important in sensory transduction (Chapter 6).

Channel opening results in one of two basic forms of electrical signals: (1) the more primitive *graded potentials*, which serve as short-distance signals that decay over distance, and (2) *action potentials*, which, as we noted earlier, signal over longer distances without decay. Let's examine these signals in more detail and then explore how neurons use these channels and signals to convey messages.

check your understanding 4.1

What are the two major types of excitable tissue in animals, and their evolutionary roots?

Define the following terms: *polarization*, *depolarization*, *hyperpolarization*, *repolarization*, and *resting potential*.

How do ions cross the plasma membrane?

4.2 Graded Potentials

Graded potentials are local changes in membrane potential that occur in varying grades or degrees of magnitude or strength. For example, membrane potential could change from -70 mV to -60 mV (a 10 mV graded potential depolarization) or from -70 mV to -90 mV (a 20 mV graded potential hyperpolarization).

The stronger a triggering event, the larger the resultant graded potential

Graded potentials are usually produced by a specific triggering event that causes gated ion channels to open in a specialized region of the excitable cell membrane. Most commonly, gated Na^+ channels open in response to the event, leading to the inward movement of Na^+ down its concentration and electrical gradients. The resultant depolarization—the graded potential—is confined to this relatively small specialized region of the plasma membrane.

The magnitude of this initial graded potential (that is, the difference between the new potential and the resting potential) is related to the magnitude of the triggering event: *The stronger the triggering event, the more gated channels that open, the greater the charge entering the cell, and the larger the graded potential at the point of origin.* Also, the longer the duration of the triggering event, the longer the duration of the graded potential (Figure 4-2). Graded potentials can either be depolarizing or hyperpolarizing. We'll examine depolarizing ones here, but later you will see how hyperpolarizing ones are important.

FIGURE 4-2 The magnitude and duration of a graded potential.

The magnitude and duration of a graded potential depend directly on the strength and duration of the triggering event, such as a stimulus.

© Cengage Learning, 2013

Graded potentials spread by passive current flow and are impeded by resistances

When a graded potential occurs locally in a nerve or muscle cell membrane, the rest of the membrane remains at resting potential. The temporarily depolarized region is called an *active area*. Note from Figure 4-3b that inside the cell, the active area is relatively more positive than the neighboring *inactive areas* that are still at resting potential. Outside the cell, the active area is relatively less positive than these adjacent areas. Because of this difference in potential, electrical charges, in this case carried by ions, passively flow between the active and adjacent resting regions on both the inside and outside of the membrane.

Any flow of electrical charges is called a **current**. By convention, the direction of current flow is always designated by the direction in which the positive charges are moving (Figure 4-3c). Inside the cell, positive charges flow through the ICF away from the relatively more positive depolarized active region toward the more negative adjacent resting regions. Similarly, outside the cell, positive charges flow through the ECF from the more positive adjacent inactive regions toward the relatively more negative active region. Ion movement (that is, current) is occurring *along* the membrane between regions next to each other on the same side of the membrane. This flow is in contrast to ionic movement *across* the membrane through ionic channels with which you are more familiar.

As a result of local current flow between an active depolarized area and an adjacent inactive area, potential in the previously inactive area alters. Positive charges have flowed into this adjacent area on the inside, while simultaneously positive charges have flowed out of this area on the outside. Thus, at this adjacent site, the inside is more positive (or less negative) than before (Figure 4-3c). Stated differently, the

(a) Entire membrane at resting potential

Triggering event opens ion channels, most commonly permitting net Na^+ entry

(b) Inward movement of Na^+ depolarizes membrane, producing a graded potential

Current flows between the active and adjacent inactive areas

(c) Depolarization spreads by local current flow to adjacent inactive areas, away from point of origin

FIGURE 4-3 Current flow during a graded potential.

(a) The membrane of an excitable cell at resting potential. (b) A triggering event opens ion channels, usually leading to net Na^+ entry that depolarizes the membrane at this site. The adjacent inactive areas are still at resting potential. (c) Local current flows between the active and adjacent inactive areas, resulting in depolarization of the previously inactive areas. In this way, the depolarization spreads away from its point of origin.

© Cengage Learning, 2013

previously inactive adjacent region has been depolarized; thus the graded potential has spread. This area's potential now differs from that of the inactive region immediately next to it on the other side, inducing further current flow at this new site, and so on. In this manner, current spreads in both directions away from the initial site of the potential change.

The amount of current that flows between two areas depends on the potential difference between the areas and on the resistance of the material through which the charges are moving. **Resistance** is the hindrance to electrical charge movement. The greater the difference in potential, the greater the current flow. Similarly, the lower the resistance, the greater the current flow. *Conductors* have low resistance and provide little hindrance to current flow. Electrical wires and the intracellular and extracellular fluid are all good conductors, so current readily flows through them. *Insulators* have high resistance and greatly hinder movement of charge. The rubber or plastic surrounding electrical wires has high resis-

tance, as do lipids. Thus, current does not flow across the plasma membrane's lipid bilayer. Current, carried by ions, can move across the membrane only through ion channels.

Graded potentials die out over short distances

The passive current flow between active and adjacent inactive areas is similar to the means by which current is carried through electrical wires. You know from experience that current can leak out of an electrical wire unless the wire is covered with an insulating material such as plastic. Likewise, current is lost across the cell membrane as charge-carrying ions leak out through the “uninsulated” parts of the membrane, that is, by moving outward down their electrochemical gradient through open channels. Because of this current loss, the magnitude of the local current progressively diminishes with increasing distance from the initial site of origin (Figure 4-4). Thus, the magnitude of the graded potential continues

* Numbers refer to the local potential in mV at various points along the membrane.

(a) Current loss across the membrane

(b) Decremental spread of graded potentials

FIGURE 4-4 Current loss across the plasma membrane leading to decremental spread of a graded potential. (a) Leakage of charge-carrying ions across the plasma membrane results in progressive loss of current with increasing distance from the initial site of the change in potential. (b) Because of leaks in current, the magnitude of a graded potential continues to decrease as it passively spreads from the initial active area. The potential dies out altogether within a few millimeters of its site of initiation.

© Cengage Learning, 2013

to decrease the farther it moves away from the initial active area. Another way of saying this is that the spread of a graded potential is **decremental** (gradually decreases). Note that in Figure 4-4, the magnitude of the initial potential change is 15 mV (a change from -70 mV to -55 mV), then decreases as it moves along the membrane, continuing to diminish the farther it moves away from the initial active area until there is no longer a potential change. In this way, these local currents die out within a few millimeters from the initial site of potential change and consequently can function as signals only for very short distances.

For this reason, this form of electrical depolarization is termed **passive conduction**. An analogy is sound waves. The magnitude of the sound waves is greatest (loudest) at the point of origin, then progressively decreases and eventually dies off as the sound waves spread out from this initial site. The passive movement of the electrical depolarization can be described by **Ohm's law**, where ΔV_m is the actual voltage change across the membrane, ΔI the amount of current (amperes), and R the resistance encountered by the current passing along the membrane (ohms).

$$\Delta V_m = \Delta I \times R \text{ or } \Delta I = \Delta V_m \times g$$

Ohm's law states that the *reduction* in voltage across a membrane in response to a current flowing through the cell is directly related to the amount of current multiplied by the resistance of the membrane. As current flows inside the cell, a constant proportion leaks through the membrane at each point. Membrane resistance is also the reciprocal of membrane **conductance** (g), where conductance depends on both the permeability and driving force for the movement of ions (the unit of conductance is the *siemen*). The passive movement of current across the cell membrane is termed **electro-**

tonic conduction. Comparable to the flow of electricity through wires, the speed of electrotonic spread is extremely rapid.

The extent of electrotonic spread is determined in part by membrane resistance and membrane capacitance. **Capacitance** is a measure of the amount of charge that can be maintained across an insulating gap. The lipid bilayer is an effective capacitor because it can maintain the separation of charged ions across a relatively narrow space. Because of these two properties of a cell membrane, there is, for every excitable cell, only a finite distance that current can passively flow from the activated region. The fraction that leaks through the membrane flows back in a path to the source, so less current is available to influence the membrane potential at a more distant site. The distance from the active area that a signal can be passively transmitted is best described by the following relationship:

$$V_x = V_0 e^{-x/\lambda}$$

In this equation, V_x is the potential measured at a distance x from the active area whereas V_0 is a measurement of the original amount of potential generated at the active area. The length constant (λ) is related to the resistance of the membrane, cytoplasm, and the ECF by the following equation:

$$\lambda = \sqrt{\frac{R_m}{R_i}}$$

In this equation R_m is the resistance of the membrane and R_i is a measurement of the internal and external resistances. Under normal circumstances the contribution of the external resistance to R_i is comparatively small. The length constant can also be defined as the distance from V_0 that the potential is reduced 63% from its initial value. Thus, when comparing the rate of signal propagation between neurons, the one with the higher value of λ indicates the higher velocity. Neurons that rely on the electrotonic flow of current for communication purposes are rarely more than a few millimeters in length and are noted for their high membrane resistance. These neurons are termed **nonspiking** neurons; examples include stretch sensory neurons in arthropods (p. 217). Determination of the length constant also provides some insight into structural adaptations that species have evolved to increase λ .

Note that λ increases as the square root of (1) an increase in the membrane resistance or (2) a decrease in the internal resistance. How can an animal accomplish either of these strategies in order to increase λ ? Vertebrates as well as some nonvertebrates can increase R_m by wrapping an insulating material around the cell, which, as you will see later (p. 126), minimizes leakage of ions through the membrane and confers fast conduction by lowering the capacitance. Alternatively, R_i can be decreased by forcing more of the current to travel inside the cell by increasing the diameter of the cell. This solution can be exaggerated in many animals that rely on a large fiber diameter—the so-called giant neurons—to conduct important messages, such as escape responses (p. 129).

Although graded potentials have limited signaling distance, they are critically important to neural function, as we explain in later chapters. The following are all graded potentials: *postsynaptic potentials*, *receptor potentials*, *end-plate potentials*, *pacemaker potentials*, and *slow-wave potentials*. These terms may be unfamiliar to you now, but you will become well acquainted with them as we continue discussing neural, sensory, and muscle physiology. We are including this list here because it is the only place in this book that we group all these graded potentials together. For now, it is enough to say that for the most part, excitable cells produce one of these types of graded potentials in response to a triggering event. In turn, graded potentials can initiate *action potentials*, the long-distance signals, in an excitable cell.

check your understanding 4.2

What properties are associated with a graded potential?

How does Ohm's law explain the passive movement of current down an axon?

4.3 Action Potentials

Action potentials are brief, rapid, large (100 mV) changes in membrane potential during which the potential actually reverses so that the inside of the excitable cell transiently becomes more positive than the outside. As with a graded potential, a single action potential involves only a small portion of the total excitable cell membrane. Unlike graded potentials, however, action potentials are conducted, or propagated, throughout the membrane in *nondecremental* fashion; that is, they do not diminish in strength as they travel from their site of initiation throughout the remainder of the cell membrane. This is why action potentials can serve as faithful long-distance signals.

Think about the nerve cell that brings about contraction of muscle cells in a mammal's leg for flexing the toes. To bend the toes, action potentials are sent via a neuron from the brain to the spinal cord to another neuron, where an action potential is initiated. This action potential travels in undiminishing fashion quickly all the way down the neuron's long axon, which runs through the leg to terminate on foot muscle cells. The magnitude of the action potential at the end of the muscle axon is identical to the magnitude of the action potential first initiated in the spinal cord; it has not weakened or died off.

FIGURE 4-5 Changes in membrane potential during an action potential.

© Cengage Learning, 2013

As we noted earlier, action potentials may have first evolved in animal-like protists, and in Chapter 5, we'll explore their use in different animal groups and their respective nervous systems. In this chapter, we will focus on basic neural physiology. Let's begin with the changes in permeability and ionic movements responsible for generating an action potential before turning our attention to the means by which action potentials spread throughout the cell membrane without diminishing.

During an action potential, the membrane potential rapidly and transiently reverses

If it is of sufficient magnitude, a graded potential can initiate an action potential before the graded potential dies off. You will discover the means by which this initiation is accomplished for the various types of graded potentials in more detail later. Typically, the portion of the excitable membrane where graded potentials are produced in response to a triggering event does not undergo an action potential. Instead, passive current flow from the region where the graded potential is taking place depolarizes adjacent portions of the membrane where action potentials can occur.

Depolarization from the resting potential of -70 mV (Figure 4-5) proceeds slowly at first until it reaches a critical level known as **threshold potential**, typically between -50 and -55 mV or $+10$ to $+15$ mV above resting potential. At threshold potential, an explosive depolarization takes place. A recording of the potential at this time shows a sharp upward deflection as the potential rapidly reverses itself so that the inside of the cell becomes positive compared to the outside. Peak potential is usually $+30$ mV to $+40$ mV, depending on the excitable cell. Just as rapidly, the membrane repolarizes, dropping back to resting potential. Often the forces responsible for driving the membrane back to resting poten-

© Cengage Learning, 2013

tial push it too far, causing a transient **after hyperpolarization**, during which the inside of the membrane briefly becomes even more negative than normal (for example, -80 mV) before the resting potential is restored.

The action potential is the entire rapid change in potential from threshold to peak and then back to resting. Unlike the variable duration of a graded potential, the duration of an action potential is always the same in a given excitable cell. In a neuron, an action potential lasts for only 1 msec (0.001 sec). It lasts longer in muscle, with the duration varying depending on the muscle type. The portion of the action potential during which the potential is reversed (between 0 mV and $+30$ mV) is called the **overshoot**. Often an action potential is called a **spike** because of its spiky appearance on an oscilloscope. Alternatively, when an excitable membrane is triggered to undergo an action potential, it is said to **fire**. Thus, the terms *action potential*, *spike*, and *firing* all refer to the same phenomenon of rapid potential reversal. If threshold potential is not reached by the initial triggering depolarization, no action potential takes place. Thus, threshold is a critical *all-or-none* event. Either the membrane is depolarized to threshold and an action potential takes place, or threshold is not reached in response to the depolarizing event and no action potential occurs.

Marked changes in membrane permeability and ion movement enhanced by positive feedback lead to an action potential

How is the membrane potential, which is usually maintained at a constant resting level, thrown out of balance to such an extent as to produce an action potential? Recall that K^+ contributes the most to establishing the resting potential because the membrane at rest is much more permeable to K^+ than to Na^+ . During an action potential, marked changes in membrane permeability to Na^+ and K^+ take place because of voltage-gated channels, permitting rapid fluxes of these ions down their electrochemical gradients. As you will see, the most rapid changes are accelerated by *positive feedback*. These ion movements carry the current responsible for the potential changes that occur during an action potential.

Voltage-Gated Na^+ and K^+ Channels Two specific types of channels are of major importance in developing an action potential: **voltage-gated Na^+ channels** and **voltage-gated K^+ channels**. Voltage-gated channels consist of proteins that have a number of charged groups. The electric field (potential) surrounding the channels can distort the channel structure as charged portions of the channel proteins are electrically attracted or repelled by charges in the fluids surrounding the membrane. Unlike the majority of membrane proteins, which remain stable despite fluctuations in membrane potential, the voltage-gated channel proteins are exquisitely sensitive to voltage changes. Small distortions in channel shape induced by potential changes can cause them to alternate to another conformation. Here is another example of how subtle changes in structure can have a profound influence on function. For example, all vertebrates, as well as many other animals evolved for speed, have comparatively fast-opening Na^+ channels; in contrast, sluggish animals such as sea slugs have Na^+ channels that open at rates approximately 10 times slower. Fast-opening channels increase survival rates because electrical impulses are more rapidly transmitted to muscles used in catching prey or avoiding predators (note that sluggish animals have other defenses).

The voltage-gated Na^+ channel has two gates: an activation gate and an inactivation gate (Figure 4-6). The **activation gate** guards the channel by opening and closing like a hinged door. The **inactivation gate** consists of a ball-and-chain-like sequence of amino acids at the channel opening facing the ICF. This gate is open when the ball is dangling free on its chain and closed when the ball binds to its receptor located at the channel opening, thus blocking the opening. Both gates must be open to permit passage of Na^+ through the channel, and closure of either gate prevents passage. This voltage-gated Na^+ channel can exist in three different conformations: (1) closed but capable of opening (activation gate closed, inactivation gate open, Figure 4-6a); (2) open, or activated (both gates open, Figure 4-6b); and (3) closed and not capable of opening (activation gate open, inactivation gate closed, Figure 4-6c). These channels are widespread in animals, with mammals having at least nine genes for different variants that evolved by gene duplication. However, while Ca^{2+} and K^+ channels are ubiquitous among organisms, gated Na^+

TABLE 4-1 Permeabilities and Gradients for Na⁺ and K⁺ at Rest and During an Action Potential

Ion	Condition	Permeability Compared to Resting P _{Na⁺}	Gradient	Direction of Gradient
Na ⁺	Resting potential (−70 mV) before an action potential	1	Concentration gradient Electrical gradient	Inward Inward
K ⁺	Resting potential (−70 mV) before an action potential	25–30×	Concentration gradient Electrical gradient	Outward Inward
Na ⁺	Threshold potential (−50 mV)	600×	Concentration gradient Electrical gradient	Inward Inward
K ⁺	Peak of action potential (+30 mV)	300×	Concentration gradient Electrical gradient	Outward Outward
Na ⁺	Resting potential (−70 mV) after an action potential	1	Concentration gradient Electrical gradient	Inward Inward
K ⁺	Resting potential (−70 mV) after an action potential	50–75×	Concentration gradient Electrical gradient	Outward Inward

channels are found almost exclusively in animals (although few protists, including certain marine diatoms, have signal-generating Na⁺ channels). Most, if not all, animal voltage-gated channels probably evolved from a common ancestral protein. Cnidaria (such as sea anemones) are a possible exception: They have Na⁺ channels that are insensitive to tetrodotoxin (see p. 143), suggesting that their structure differs from that of other animals’ channels.

The basic voltage-gated K⁺ channel of excitable tissues is simpler. It has only one gate, which can be either open or closed (Figure 4-6d and e). This is an ancient type of channel; related ones have been found in most organisms, including bacteria and plants. Neurons have a specific subclass of gated K-channels called **shaker K⁺-channels** (because mutant forms in fruit flies cause uncontrollable leg shaking). They represent an ancient family found in all animal neurons. For example, the simple nervous systems of jellies (Cnidaria) express at least two shaker-type genes; and the genome of the electric fish *Apteronotus* has at least 10 such genes (electric fish are discussed in Chapter 6).

unanswered Questions How do voltage gates actually open and close?

It is still not fully understood how the so-called gates on neural voltage-gated channels actually work. However, recent studies on voltage-gated K⁺ channels are revealing.

Researchers used X-ray crystallography to get detailed pictures of these channels from bacteria and mammals. Both channels contain a central pore for K⁺ ions, surrounded by what the researcher’s term “voltage-sensor paddles.” These are folds on the outside of the protein with hydrophobic and cationic (positively charged) amino acids, and with flexible hinge regions. These features suggest that paddles react to voltage changes in the nearby membrane and move on their hinges in response. The paddle’s

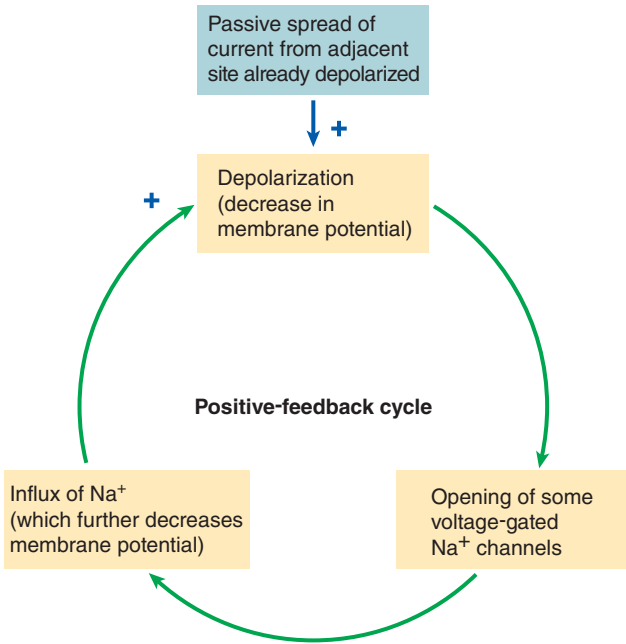

FIGURE 4-7 Positive-feedback cycle responsible for opening Na⁺ channels at threshold.

© Cengage Learning, 2013

structure appears to be ancient and highly conserved: When the gene for a rat shaker K⁺ channel was modified by replacing its paddle code with that from a deep-sea archaean from a hydrothermal vent, the resulting protein still worked normally! <<

Changes in Permeability and Ion Movement during an Action Potential As we noted earlier, the action potential is rapid due to positive feedback. Figure 4-7 shows the overall feedback cycle, while Figure 4-8 summarizes the key channel

- 1 Resting potential: all voltage-gated channels closed.
- 2 At threshold, Na⁺ activation gate opens and P_{Na⁺} rises.
- 3 Na⁺ enters cell, causing explosive depolarization to +30 mV, which generates rising phase of action potential.
- 4 At peak of action potential, Na⁺ inactivation gate closes and P_{Na⁺} falls, ending net movement of Na⁺ into cell. At the same time, K⁺ activation gate opens and P_{K⁺} rises.
- 5 K⁺ leaves cell, causing its repolarization to resting potential, which generates falling phase of action potential.
- 6 On return to resting potential, Na⁺ activation gate closes and inactivation gate opens, resetting channel to respond to another depolarizing triggering event.
- 7 Further outward movement of K⁺ through still-open K⁺ channel briefly hyperpolarizes membrane, which generates after hyperpolarization.
- 8 K⁺ activation gate closes, and membrane returns to resting potential.

FIGURE 4-8 Permeability changes and ion fluxes during an action potential.

and potential changes. At resting potential (−70 mV), all the voltage-gated Na⁺ and K⁺ channels are closed (step 1 of Figure 4-8), with the Na⁺ channels' activation gates closed and their inactivation gates open; that is, the "closed but capable of opening" conformation. Therefore, passage of Na⁺ and K⁺ is prevented through these channels at resting potential. However, because of the presence of many K⁺ leak channels, the resting membrane is 25 to 30 times more permeable to K⁺ than to Na⁺ (Table 4-1).

When current spreads passively from an adjacent site already depolarized into a new region at resting potential, the new region of membrane starts to depolarize toward threshold (top of Figure 4-7), causing the activation gates of some of its voltage-gated Na⁺ channels to open, so that both gates of these activated channels are now open (step 2 of Figure 4-8). Because both the concentration and electrical gradients for Na⁺ favor its movement into the cell, Na⁺ starts to move in (step 3). The inward movement of positively charged Na⁺

depolarizes the membrane further, thereby opening adjacent voltage-gated Na^+ channels and allowing more Na^+ to enter. As a result, still further depolarization occurs, opening more Na^+ channels, and so on, in an explosive positive-feedback cycle (full cycle of Figure 4-7).

At threshold potential, positive feedback ensures an explosive increase in Na^+ permeability, which is symbolized as P_{Na^+} , as the membrane becomes 600 times more permeable to Na^+ than to K^+ (Table 4-1). Each individual channel is either closed or open and cannot be partially open. However, the delicately poised gating mechanisms of the various Na^+ channels are jolted open by slightly different voltage changes. During the early depolarizing phase, more and more Na^+ channels open as the potential progressively decreases. At threshold, enough Na^+ gates have opened to set off the positive-feedback cycle that rapidly causes the remaining Na^+ gates to swing open. Now Na^+ permeability dominates the membrane potential, in contrast to the K^+ domination at resting potential. Thus, at threshold Na^+ rushes into the cell, rapidly eliminating the internal negativity and even making the inside of the cell more positive than the outside in an attempt to drive the membrane potential to the Na^+ equilibrium potential (which is +60 mV; see p. 106) (step 3 of Figure 4-8). The potential reaches +30 mV, close to the Na^+ equilibrium potential. The potential does not become any more positive, because at the peak of the action potential the Na^+ channels close to the inactivated state (step 4), and P_{Na^+} falls to its low resting value.

What causes the Na^+ channels to close? When the membrane potential reaches threshold, two closely related events take place in the gates of each Na^+ channel. First, the activation gates are triggered to *open rapidly* in response to the depolarization, converting the channel to its open (activated) conformation (Figure 4-6b). Surprisingly, the conformational change that opens the channel also allows the inactivation gate's ball to bind to the channel opening, thereby physically blocking the mouth of the channel. This might seem counterproductive, but the closure process takes time, so the inactivation gate *closes slowly* compared to the rapidity of channel opening (Figure 4-6c). Meanwhile, during the 0.5-msec delay after the activation gate opens and before the inactivation gate closes, both gates are open and Na^+ rushes into the cell through these open channels, bringing the action potential to its peak. Then the inactivation gate closes, membrane permeability to Na^+ plummets to its low resting value, and further Na^+ entry is prevented. The channel remains in this "*closed and not capable of opening*" conformation until the membrane potential has been restored to its resting value.

Simultaneous with inactivation of the Na^+ channels at the peak of the action potential, the voltage-gated K^+ channels are opened (step 4, Figure 4-8). This opening of the K^+ channel gate is a delayed voltage-gated response triggered by the initial depolarization to threshold. Thus, three action potential-related events occur at threshold: (1) the rapid opening of the Na^+ activation gates, which permits Na^+ to enter, moving the potential from threshold to its positive peak; (2) the slow closing of the Na^+ inactivation gates, which halts further Na^+ entry after a brief time delay, thus keeping the potential from rising any further and thus stopping the positive feedback; and (3) the slow opening of the K^+ gates, which, is in large part responsible for the potential plummeting from its peak back to resting.

The membrane potential would gradually return to resting after closure of the Na^+ channels in concert with the steady leakage of K^+ out of the cell. However, the return to resting is hastened by the opening of K^+ gates at the peak of the action potential. Opening of the voltage-gated K^+ channels greatly increases the K^+ permeability (P_{K^+}) to about 300 times the resting P_{Na^+} (Table 4-1). This marked increase in P_{K^+} causes K^+ to rush out of the cell down its concentration gradient, carrying positive charges back to the outside (step 5). Note that at the peak of the action potential, the internal positivity of the cell tends to repel the positive K^+ ions, so the electrical gradient for K^+ is also outward, unlike at resting potential. The outward movement of K^+ rapidly restores the negative resting potential (step 6).

As the potential returns to resting, the changing voltage shifts the Na^+ channels to their "closed but capable of opening" conformation, with the activation channel closed and the inactivation channel open (step 6). Now the channel is reset, ready to respond to another triggering event. The newly opened voltage-gated K^+ channels also close, so the membrane returns to the resting number of open K^+ leak channels (step 7). Typically, the voltage-gated K^+ channels are slow to close. As a result of this persistent increased permeability to K^+ , more K^+ leaves than is necessary to bring the potential to resting. This slight excessive K^+ efflux causes the interior of the cell to become transiently hyperpolarized (step 7). Only after final closure of these channels is the membrane potential restored (step 8).

To review the primary signal spike (steps 2–6 of Figure 4-8), *the rising phase of the action potential* (from threshold to +30 mV) *is due to Na^+ influx* (Na^+ entering the cell) induced by an explosive increase in P_{Na^+} at threshold. *The falling phase* (from +30 mV to resting potential) *is brought about by K^+ efflux* (K^+ leaving the cell) caused by the marked increase in P_{K^+} occurring simultaneously with the inactivation of the Na^+ channels at the peak of the action potential.

The Na^+/K^+ ATPase pump gradually restores the concentration gradients disrupted by action potentials

At the completion of an action potential, the membrane potential has been restored to its resting condition, but the ion distribution has been altered slightly. Sodium has entered the cell during the rising phase, and a comparable amount of K^+ has left during the falling phase. Recall that the bulk of the cell is electrically neutral; the potential difference between the ECF and ICF is measurable only nm (nanometers) deep along the surface of the membrane. It is the task of the Na^+/K^+ pump (a slow modified channel requiring ATP, Figure 3-14) to restore these ions to their original locations in the long run, but not after each action potential.

The active pumping process takes much longer to restore Na^+ and K^+ to their original locations than it takes for the passive fluxes of these ions during an action potential. However, the membrane does not need to wait until the Na^+/K^+ pump slowly restores the concentration gradients before it can undergo another action potential. Actually, the movement of only relatively few of the total number of Na^+ and K^+ ions present is responsible for the dramatic

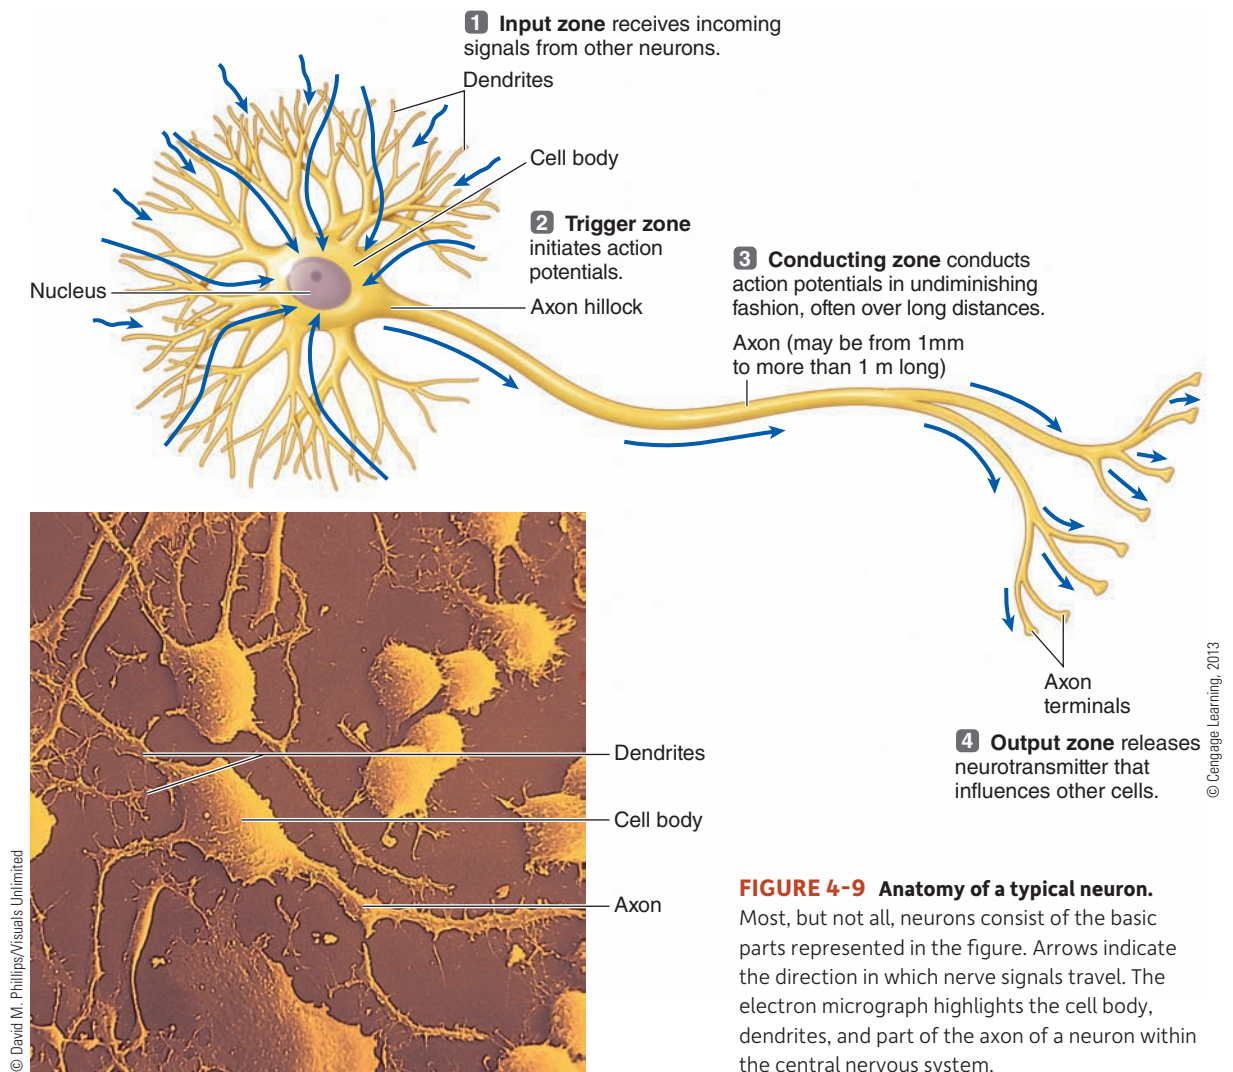

FIGURE 4-9 Anatomy of a typical neuron.

Most, but not all, neurons consist of the basic parts represented in the figure. Arrows indicate the direction in which nerve signals travel. The electron micrograph highlights the cell body, dendrites, and part of the axon of a neuron within the central nervous system.

swings in potential that occur during an action potential. Only about 1 out of every 100,000 K^+ ions present in the cell leaves during an action potential, while a comparable number of Na^+ ions enter from the ECF. The movement of this extremely small proportion of the total Na^+ and K^+ during a single action potential produces dramatic 100 mV changes in potential (between -70 and $+30$ mV) but only infinitesimal changes in the ICF and ECF concentrations of these ions. Much more K^+ is still inside the cell than outside, and Na^+ is still predominantly an extracellular cation. Consequently, the Na^+ and K^+ concentration gradients still exist, so repeated action potentials can occur without the pump having to keep pace to restore the gradients.

Were it not for the pump, of course, after a finite number of fluxes, equilibrium would be reached and generation of action potentials would be impossible. If the concentrations of Na^+ and K^+ were equal between the ECF and ICF, changes in permeability to these ions would not bring about ionic fluxes, so no change in potential would occur. Thus, the Na^+/K^+ pump is critical to maintaining the concentration gradients in the long run. However, it is not directly involved in the ion fluxes or potential changes that occur during an action potential.

Action potentials are propagated from the axon hillock to the axon terminals

A single action potential involves only a small patch of the total surface membrane of an excitable cell. But if action potentials are to serve as long-distance signals, they cannot be merely isolated events occurring in a limited area of a neuron or muscle cell membrane. Mechanisms must exist to conduct or spread the action potential throughout the entire cell membrane. Furthermore, the signal must somehow be transmitted from one cell to the next cell (for example, along specific nerve pathways). Let's first examine how an action potential (nerve impulse) is conducted throughout a neuron before turning our attention to how the impulse is passed to another cell.

A single nerve cell, or **neuron**, consists of three basic parts: the *cell body*, the *dendrites*, and the *axon*, although there are variations in structure, depending on the location and function of the neuron. (The distinctions of other specialized neurons are described later.) The nucleus and organelles are housed in the **cell body** (Figure 4-9), from which numerous extensions known as **dendrites** typically project like antennae to increase the surface area available

for receiving signals from other nerve cells. Some neurons have up to 400,000 dendrites. In most neurons, the plasma membrane of the dendrites and cell body contain protein receptors that bind chemical messengers from other neurons. Therefore, the dendrites and cell body are the neuron's *input zone* because these components receive and integrate incoming signals. This is the region where graded potentials are produced in response to triggering events, in this case, incoming chemical messengers.

The **axon**, or **nerve fiber**, is a single, elongated, tubular extension that conducts action potentials *away from* the cell body and eventually terminates at other cells. A **nerve** (as opposed to a neuron or nerve cell) is defined as a bundle of axons outside the central nervous system (CNS; see Chapter 5), whereas a **fiber tract** is a bundle of axons inside the CNS. The axon frequently gives off side branches, or **collaterals**, along its course. The first portion of the axon plus the region of the cell body from which the axon leaves is known as the **axon hillock**. The axon hillock is the neuron's *trigger zone* because it is the site where action potentials are triggered by a graded potential if it is of sufficient magnitude.

Action potentials can be initiated only in portions of the membrane with abundant voltage-gated Na^+ channels that can be triggered to open by a depolarizing event. Typically, regions of excitable cells where graded potentials take place do not undergo action potentials because voltage-gated Na^+ channels are sparse there. Therefore, sites specialized for graded potentials do not undergo action potentials, even though they might be considerably depolarized. However, before dying out, graded potentials can trigger action potentials in adjacent portions of the membrane by bringing these more sensitive regions to threshold through local current flow spreading from the site of the graded potential. In a typical neuron, for example, graded potentials are generated in the dendrites and cell body in response to incoming chemical signals. If these graded potentials have sufficient magnitude by the time they have spread to the axon hillock, they initiate an action potential (see p. 138).

The action potentials are then conducted along the axon from the axon hillock to the typically highly branching endings at the **axon terminals**. These terminals release chemical messengers that simultaneously affect target cells with which they come into close association. Functionally, therefore, the axon is the *conducting zone* of the neuron, whereas the axon terminals constitute the *output zone*. (The major exception to this typical neuronal structure and functional organization are neurons specialized to carry sensory information, as described in Chapter 6).

Axons vary in length from less than a millimeter in neurons that communicate only with neighboring cells to longer than a meter in neurons that communicate with distant parts of a nervous system or with peripheral organs. For example, the axon of the nerve cell innervating a mammalian foot must travel the distance between the origin of its cell body within the posterior spinal cord all the way down the leg to the foot.

Once initiated, action potentials are conducted over the surface of an axon

Once an action potential is initiated at the axon hillock, no further triggering event is necessary to activate the remainder of the axon. The action potential is automatically con-

ducted throughout the neuron, without further stimulation, by one of two methods of propagation: *contiguous conduction* or *saltatory conduction*.

Contiguous conduction involves the spread of the action potential along every patch of membrane down the length of the axon (*contiguous* means “touching” or “next to in sequence”). This process is illustrated in Figure 4-10, which represents a longitudinal section of the axon hillock and the portion of the axon immediately beyond it. The membrane at the axon hillock is at the peak of an action potential. The inside of the cell is positive in this active area because Na^+ has already rushed into the neuron at this point. The remainder of the axon, still at resting potential and negative inside, is considered inactive. For the action potential to spread from the active to the inactive areas, the inactive areas must somehow be depolarized to threshold. This depolarization is accomplished by local current flow between the area already undergoing an action potential and the adjacent inactive area, similar to the spread of graded potentials. Recall that the rate at which the region ahead of the active area is depolarized depends on the length constant λ . Because opposite charges attract, current can flow locally between the active area and the neighboring inactive area on both the inside and the outside of the membrane. This local current flow in effect neutralizes or eliminates some of the unbalanced charges in the inactive area, a depolarizing effect that quickly brings the involved inactive area to threshold, at which time the voltage-gated Na^+ channels in this region of the membrane are all thrown open by positive feedback, leading to an action potential in this previously inactive area. Meanwhile, the original active area returns to resting potential as a result of K^+ efflux.

In turn, beyond the new active area is another inactive area, so the same thing happens again. This cycle repeats itself in a chain reaction until the action potential has spread to the end of the axon. *Once an action potential is initiated in one part of a neuron membrane, a self-perpetuating cycle is initiated so that the action potential is propagated throughout the rest of the fiber automatically.* In this way, the axon is like a firecracker fuse that needs to be lit at only one end. Once ignited, the fire spreads down the fuse; it is not necessary to hold a match to every separate section of the fuse. Therefore, a new action potential can be initiated in two ways, in both cases involving passive spread of current from an adjacent site already depolarized. An action potential is initiated in the axon hillock in the first place by depolarizing current spreading from a graded potential in the cell body and dendrites. During propagation of the action potential down the axon, each new action potential is initiated by depolarizing local current flow spreading from the preceding site undergoing an action potential.

Note that the original action potential waveform does not travel along the membrane. Instead, it triggers an identical new action potential in the adjacent area of the membrane, with this process being repeated along the axon's length. An analogy is the spectator “wave” often seen at a sports stadium. Each section of spectators stands up (the rising phase of an action potential), then sits down (the falling phase) in sequence one after another as the wave moves around the stadium. The wave, not individual spectators (individual action potentials), travels around the stadium (conduction of the action potential along the axon). Because each new action potential in the conduction process is a fresh event dependent on the induced permeability changes and electrochemical

FIGURE 4-10 Contiguous conduction. Local current flow between the active area at the peak of an action potential and the adjacent inactive area still at resting potential reduces the potential in this contiguous inactive area to threshold, which triggers an action potential in the previously inactive area. The original active area returns to resting potential, and the new active area induces an action potential in the next adjacent inactive area by local current flow as the cycle repeats itself down the length of the axon.

© Cengage Learning, 2013

gradients, which are virtually identical down the length of the axon, the action potential arriving at the end of the axon is identical to the original one, no matter how long the axon. Thus, an action potential is spread throughout the axon in undiminished fashion. In this way, action potentials can serve as long-distance signals without attenuation or distortion.

Again, this nondecremental propagation of an action potential is in contrast to the decremental spread of a graded potential, which dies out over a very short distance because it is not able to regenerate itself. Table 4-2 summarizes the differences between graded potentials and action potentials, some of which are yet to be discussed.

TABLE 4-2 Comparison of Graded Potentials and Action Potentials

Property	Graded Potentials	Action Potentials
Triggering Events	Triggered by a specific stimulus, or by the binding of neurotransmitter with receptor on the postsynaptic membrane	Triggered through the passive spread of depolarization from adjacent area undergoing a graded potential or action potential
Ion Movement Producing Change in Potential	Produced by net movement of Na^+ , K^+ , Cl^- , or Ca^{2+} across plasma membrane	Produced by sequential movement of Na^+ into and K^+ out of cell through voltage-gated channels
Coding of Magnitude of Triggering Event	Varies with the magnitude of the triggering event	All-or-none membrane response; magnitude of triggering event coded in frequency rather than amplitude of action potentials
Duration	Varies with duration of triggering event	Constant
Magnitude of Potential Change with Distance from Initial Site	Decremental conduction; magnitude diminishes with distance from the initiation site	Propagated throughout the membrane in undiminishing fashion; self-regenerated in neighboring inactive areas of membrane
Refractory Period	None	Relative, absolute
Summation	Temporal, spatial	None
Potential Change	Can be depolarization or hyperpolarization	Always depolarization and reversal of charges
Location	Occurs in specialized regions of membrane designed to respond to the triggering event	Occurs in regions of membrane with a sufficient number of voltage-gated Na^+ channels

© Cengage Learning, 2013

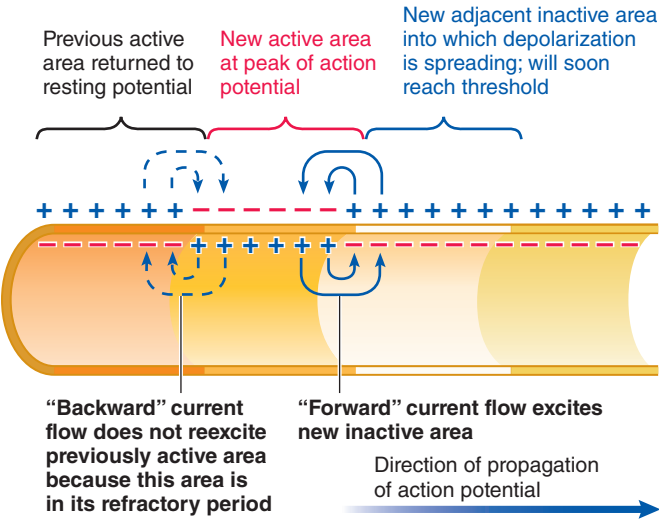

FIGURE 4-11 Value of the refractory period. The refractory period prevents “backward” current flow. During an action potential and slightly afterward, an area cannot be restimulated by normal events to undergo another action potential. Thus, the refractory period ensures that an action potential can be propagated only in the forward direction along the axon.

© Cengage Learning, 2013

The refractory period ensures unidirectional propagation of the action potential

What ensures the one-way propagation of an action potential away from the initial site of activation? Note from Figure 4-11 that once the action potential has been regenerated

at a new neighboring site (now positive inside) and the original active area has returned to resting (once again negative inside), the close proximity of opposite charges between these two areas is conducive to local current flow taking place in the backward direction as well as in the forward direction (into as yet unexcited portions of the membrane). If such backward current flow were able to bring the just inactivated area to threshold, another action potential would be initiated here, which would spread both forward and backward, initiating another action potential, and so forth. The situation would be chaotic, with numerous action potentials bouncing back and forth along the axon until the nerve cell eventually fatigued. Fortunately, neurons are saved from this fate of oscillating action potentials by the existence of the **refractory period**, during which a new action potential cannot be initiated by normal events in a region that has just undergone an action potential.

Because of the changing status of the voltage-gated Na^+ and K^+ channels during and after an action potential, the refractory period has two components: the *absolute refractory period* and the *relative refractory period*. During the time that a particular patch of axonal membrane is undergoing an action potential, it is incapable of initiating another action potential, no matter how strongly it is stimulated by a triggering event. This time period when a recently activated patch of membrane is completely refractory (meaning “stubborn” or unresponsive) to further stimulation is known as the **absolute refractory period** (Figure 4-12). Once the voltage-gated Na^+ channels have flipped to their open, or activated, state, they cannot be triggered to open again in response to another depolarizing triggering event, no matter how strong, until resting potential is restored and the channels are reset to their original positions. Accordingly, the absolute refractory period lasts the entire time from opening of the voltage-gated Na^+ channels’

FIGURE 4-12 Absolute and relative refractory periods. During the absolute refractory period, the portion of the membrane that has just undergone an action potential cannot be restimulated. This period corresponds to the time during which the Na⁺ gates are not in their resting conformation. During the relative refractory period, the membrane can be restimulated only by a stronger stimulus than is usually necessary. This period corresponds to the time during which the K⁺ gates opened during the action potential have not yet closed, coupled with lingering inactivation of the voltage-gated Na⁺ channels.

© Cengage Learning, 2013

activation gates at threshold, through closure of their inactivation gates at the peak of the action potential (“closed and not capable of opening” state), until the return to resting potential when the channels’ activation gates close and inactivation gates open once again; that is, until the channels are in their “closed but capable of opening” conformation. Only then can they respond to another depolarization to initiate another action potential. Because of this absolute refractory period, one action potential must be over before another can be initiated at the same site. Action potentials cannot overlap or be added one on top of another “piggyback fashion.”

Following the absolute refractory period is a **relative refractory period**, during which a second action potential can be produced only by a triggering event considerably stronger than usual. The relative refractory period occurs after the action potential is complete because of a twofold effect: lingering inactivation of the voltage-gated Na⁺ channels and slowness to close of the voltage-gated K⁺ channels that opened at the peak of the action potential. During this time, fewer than normal voltage-gated Na⁺ channels are in a position to be jolted open by a depolarizing triggering event. Simultaneously, K⁺ is still leaving through its slow-to-close channels during the *after hyperpolarization phase*. The less-than-normal Na⁺ entry in response to another triggering event is opposed by a persistent hyperpolarizing outward leak of K⁺ through its not-yet-closed channels, and thus a greater-than-normal depolarizing triggering event is needed to bring the membrane to threshold during the relative refractory period.

By the time the original site has recovered from its refractory period and is capable of being restimulated by normal

current flow, the action potential is so far away that it can no longer influence the original site. Thus, *the refractory period ensures the unidirectional propagation of the action potential down the axon away from the initial site of activation.*

The refractory period also limits the frequency of action potentials

The refractory period also sets an upper limit on the *frequency* of action potentials; that is, it determines the maximum number of new action potentials that can be initiated and propagated along the fiber in a given period of time. As you will see shortly, frequency is the major method of carrying information by action potentials. The length of the refractory period varies for different types of neurons. The longer the refractory period, the greater the delay before the new action potential can be initiated and the lower the frequency with which a neuron can respond to repeated or ongoing stimulation.

Action potentials occur in all-or-none fashion

If any portion of the neuronal membrane is depolarized to threshold, an action potential is initiated and relayed throughout the membrane in undiminished fashion. Furthermore, once threshold has been reached, the resultant action potential always goes to maximal height. The reason for this effect is the positive-feedback aspect we discussed earlier (Figure 4-7), whose magnitude is not altered by the strength of the depolarizing triggering event. However, a triggering event that fails to depolarize the membrane to threshold does not trigger an action potential at all. Thus, *an excitable membrane either responds to a triggering event with a maximal action potential that spreads nondecrementally throughout the membrane, or it does not respond with an action potential at all.* This property is called the **all-or-none law**.

This all-or-none concept is like lighting a fuse with applied heat. Either a heated fuse does not reach its ignition temperature (threshold is not reached), or it is heated enough to start combustion (threshold is reached), which then self-propagates down the fuse. A higher amount of applied heat does not produce a greater or faster fuse fire. Just as it is not possible to ignite a fuse halfway, it is normally not possible to have a halfway action potential.

The threshold phenomenon allows some discrimination between important and unimportant stimuli or other triggering events. Stimuli too weak to bring the membrane to threshold do not initiate an action potential and therefore do not clutter up the nervous system by transmitting insignificant signals.

The strength of a stimulus is coded primarily by the frequency of action potentials

How is it possible to differentiate between two stimuli of varying intensities if both bring the membrane to threshold and generate action potentials of the same magnitude? For example, how can an animal distinguish between a warm and a hot surface if both trigger identical action potentials in a nerve fiber relaying information about skin temperature to the central nervous system? The answer lies primarily in the *frequency* with which the action potentials

are generated. A stronger stimulus does not produce a larger action potential, but it does trigger a greater *number* of action potentials per second to be propagated along the fiber. This occurs because graded potentials that depolarize neurons typically last much longer than one action potential. A strong graded potential will rapidly push the neuron back to threshold repeatedly after each refractory period. In contrast, a weak graded potential will only gradually do so, resulting in many fewer action potentials per unit of time.

In addition, a stronger stimulus in a region will result in more neurons reaching threshold, thus increasing the total information sent to the central nervous system. For example, lightly touch this page with your finger and note the area of skin in contact with the page. Now, press down more firmly and note that a larger surface area of skin is in contact with the page. Therefore, more neurons are brought to threshold with this stronger touch stimulus.

Recent research suggests that more complex coding mechanisms also occur in some neural systems. For example, the *temporal (timing) pattern* of action potentials can carry information. Suppose two neurons are both transmitting 100 action potentials per second. If one does so in an even pattern, but the other does so in five dense groups of 20 action potentials separated by long time gaps, the target neuron reacts differently to each. The degree to which neurons use frequency versus temporal coding, particularly inside brains, is still uncertain.

Once initiated, the velocity, or speed, with which an action potential travels down the axon depends on two factors: (1) whether the fiber is *myelinated* and (2) the diameter of the fiber. Contiguous conduction occurs in unmyelinated fibers. In this case, as we just said, each individual action potential initiates an identical new action potential in the next contiguous (bordering) segment of the axon membrane so that every portion of the membrane undergoes an action potential as this electrical signal is conducted from the beginning to the end of the axon. A faster method of propagation, *saltatory conduction*, takes place in myelinated fibers. Next let's see how a myelinated fiber compares with an unmyelinated fiber, then see how saltatory conduction compares with contiguous conduction.

Myelination increases the speed of conduction of action potentials and conserves energy in the process

Myelinated fibers, found in vertebrates (excluding lampreys and hagfishes) and a few other animals, are axons covered with myelin at regular intervals along the length of the axon (Figure 4-13a). **Myelin** consists primarily of lipids. Because the water-soluble ions responsible for carrying current across the membrane cannot permeate this thick lipid barrier, the myelin coating acts as an insulator, just like rubber around an electrical wire, to prevent current leakage across the myelinated portion of the membrane. Myelin is not actually a part of the nerve cell but consists of separate myelin-forming cells that tightly wrap themselves around the axon in concentric rings. These myelin-forming cells are **oligodendrocytes** in the central nervous system (the brain and spinal cord) and **Schwann cells** in the peripheral nervous system (the nerves running between the central nervous system and the various regions of the body) (Figure 4-13b and c). Each

patch of lipid-rich myelin consists of multiple layers of the myelin-forming cell's plasma membrane (predominantly the lipid bilayer) as the cell wraps itself around and around the axon. A patch of vertebrate myelin might be made up of as many as 300 layers of wrapped lipid bilayers.

Myelin appears to be rare outside of vertebrates (see *Unanswered Questions: How many animal groups have myelin?*). Disadvantages of myelin include the significant costs in metabolic and biosynthetic resources required to produce the many layers of lipid-rich membrane; and for some species, key components of myelin may be limiting such as cholesterol, which is not synthesized by protostomes and hence is an essential nutrient in their diet.

Between the myelinated regions, the axonal membrane is bare and exposed to the ECF. Only at these bare spaces, called **nodes of Ranvier**, can membrane potential exist and current flow across the membrane (Figure 4-13). Voltage-gated Na^+ channels are concentrated at the nodal areas; the myelin-covered regions are almost devoid of these special passageways. By contrast, an unmyelinated fiber has a uniform density of voltage-gated Na^+ channels throughout its entire length. As you know, action potentials can be generated only at portions of the membrane furnished with an abundance of these channels. Spread of action potentials in myelinated fibers is called *saltatory conduction*, which we will now examine.

The nodes are usually about 1 mm apart, close enough that local current from an active node can reach an adjacent node before dying off. When an action potential occurs at one of the nodes, opposite charges attract from the adjacent inactive node, reducing its potential to threshold so that it undergoes an action potential, and so on. Consequently, in a myelinated fiber, the impulse “jumps” from node to node, skipping over the myelinated sections of the axon (Figure 4-14); this process is called **saltatory conduction** (the Latin word *saltere* means “to leap”). Saltatory conduction propagates action potentials more rapidly than does conduction by local current flow because the action potential leaps over myelinated sections but must be regenerated within every section of an unmyelinated axonal membrane from beginning to end. Myelinated fibers conduct impulses about 50 times faster than unmyelinated fibers of comparable size. You can think of myelinated fibers as the “superhighways” and unmyelinated fibers as the “back roads” of the nervous system when it comes to the speed with which information can be transmitted. Thus, the most urgent types of information are transmitted via myelinated fibers, whereas nerve pathways carrying less urgent information are unmyelinated.

Besides permitting action potentials to travel faster, myelination also conserves energy. Because the ion fluxes associated with action potentials are confined to the nodal regions, the energy-consuming Na^+/K^+ pump must restore fewer ions to their respective sides of the membrane after propagation of an action potential.

Insect neurons are coated with a sheath that regulates ion balance

Insects do not have a myelin sheath per se but, rather, loosely coat the axon with a cellular *nerve sheath*. There are no nodes for enhancing conduction speed. The purpose of the sheath becomes evident when you examine the concen-

tration of ions in the hemolymph of herbivorous (plant-eating) insects. Plants and fruits are high in K^+ but low in Na^+ content, so animals that feed exclusively on plant material potentially may consume insufficient Na^+ . In herbivorous insects, concentrations of Na^+ in the hemolymph range from 2 to 15 mM lower than that measured in the ICF—too low to sustain propagation of an action potential. Com-

pared to vertebrates, concentrations of K^+ are elevated in the hemolymph (20 to 60 mM), although still lower than in the ICF. These insects have solved the dietary ion problem by evolving the nerve fat-body sheath, which aids in propagation of an action potential. Because the nerve sheath is only loosely wrapped around the axon, it can actively regulate the local fluid bathing the axon. Measurement of Na^+

concentrations in this fluid reveals concentrations about 10-fold higher than in the hemolymph, concentrations now high enough to sustain propagation of an action potential. In contrast, herbivorous mammals such as deer meet this Na^+ need by locating natural salty minerals (“licks”), while farmers provide dietary mineral supplements to domesticated species or provide access to artificial salt licks.

unanswered Questions How many animal groups have myelin?

For decades, scientists thought only vertebrates accelerate action potentials with insulation. For example, most protostomes, which include mollusks and insects, completely lack myelin. In recent years, however, researchers have found such insulation in several nonvertebrates. For example, neurons of *Oligochaetes* (annelids

such as earthworms) have wrappings of 20 to 200 bilayers. Myelin structures have also been found in shrimp and, unexpectedly, in copepods. Copepods are tiny (almost microscopic) planktonic crustaceans that inhabit all oceans and, as the primary ocean herbivores, are thought to be the most numerous animals on Earth. But scientists always assumed their tiny size meant unmyelinated axons would work fast enough. In 1998, a chance microscopic observation by researchers at the University of Hawaii led to the discovery that copepods have myelin-like insulation with spiral wrapping. What purpose might this serve in the survival of this important but tiny animal? And how many other types of animals might have myelin that we have not yet discovered? See Suggested Readings by Lenz, Hartline, and Davis (2000) and Hartline (2008). <<

Fiber diameter also influences the velocity of action potential propagation

Besides the effect of myelination, the diameter of the fiber also influences the speed with which an axon can conduct action potentials. The magnitude of current flow (that is, the amount of charge that moves) depends not only on the difference in potential between two adjacent electrically charged regions but also on the resistance to electrical charge movement between the two regions. When fiber diameter increases, the resistance to local current decreases. Thus, the larger the diameter of the nerve fiber, the faster it can propagate action potentials. Fast conduction of an impulse increases the possibility of an animal escaping from a predator. Other uses include prey capture or a response to stress. Compared to slow conduction pathways, fast conduction requires considerably greater energy expenditure.

In some species, fiber diameters have become so large that they are called **giant nerve axons**. They are characterized as axons with diameters that are markedly larger than the diameters of other axons in the same animal and by their role in the coordination of abrupt withdrawal or escape movements. Giant axons may arise from the fusion of smaller fibers (up to 1,500 cell bodies). Such multicellular forms occur in numerous groups, including annelids, decapod crustaceans, and cephalopods and in many vertebrates. Giant axons were first identified in the squid *Loligo*; indeed, researchers first used these axons to uncover the mechanisms of resting and action potentials (see opening picture of this chapter).

There are also unicellular giant axons, found in cockroaches, crayfish, and some annelids. They are important for escaping predators or catching prey. For example, in a crayfish, the perception of danger is relayed by a giant axon to muscles for the tail, which rapidly flips, propelling the animal away from the danger. Some vertebrates also have giant axons called **Mauthner neurons** that, in fish and larval amphibians, arise from the brain stem and run to tail muscles. These too are used for tail-flip escape behaviors.

Even with increased size, unmyelinated nerves are slower than many myelinated ones. In the former, an action potential in a giant axon is conducted at velocities from 5 to 25 meters/sec, compared with a velocity of 0.7 meters/sec in small unmyelinated fibers such as those supplying a vertebrate digestive tract. In contrast, large myelinated fibers, such as those supplying skeletal muscles, can conduct action potentials at a speed of up to 120 meters/sec. This variability in speed of propagation of action potentials is related to the urgency of the information being conveyed. A signal to skeletal muscles to execute a particular movement (for example, to prevent you from falling as you trip on something) must be transmitted more rapidly than a signal to modify a slow-acting digestive process. Were it not for myelination, axon diameters within urgent nerve pathways would have to be very large to achieve the necessary conduction velocities, as you have seen. Vertebrates (and at least some annelids and crustacea) have escaped the necessity of very large fibers by wrapping the axons in myelin to permit economical, rapid, long-distance signaling.

Define the following terms: *threshold potential*, *action potential*, *refractory period*, and *all-or-none law*.

How does each of the three components of a neuron contribute to its function?

Compare contiguous conduction with saltatory conduction, and the ways by which various animal neurons increase the speed of both.

4.4 Electrical and Chemical Synapses

What happens once an action potential reaches the end of an axon? Where the action potential waveform must somehow transmit its message to another cell—called the *target cell*—is at the region termed the **synapse** (*synapsis* means “junction”). Charles Sherrington in 1897 first recognized that a different form of communication occurred at this juncture.

The signaling cell is called the *presynaptic* neuron, and its target, also called *postsynaptic* cell, is typically another neuron or effector such as a gland or muscle. When the action potential waveform reaches the presynaptic axon terminal, it alters the activity of the target cells on which the neuron terminates. There are only two basic kinds of transmission of signals at this point: electrical (direct) or chemical (indirect), which differ in signal transfer mechanisms. Although electrical transmission is not as common as chemical, it is much simpler. Initially, let's consider electrical transmission, to set the stage for the more complex chemical transmission process.

Electrical synapses transfer action potential waveforms through gap junctions

Action potential waveforms are essentially transmitted across **electrical synapses** unperturbed, moving along the axon as if the synapse was not present. This is so because the cytoplasm of the presynaptic neuron is in direct contact with the postsynaptic neuron via *gap junctions* (Chapter 2, pp. 66–67). Because the resistance of the gap junction membranes to the flow of current is low, this permits a nearly full-strength signal to be induced in the postsynaptic cell. Also, compared to a chemical synapse, electrical transmission occurs with negligible time delay. This feature makes electrical synapses useful as a mechanism for escape responses in nonvertebrates. Electrical synapses were first discovered in the abdominal nerve cord of crayfish in 1959 by E. Furshpan and D. Potter and have since been identified in numerous other animals, including some vertebrate excitable cells such as retinal neurons and smooth and cardiac muscle fibers. The rapidity of electrical communication is a feature exploited by these vertebrate tissues to coordinate the activity of a group of cells (for cardiac cells, see Chapter 9). In addition, in some neural pathways, signal transmission is both electrical and chemical. This is found in the escape response of some fishes, which flip their tails quickly when startled.

Chemical synapses convert action potentials into organic chemical messengers that are exocytosed into the synaptic gap

Nerves and their target cells do not actually make direct contact at the second type of synapse, the **chemical synapse**. The gap, or **synaptic cleft**, between these two structures is too large (approximately 20 to 40 nm wide) to permit electrical transmission of an impulse between them (that is, the action potential cannot “jump” that far). Instead, an organic *chemical messenger*—generically called a **neurotransmitter**—is used to carry the signal between the neuron terminal and the target cell. Briefly, the messenger is exocytosed from the neuron and diffuses to the target, where it binds to **receptor** proteins. The receptors in turn alter the activity of the target cell. (Again, as with ions in action potentials, the giant neurons of squid provided the first evidence that transmission of a neural signal across the synapse required the release of a transmitter substance.) Because chemical synapses rely on diffusion of the neurotransmitter, they are much slower (by several orders of magnitude) than electrical synapses; but they have two advantages over electrical synapses. (1) They typically operate in one direction only, so that false messages do not inadvertently travel from effectors to integrators; that is, the presynaptic neuron brings about changes in membrane potential of the postsynaptic (target) membrane, but not vice versa. However, we later discuss *retrograde* messengers in which a signal is sent “backward.” (2) They allow for various kinds of signaling events other than simply triggering action potentials in the target. How these features arise and how they are used will shortly become apparent when we examine the events that occur at a synapse.

Neurotransmitters come in several chemical classes of signal molecules (Chapter 3, p. 93), but the most common ones are *amines* (Table 4-3, listing classical neurotransmitters). Examples you will encounter later in this chapter include glutamate, norepinephrine, dopamine, and serotonin. Some of these are highly conserved in evolution, serving as neurotransmitters in many different animal phyla. For example, *serotonin* is found in vertebrate nervous systems; it is used in synapses involved with sleep, pain, aggression, sexual behavior, and food intake. The transmitter *dopamine* is found in mammalian neurons involved with control of locomotion and reward. In snails (a mollusk), serotonin has been found to stimulate foot locomotion, whereas dopamine inhibits it. Serotonin has even been found (using immunofluorescence, p. 34) in synaptic vessels of a sea anemone (a cnidarian).

Depending on where a neuron terminates, a chemical synapse can cause another neuron to convey an electrical message along a nerve pathway, a muscle cell to contract, a gland cell to secrete, or some other function. When a neuron terminates on an effector, the neuron is said to **innervate** the structure. The junctions between nerves and glands that they innervate are described later. For now, we will concentrate on the junction between two neurons, and between a neuron and a skeletal muscle. Let’s begin with two neurons.

check your understanding 4.4

- List some characteristics of neurotransmitters.
- Why do synapses normally operate in one direction only?
- Why is transmission across a chemical synapse slower than an electrical synapse?

4.5 Neuron-to-Neuron Synapses

Typically, a neuron-to-neuron synapse involves a junction between an axon terminal of a presynaptic neuron and the dendrites or cell body of a postsynaptic neuron. Less frequently, axon-to-axon and dendrite-to-dendrite connections occur. Most neuronal cell bodies and associated dendrites receive thousands of synaptic inputs, which are axon terminals from many other neurons. Neurologists have estimated that some neurons within the central nervous system receive as many as 100,000 synaptic inputs (Figure 4-15).

The anatomy of one of these synapses is shown in Figure 4-16. The axon terminal of the presynaptic neuron, which conducts its action potentials *toward* the synapse, ends in a slight swelling, the **synaptic knob**. The synaptic knob contains synaptic vesicles, which store neurotransmitters synthesized and packaged by the Golgi apparatus (p. 41) of the presynaptic neuron. The synaptic knob comes into close proximity to, but (because of the cleft or gap) does not actually directly contact, the postsynaptic neuron. The part of the postsynaptic membrane immediately underlying the synaptic knob is the **subsynaptic membrane** (*sub*, “under”).

A neurotransmitter carries the signal across a fast synapse and opens a chemically gated channel

Most, but not all, neurotransmitters function by changing the conformation of *chemically gated channels*, thereby altering membrane permeability and ionic fluxes across the postsynaptic membrane. Synapses involving these rapid responses are considered “**fast**” synapses. The events that occur at these common types of synapse are summarized next and illustrated in Figure 4-16 (we investigate “**slow**” synapses later):

- When an action potential in a presynaptic neuron has been propagated to the axon terminal (step 1 in Figure 4-16), this change in potential triggers the opening of voltage-gated Ca^{2+} channels in the synaptic knob.
- Because Ca^{2+} is in much higher concentration in the ECF, and because the cell has a negative charge, this ion flows into the synaptic knob through the opened channels (step 2).

FIGURE 4-15 Synaptic inputs (presynaptic axon terminals) to the cell body and dendrites of a single postsynaptic neuron. Note that the drying process used to prepare the neuron for the electron micrograph has toppled the presynaptic axon terminals and pulled them away from the postsynaptic cell body.

- 1 Action potential reaches axon terminal of presynaptic neuron.
- 2 Ca^{2+} enters synaptic knob (presynaptic axon terminal).
- 3 Neurotransmitter is released by exocytosis into synaptic cleft.
- 4 Neurotransmitter binds to receptors that are an integral part of chemically gated channels on subsynaptic membrane of postsynaptic neuron.
- 5 Binding of neurotransmitter to receptor opens that specific channel.

FIGURE 4-16 Structure and function of a single synapse. The numbered steps designate the sequence of events that take place at a synapse. The blowup depicts the release by exocytosis of neurotransmitter from the presynaptic axon terminal and its subsequent binding with receptors specific for it on the subsynaptic membrane of the postsynaptic neuron.

© Cengage Learning, 2013

3. Ca^{2+} induces the release of a neurotransmitter from some of the synaptic vesicles into the synaptic cleft (step 3). The release is accomplished by exocytosis (see p. 41).
4. The released neurotransmitter diffuses across the cleft and combines with specific protein receptor sites on the **subsynaptic membrane**, the portion of the postsynaptic membrane immediately underlying the synaptic knob (*sub* means “under”) (step 4).
5. This binding triggers the opening of specific ion channels in the subsynaptic membrane, changing the permeability of the postsynaptic neuron (step 5). These are chemically gated channels, in contrast to the voltage-gated channels responsible for the action potential and for the Ca^{2+} influx into the synaptic knob.

Finally, a mechanism is needed to stop the signal. We will look at mechanisms for this later.

Because only the presynaptic terminal can release a neurotransmitter and only the subsynaptic membrane of the postsynaptic neuron has receptor sites for the neurotransmitter, the synapse can operate only in the direction from presynaptic to postsynaptic neuron. This advantage over electrical synapses prevents signals from moving backward, which would interfere with the ability of neurons to control their targets.

Conversion of the electrical signal in the presynaptic neuron (an action potential) to an electrical signal in the postsynaptic neuron by chemical means (via the neurotransmitter-receptor combination) takes time. This **synaptic delay** (the major disadvantage of chemical compared to electrical synapses) is usually about 0.5 to 1 msec. Chains of neurons often must be traversed along a specific neural pathway. The more complex the pathway, the more synaptic delays and the longer the *total reaction time* (the time required to respond to a particular event).

Some neurotransmitters excite the postsynaptic neuron, whereas others inhibit the postsynaptic neuron

Each presynaptic neuron usually releases only one neurotransmitter (exceptions are noted later); however, different neurons vary in the neurotransmitter they release. On binding with their subsynaptic receptor sites, different neurotransmitters cause different permeability changes. There are two broad types of chemical synapses, depending on the permeability changes induced in the postsynaptic neuron by the combination of neurotransmitter with receptor sites: *excitatory synapses* and *inhibitory synapses*. This situation is unlike that found at the vertebrate neuromuscular junction (as you will see later) where the communication is always excitatory.

Excitatory Synapses At an **excitatory synapse**, the response to the binding of neurotransmitter to the receptor-channel is the opening of nonspecific cation channels in the subsynaptic membrane that permit simultaneous passage of Na^+ and K^+ through them. (These are a different type of channel from those you have encountered before.) Thus, permeability to both these ions is increased at the same time. How much of each ion conducts and/or diffuses through an open channel

depends on the electrochemical gradients. At resting potential, both the concentration and electrical gradients for Na^+ favor its movement into the postsynaptic neuron, whereas only the concentration gradient for K^+ favors its movement outward (Table 4-1). Therefore, the permeability change induced at an excitatory synapse results in the simultaneous movement of a few K^+ ions out of the postsynaptic neuron while a relatively larger number of Na^+ ions enter this neuron. The result is a net movement of positive ions into the cell. This makes the inside of the membrane slightly less negative than at resting potential, thus producing a *small depolarization* of the postsynaptic neuron.

Activation of one excitatory synapse can rarely depolarize the postsynaptic neuron sufficiently to bring it to threshold. Too few channels are involved at a single subsynaptic membrane to permit adequate depolarizing fluxes to reduce the potential to threshold. This small depolarization, however, does bring the membrane of the postsynaptic neuron closer to threshold, increasing the likelihood that threshold will be reached (in response to further excitatory input) and an action potential will occur. That is, the membrane is more excitable (easier to bring to threshold) than when at rest. Accordingly, such a postsynaptic potential change occurring at an excitatory synapse is called an **excitatory postsynaptic potential**, or EPSP (Figure 4-17a).

Inhibitory Synapses The second advantage of a chemical over an electrical synapse is the ability to trigger responses other than simple stimulation. One of these other responses is inhibition. At an **inhibitory synapse**, the combination of a chemical messenger with its receptor site increases the permeability of the subsynaptic membrane to either K^+ or Cl^- by altering these ions' respective channel conformations. In either case, the resulting ion movements bring about a *small hyperpolarization* of the postsynaptic neuron (greater internal negativity). In the case of increased P_{K^+} , more positive charges leave the cell via K^+ efflux, leaving more negative charges behind on the inside. In the case of increased P_{Cl^-} , because the concentration of Cl^- is higher outside the cell, more negative charges enter the cell in the form of Cl^- ions than are driven out by the opposing electrical gradient established by the resting membrane potential. In either case, this small hyperpolarization moves the membrane potential even farther away from threshold (Figure 4-17b), lessening the likelihood that the postsynaptic neuron will reach threshold and undergo an action potential. That is, the membrane would be harder to bring to threshold by excitatory input than when it is at resting potential. Under these circumstances the membrane is said to be inhibited, and the small hyperpolarization of the postsynaptic cell is called an **inhibitory postsynaptic potential**, or IPSP.

In cells where the equilibrium potential for Cl^- exactly equals the resting potential, an increased P_{Cl^-} does not result in a hyperpolarization because there is no driving force to produce Cl^- movement. Nevertheless, opening of Cl^- channels in these cells is still inhibitory because it tends to hold the membrane at resting potential, thus reducing the likelihood that threshold will be reached. That is, if a small amount of Na^+ enters from another channel, the cell becomes slightly less negative, which in turn allows some Cl^- to enter the cell, offsetting the effect of Na^+ .

(a) Excitatory synapse

(b) Inhibitory synapse

FIGURE 4-17 Postsynaptic potentials. (a) An excitatory postsynaptic potential (EPSP) brought about by activation of an excitatory presynaptic input brings the postsynaptic neuron closer to threshold potential. (b) An inhibitory postsynaptic potential (IPSP) brought about by activation of an inhibitory presynaptic input moves the postsynaptic neuron farther from threshold potential.

© Cengage Learning, 2013

Each neurotransmitter–receptor combination always produces the same response

The binding of a specific neurotransmitter at fast synapses with the appropriate subsynaptic receptors always leads to the same change in permeability and resultant change in potential of a particular postsynaptic membrane. That is, the response to a given neurotransmitter–receptor combination is always constant. Some neurotransmitters (for example, glutamate, the most common excitatory neurotransmitter in the brain) typically bring about EPSPs, whereas others (for example, *gamma-aminobutyric acid*, or GABA, the vertebrate brain's main inhibitory neurotransmitter) always induce IPSPs. Moreover, a single fast neuron only makes one class of neurotransmitter (excitatory or inhibitory). That is, *a given synapse is either excitatory or inhibitory*. However, this does not necessarily mean that synapses are invariant over the long term. At least in developing spinal cord in frog embryos, artificially varying the rate of electrical stimulation can change the type of neurotransmitter an individual neuron makes from excitatory to inhibitory and vice versa.

How frequently this type of switching occurs in nature—if at all—is unknown.

Although each neurotransmitter–receptor combination yields the same response, some neurotransmitters (for example, norepinephrine) may produce an EPSP at one synapse and an IPSP at another synapse. This is a result of having different types of receptors (an example of the “same key, different locks” principle, p. 93).

Recent evidence suggests that in some instances two different neurotransmitters can be released simultaneously from a single axon terminal; however, they are not in conflict. For example, glycine and GABA, both of which produce inhibitory responses, can be packaged and released from the same synaptic vesicles. Scientists speculate that the fast-acting glycine and the more slowly acting GABA may complement each other in the control of activities that depend on precise timing, for example, coordination of complex movements. The brain can also synthesize neurosteroids, which enhance GABA receptor function, and so fine-tune neuronal activity.

Neurotransmitters are quickly removed from the synaptic cleft

As long as the neurotransmitter remains bound to the receptor sites, the alteration in membrane permeability responsible for the EPSP or IPSP continues. It is important that the neurotransmitter be removed after producing the appropriate response in the postsynaptic neuron so that the postsynaptic “slate” is “wiped clean,” ready to receive additional messages from the same or other presynaptic inputs. Thus, after combining with the postsynaptic receptor chemical, transmitters are removed and the response is terminated. This occurs in three general ways. The neurotransmitter may (1) *diffuse* away from the synaptic cleft, (2) be *inactivated by a specific enzyme* in a subsynaptic membrane, or (3) be transported back into the axon terminal by *reuptake* carriers in the presynaptic membrane. Once within the synaptic knob, the transmitter can be stored and released another time (recycled) in response to a subsequent action potential or destroyed by enzymes within the synaptic knob. The method employed depends on the particular synapse. We describe a detailed example at neuromuscular synapses shortly.

Neurotransmitters in slow synapses function through intracellular second-messenger systems

As we have seen, neurotransmitters usually function by changing the conformation of chemically gated channels, in so-called fast synapses. Another mode of synaptic transmission used by some neurotransmitters, such as *serotonin*, involves the activation of intracellular second messengers, such as cAMP (see p. 97), within the postsynaptic neuron (these neurotransmitters are sometimes called *neuromodulators*, as are *neuropeptides*; we will discuss these later). Synapses that lead to responses mediated by second messengers are known as “*slow*” synapses because these responses take longer and often last longer (because of second-messenger cascades, Figure 3-17c) than those accomplished by fast synapses. Activation of the intracellular messenger, cyclic AMP, can induce both short- and long-term effects. In the short term, cAMP can lead to a prolonged opening of specific ionic gates. The gating effects can be either excitatory or inhibitory. In addition, cAMP may trigger more long-term changes in the post-

synaptic cell, even to the extent of altering the cell's genetic expression by (indirectly) activating transcription factors. Such long-term cellular changes are linked to neuronal growth and development and play a role in learning and memory, which we will discuss in detail in the next chapter (p. 194).

How are so-called fast synapses different from slow synapses?

Compare the events that occur at excitatory and inhibitory synapses.

4.6 Neuromuscular Synapses

Now let's turn to a second example of a chemical synapse. Action potentials are conducted from the cell body in the CNS to skeletal muscle through large, myelinated **motor neurons**. As the axon approaches a muscle, it divides into many terminal branches and loses its myelin sheath. Each of these axon terminals forms a special synaptic junction, a **neuromuscular junction**, with one of the many muscle cells that compose the whole muscle (Figure 4-18). Each branch innervates only one muscle cell; therefore, each muscle cell has only one neuromuscular junction. A single muscle cell, called a **muscle fiber**, is long and cylindrical in shape. The axon terminal is enlarged into a knoblike structure, the **terminal button**, or **bouton**, which fits into a shallow depression, or groove, in the underlying muscle fiber (Figure 4-19). Some scientists alternatively call the neuromuscular junction a *motor end plate*. However, we reserve the term **motor end plate** for the specialized portion of the muscle cell membrane immediately under the terminal button.

Normally, each vertebrate muscle fiber is innervated at one or two end plates, although in amphibians and lizards specialized "slow" muscle fibers receive multiterminal innervation; that is, they are innervated by numerous chemical synapses along the length of each fiber. Interestingly, these fibers lack all-or-none action potentials and rather depend on the copious distribution of neuromuscular junctions to generate graded contractions. Tension produced in these muscles thus depends on the frequency of motor neuron output and is associated with slow, sustained contractions. (See Chapter 8 for details on typical neuromuscular control.)

Acetylcholine, a fast excitatory neurotransmitter, links electrical signals in motor neurons with electrical signals in skeletal muscle cells

Here let's take a look at the events at a muscle synapse in a vertebrate, following Figure 4-19. We will focus on one terminal button, but the same events take place concurrently at all the terminal buttons of a given neuromuscular junction. Each terminal button contains thousands of vesicles that store many molecules of the neurotransmitter **acetylcholine (ACh)**. Arrival of an action potential at the axon terminal triggers events similar to steps at the neuron-to-neuron synapse (Figure 4-16), with steps 1–2 being identical. These are followed by (Figure 4-19):

FIGURE 4-18 Motor neuron innervating skeletal muscle cells.

When a motor neuron reaches a skeletal muscle, it divides into many terminal branches, each of which forms a neuromuscular junction with a single muscle cell (muscle fiber).

3. Release of ACh by exocytosis from several hundred of the vesicles into the cleft, and diffusion of ACh across the cleft (step 3).
4. Binding of ACh molecules to **receptors** in the postsynaptic membrane (step 4) (these **cholinergic receptors** are of the *nicotinic* type; see p. 164).
5. Opening of chemical-messenger-gated channels in the motor end plate, which depolarizes the motor end plate (step 5).

Steps 6–8 involve changes in the muscle potential, a graded one known as the **end-plate potential (EPP)**. The motor end-plate region itself does not have a threshold potential, so an action potential cannot be initiated at this site. However, an EPP brings about an action potential in the rest of the muscle fiber, as follows (continuing with Figure 4-19):

6. The neuromuscular junction is usually located in the middle of the long cylindrical muscle fiber. When an EPP takes place at the motor end plate, local current flow occurs between the depolarized end plate and the adjacent, resting cell membrane in both directions, reducing the potential to threshold in the adjacent areas (step 6).
7. The subsequent action potential initiated at these sites is propagated throughout the muscle fiber membrane by contiguous conduction (opening voltage-gated Na^+ channels) (step 7) and thus conduction (see Figure 4-10).
8. The spread runs in both directions, away from the motor end plate toward both ends of the fiber. This electrical activity initiates contraction of the muscle fiber (step 8).

1 An action potential in a motor neuron is propagated to the axon terminal (terminal button).

2 This local action potential triggers the opening of voltage-gated Ca^{2+} channels and the subsequent entry of Ca^{2+} into the terminal button.

3 Ca^{2+} triggers the release of acetylcholine (ACh) by exocytosis from a portion of the vesicles.

4 ACh diffuses across the space separating the nerve and muscle cells and binds with receptor-channels specific for it on the motor end plate of the muscle cell membrane.

5 This binding brings about the opening of these nonspecific cation channels, leading to a relatively large movement of Na^{+} into the muscle cell compared to a smaller movement of K^{+} outward.

6 The result is an end-plate potential. Local current flow occurs between the depolarized end plate and the adjacent membrane.

7 This local current flow opens voltage-gated Na^{+} channels in the adjacent membrane.

8 The resultant Na^{+} entry reduces the potential to threshold, initiating an action potential, which is propagated throughout the muscle fiber.

9 ACh is subsequently destroyed by acetylcholinesterase, an enzyme located on the motor end-plate membrane, terminating the muscle cell's response.

FIGURE 4-19 Events at a neuromuscular junction.

© Cengage Learning, 2013

The graded EPP is similar to an EPSP (p. 132) except that the magnitude of an EPP is much larger for the following reasons: (1) a neuromuscular junction consists of multiple terminal buttons, each of which simultaneously releases ACh on activation of the axon terminal; (2) more transmitter is released from a terminal button than from a *presynaptic knob* in response to an action potential; (3) the motor end

plate has a larger surface area bearing a higher density of transmitter receptor sites, and so, accordingly, has more sites for binding with transmitter than does a subsynaptic membrane; and (4) accordingly, many more receptor-channels are opened in response to the transmitter-receptor complex in the motor end plate. This permits a greater net influx of Na^{+} ions and a larger depolarization.

Thus by means of ACh, an action potential in a motor neuron brings about an action potential and subsequent contraction in the muscle fiber. Unlike synaptic transmission among neurons, the magnitude of a single EPP is normally sufficient to cause an action potential in the muscle cell.

Therefore, one-to-one transmission of an action potential typically occurs at a neuromuscular junction; one action potential in a nerve cell triggers one action potential in a muscle cell that it innervates.

The development of patch clamp recording technology (p. 112) enabled researchers to measure current flow through a single ACh receptor channel. Generally, the ACh channel remains open for 1 to 3 msec and permits approximately 1 to 5×10^4 ions to flow through it.

Unlike most vertebrate neuromuscular systems (as you will see later), neurons that innervate arthropod muscles are both inhibitory as well as excitatory. For example, the neuromuscular systems regulating claw opening and closing in decapod crustaceans (such as crabs) contain both excitatory and inhibitory motor input. Inhibitory motor neurons also have endings on the presynaptic terminals of the excitatory motor neurons. This feature specifically protects the excitatory synapse from neurotransmitter depletion by limiting the amount released.

Acetylcholinesterase terminates acetylcholine activity at the neuromuscular junction

To ensure purposeful movement, a muscle cell's electrical activity and the resultant contraction must be turned on by motor neuron action potentials and must be switched off promptly when there is no longer a signal from the motor neuron. The muscle cells electrical response is turned off by an enzyme present in the motor end-plate membrane, **acetylcholinesterase (AChE)**, which inactivates ACh. This occurs because ACh binding to the receptor is reversible (Figure 4-19):

9. As a result of diffusion, many of the released ACh molecules come into contact with and bind to receptor-channels on the surface of the motor end-plate membrane. However, some of the ACh molecules bind with AChE, which is also at the end-plate surface. Being quickly inactivated, this ACh never contributes to the end-plate potential. The acetylcholine that does bind with receptor-channels does so very briefly (for about 1 millionth of a second), then detaches. Some of the ACh molecules quickly rebind with receptor-channels, keeping the end-plate channels open, but some diffuse deeper into the folds of the motor end plate, where AChE is located. AChE cleaves ACh into fragments, deactivating it (step 9). As this process is repeated, more and more ACh is inactivated until it has been virtually removed from the cleft within a few milliseconds after its release.

Removal of ACh terminates the EPP so the remainder of the muscle cell membrane returns to resting potential. Now the muscle can relax. Or, if sustained contraction is essential for the desired movement, another motor neuron action potential leads to the release of more ACh, which keeps the contractile process going (see p. 352). By removing contraction-inducing ACh from the motor end plate, AChE permits the choice of allowing relaxation to take place (no more ACh released) or keeping the contraction going (more ACh released), depending on the body's momentary needs.

ACh receptors were first isolated from the electric organs of marine electric fish (see p. 203). Because the electric organs of electric rays, for example, consist of high concentrations of modified neuromuscular junctions with a high density of

ACh receptors, this feature aided investigators in characterizing these proteins.

How is the response to excitatory stimuli turned off at the neuromuscular junction?

How are nonvertebrate neuromuscular systems different from those of vertebrate systems?

4.7 Synapses and Integration

Let's end this exploration of synapses with one of the most important functions found in animals: that of **summation** at chemical synapses. Summation is the ultimate basis of decision making (that is, whether to act or not, and if so, how strongly) in all animal activities involving neural control. Summation is most evident at neuron-to-neuron synapses, to which we now return.

The grand postsynaptic potential depends on the sum of the activities of all presynaptic inputs

EPSPs and IPSPs are graded potentials. Unlike action potentials, which behave according to the all-or-none law, we have seen that graded potentials can be of varying magnitude, have no refractory period, and can be summed (added on top of one another). What are the mechanisms and significance of summation?

The events that occur at a single neuron-to-neuron synapse (and some other kinds) result in either an EPSP or an IPSP at the postsynaptic neuron. But if a single EPSP is inadequate to bring the postsynaptic neuron to threshold and an IPSP moves it even farther from threshold, how is it possible to initiate an action potential in the postsynaptic neuron? Recall that a typical neuronal cell body receives thousands of presynaptic inputs from many other neurons. Some of these presynaptic inputs may be carrying sensory information brought from the environment; some may be signaling internal changes in homeostatic balance; others may be transmitting signals from control centers in the brain; and still others may arrive carrying other bits of information. At any given time, any number of these presynaptic neurons (probably hundreds) may be firing and thus influencing the postsynaptic neuron's level of activity. The total potential in the postsynaptic neuron, the **grand postsynaptic potential (GPSP)**, is a composite of all EPSPs and IPSPs occurring at approximately the same time.

The postsynaptic neuron can be brought to threshold in two ways: (1) *temporal summation* and (2) *spatial summation*. To illustrate these methods of summation, we will examine the possible interactions of three presynaptic inputs—two excitatory (Ex1 and Ex2) and one inhibitory (In1)—on a hypothetical postsynaptic neuron (Figure 4-20). The recording represents the potential in the postsynaptic cell. Bear in mind during our discussion of this simplified version that many thousands of synapses are actually interacting in the same way on a single cell body and its dendrites.

(a) If an excitatory presynaptic input (Ex1) is stimulated a second time after the first EPSP in the postsynaptic cell has died off, a second EPSP of the same magnitude will occur.

(b) If, however, Ex1 is stimulated a second time before the first EPSP has died off, the second EPSP will add onto, or sum with, the first EPSP, resulting in *temporal summation*, which may bring the postsynaptic cell to threshold.

(c) The postsynaptic cell may also be brought to threshold by *spatial summation* of EPSPs that are initiated by simultaneous activation of two (Ex1 and Ex2) or more excitatory presynaptic inputs.

(d) Simultaneous activation of an excitatory (Ex1) and inhibitory (In1) presynaptic input does not change the postsynaptic potential, because the resultant EPSP and IPSP cancel each other out.

FIGURE 4-20 Determination of the grand postsynaptic potential by the sum of activity in the presynaptic inputs. Two excitatory (Ex1 and Ex2) and one inhibitory (In1) presynaptic inputs terminate on this hypothetical postsynaptic neuron. The potential of the postsynaptic neuron is being recorded. For simplicity in the figure, summation of two EPSPs brings the postsynaptic neuron to threshold, but in reality, many EPSPs must sum to reach threshold.

© Cengage Learning, 2013

Temporal Summation Suppose Ex1 has an action potential that causes an EPSP in the postsynaptic neuron. After this EPSP has died off, if another action potential occurs in Ex1, an EPSP of the same magnitude takes place before dying off (Figure 4-20a). Next suppose that Ex1 has two action potentials in close succession to each other (Figure 4-20b). The first action potential in Ex1 produces an EPSP in the postsynaptic neuron. Although the postsynaptic membrane is still partially depolarized from this first EPSP (before it has returned to resting), the second presynaptic action potential produces a second EPSP in the postsynaptic neuron. Because graded potentials do not have a refractory period, the second EPSP adds on to the first EPSP, bringing the membrane to threshold, so that an action potential can occur in the postsynaptic neuron.

The summing of several EPSPs occurring very close together in time because of successive firing of a single presynaptic neuron is known as **temporal summation** (the Latin word *tempus* means “time”). In reality, up to 50 EPSPs might be needed to bring the postsynaptic membrane to threshold. Each action potential in a presynaptic neuron triggers the emptying of a certain number of synaptic vesicles. The amount of neurotransmitter released and the resultant magnitude of the change in postsynaptic potential are thus directly related to the frequency of presynaptic action poten-

tials. One way, then, in which the postsynaptic membrane can be brought to threshold is through rapid, repetitive excitation from a single, persistent input.

Spatial Summation Let’s now see what will happen in the postsynaptic neuron if both excitatory inputs are stimulated simultaneously (Figure 4-20c). An action potential in either Ex1 or Ex2 will produce an EPSP in the postsynaptic neuron; however, neither of these alone will bring the membrane to threshold to elicit a postsynaptic action potential. But simultaneous action potentials in Ex1 and Ex2 produce EPSPs that add to each other, bringing the postsynaptic membrane to threshold, so that an action potential does occur. Such summation of EPSPs originating simultaneously from several different presynaptic inputs (that is, from different points in “space”) is known as **spatial summation**. A second way, therefore, to elicit an action potential in a postsynaptic cell is through concurrent activation of several excitatory inputs. Again, in reality, up to 50 EPSPs arriving simultaneously on the postsynaptic membrane are required to bring it to threshold.

Similarly, IPSPs can undergo temporal and spatial summation. As IPSPs add together, however, they progressively move the potential farther from threshold.

Cancellation of Concurrent EPSPs and IPSPs If an excitatory and an inhibitory input are simultaneously activated, the concurrent EPSP and IPSP more or less cancel each other out. The extent of cancellation depends on their respective magnitudes. In most cases, the postsynaptic membrane potential remains close to resting (Figure 4-20d).

Importance of Postsynaptic Neuronal Integration The magnitude of the GPSP depends on the sum of activity in all the presynaptic inputs and, in turn, determines whether or not the neuron will undergo an action potential to pass information on to the cells at which the neuron terminates. The following oversimplified real-life example demonstrates the benefits of this neuronal integration. The explanation is not completely accurate, technically, but the principles of summation are accurate.

Assume for simplicity's sake that urination is controlled by a postsynaptic neuron supplying the urinary bladder in a mammal. Glutamate released at this neuron opens Na^+ channels, while GABA opens Cl^- channels. When this neuron fires due to the former, its own neurotransmitter release induces the bladder to contract. (Actually, the control of urination also involves urethral sphincter muscles, but we will simplify the process here.) As the bladder starts to fill with urine and becomes stretched, a reflex is initiated that ultimately produces EPSPs in the postsynaptic neuron responsible for causing bladder contraction. Partial filling of the bladder does not cause sufficient excitation to bring the neuron to threshold, so urination does not take place (Figure 4-20a). As the bladder progressively fills, the frequency of action potentials progressively increases in the presynaptic neuron Ex1, leading to more rapid formation of EPSPs in the postsynaptic neuron (Ex1 in Figure 4-20b). Thus, the frequency of EPSP formation arising from Ex1 activity signals the postsynaptic neuron of the extent of bladder filling. When the bladder becomes sufficiently stretched that the Ex1-generated EPSPs are temporally summed to threshold, the postsynaptic neuron undergoes an action potential that stimulates bladder contraction.

What if the time is inopportune for urination? Consider a pet dog with its eye set on a favorite fire hydrant or a bobcat moving to the boundary of its territory to mark it, each needing to stop urination before the animal reaches its goal. Presynaptic inputs originating in higher levels of the brain responsible for voluntary control can produce IPSPs (using GABA) at the bladder postsynaptic neuron (In1 in Figure 4-20d). These “voluntary” IPSPs in effect cancel out the “reflex” EPSPs triggered by stretching of the bladder. Thus, the postsynaptic neuron remains at resting potential and does not have an action potential, so the bladder is prevented from contracting and emptying even though it is full.

What if the bladder is only partially filled, so that the presynaptic input originating from this source (Ex1) is insufficient to bring the postsynaptic neuron to threshold to cause bladder contraction, yet what if the dog has found another inviting fire hydrant? The dog can voluntarily activate an excitatory presynaptic neuron (Ex2 in Figure 4-20c), which spatially summates with the reflex-activated presynaptic neuron (Ex1) to bring the postsynaptic neuron to threshold. This achieves the action potential necessary to stimulate bladder contraction, even though the bladder is not full, so the animal can leave its mark.

This example illustrates the importance of postsynaptic neuronal integration. Each postsynaptic neuron in a sense “computes” all the input it receives and makes a “decision” about whether to pass the information on (that is, whether threshold is reached and an action potential is transmitted down the axon). In this way, neurons serve as complex computational devices, or integrators. The dendrites function as the primary processors of incoming information. They receive and tally the signals coming in from all the presynaptic neurons. Each neuron's output in the form of frequency of action potentials to other cells (muscle cells, gland cells, or other neurons) reflects the balance of activity in the inputs it receives via EPSPs or IPSPs from the thousands of other neurons that terminate on it. Each postsynaptic neuron filters out information it receives that is not significant enough to bring it to threshold and does not pass it on. If every action potential in every presynaptic neuron that impinges on a particular postsynaptic neuron were to cause an action potential in the postsynaptic neuron, the neuronal pathways would be overwhelmed with trivia. Only if an EPSP is reinforced by other supporting signals through summation is the information passed on. Furthermore, interaction of EPSPs and IPSPs provide a way for one set of signals to offset another allowing a fine degree of discrimination and control in determining what information will be passed on. Thus, unlike an electrical synapse, a chemical synapse is more than a simple on–off switch because many factors can influence the generation of a new action potential in the postsynaptic cell. Whether or not the postsynaptic neuron has an action potential or not depends on the relative balance of information coming in via presynaptic neurons at all of its excitatory and inhibitory synapses.

Let's now see why action potentials are initiated at the axon hillock.

Action potentials are initiated at the axon hillock because it has the lowest threshold

Threshold potential is not uniform throughout the postsynaptic neuron. The lowest threshold is present at the axon hillock because this region has a much greater density of voltage-gated Na^+ channels than anywhere else in the neuron. For this reason, the axon hillock is considerably more responsive than the dendrites or remainder of the cell body to changes in potential. Because of local current flow, changes in membrane potential (EPSPs or IPSPs) occurring anywhere on the cell body or dendrites spread throughout the cell body, dendrites, and axon hillock. When summation of EPSPs takes place, the lower threshold of the axon hillock is reached first, whereas the cell body and dendrites at the same potential are still considerably below their own much higher thresholds. Therefore, an action potential originates in the axon hillock and is propagated from there to the end of the axon.

Neuropeptides act primarily as neuromodulators

Researchers recently discovered that in addition to the classical neurotransmitters just described, some neurons also release *neuropeptides* (Table 4-4). Neuropeptides differ from classical neurotransmitters in several important ways. Classical neurotransmitters at fast synapses are small mol-

FIGURE 4-21 Two-way vesicular axonal transport facilitated by the microtubular “highway” in a neuron. Secretory vesicles are transported from the site of production in the cell body along a microtubule “highway” to the terminal end for secretion. Vesicles containing debris are transported in the opposite direction for degradation in the cell body. The top enlargement depicts kinesin, a molecular motor, carrying a secretory vesicle down the microtubule by using its “feet” to “step” on one tubulin molecule after another. The bottom enlargement depicts another molecular motor, dynein, transporting the debris up the microtubule.

© Cengage Learning, 2013

ecules that typically trigger the opening of specific ion channels to bring about a change in potential in the postsynaptic neuron (an EPSP or IPSP) within a few milliseconds or less. Most classical neurotransmitters are primarily amino acids or closely related compounds synthesized and packaged locally in small synaptic vesicles in the cytosol of the axon terminal. Neurotransmitters at slow synapses activate slower second-messenger systems, but they are made and released in the same way and have similar structures as fast neurotransmitters.

Neuropeptides are larger molecules made up of anywhere from 2 to about 40 amino acids. They are synthesized in the neuronal cell body in the endoplasmic reticulum and Golgi complex (see p. 41) and are subsequently moved by axonal transport along the microtubular highways to the axon terminal (Figure 4-21). Neuropeptides are not stored within small synaptic vesicles but instead are packaged in large **dense-core vesicles**, which are also present in the axon terminal. The dense-core vesicles undergo Ca^{2+} -induced exocytosis and release neuropeptides at the same time that the neurotransmitter is released from the synaptic vesicles. An axon terminal typically releases only a single classical

TABLE 4-4 Some Known or Suspected Neuropeptides

β-endorphin	Motilin
Adrenocorticotrophic hormone (ACTH)	Insulin
α-melanocyte-stimulating hormone (MSH)	Glucagon
Thyrotropin-releasing hormone (TRH)	Angiotensin II
Gonadotropin-releasing hormone (GnRH)	Bradykinin
Somatostatin	Vasopressin
Vasoactive intestinal polypeptide (VIP)	Oxytocin
Cholecystokinin (CCK)	Carnosine
Leucine enkephalin	Bombesin

FIGURE 4-22 Presynaptic inhibition. A, an excitatory terminal ending on postsynaptic cell C, is itself innervated by inhibitory terminal B. Stimulation of terminal A alone produces an EPSP in cell C, but simultaneous stimulation of terminal B prevents the release of excitatory neurotransmitter from terminal A. Consequently, no EPSP is produced in cell C despite the fact that terminal A has been stimulated. Such presynaptic inhibition selectively depresses activity from terminal A without suppressing any other excitatory input to cell C. Stimulation of excitatory terminal D produces an EPSP in cell C even though inhibitory terminal B is simultaneously stimulated because terminal B only inhibits terminal A.

© Cengage Learning, 2013

neurotransmitter, but the same terminal may also contain one or more neuropeptides that are cosecreted along with the neurotransmitter.

Even though neuropeptides are currently the subject of intense investigation, knowledge about their functions and control is still sketchy. For example, proteomic and genomic analysis of the honeybee has revealed 36 genes that code for 100 neuropeptides in the bees' brains, but the functions of these proteins are largely unknown. Some neuropeptides may function as true neurotransmitters, but most are believed to function as neuromodulators. **Neuromodulators** are chemical messengers that do not cause the formation of EPSPs and IPSPs but rather bring about long-term changes that subtly *modulate*—depress or enhance—the action of the synapse. (Neurotransmitters like serotonin at slow synapses also activate slower second-messenger systems and are called neuromodulators by some investigators.) Neuromodulators can bind to neuronal receptors at nonsynaptic sites and they often activate second-messenger systems. These in turn may, for example, alter the sensitivity of the postsynaptic neuron to a particular neurotransmitter by causing long-term changes in the number of subsynaptic receptor sites for the neurotransmitter. Neuromodulators may also act on presynaptic sites. For example, a neuromodulator may influence the level of an enzyme critical in the synthesis of a neurotransmitter by a presynaptic neuron. Thus, neuromodulators delicately fine-tune the synaptic response. The effect may last for days or even months or years. Like some slow neurotransmitters, neuromodulators are involved with more long-lasting events such as learning and motivation.

Interestingly, in “same-key-different-locks” fashion (p. 93), vertebrate neuromodulators include many substances that also have distinctly different roles in other body regions as hormones released into the blood from neural and nonneural tissues. For example, *cholecystikinin* (CCK) is a well-known hormone released from the small intestine that causes the gallbladder to contract and release

bile into the intestine (see Chapter 14). CCK has also been found in axon terminal vesicles in various areas of the rat brain, where it mediates satiety (the feeling of no longer being hungry; Chapter 15) and perhaps other unknown activities. As is the case for many neuropeptides, CCK was named for its first-discovered role as a hormone (*chole*, “bile”; *cysto*, “bladder”; *kinin*, “contraction”).

Presynaptic inhibition or facilitation can selectively alter the effectiveness of a given presynaptic input

Besides neuromodulation, presynaptic inhibition or facilitation is another means of depressing or enhancing synaptic effectiveness. Sometimes a third neuron influences activity between a presynaptic ending and a postsynaptic neuron. A presynaptic axon terminal (labeled A in Figure 4-22) may itself be innervated by another axon terminal (labeled B). The neurotransmitter released from modulatory terminal B binds with receptor sites on terminal A. This binding alters the amount of transmitter released from terminal A in response to action potentials. If the amount of transmitter released from A is reduced, the phenomenon is known as **presynaptic inhibition**. If the release of transmitter is enhanced, the effect is **presynaptic facilitation**.

Let's look more closely at how this process works. You know that Ca^{2+} entry into an axon terminal induces the release of neurotransmitter by exocytosis of synaptic vesicles. The amount of neurotransmitter released from terminal A depends on how much cytosolic Ca^{2+} enters this terminal in response to an action potential. Ca^{2+} entry into terminal A, in turn, can be influenced by activity in modulatory terminal B. Let's use presynaptic inhibition to illustrate (Figure 4-22). The amount of transmitter released from presynaptic terminal A, an excitatory input in our example, influences the potential in the postsynaptic neuron on which it terminates (labeled C

FIGURE 4-23 Convergence and divergence. Arrows indicate the direction in which information is being conveyed.

© Cengage Learning, 2013

in the figure). Firing of A alone will bring about an EPSP in postsynaptic neuron C. Now consider that B is stimulated simultaneously with A, reducing Ca^{2+} entry into terminal A. Less Ca^{2+} entry means less neurotransmitter release from A. Note that modulatory neuron B can suppress neurotransmitter release from A only when A is firing. If this presynaptic inhibition by B prevents A from releasing its neurotransmitter, the formation of EPSPs on postsynaptic membrane C from input A is specifically prevented. As a result, no change in the potential of the postsynaptic neuron occurs despite action potentials in A.

Could the same thing be accomplished by a simultaneous production of an IPSP through activation of an inhibitory input to negate an EPSP produced by activation of A? Not quite. Activation of an inhibitory input to cell C in Figure 4-22 would produce an IPSP in cell C, but this IPSP could cancel out not only an EPSP from excitatory presynaptic input A, but also any EPSPs produced by other excitatory terminals, such as terminal D in the figure. The entire postsynaptic membrane is hyperpolarized by IPSPs, negating (canceling) excitatory information fed into any part of the cell from any presynaptic input. By contrast, presynaptic inhibition (or presynaptic facilitation) works in a much more specific way than does the action of inhibitory inputs to the postsynaptic cell.

Presynaptic inhibition provides a means by which certain inputs to the postsynaptic neuron can be *selectively* inhibited without affecting contributions of any other inputs. For example, firing of B specifically prevents formation of an EPSP in the postsynaptic neuron from excitatory presynaptic neuron A but does not influence other excitatory presynaptic inputs. Excitatory input D can still produce an EPSP in the postsynaptic neuron even when B is firing. This type of neuronal integration is another means by which electrical signaling between neurons can be carefully fine-tuned.

Retrograde messengers travel “backward” and also modulate synaptic function

Although the primary message being relayed through a synapse travels in one direction in most animals, researchers are finding an increasing number of examples of **retrograde**

signals. In such cases, a stimulated postsynaptic cell may produce and release a signal molecule that diffuses backward, that is, to the presynaptic terminal. Once there, it does not trigger a message to travel up the axon; rather, it modifies the sensitivity of the terminal in a prolonged or long-term way (a type of neuromodulation). One example is in the neuromuscular synapse of the laboratory fruit fly (*Drosophila*). The primary neurotransmitter from the neuron to the muscle is glutamate (not ACh as in vertebrates). The (postsynaptic) muscle cell also produces a peptide that travels to the (presynaptic) neuron. There it enhances release of glutamate. The system appears to work in negative-feedback fashion for “synaptic homeostasis.” The muscle produces *more* peptide when it is unstimulated and *less* when stimulated. This tends to keep the amount of glutamate released at a consistent level. In the next chapter, we describe how *nitric oxide* in a vertebrate can be used in a positive-feedback retrograde system (p. 199).

Neurons are linked to each other through convergence and divergence to form complex nerve pathways

Two important relationships exist between neurons: convergence and divergence. A given neuron may have many other neurons synapsing on it. Such a relationship is known as **convergence** (Figure 4-23). Through this converging input, a single cell is influenced by thousands of other cells. This single cell, in turn, influences the level of activity in many other cells by divergence of output. The term **divergence** refers to the branching of axon terminals so that a single cell synapses with and influences many other cells.

Note that a particular neuron is postsynaptic to the neurons converging on it but presynaptic to the other cells on which it terminates. Thus, the terms *presynaptic* and *postsynaptic* refer only to a single synapse. Most neurons are presynaptic to one group of neurons and postsynaptic to another group.

There are an estimated 100 billion neurons and 10^{14} (100 quadrillion) synapses in the human brain alone. When

you consider the vast and intricate interconnections possible between these neurons through converging and diverging pathways, you can begin to imagine how complex the wiring mechanism of an animal's nervous system can be. Even the most sophisticated computers are far less complex than the vertebrate brain. For this reason, scientists (using the Krogh principle, p. 3) look at simpler systems (mainly certain non-vertebrates) to study neural function. This approach has been very successful because the “language” of *all* nervous systems is in the form of graded potentials, action potentials, neurotransmitter signaling across synapses, and other forms of chemical chatter such as neuromodulation. All activities for which the nervous system is responsible—every sensation in an animal, every command to move a muscle, every thought, every memory, every spark of creativity—all depend on the patterns of electrical and chemical signaling between neurons along these complexly wired neural pathways. In the next chapter, you will see how using simpler nervous systems reveals universal principles.

Why are action potentials initiated at the axon hillock?

How does presynaptic inhibition or facilitation depress or enhance synaptic activity?

Through what process does a single neuron influence the activity of others? How is a single neuron influenced by other neurons?

4.8 Neural Signaling and External Agents

Neural signaling mechanisms are the targets of many external chemical and physical agents. Their effects play an important role in evolutionary adaptation, research, and medicine. Some are accidentally acquired as poisons or by disease processes, and some are toxins evolved in prey organisms for defense and in predators for paralyzing or killing prey. Many plants and fungi, for example, have evolved defensive neurotoxins presumably because there is no chance these can poison their own tissues. In addition, some of those agents as well as purely human-made ones can be used to help researchers probe the mechanisms of neural signaling, and may also be used as pharmacologic agents (drugs). Virtually every step of signal transmission is vulnerable. We end this chapter with illustrative examples.

Synthetic and natural toxins can alter resting potentials and action potentials

Let's start with the electrical signaling processes. External chemicals have long been used for research and medicine. For example, researchers have studied the role of K^+ channels in resting and action potentials using the synthetic compound *tetraethylammonium* (TEA). TEA selectively blocks most types of gated K^+ channels when placed at either the ICF or ECF. However, it does not block the K^+ leak

channels. Many predators and prey have toxins that also target axonal transmission; some that are used in research and medicine include:

- *Ouabain* (p. 87), a plant poison that stops the Na^+/K^+ pump. In research, it has been used to show that this pump is not directly involved in the firing of action potentials.
- One type of *tarantula venom* specifically targets the paddle (see box, p. 118) of shaker K -channels, and its use in the laboratory helps reveal the paddle's role in gating.
- *Conotoxins* from certain predatory cone snails are used to block ion channels in pain neurons, as you may recall from Chapter 2 (see box, p. 34).

There are many other examples too numerous to list here. For details on the evolution of one toxin, see the box, *Molecular Biology and Genomics: Neurotoxins in War and Peace*.

Drugs, natural toxins, and pollutants can modify synaptic transmission between neurons

Most drugs that influence the nervous system perform their function by altering synaptic mechanisms. Synaptic drugs may block an undesirable effect (antagonist) or enhance a desirable effect (agonist). Possible actions include (1) altering the synthesis, axonal transport, storage, or release of a neurotransmitter; (2) modifying neurotransmitter interaction with the postsynaptic receptor; (3) influencing neurotransmitter reuptake or destruction; and (4) replacing a deficient neurotransmitter with a substitute transmitter.

Consider the reuptake step. The widely prescribed drug *Prozac* (fluoxetine), used for treatment of some abnormal moods and behaviors, alters serotonin reuptake (see the box, *Challenges and Controversies: Synaptic Solutions to Pet Problems*). Similarly, *cocaine* (an *alkaloid* from the coca plant where it is thought to poison insect nerves) blocks reuptake of the neurotransmitter **dopamine** at presynaptic terminals by competitively binding with the dopamine reuptake transporter, a protein molecule that picks up released dopamine from the synaptic cleft and shuttles it back to the axon terminal. With cocaine occupying the dopamine transporter, dopamine remains in the synaptic cleft longer than usual and continues to interact with its postsynaptic receptor sites. The result is prolonged activation of neural pathways that use this chemical as a neurotransmitter. Among these pathways are those that play a role in emotional responses, especially feelings of reward (at least in humans). In essence, when cocaine is present, the neural switches in the reward pathway are locked in the “on” position.

Cocaine is addictive to humans and laboratory rodents (who will choose cocaine over food and water even to the point of death) because the involved neurons become *desensitized* to the drug. Permanent molecular changes of the involved neurons result from cocaine usage such that they cannot transmit normally across synapses without increasingly higher doses of the drug. After the neurons have been incessantly stimulated for an extended time by cocaine, a transcription factor (p. 31) called δ -*FosB* is activated by unknown means. This factor, in turn, activates the gene for an enzyme called *cyclin-dependent kinase 5* or *Cdk5*. *Cdk5* greatly reduces sensitivity for cocaine (again, by unknown

Molecular Biology and Genomics

Neurotoxins in War and Peace

Neurotoxins in nature are widespread “warfare” mechanisms for both attack and defense; their targets are animal nerves, but they are made not only in some animals but also in some bacteria, protists, fungi, and plants. A well-studied example is **tetrodotoxin (TTX)**, best known in the tropical marine Japanese pufferfish (*Fugu rubripes*) and related species. Because of the toxicity of this compound, chefs in Japan require years of training before they are permitted to serve pufferfish to their patrons. TTX is specific for voltage-gated Na^+ channels and binds to the extracellular region of the channel. However, if injected inside the neuron, TTX has no effect on action potential propagation, demonstrating that TTX is specific in blocking the entry of Na^+ .

TTX is widespread in the animal kingdom, found not only in pufferfish but also in other not closely related fish, the blue-ringed octopus, some seastars, crabs, snails, tunicates, flatworms, ribbon worms, some terrestrial frogs and newts, and even algae. Have these diverse organisms evolved the genes for this toxin independently, or do they all have something in common? Recent studies make

it clear that most, or perhaps all of these organisms, lack the ability to synthesize TTX. Pufferfish, one of the animals whose genome has been sequenced, have no genes related to TTX synthesis, and they cannot make it if grown in isolated aquaria. It is now clear that *symbiotic bacteria* manufacture the toxin for their hosts. The blue-ringed octopus of Australia, for example, has been found to harbor these bacteria. Thus, it now seems that a peaceful, beneficial coexistence has independently evolved between these bacteria and a number of animal hosts. Presumably, the bacteria are given nourishment and protection in the symbiosis. In turn, the TTX made by the bacteria is used by some of these organisms as defense (such as algae and pufferfish) and by others to kill prey (such as carnivorous snails).

TTX is one of the most potent blockers of animal sodium channels known. How do the host animals themselves survive their bacterial partners? Genetic analysis reveals that the pufferfish has a single point muta-

tion in its sodium-channel gene, rendering the channel protein resistant to TTX binding. Presumably similar mutations have occurred in other TTX hosts. But resistant channels are found elsewhere: Garter

Photo: © Masa Ushioda/Imagoequestmarine.com

snakes that eat TTX-bearing newts have recently been found to have these as well.

The TTX story illustrates a general principle of biology called **coevolution**, in which adaptations in one species select for new adaptations in other species—those that are prey, predator, competitor, or symbiote. In turn, these changes in the second species may lead to yet newer adaptations in the first species . . . and so on.

mechanisms). Whatever the mechanism, the synapses require more and more cocaine to achieve a stimulus and thus a reward feeling. When cocaine is no longer available, the sense of reward cannot be achieved, because the normal level of dopamine release is no longer sufficient to stimulate the postsynaptic neuron. Note that this is a form of *acclimatization* or *downregulation* (p. 17).

Other drugs and toxins may cause nervous system disorders by acting at either presynaptic or postsynaptic sites agonistically or antagonistically. For example, *caffeine*, another compound in certain plants that disrupts neural function in herbivorous insects, blocks the receptors for the inhibitory neuromodulator *adenosine*. Adenosine is used in the sleep circuits of mammalian brains, explaining caffeine’s stimulatory effects. *Ethyl alcohol*, in contrast, enhances the action of inhibitory GABA receptors (p. 133), one of the reasons it lowers reaction speeds.

Two other neural poisons, *strychnine* and *tetanus toxin*, act at different synaptic sites to block inhibitory impulses, yet have similar outcomes. One (strychnine) blocks specific postsynaptic inhibitory receptors, whereas the other (tetanus toxin) prevents the presynaptic release of a specific inhibitory neurotransmitter:

- *Strychnine*, a poison used to kill rodents that infest buildings, competes with an inhibitory neurotransmitter,

glycine, at the postsynaptic receptor site. This antagonist combines with the receptor but does not directly alter the potential of the postsynaptic cell. Instead, strychnine blocks the receptor so that glycine cannot bind when it is released from the inhibitory presynaptic ending. Thus, postsynaptic inhibition (formation of IPSPs) is abolished in nerve pathways that use glycine as an inhibitory transmitter. Unchecked excitatory pathways lead to convulsions, muscle spasticity, and death.

- *Tetanus toxin* from *Clostridium tetani* bacteria, in contrast, prevents release of another inhibitory transmitter, gamma-aminobutyric acid (GABA), from inhibitory presynaptic inputs terminating on neurons that supply skeletal muscles. Unchecked excitatory inputs to these neurons result in uncontrolled muscle spasms. These spasms occur especially in the jaw muscles early in the disease, giving rise to the common name of **lockjaw** for this condition. Later, they progress to the muscles responsible for breathing, at which point the disease proves fatal.

Some pollutants can inhibit neural signaling. Lead (Pb^{2+}), for example, is an important environmental toxicant because it competes with Ca^{2+} for entry into the terminal button. Once ingested by an animal, Pb^{2+} at high doses inhibits neural transmission, which can kill the animal.

Challenges and Controversies

Synaptic Solutions to Pet Problems

Ever since the identification of the synapse as the functional junction between two neurons, the synapse has been regarded as the most vulnerable physiological site for manipulation and artificial regulation. Behavioral pharmacotherapy, the use of drugs to treat behavioral problems, is an example of a science that has evolved from this original precept. Interestingly, scientists observed that during the course of treatment with antihistamines for congestion, some human patients noted a significant improvement in emotional state. In fact, many psychoactive drugs are chemically similar to antihistamines. Psychoactive drugs exert their behavioral effects by acting on neurotransmitters and neuromodulators in the brain (see p. 189). For example, treatment with drugs that selectively inhibit reuptake of *serotonin* into the neuron (such as **Prozac**, an **SSRI**—selective serotonin reuptake inhibitor) results in a higher level of activity in any part of the nervous system that uses serotonin as a chemical signal.

Serotonin is the common name for **5-hydroxytryptamine (5-HT)**. It is synthesized in the brain from the amino acid tryptophan. Because there are at least nine different serotonin receptor subtypes, each localized separately in the mammalian brain and responsible for different behavioral responses, regulation of the se-

rotonin receptor system is particularly complex. In mammals, serotonin plays an important role in the control of sleep, pain, aggression, sexual behavior, and food intake. This diverse range of responses is not surprising, considering that serotonin neurons project fibers to virtually all parts of the central nervous system. Documented effects of SSRIs in dogs include a reduction in the intensity of obsessive-compulsive disorders such as excessive licking behavior, tail mutilation, separation anxieties, dominance-related aggression, and so forth. In cats, SSRIs are used for the treatment of psychogenic alopecia (unnatural loss of hair), offensive aggression, and urine spraying. Prozac has been used to treat cribbing (force-swallowing gulps of air) in horses and bulimia (episodes of binge eating that continue until terminated by abdominal pain or vomiting) in pigs.

Tricyclic antidepressants (so called because of their three-ringed chemical structure) also block the reuptake of serotonin and catecholamines from synapses, which promotes a state of calmness. Tricyclics can be used to treat urine spraying in cats, urine marking in dogs, and separation anxiety in both cats and dogs. These drugs are also useful in the treatment of stereotypies. **Stereotypies** are repetitive behaviors that perform no function (such as pacing in zoo animals). They

arise from chronic confinement, chronic conflict, or sensory deprivation, and researchers suggest they provide some relief. Chemical intervention is normally warranted to eliminate stereotypies because, once incorporated into an animal's behavioral repertoire, the stereotypy continues to be performed even in the absence of the initiating stressor.

Neuroleptics represent a family of drugs whose mode of action is the antagonism of dopamine (p. 189) and are effective in treating certain phobias, fears, and anxieties. Phobias are extreme and apparently irrational fears whose origins can normally be identified. For example, animals may be fearful of people or of other animals, sensory stimuli such as sounds (thunderstorms), odors, or touch, or exhibit phobias under specific circumstances such as visiting the veterinarian's office. These compounds are also effective in preventing anxiety-related inappropriate urine marking and spraying in cats. Neuroleptics are used in the treatment of stereotypic disorders such as flank biting in horses, fur sucking in cats, and feather picking in birds. Although many of these and other drugs show promise in the treatment of fear-based conditions in pets, veterinarians recommend that chemical therapy be combined with behavioral modification in order to achieve long-lasting results.

Other drugs and diseases that influence synaptic transmission are too numerous to mention, but as these examples illustrate, any site along the synaptic pathway is vulnerable to interference, either pharmacologic (drug induced) or pathologic (disease induced).

The neuromuscular junction is vulnerable to several chemical agents and diseases

Several chemical agents and diseases affect the neuromuscular synapse by acting at different sites in the transmission process. Two well-known toxins—*black widow spider venom* and *curare*—alter the function of ACh, but in different ways.

The venom of black widow spiders exerts its deadly effect on small prey animals (not humans) by causing an explosive release of ACh from the storage vesicles, not only at neuromuscular junctions but at all cholinergic sites. Thus, the toxin is an agonist (p. 101). All cholinergic sites undergo

prolonged depolarization, the most detrimental consequence of which is respiratory failure in a bitten mammal. Breathing is accomplished by alternate contraction and relaxation of skeletal muscles, particularly the diaphragm. Respiratory paralysis occurs as a result of prolonged depolarization of the mammalian diaphragm. During this so-called **depolarization block**, the voltage-gated Na⁺ channels are trapped in their inactivated state (that is, their activation gate remains open and their inactivation gate remains closed; they are in their “closed and not capable” of opening conformation; see p. 120). This depolarization block prohibits the initiation of new action potentials and resultant contraction of the diaphragm. As a consequence, the spider's victim cannot breathe.

Other chemicals are antagonists (p. 100) that interfere with neuromuscular junction activity by blocking the effect of released ACh. The best-known example is **curare** (curare is derived from *wurari* meaning “poison,” a word from the Carib language of the Macusi Indians of Guyana), which is

obtained from tropical plants of the family Loganiaceae in South America. Curare reversibly binds to the ACh receptor sites on the motor end plate. Unlike ACh, however, curare does not alter membrane permeability, nor is it inactivated by AChE. When ACh receptor sites are occupied by curare, ACh cannot combine with these sites to open the channels that would permit the ionic movement responsible for an EPP. Consequently, because muscle action potentials cannot occur in response to nerve impulses to these muscles, paralysis ensues. The toxin presumably evolved to protect these frogs from predators: When sufficient curare is present to effectively block a significant number of ACh receptor sites, the predator dies from respiratory paralysis caused by an inability to contract the diaphragm. Some indigenous people in South America use curare as a deadly arrowhead poison. Curare and related drugs have also been used medically (at very low doses!) during surgery to help achieve more complete skeletal muscle relaxation with less anesthetic.

An example of a disease that affects the junction is *myasthenia gravis*, characterized by extreme muscle weakness. It is caused by antibodies of an animal's own immune system that attack ACh receptors of the junction. This *autoimmune* (p. 486) disease has been documented in cats, dogs, and humans. The drug **neostigmine**, which inhibits AChE, is used to treat this because its action prolongs the activity of whatever amount of ACh is released at the synapse.

Temperature and pressure also influence action potentials and synapses

Finally, evolutionary adaptation of animals has been greatly affected by physical factors that alter neural functions. In particular, temperature as well as pressure exerts pronounced effects on membrane processes. Recall from Chapter 3 (p. 71) that cold temperatures can make membranes too rigid, and high temperatures can make them too fluid. Temperature also directly affects the rates of all reactions and protein structures (p. 13), including channel opening and closing. The effects of temperature are discussed in detail in Chapter 15.

Effects of an increase in pressure on cells are more complex, and most are not discussed here. Briefly, high pressure can inhibit the proper folding of proteins, reduce movement of proteins during shape changes, and reduce membrane fluidity. Such effects presumably explain the effects of pressure on animals that are unadapted to pressure, which include the following:

- A reduction in the activity of the Na^+/K^+ pump
- A decrease in the rate at which an action potential is propagated
- A decrease in the rate of axonal repolarization and an increase in axon potential duration
- Inhibition of excitatory synaptic transmission, because of reduced neurotransmitter release from the presynaptic terminal
- Reduced binding of ACh to its receptor on the muscle membrane

All these effects are potentially detrimental to animals living permanently in the deep sea. However, some of these effects are minimized or not apparent in such animals (e.g., deep-sea fish and shrimp). Adaptations include membranes with

higher fluidity, achieved by a decrease in the ratio of saturated to unsaturated fatty acids (as you saw in Chapter 3 for temperature, p. 72). We discuss another form of adaptation in Chapter 13.

Such adaptations have not occurred in shallow-living animals that occasionally experience high pressure—in particular, deep-diving marine mammals such as Weddell seals and sperm whales. However, these effects may be useful to these divers, contributing to an energy-saving reduction in heart rate when the animals descend to depth. For example, at high pressures (150 atm), the conduction velocity of an impulse in a seal's heart is reduced by 40%. We explore these and other aspects of deep diving in Chapter 11.

How Neuronal Physiology Contributes to the Body as a Whole

Neurons are specialized to receive, process, encode, and rapidly transmit information from one part of the body to another. The information is transmitted over intricate nerve pathways by propagation of action potentials along the neuron's length as well as by chemical transmission of the signal from neuron to neuron and from neuron to muscles and glands through neurotransmitter–receptor interactions at synapses and from neuron to muscles and glands through other neurotransmitter–receptor interactions at these junctions.

Collectively, neurons make up the nervous system, one of the two major control systems of the body. To maintain homeostasis, cells must communicate so that they work together to accomplish life-sustaining activities. Many of the activities controlled by the nervous system are thus geared toward maintaining homeostasis. Some neuronal electrical signals convey information about changes to which the body must respond in order to maintain homeostasis—for example, these signals convey information about a reduction in blood pressure. Other neuronal electrical signals convey messages to muscles and glands to stimulate appropriate responses to counteract these changes—for example, the nervous system through its electrical signals initiates adjustments in heart and blood vessel activity to restore blood pressure to normal when it starts to fall, or to initiate behaviors that aid survival such as feeding when low internal energy supplies are sensed.

The specialization of muscle cells, contraction, also depends on these cells' ability to undergo action potentials. Action potentials trigger muscle contractions, many of which are important in maintaining homeostasis. For example, beating of the heart, mixing of ingested food with digestive enzymes, and shivering to generate heat when a mammal is cold are all accomplished by muscle contractions.

Chapter Summary

- Neurons and muscle cells are excitable tissues; that is, they can produce electrical signals when stimulated.
- Electrical signals are produced by changes in ion movement through ion channels across the plasma membrane. There are two types of channels: leak channels, or nongated channels, which are open all the time; and gated channels, which can be opened or closed in response to specific triggering events.
- There are at least three kinds of gated channels: (1) voltage-gated ion channels, which open or close in response to changes in membrane potential; (2) chemically gated channels, which change in response to the binding of a specific chemical messenger with a membrane receptor that is in close association with the channel; and (3) mechanically gated channels, which respond to stretching or other mechanical deformation.
- There are two basic forms of electrical signals: (1) the more primitive graded potentials, which serve as short-distance decaying signals, and (2) action potentials, which signal over longer distances without decaying.
- The stronger a triggering event, the larger the resultant graded potential.
- The passive movement of the electrical depolarization in a graded potential can be described by Ohm's law, where ΔV_m is the actual voltage change across the membrane, ΔI the amount of current (amperes), and R the resistance encountered by the current passing along the membrane (ohms).
- Action potentials are brief, rapid, large (100 mV) changes in membrane potential during which the potential actually reverses so that the inside of the excitable cell transiently becomes more positive than the outside. Action potentials are propagated from the axon hillock to the axon terminals. Action potentials occur in all-or-none fashion.
- The action potential is an electrical waveform composed of depolarization, repolarization, and hyperpolarization. The rising phase of the action potential (from threshold to +30 mV) is due to Na^+ influx (Na^+ entering the cell) induced by an explosive increase in P_{Na^+} at threshold. The falling phase (from +30 mV to resting potential) is brought about by K^+ efflux (K^+ leaving the cell) caused by the marked increase in P_{K^+} occurring simultaneously with the inactivation of the Na^+ channels at the peak of the action potential.
- The Na^+/K^+ ATPase pump gradually restores the concentration gradients disrupted by action potentials.
- A single nerve cell, or neuron, consists of three basic parts: the cell body, the dendrites, and the axon, although there are variations in structure, depending on the location and function of the neuron.
- An excitable membrane either responds to a triggering event with a maximal action potential that spreads nondecrementally throughout the membrane, or it does not respond with an action potential at all. Once initiated, action potentials are conducted over the surface of an axon.
- The refractory period ensures unidirectional propagation of the action potential and limits the frequency of action potentials. The strength of a stimulus is coded by the frequency of action potentials.
- Myelination increases the speed of conduction of action potentials and conserves energy in the process. In a myelinated fiber, the impulse "jumps" from node to node, skipping over the myelinated sections of the axon; this process is called saltatory conduction. Fiber diameter also influences the velocity of action potential propagation.
- Electrical synapses transfer action potential waveforms through gap junctions, whereas chemical synapses convert action potentials into organic chemical messengers that are exocytosed into the synaptic gap.
- Most, but not all, neurotransmitters function by changing the conformation of chemically gated channels, thereby altering membrane permeability and ionic fluxes across the postsynaptic membrane. Some neurotransmitters excite the postsynaptic neuron, whereas others inhibit the postsynaptic neuron.
- Acetylcholine, a fast excitatory neurotransmitter, links electrical signals in motor neurons with electrical signals in skeletal muscle cells. Acetylcholinesterase terminates acetylcholine activity at the neuromuscular junction.
- The grand postsynaptic potential depends on the sum of the activities of all presynaptic inputs. The postsynaptic neuron can be brought to threshold in two ways: (1) temporal summation and (2) spatial summation.
- Presynaptic inhibition or facilitation can selectively alter the effectiveness of a given presynaptic input. Retrograde messengers travel "backward" and also modulate synaptic function.
- Neurons are linked to each other through convergence and divergence to form complex nerve pathways.
- Drugs and natural toxins, such as ouabain, tetrodotoxin, caffeine, cocaine, and Prozac, as well as pollutants such as lead, can modify action potentials and synaptic transmission between neurons and the neuromuscular junction.

Review, Synthesize, and Analyze

1. Why is the electrotonic flow of current along a membrane faster than current flow generated by action potentials?
2. What is the relative importance of the Na^+/K^+ pump in action potential propagation?
3. How does a neuron ensure that action potential propagation is one-way?
4. Compare the role of myelin in vertebrates with that in nonvertebrates. Consider that the rate of nerve conduction observed in the myelinated axons of the penaeid shrimp is comparable to that observed in vertebrates (200 m/sec).
5. Why does that portion of the excitable membrane where graded potentials are initiated not undergo an action potential?

6. How does the delayed opening of K^+ channels lead to the repolarization stage of impulse propagation?
7. Can the movement of charges along an axon truly be considered a “flow”?
8. Through what process can the postsynaptic membrane influence the activity of the presynaptic membrane? Under what circumstances is this communication important?
9. Why are there multiple neurotransmitters? Would it not be simpler to have fewer neurotransmitters associated with postsynaptic receptors specific to a particular function?
10. The synthetic compound *tetraethylammonium (TEA)* selectively blocks most types of gated K^+ channels, but it does not block the K^+ leak channels. Explain what happens to membrane potential after an action potential spike with TEA present, and why.

Nervous Systems

5.1 Evolution of Nervous Systems

With this chapter, we begin examining the organ systems of animals, starting with those involved in whole-body regulation. The nervous system is one of two such control systems of an animal body, the other being the endocrine system (although some researchers include the immune system as a third). In general, the nervous system coordinates rapid responses, whereas the endocrine (hormonal) system (Chapter 7) regulates activities that require duration rather than speed. Consider that electrical conduction is faster and more precise than

the diffusion of chemicals, something that enables more rapid detection and a coordinated response to either perceived threats or available opportunities. With increasing complexity, a nervous system can recall past experiences and anticipate the future.

Nervous systems evolved from simple reflex arcs to centralized brains with distributed, hierarchic regulation

In all animals the ultimate function of the nervous system is to rapidly translate sensory information into action potentials (APs), which can be processed (integrated) into an adaptive response via activation of effector organs. The adaptive response is often one that, in negative-feedback fashion, corrects in some way for a disturbance that initiated the sensory information (see Figure 1-8). Although feedback regulation can occur locally within cells and tissues, nervous systems have

the advantages of (1) providing rapid regulation over greater distances, and (2) coordinating multiple organs. If the regulatory response involves movement via one or more effector skeletal muscles, the response is called a **behavior**. The most basic pathway for accomplishing this is known as a **reflex arc**, with the simplest of these having a sensory neuron that also controls an effector cell directly, as shown in Figure 5-1a.

However, most reflex arcs have two or more neurons involved, with information being transmitted through one or more intermediate synapses (Figure 5-1b, c). These intermediate synapses constitute the simplest form of a **central nervous system (CNS)**, where signals from more than one neuron can be integrated. The ability to have multiple synaptic connections allowed for the evolution of complex control of responses. For example, an integrator neuron can have inputs from a “higher” integrator such as a brain (Figure 5-1d). The higher regulatory center modifies the basic reflex response: It may

© Cengage Learning, 2013

suppress the reflex, alter its sensitivity, or activate it in advance of a disturbance in *anticipation* fashion. The “higher” input may modify the reflex based on past experience, that is, on *memory*. Integrating neurons in a CNS also allows for sophisticated behaviors, which involve multiple sensory inputs and multiple controls of effector muscles.

Because of these advantages, the evolution of a CNS is a major trend in animal evolution. This has been generally associated with two other significant trends: (1) the evolution of longitudinal *centralization*, the association of diffuse neuronal cell bodies into a distinct longitudinal *nerve cord*, as well as (2) *cephalization*, the concentration of neurons in

the head, the leading part of an animal’s body that typically deals with more environmental information than do other parts. That is, over evolutionary time in many animal groups, the interneuronal component progressively expanded, formed more complex interconnections especially at the head end of the nervous system, forming a brain. From the brain, many neural control pathways became routed through the centralized nerve cords. Associated with this evolution was the acquisition of more specialized receptors for sensing the external environment and the routing of their information through the nerve cord to the brain for processing.

Let's examine the relationship between simple reflex circuits and a CNS with cephalization in more detail. Although more advanced animals do indeed have centralized brains, it is important to note that no animal has fully centralized cephalic control of all its functions. As you saw in Chapter 1, many functions in advanced animals remain regulated at the *intrinsic* cell/organ levels and at "lower" neural reflex levels, that is, regulation is *distributed* in a hierarchy from simple functions at the local level to complex functions at the cephalic level. There is a very important reason for this: the time-delay phenomenon for feedback regulation, as discussed in Chapter 1 (p. 16). A centralized brain is not always necessary and may even be detrimental for some kinds of neural regulation. A simple example—the *withdrawal reflex* in a mammal (Figure 5-1e)—illustrates this. Here, a potentially harmful stimulus to the skin such as intense heat triggers heat and pain sensors, which send action potentials to a spinal (CNS) integrating synapse and neuron that then sends signals back to a skeletal muscle, the effector, which then rapidly pulls the stimulated area away from the heat. Consider what would happen were this reflex regulated by fully centralized cephalic control. The signal would need to go all the way to the brain, presumably passing through many more synapses, before the muscle could be activated. By that time, the skin would be seriously burned. Thus, advanced neural regulation involves distributed control, with simple, *common homeostatic functions typically remaining at the reflex level* through a central nerve cord (or physically close brain regions) with a minimal number of synapses. However, the brain's usefulness comes into play in other situations, such as anticipation. For example, based on past experience of a burn, the brain may detect a potentially hot object from a distance and trigger the limb (or body) to move away *before* the skin sensors register painful heat.

The logic of this distributed control hierarchy is being used by human engineers building robots that mimic animal locomotion. Initially, engineers designed all movements to be controlled by a centralized computer using sensor inputs and outputs to motors. These robots were invariably clumsy at even the simplest walking movement because of the time delays. Later, using "biologically inspired" distributed control, engineers began to build robots that were much more stable and agile. To do so, they incorporated the simplest walking movements into the legs themselves, with the central computer reserved for dealing with unusual, complex motions.

Now let's examine the evolutionary trends in animal nervous systems in more detail.

Sponges have no nerves but can respond to stimuli using electrical signals

Sponges are interesting because they are the only animals without neurons. Yet some sponges react to external stimuli in reflex fashion. For example, the deep-sea sponge *Rhabdocalyptus dawsoni* stops its feeding currents if sediment-laden water enters its pores (threatening to clog them) or if the body is touched. Action potentials have been measured spreading from the outer cells to the rest of the sponge body, including the flagellate cells that create feeding currents (see Chapter 9, p. 386). Unlike action potentials that last for 1 msec in more complex animals, the action potential in the sponge lasts for about 5 seconds. The electrical pathway is thought to be the *trabecular reticulum*, a **syncytium** (a group of joined cells act-

ing as one functional unit) that connects all parts of the sponge. The reticulum is not made of true neurons. Sponges do, however, contain some of the genes associated with the production of proteins localized on the postsynaptic membrane of a nerve. In more complex nervous systems, these proteins characteristically anchor the neurotransmitter receptors in the membrane. Intriguingly, cells in the sponge's larvae express genes whose products stimulate neural stem cells in more complex animals to differentiate into fully functional neurons. Studies have demonstrated that the insertion of the larval sponges' genes into frog embryos or fruit fly larvae result in the generation of extra neurons.

Nerve nets are the simplest nervous systems and are found in most animals

The simplest existing nervous system (with true neurons) is the nerve net in Cnidarians (such as hydra, sea anemones, and jellies) (Figure 5-2a, b). These consist of diffuse networks of neurons without centralization or cephalization. Of course, Cnidarian nervous system evolution has occurred over a period of perhaps 700 million years, so nerve nets, although comparatively simple and diffuse in structure, should not be considered primitive but rather a successful evolutionary strategy that has enabled survival of these widespread animals. The nerve net extends throughout the animal's body, monitoring the environment through sensory neurons responsive to mechanical, chemical, and sometimes light stimuli. Motion is controlled by *motor-neurons* that synapse on muscle cells, which stimulate simple movements of the body wall and tentacles; for example, in jellies, the net primarily commands the body wall to slowly contract and expand for swimming and the tentacles to move through the water. The axons of the sensory neurons sometimes make direct connections to motoneurons, which then activate muscles with little or no integration. But in some cases, there are intermediate interneurons, which integrate information.

Of particular interest (following the Krogh principle, p. 3) is the freshwater hydra, a Cnidarian that continuously replaces all its tissues, and thus, unless eaten, is immortal! Therefore, it is an excellent model animal for studying neural growth and development and the most basic neural functions and behaviors. Hydra neurons are continually sloughed at the extremities, so that individual neurons continually change their relative position to each other. New neurons are formed by differentiation from *stem cells* (p. 3), and synapses are formed where neurons cross each other. For this reason, excitations originating in one neuron spread in all directions along multiple paths. Sensory cells are situated in the epidermis such that the animal can respond to external stimuli from any direction. Branches of the nerve net are connected to these sensors and to epithelial cells that have contractile properties.

Neuron density in the nerve net is higher in the hydra's head and foot region compared to its body column, but it is insufficient to label either of these regions as an integrating center in the sense of a CNS. However, not all hydra neurons are in diffuse nets. Some neurons are concentrated in well-defined bundles, which are believed important in simple reflex behavioral responses. Feeding behavior, for example, involves interconnections between sensory neurons in the tentacles and contractile epithelial cells lining the tentacles

FIGURE 5-2 **Nerve net of a sea anemone, a Cnidarian.** (a) A living anemone. (b) Diagram of nerve net with sensory and contractile cells. The cell types are embedded in epithelium between the outer epidermis and a jellylike midlayer (*mesoglea*) of the body wall. (c) Model of possible origin of the nervous system in a Cnidarian. A *multifunctional cell* (as found in some larvae jellies) with a sensory body that triggered its own contractile region (left panel) may have split into separate sensory and muscle cells with a connecting interneuron.

and surrounding the mouth. When the sensory receptors come into contact with a potential food item, the ensuing signals generate a reflex response that ultimately draws the food item into the mouth. These bundles may represent the evolutionary precursors of central nervous systems.

Nerve nets are found not just in Cnidarians. Every phylum, including the chordates, has diffuse nerve nets retained from early evolutionary stages. In vertebrates, nets take the form of a **nerve plexus** (network of interwoven nerves),

located in the intestinal wall, which is responsible for propelling digesta (food being processed) along the intestine (p. 661). In some animals, the nerve net may have a sensory function, whereas in others, nerve nets are used to modulate the activity of an organ by releasing neurotransmitters or neuromodulators (p. 138). And in some instances, nerve nets may be used to coordinate behavior such as locomotion. In mollusks, for example, motor nerve nets are associated with local reflex pathways.

unanswered Questions | How did nervous systems evolve?

We do not know how the first nervous system evolved, but a clue comes from primitive excitable cells in the bells of some jelly (Cnidarian) larvae (Figure 5-2c). These *multifunctional* cells are both sensors and effectors: If the outer sensory part of the cell is touched, action potentials are initiated that travel to the inner musclelike part of the cell, which contracts to cause the jelly to swim. This cell may have evolved into separate sensors and muscles with interconnecting neurons (also found in jellies) as a way to coordinate distant regions of the body. See the Suggested Reading by Miller (2009).

As more complex animals evolved, nervous systems made of tens of thousands to billions of neurons arose. These cells form networks in which the “wiring” is often very precise; that is, individual neurons make specific connections with other neurons or target organs in the same locations in different individuals of the same species. As some researchers have put it, it is as if every single neuron has its own unique genetically coded “address.” How can this happen when there are far more neurons than genes? We don’t yet fully know, but at least part of the answer lies in *alternative RNA splicing* (p. 32). In a remarkable finding, Dietmar Schmucker, James Clemens, and colleagues documented in *Drosophila* (fruit flies) that one gene called *Dscam* (Down syndrome cell adhesion molecule) could generate over 38,000 different proteins via alternative splicing! Dscams (so named for the similar gene in humans that plays a role in Down syndrome) act as CAM receptors (p. 74) on growing axons that help specify connections to target cells. (See also p. 490 for Dscam’s role in immunity.)

Another mechanism to explain neuronal specificity and diversity is *RNA editing*. Here, an existing mRNA’s code is altered by an enzyme; for example, cytidine (C) can be changed to a uridine (U). This further amplifies the number of proteins that can arise from one gene, and occurs widely in all eukaryotes and tissues, but most prominently in neural tissue. Considerable levels of both alternative splicing and RNA editing occur in vertebrate brain development. Intriguingly, neural RNA editing appears to have greatly increased in the evolution of primates, with the highest level being found in humans. <<

Simple ganglia and nerve rings evolved for more complex behavior

More complicated neural circuitry can be found in *medusae* (free-swimming forms such as scyphozoan or true jellies, cubomedusae or box jellies, and hydromedusae—jellylike larvae of hydroids). In these radially symmetric animals, a distribution of sensory structures over a full 360 degrees is advantageous because there is no optimal direction from which sensory information is received. Unlike sessile hydra, however, swimming Cnidarians must coordinate more complex behaviors, especially swimming and orienting in the

open water. In these animals, radial symmetry is often associated with (1) a **nerve ring** or “ring brain,” and (2) (in some of these animals) selected neurons are condensed into simple *ganglia*. A **ganglion** (singular of *ganglia*) is a group or cluster of nerve cell bodies, often with related functions. Like hydra bundles, ganglia and rings represent steps of centralization between nerve nets and true brains.

An example of ganglia is found in the **rhopalium**, a complex of primitive sensory organs and integrating ganglia in medusae. It has **ocelli** (simple eye structures, p. 240) and **statocysts** (fluid-filled sacs that help indicate position as the animal moves, p. 218). The rhopalium ganglia in scyphomedusae (true jellies) also function as **pacemakers** (excitable cells that fire spontaneously), which generate the swimming rhythm by continually stimulating waves of contraction. Transmission of action potentials in either direction down an axon is achieved by the presence of gap junctions as well as *bidirectional chemical synapses*, which allow neurons to transmit in either direction. In these simple nerve nets, each synaptic ending is simultaneously pre- and postsynaptic because neurotransmitter vesicles are present on both sides of the synaptic junction.

Now let’s look at nerve rings. The hydromedusa *Aglantha* uses two: an inner pacemaker ring that controls normal, slow swimming, and an outer ring in the bell margin that controls escape swimming behavior in response to mechanical stimuli to the body. The outer ring has a single giant axon (35 mm) that is unique: It forms a perfect *annulus* (ringlike body part) with neither a beginning nor an end. Action potentials are conducted at rates up to 4 m/sec. Firing of the ring giant axons generates action potentials (approximately 95 mV), which lead to forceful contractions of the swimming muscle and pulsation of the bell. In contrast, slow swimming is generated by smaller-amplitude action potentials (approximately 27 mV), which originate from the pacemaker system.

Nerve rings are also found in the radially symmetric echinoderms (seastars, sea urchins, and so on). These animals are considered more advanced than Cnidarians, and their ancestors had bilateral symmetry with a CNS. But presumably because they “re-evolved” radial symmetry, they have also independently evolved a nerve ring system. In seastars, the parallel with hydromedusae is even more striking because seastars have primitive eyespots on the tips of their arms that send information about light into the central ring.

A true CNS first evolved with bilateral symmetry

As you have seen, radially symmetric animals do not have a true CNS, although they may have some centralization in the form of bundles, ganglia and rings. Only when we progress to bilaterally symmetric animals such as platyhelminths (flatworms, tapeworms, and so on) do we find the beginnings of a true CNS—longitudinal nerve cords that coordinate nervous activity—in conjunction with a **peripheral nervous system (PNS)**, a communication network that extends between the CNS and all parts of the animal’s body. Flatworms represent an early stage in the evolution of a CNS (Figure 5-3a). They have two anterior ganglia from which branch two principal nerve cords with lateral neurons connecting the two cords and projecting to the various regions of the body. Collectively, the ganglia can be thought of as a rudimentary brain because they serve as an integrat-

ing center for particular nerve pathways. Ganglia within the head of a flatworm coordinate signals arising from sensory organs such as the eyespots. The longitudinal nerve cord evolved for transmitting motor signals to effectors located bilaterally along the animal's elongated body.

The next evolutionary advance is found in a more complex ganglionic CNS, a characteristic of more advanced protostomes such as annelids, arthropods, and some mollusks (Figure 5-3b, c, d, e). In segmented animals, the CNS consists of a chain of *segmental ganglia*. Paired bundles of axons, termed **connectives**, link one ganglia to its neighbors. For example, the CNS of annelids (Figure 5-3b) consists of a bilobed *brain* with a double nerve cord with ganglia (one in most body segments), connecting with separate sensory and motor neurons (in the PNS). These networks rely on one-way conduction along the nerve axons. Ganglia are larger in arthropods (Figure 5-3c, d) and are associated with more highly developed sense organs. Generally, there is one ganglion for each thoracic and abdominal body segment, although some arthropods show secondary fusion of some of these ganglia. Ganglia in each segment are specialized in coordinating the regional function of each body segment, that is, legs, wings, tail or abdomen, and structures on the head. *Decentralized* brain function best describes the neural circuitry of these animals. For example, the ability to copulate is not in the least impaired in a decapitated male praying mantis. The female can be steadily consuming her mate while

being inseminated at the same time! (Nutrients provided by the male in this manner ultimately help ensure the development of the ova within the female.) You will soon see that elements of segmental organization are also found in vertebrates and govern the regulation of many reflex actions.

Arthropod ganglia consist of an outer rind and an inner core. In some ganglia, virtually all the neuron cell bodies are located in the rind, with the central region containing the synaptic contacts and bundles of nerve processes (called the

neuropil). The packing of pre- and postsynaptic neuronal branches into a dense neuropil reduces transmission delays that are characteristic of animals with diffuse nerve nets. The degree to which the nervous system is organized into a cellular rind varies among species.

True brains evolved at the anterior end of complex animals

Finally, in some groups there has been an evolutionary trend for the most anterior region of the CNS to be larger and contain sizable clusters of neurons, which contributed to the evolution of a so-called *superganglion* or **brain**. These are found in the more complex nonvertebrates that we just discussed (Figure 5-3b, c, d, e). As we noted earlier, the anterior position of brains is believed to be an evolutionary adaptation resulting from the tendency of the head of bilaterally symmetric animals to move forward, so that newly acquired sensory information about the environment is initially detected in the anterior region. Some sensory information is then integrated in the brain, and command signals are sent to modulate the functioning of particular effectors, especially skeletal muscles. Again, in the logic of distributed hierarchic control, the simplest basic responses remain regulated at “lower” levels of the CNS in most animals, but cephalization allows for more complex functions such as processing complex sensory information (such as images), learning and memory, and ultimately self-awareness.

As an example, the brain of insects consists of three pairs of lobes, the **protocerebrum**, which innervates the compound eyes and ocelli and also responds to olfactory input, the **deutocerebrum**, which innervates the antennae, and the **tritocerebrum**, which innervates the foregut and labrum (upper lip). These centers process sensory information for whole-body coordination, such as moving towards an odorous food source. However, as we noted earlier, some functions such as copulation in praying mantises are located in “downstream” ganglia.

The most advanced brains are found in the cephalopod mollusks (squids, cuttles, nautiloids, and octopods; Figure 5-3e) and in vertebrates (which we examine in detail later). In general, evolution has favored the addition of new structures to brains rather than modification of existing ones. More primitive structures have retained their basic functions and, in vertebrates, are layered beneath the newly evolved ones. This preserves the important distributed hierarchy of control we discussed earlier, but it can also lead to maladaptive behaviors (as you will see later). The relative proportion of a particular region of the brain indicates the relative importance of that function to the animal. For example, in vertebrates relying primarily on tactile stimuli for perception, the regions of the brain that process this information are significantly larger. The large *optic lobe* of birds and *visual cortex* of primates are examples of the importance of visual information for survival in these animals. In contrast, weakly electrical fish that use electrical currents for intraspecies communications exhibit relative hypertrophy of the *cerebellum* and *rhombencephalon*, those areas of the brain involved in processing electrosensory information.

It has generally been thought that the brains of protostomes, such as annelids and arthropods, evolved independently of deuterostome (e.g., chordate) brains (see Figure 1-1). However, recent studies by Detlev Arendt and col-

leagues may have overthrown this idea. They examined the expression of microRNAs (regulators of gene expression; p. 33) and also 42 genes essential to brain development in the brains of a marine annelid, an insect, and a vertebrate. To everyone’s surprise, they found that the timing and location of the microRNAs and genes were amazingly similar in all three animals. Thus, cephalization may have begun only once in the history of evolution.

Cephalopod brains have complex structures supporting complex behaviors

An illustrative trend of cephalization and centralization occurred in cephalopods. Mollusks in general have two nerve cords running down each side of the body (in contrast to the single cord in many other animal types; see Figure 5-3). Along the cords are several pairs of ganglia. The most anterior ganglia are joined and enlarged in some species, forming a brain that in most mollusks is small. In cephalopods, however, these joined ganglia are greatly enlarged and organized into a series of specialized, tightly packed lobes (Figure 5-3e). The brain has many similarities to those of vertebrates: Both have lobes with complex folds, and both generate similar electrical wave patterns. Distinct visual and tactile memory centers have also been identified in cephalopod brains, and one area, the vertical lobe, is involved in learning tasks. Another vertebrate attribute, specialization in the brain’s hemispheres (p. 194), has also been demonstrated in octopods. For example, octopuses, which rely on monocular vision, favor one eye over the other.

The cephalopod CNS shows the hierarchic distributed arrangement that we have discussed earlier. Indeed, one recent study revealed that the octopus’s arms contain simple motor programs that are completely independent of the brain. That is, certain stereotypical movements used daily, such as reaching out and then curling up around prey animals, occur even in a stimulated arm removed from the animal. Thus, the brain probably sees the prey, sends a “go” command to the arms, and the local “reach out and grab” program in the arm itself does the rest. Again, this avoids feedback delays to the brain that might allow the prey to escape. (As you will see, many motor programs in vertebrates are similarly arranged.)

The large brain of cephalopods is involved more directly in other, more complex processes. Controversial evidence suggests that octopods can learn as effectively as some mammals and may even be able to learn by observing other octopods. Moreover, individual octopods and cuttles seem to “invent” unique behaviors not found in others of their species, suggesting that such behaviors are probably not innate. Squid, cuttle, and octopod brains also control an elaborate array of **chromatophores** in their skins. These pigment cells of varying colors can be neuronally (and therefore rapidly) expanded or contracted to display different color patterns. In some cuttles, around 40 distinct color patterns have been observed being used in various behaviors such as mating, territorial displays, and possibly other social interactions such as alarm warnings. Cuttlefish are the only nonvertebrates known to exhibit specific reactions to different kinds of predators. Some researchers have even proposed that these patterns form a kind of language. Color patterns are also used for camouflage, often in complex ways. In some octopods, camouflage patterns are coupled with sophisticated

mimicry behavior; for example, a Malaysian octopod species has been seen using its arms and colors to simulate sea snakes and molding its entire body to mimic a flounder or a seastar (p. 357).

Despite similarities between cephalopod and vertebrate brains, they clearly evolved independently, because detailed structures are quite different. For example, the cephalopod brain is wrapped around the esophagus instead of lying in a cranium. An example of the often-illogical nature of evolution (pp. 2–3), this is not a very good “design” because spines of prey animals can actually pierce the cephalopod brain if they get caught in the esophagus!

Vertebrate brain size varies up to 30-fold for a given body size

The total number of neurons in nervous systems ranges from only several hundred in simple animals, such as nematodes (approximately 300 neurons), to approximately 10^8 in some cephalopods and 10^{11} in large mammals. Because of these numbers as well as the complexity of their neural circuitry, brain function in cephalopods rivals that of some vertebrates, as evidenced by the intricacy of their behavior compared to other nonvertebrates. In the human brain, the number of neurons is approximately 8 to 9×10^{10} , whereas larger mammals such as elephants and whales show a further twofold increase in number. This example illustrates that the total number of neurons does not correspond to intellect! The exhibition of specific behavioral patterns is far more dependent on the internal wiring of the brain rather than on its overall size and depends on the ratio of the brain size to body size.

The logarithm of brain weight as a function of body weight is typically linear for a variety of vertebrates, with a positive slope indicating that the overall size of an animal is related to its relative brain size (Figure 5-4). (The slope is less than 1.0, meaning that brain size does not increase as much as body weight does. This *scaling* phenomenon is explored for metabolism in Chapter 15.) However, as you have just seen, the various regions of the brain do not necessarily vary directly with body weight. For example, the forebrain shows a disproportionately large size relative to body weight in primates, whereas there is a relatively large cerebellum and rhombencephalon in many bony fishes. There are also significant exceptions to the basic scaling of total brain size with some species exhibiting five times the predicted size, whereas others have approximately one-fifth the predicted size. Brain size varies approximately 30-fold for a given body size when considered across all vertebrate radiations. Some interesting trends include:

- Agnathans (hagfish, lampreys) generally have the smallest brains for their body size, but hagfishes have brains two to three times larger than lampreys of the same body size.
- Many cartilaginous fishes (sharks and rays) have brains as large for their body size as those of many birds and mammals.
- Among amphibians, frogs generally have larger brains than salamanders, whereas the brains of reptiles are two to three times larger than the brains of most amphibians of the same body size.
- The most complex vertebrate classes, birds and mammals, have brains that are up to 10-fold larger than the brains of reptiles of the same body size. Interestingly, the

FIGURE 5-4 Weights of adult cephalopod brains compared to those of various vertebrates. Upward triangle *Sepia* squid; downward triangle *Loligo* squid; 1, *Octopus vulgaris*; 2, *O. salutilii*; 3, *O. defillipi*; 4 and 5, squids *Illex* and *Todarodes*.

Sources: Modified from H. J. Jerison (1976), Paleoneurology and the evolution of mind, *Scientific American* 234:90–100; and K. Mangold-Wirz (1966), Cerebrisation und Ontogenesemodus bei Eutherien, *Acta Anatomica* 63:449–508

brains of octopods and squids are larger on average (relative to body size) than most animals, except some cartilaginous fishes, birds, and mammals (Figure 5-4).

- The largest brains relative to body size among birds are found in the perching birds (woodpeckers and parrots), whereas the smallest brains are in the granivores (quail and pigeons).
- The brains of migratory birds and bats are generally smaller than those of similar-sized nonmigrators, suggesting that the weight of a large brain is too costly for long-range migration.
- Brain size of primates, in general, is much greater than the average for mammals of the same body size, although the second largest relative brain size (after humans) is found in dolphins (cetaceans). In contrast, the insectivores, rodents, and nonplacental mammals (marsupials, monotremes) have the smallest brains.

For primates, numerous theories have been put forward to explain differences in relative brain size. For example, primates that consume leaves generally have smaller brains than those that eat fruits. This observation leads to the idea that a larger brain is required of animals that must use their intellect to locate ripened fruits, compared to those that simply find leaves. Carnivores (who must hunt wary prey) also tend to have larger brains than herbivores. Also, selection for an increase in the size of a single brain center leads to an overall increase in brain size. For example, dolphins with their relatively large brains are carnivores that use echolocation, a process requiring considerable neural power, corresponding to a relative large auditory cortex. In contrast, baleen whales, which do not echolocate and do not hunt wary prey, have brains that are relatively small for their body size. A relationship between relative size of the brain and the complexity of social organization (which is quite advanced in dolphins, for example) has also been suggested.

Relative brain size may be explained by the expensive-tissue hypothesis

Scientists have also proposed the **expensive-tissue hypothesis** to explain relative brain size, following the concept of evolutionary cost–benefit trade-offs you saw in Chapter 1 (pp. 2–3). The metabolic cost of neural tissue is comparatively very high because of the energy required to maintain the membrane potential across axonal membranes. Thus, neurons contain numerous energy-consuming ion pumps. Energy is also expended by the continuous synthesis and reuptake of neurotransmitters. The larger the brain, the greater the expenditure of energy. In this model, the cost of maintaining increasingly larger brains is offset by a corresponding reduction in the size of the intestinal tract. The splanchnic organs (liver, gastrointestinal tract) are equally as expensive, in terms of energy expenditure, as neural tissue. Because gut size is highly correlated with the quality of diet (see Chapter 14), and relatively small intestinal tracts are associated with high-quality foodstuffs, a reduction in the size of one of these metabolically expensive organs is “traded off” against a greater degree of cephalization. Thus, the increase in brain size could not have been achieved without a concomitant increase in quality of the diet, and high-quality diets are associated with reduced size (and energy cost) of the intestinal tract. This pattern is seen in a general comparison between carnivores and herbivores: The former are large-brained, with high-quality diets, whereas the latter are small-brained and often eat low-quality fibrous plants that require large digestive tracts to process.

This largely *proximate* (p. 1) hypothesis does not explain which evolved first: a higher-quality diet (which then favored greater intelligence), or nondietary selective forces favoring a larger brain (which then gave the ability to find higher-quality food). Also, an exception to this relationship has been found in bats: Insect-eating bats have smaller brains than their fruit-eating relatives. In this example, researchers found no correlations either with social complexity or with the relative size of the digestive tract. Finally, an additional explanation for the relative brain size of mammals takes into account the relative brain size of the mother and the brain size of the developing offspring. The **maternal-energy hypothesis** states that ultimate brain size depends on the allocation of maternal resources to fetal and postnatal development. Because development of the brain begins at an early stage of development, resources provided by the mother can be directly linked to brain development in her offspring, particularly in placental mammals. Note, though, that this is also a proximate hypothesis that does not explain what selective forces would be at work in maternal allocation.

Some nervous systems exhibit plasticity

Ultimately, the way animals act and react depends on organized, discrete neuronal processing. In addition to brain–body size ratios, another key factor in complexity of this processing is change during development and aging. Many nonvertebrate nervous systems appear to have “hard-wired” processing; that is, the neural cell structures underlying behavior are relatively fixed once they have formed. However, cephalopods and vertebrates have nervous systems with some degree of **plasticity** (modifiable cell structures, particularly the number of synaptic connections, axonal and dendritic branches, and neurons). When the immature nervous system develops according to its

genetic plan, an overabundance of neurons and synapses is formed in most vertebrates. Depending on external stimuli and the extent that these pathways are used, some are retained, firmly established, and even enhanced with new branches and connections, whereas others are eliminated. Once the nervous system has matured, ongoing modifications still occur as an animal continues to learn from its unique set of experiences, though less readily. The ability of neurons to respond structurally to usage and incoming stimuli is the basis for certain forms of learning as well as for nervous system regeneration. The nervous system in complex animals thus represents a network of living cells that are modifiable throughout a lifetime.

5.2 The Vertebrate Nervous System: Overview and Peripheral System

As with bilateral animals in general, the nervous system of vertebrates is functionally organized into a *central nervous system (CNS)* and a *peripheral nervous system (PNS)*. In vertebrates, the CNS consists of the brain and spinal cord, and the PNS consists of nerve fibers that carry information between the CNS and other parts of the body (the periphery) (Figure 5-5). In contrast to the organization of the arthropod CNS, which consists of a brain and discontinuous ganglia linked by connectives, the vertebrate CNS arises from a single neural tube and is organized into a continuous column of neuron cell bodies and bundles of diverse axons. There is some similarity, however, in that branches of the vertebrate PNS have a segmented pattern (Table 5-1). Most of the neuronal cell bodies are contained within the CNS. However, the PNS also includes ganglia (also in a segmented pattern) that contain the cell bodies of most sensory neurons and some nonmotor effector neurons. The PNS is further subdivided into *afferent* and *efferent* divisions. The afferent division (*a* is from *ad*, “toward,” as in *advance*; and *ferent*, “carrying”) carries information from *sensors* to the CNS, appraising it of the external environment and providing status reports on internal activities being regulated by the nervous system. In the next chapter, on sensory physiology, we focus on this afferent division. The **efferent division** (*e* is from *ex*, “from,” as in *exit*) transmits instructions from the CNS to **effector organs**—the muscles, glands, and other organs that carry out the orders to bring about the desired action. The efferent nervous system in turn has two or three components (Figure 5-5):

1. The **autonomic nervous system** fibers, which innervate smooth muscle, cardiac muscle, glands, and other non-

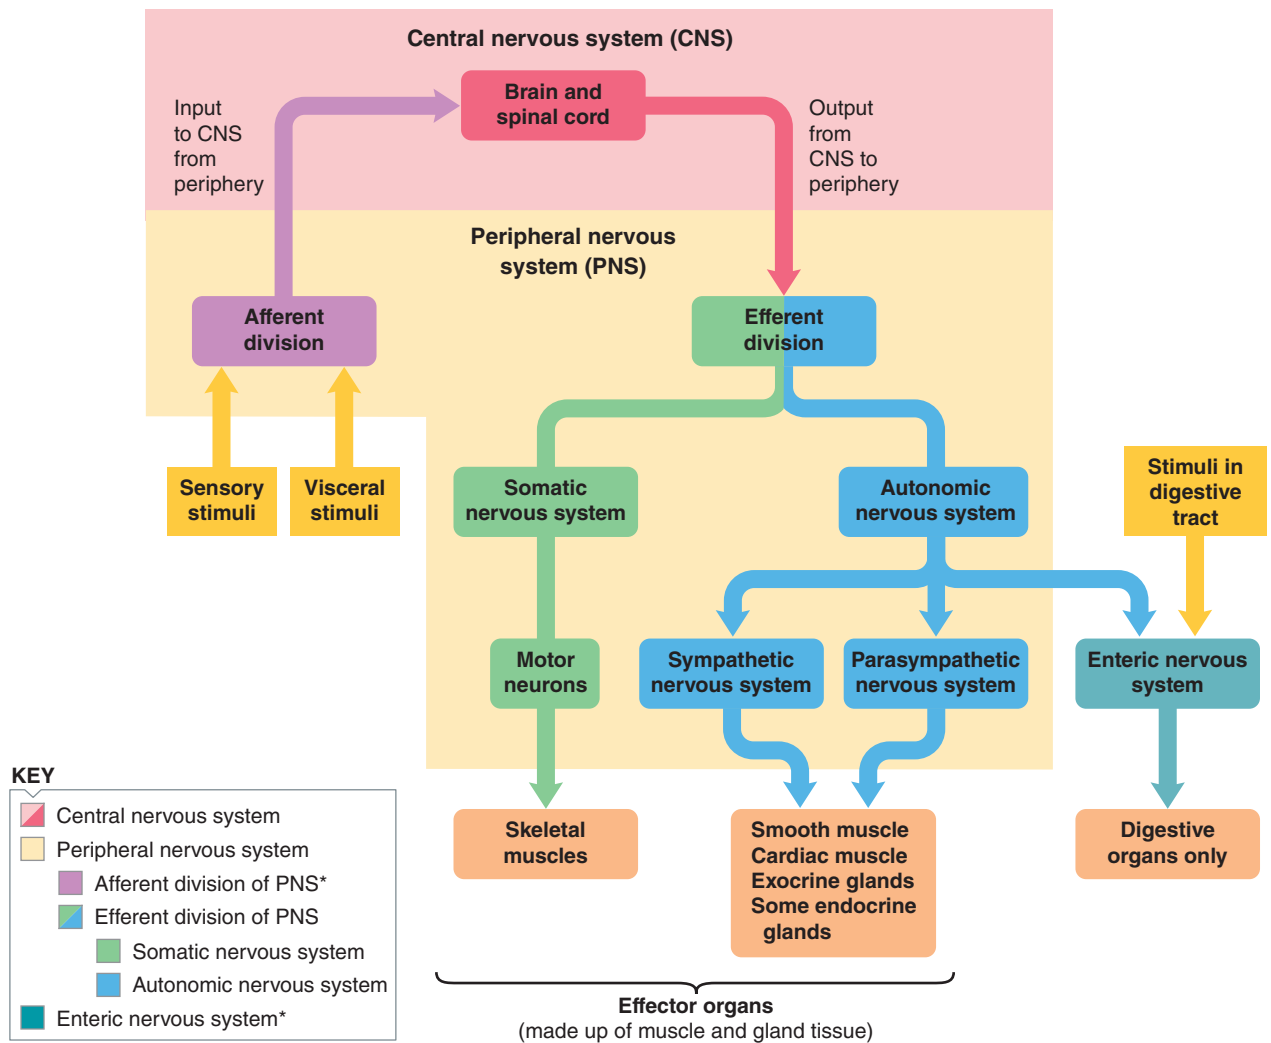

FIGURE 5-5 Organization of the vertebrate nervous system. Afferent fibers travel within the same nerves as efferent fibers but in the opposite direction. The enteric nervous system lies entirely within the wall of the digestive tract.

© Cengage Learning, 2013

motor organs (such as brown adipose tissue, p. 746, and some immune organs, p. 488). In most vertebrates, this system is further subdivided into the **sympathetic nervous system** and the **parasympathetic nervous system**, both of which innervate most of the visceral organs. Not all vertebrates have such clear subdivisions, as evidenced in lampreys where the sympathetic and parasympathetic divisions are difficult to distinguish. In hagfish, the autonomic nervous system is poorly developed.

2. The **somatic nervous system**, which consists of the fibers of the **motor neurons** that supply the skeletal muscles.
3. In addition to the CNS and PNS, the **enteric nervous system** is an extensive nerve network in the wall of the digestive tract. Digestive activities are controlled by the autonomic nervous system and the enteric nervous system as well as by hormones. The enteric nervous system can act independently of the rest of the nervous system but is also influenced by autonomic fibers that terminate on the enteric neurons. Sometimes the enteric nervous system is considered a third component of the autonomic nervous system, one that supplies the digestive organs only.

The somatic system is sometimes called the *voluntary* system, whereas the autonomic and enteric systems are often termed *involuntary*. However, these terms are based on human biology. For other vertebrates, it is more accurate to say simply that the somatic (motor) system controls reflex and more complex nonreflex *skeletal muscle* actions, whereas the other systems operate all other innervated effector organs, generally independently of higher brain regions involved in locomotion, learning, and memory. It is also important to recognize that all these “nervous systems” are really subdivisions of a single, integrated nervous system. They are arbitrary divisions based on differences in the structure, location, and functions of the various diverse parts of the whole nervous system.

The three classes of neurons are afferent neurons, efferent neurons, and interneurons

Three classes of neurons make up the nervous system: *afferent neurons*, *efferent neurons*, and *interneurons*. The afferent division of the PNS consists of **afferent neurons**, which

TABLE 5-1 Comparison of Arthropod and Vertebrate Nervous Systems

Arthropod Nervous System	Vertebrate Nervous System
Anterior brain or large ganglion, with ganglia in body segments linked by paired bundles of connective fibers	Anterior brain with spinal cord having segmental branching pattern

Ganglia are discrete entities within the CNS	Ganglia are a collection of neuronal cell bodies outside the CNS

© Cengage Learning, 2013

are shaped differently from efferent neurons and interneurons (Figure 5-6). At its peripheral ending, an afferent neuron has a **sensory receptor** (Chapter 6) that generates action potentials in response to a particular type of stimulus. (This neuronal receptor should not be confused with the special protein receptors that bind chemical messengers in the plasma membrane of all cells.) The afferent-neuron cell body, which lacks dendrites and presynaptic inputs, is located adjacent to the spinal cord in a ganglion (in the *dorsal root* of a spinal nerve). A long *peripheral axon*, commonly called the *afferent fiber*, extends from the receptor to the cell body, and a short *central axon* passes from the cell body into the spinal cord. Action potentials initiated at the receptor end of the peripheral axon in response to a stimulus are propagated along the peripheral axon and central axon toward the spinal cord. The terminals of the central axon diverge and synapse with other neurons within the spinal cord, disseminating information about the stimulus. Afferent neurons lie primarily within the PNS: only a small portion of their central axon endings project into the spinal cord to relay signals from the periphery to the CNS.

Efferent neurons also lie primarily in the PNS (Figure 5-6). The cell bodies of efferent neurons originate in the CNS, where many centrally located presynaptic inputs converge on them to influence their outputs to the effector organs. Efferent axons (*efferent fibers*) leave the CNS to course their way to the muscles or glands they innervate, conveying their integrated output for the effector organs to put into effect. (An autonomic pathway actually consists of a two-neuron chain between the CNS and the effector organ.)

Interneurons lie entirely within the CNS. In mammals, about 99% of all neurons belong to this category. The human CNS is estimated to have 100 billion interneurons! These neurons, which are the integrator neurons we saw at the beginning of this chapter, serve two main roles. First, as their name implies, they lie between (*inter*, “between”) the afferent and efferent neurons and are important in the integration of peripheral responses to peripheral information, as you saw with the withdrawal reflex earlier (Figure 5-1e). The more complex the required action, the greater the number of interneurons interposed between the afferent message and efferent response. Second, in the most advanced vertebrates, interconnections between interneurons themselves are re-

sponsible for the abstract phenomena associated with the “mind,” such as planning, memory, creativity, intellect, and motivation. These activities are the least understood functions of the nervous system. With this brief introduction to the types of neurons and their location in the various divisions of the nervous system, let’s now turn our attention to the autonomic nervous system and CNS, followed in the next chapter by a discussion of the sensory function of the PNS—the conversion of an environmental stimulus into action potentials.

The efferent division of the vertebrate PNS controls the activities of various effector organs

The efferent division of the PNS is the communication link by which the CNS controls the activities of muscles, glands, and other effector organs that carry out actions, such as making feedback corrections. Efferent output typically influences either movement or secretion. Much of this efferent output is directed toward maintaining homeostasis, but some is not. For example, the efferent output to skeletal muscles is also directed toward nonhomeostatic behaviors, such as play. (It is important to realize that many effector organs are also subject to hormonal control and/or intrinsic control mechanisms.)

How many different neurotransmitters would you guess are released from the various efferent neuronal terminals to elicit essentially all the controlled effector organ responses? The answer: Only two—**acetylcholine (ACh)** and **norepinephrine (NE)**!¹ Acting independently, these neurotransmitters bring about such diverse effects as salivary secretion, bladder contraction, and skeletal-muscle (motor) movements. These effects are a prime example of how the same chemical messenger may elicit a multiplicity of responses from various tissues, depending on specialization of the effector organs (the “same key, different locks” principle, p. 93).

The sympathetic and parasympathetic branches of the autonomic system innervate most visceral organs to control essential visceral functions

Functionally, the autonomic nervous system is involved in many basic, physiological functions that are critical to the survival of a vertebrate. Specifically, it regulates visceral activities normally outside the realm of higher brain control, such as circulation, digestion, thermoregulation, and pupil size (to name a few), and afferent information arising from the viscera (internal organs) usually does not reach higher brain levels (conscious levels in humans). Examples of visceral afferent information include input from the baroreceptors that monitor blood pressure and input from the chemo-

¹ *Noradrenaline (norepinephrine)* is chemically very similar to *adrenaline (epinephrine)*, the primary hormone product secreted by the adrenal medulla gland. Because a U.S. pharmaceutical company marketed this product for use as a drug under the trade name *Adrenalin*, the scientific community in the United States prefers the alternative name “epinephrine” as a generic term for this chemical messenger, and accordingly, “noradrenaline” is known as “norepinephrine.” In most other English-speaking countries, however, “adrenaline” and “noradrenaline” are the terms of choice.

FIGURE 5-6 Structure and location of the three functional classes of neurons.

*Efferent autonomic nerve pathways consist of a two-neuron chain between the CNS and the effector organ.

© Cengage Learning, 2013

receptors that monitor the protein or fat content of ingested food. This input is used to direct the activity of the autonomic efferent neurons.

Most visceral organs are innervated by both sympathetic and parasympathetic nerve fibers (Figure 5-7). Innervation of a single organ by both branches of the autonomic nervous system is known as **dual innervation**. Table 5-2 summarizes the major effects of these autonomic branches. Although the details of this wide array of autonomic responses are described more fully in later chapters that discuss the individual organs involved, several general concepts can be derived now. As can be seen from the table, the sympathetic and parasympathetic nervous systems generally exert opposite effects in a particular organ. For example, sympathetic stimulation increases the heart rate, whereas parasympathetic stimulation decreases it; sympathetic stimulation slows down movement within the digestive tract, whereas parasympathetic stimulation enhances digestive motility. Note that both systems increase the activity of some organs and reduce the activity of others.

Rather than memorizing a list such as that presented in Table 5-2, you will do better to logically deduce the actions of the two systems based on an understanding of the circumstances under which each system dominates. Usually, both systems are partially active; that is, normally some level of action potential activity exists in both the sympathetic and the parasympathetic fibers supplying a particular organ. This ongoing activity is called **sympathetic** or **parasympathetic tone** or **tonic activity**. Under given circumstances, activity of one division can dominate the other. *Sympathetic dominance* to a particular organ exists when the sympathetic fibers' rate of firing to that organ increases above tonic level, coupled

with a simultaneous decrease below tonic level in the parasympathetic fibers' frequency of action potentials to the same organ. The reverse situation is true for *parasympathetic dominance*. Shifts in balance between sympathetic and parasympathetic activity can be accomplished discretely for individual organs to meet specific demands (for example, sympathetically induced dilation of the pupil in dim light; see p. 242), or a more generalized, widespread discharge of one autonomic system in favor of the other can be elicited to control bodywide functions. Massive widespread discharges take place more frequently in the sympathetic system. The value of this potential for massive sympathetic discharge is evident, considering the circumstances during which this system usually dominates.

The sympathetic system dominates in times of “fight or flight”

The sympathetic system promotes responses that prepare a vertebrate for strenuous physical activity in the face of emergency or other stressful situations, such as a physical threat from the environment. This response is typically referred to as a **fight-or-flight response** because the sympathetic system readies the body to fight against or flee from the threat. The changes are not homeostatic in every case; rather, many physiological systems are *reset* (p. 18) to different levels. In other cases, the changes are anticipatory, to maintain homeostasis with little or no delays. Think about the body resources needed in such circumstances. The heart beats more rapidly and more forcefully; the respiratory airways open wide to permit maximal air flow; glycogen (stored sugar) and fat stores are broken down to release extra fuel into the blood; and blood vessels supplying skeletal muscles dilate (open more widely). All these responses are aimed at providing increased flow of oxygenated, nutrient-rich blood to the skeletal muscles in anticipation of strenuous physical activity. Furthermore, the pupils dilate and the eyes adjust for far vision, enabling the animal to make a quick visual assessment of the entire threatening scene. In some species, sweating or panting is promoted, in anticipation of excess heat production by the physical exertion. Because digestive and urinary activities are inessential in meeting the threat, the sympathetic system inhibits (i.e., restricts lower) these activities.

The parasympathetic system dominates in times of “rest and digest”

The parasympathetic system, in contrast, dominates in quiet, relaxed situations. Under such nonthreatening circumstances, the body can be concerned with its own “general housekeeping” activities, such as digestion and emptying of the urinary bladder. The parasympathetic system promotes these types of bodily functions while slowing down those activities that are enhanced by the sympathetic system. In a tranquil setting, for example, the animal does not need to have its heart beating rapidly and forcefully.

TABLE 5-2 Effects of the Autonomic Nervous System on Various Organs

Organ	Effect of Sympathetic Stimulation (and Types of Adrenergic Receptors)	Effect of Parasympathetic Stimulation
Heart	Increased rate, increased force of contraction (of whole heart) (β_1)	Decreased rate, decreased force of contraction (of atria only)
Blood Vessels	Constriction (α_1)	Dilation of vessels supplying the penis and clitoris only
Lungs	Dilation of bronchioles (β_2) Inhibition of mucus secretion (α)	Constriction of bronchioles Stimulation of mucus secretion
Digestive Tract	Decreased motility (α_2, β_2) Contraction of sphincters (to prevent forward movement of contents) (α_1) Inhibition of digestive secretions (α_2)	Increased motility Relaxation of sphincters (to permit forward movement of contents) Stimulation of digestive secretions
Gallbladder	Relaxation	Contraction (emptying)
Urinary Bladder	Relaxation (β_2)	Contraction (emptying)
Eye	Dilation of pupil (contraction of radial muscle) (α_1) Adjustment for far vision (β_2)	Constriction of pupil (contraction of circular muscle) Adjustment for near vision
Liver (Glycogen Stores)	Glycogenolysis (glucose released) (β_2)	None
Adipose Cells (Fat Stores)	Lipolysis (fatty acids released) (β_2)	None
Exocrine Glands		
<i>Exocrine pancreas</i>	Inhibition of pancreatic exocrine secretion (α_2)	Stimulation of pancreatic exocrine secretion (important for digestion)
<i>Sweat glands</i>	Stimulation of secretion by most sweat glands (α_1)	Stimulation of secretion by some sweat glands
<i>Salivary glands</i>	Stimulation of small volume of thick saliva rich in mucus (α_1)	Stimulation of large volume of watery saliva rich in enzymes
Endocrine Glands		
<i>Adrenal medulla</i>	Stimulation of epinephrine and norepinephrine secretion (cholinergic)	None
<i>Endocrine pancreas</i>	Inhibition of insulin secretion; stimulation of glucagon secretion (α_2)	Stimulation of insulin and glucagon secretion
Genitals	Ejaculation and orgasmic contractions (males); orgasmic contractions (females) (α_1)	Erection (caused by dilation of blood vessels in penis [male] and clitoris [female])
Brain Activity	Increased alertness (receptors unknown)	None

Dual innervation gives precise, antagonistic control

What is the advantage of dual innervation of organs with nerve fibers whose actions oppose each other? It enables precise control over an organ's activity, like having both an accelerator and a brake to control the speed of a car. If an animal suddenly darts across the road as you are driving, you could eventually stop if you simply took your foot off

the accelerator, but you might stop too slowly to avoid hitting the animal. If you simultaneously apply the brake as you lift up on the accelerator, however, you can come to a more rapid, controlled stop. In a similar manner, a sympathetically accelerated heart rate could gradually be slowed to normal after a stressful situation by decreasing the rate of firing in the cardiac sympathetic nerve (letting up on the accelerator), but the heart rate can be reduced more rapidly by simultaneously increasing activity in the parasympathetic

FIGURE 5-8 Autonomic nerve pathway.

© Cengage Learning, 2013

supply to the heart (applying the brake). Indeed, the two divisions of the autonomic nervous system are usually reciprocally controlled; increased activity in one division is accompanied by a corresponding decrease in the other. Thus, dual innervation of an organ by the two branches of the autonomic system permits more precise control over the organ. This is the *antagonistic negative-feedback* design we saw in Chapter 1 (p. 16).

There are several exceptions to the general rule of dual reciprocal innervation by the two branches of the autonomic nervous system (Table 5-2); the most notable are the following:

- *Innervated blood vessels* (most arterioles and veins are innervated; arteries and capillaries are not) for the most part receive only sympathetic nerve fibers. Regulation is accomplished by increasing or decreasing the firing rate above or below the tonic level in these sympathetic fibers. The only blood vessels to receive both sympathetic and parasympathetic fibers are those supplying the penis and clitoris. The precise vascular control this dual innervation affords these organs is important in accomplishing erection (see Chapter 16).
- *Most sweat glands* are innervated only by sympathetic nerves. The postganglionic fibers of these nerves are unusual because they secrete ACh rather than NE.
- *Salivary glands* are innervated by both autonomic divisions, but unlike elsewhere, sympathetic and parasympathetic activity is not antagonistic. Both stimulate salivary secretion, but the saliva's volume and composition differ, depending on which autonomic branch is dominant.

An autonomic nerve pathway consists of a two-neuron chain

Each autonomic nerve pathway extending from the CNS to an innervated organ consists of a two-neuron chain (Figure 5-8) (except to the adrenal medulla; you will learn more about this exception later). The cell body of the first neuron in the series is located in the CNS. Its axon, the **preganglionic fiber**, synapses with the cell body of the second neuron, which lies within a ganglion outside of the CNS. The axon of the second neuron, the **postganglionic fiber**, innervates the effector organ.

Sympathetic nerve fibers originate in the thoracic and lumbar regions of the spinal cord (see p. 176). Most sym-

thetic preganglionic fibers in birds and mammals are very short, synapsing with cell bodies of postganglionic neurons within paravertebral (*para*, “near”) ganglia that lie in a **sympathetic ganglion chain** (the **sympathetic trunk**) located along either side of the spinal cord (Figures 5-7 and 5-9). Long, postganglionic fibers originating in the ganglion chain terminate on the effector organs. Some preganglionic fibers pass through the ganglion chain without synapsing and terminate later in sympathetic *collateral ganglia* located about halfway between the CNS and the innervated organs, with postganglionic fibers traveling the remainder of the distance. An unusual group of ganglia found in birds, referred to as the *intestinal* or *Remak's* nerve, consists of both sympathetic and parasympathetic components. This nerve is located along the entire length of the alimentary canal from the duodenum to the cloaca.

Parasympathetic preganglionic fibers arise from the cranial (brain) and sacral areas (lower spinal cord) of the CNS. (Some cranial nerves contain parasympathetic fibers.) These fibers are long in comparison to sympathetic preganglionic fibers because they do not end until they reach **terminal ganglia** that lie in or near the effector organs. Very short postganglionic fibers terminate on the cells of the organ itself.

Parasympathetic postganglionic fibers release acetylcholine; sympathetic ones release norepinephrine

Sympathetic and parasympathetic preganglionic fibers release the same neurotransmitter, ACh (acetylcholine), but the postganglionic endings of these two systems release different neurotransmitters that influence the effector organs. Parasympathetic postganglionic fibers release acetylcholine. Accordingly, they, along with all autonomic preganglionic fibers, are called **cholinergic fibers**. Most sympathetic postganglionic fibers, in contrast, are called **adrenergic fibers** because they release NE (norepinephrine or noradrenaline). Both acetylcholine and norepinephrine also serve as chemical messengers elsewhere in the body (Table 5-3).

Postganglionic autonomic fibers do not end in a single terminal swelling like a synaptic knob. Instead, the terminal branches of autonomic fibers contain numerous swellings, or **varicosities**, that simultaneously release neurotransmitter over a large area of the innervated organ rather than on single cells (Figures 5-8 and 8-31). This diffuse release of neurotransmitter, coupled with the fact that any resulting change in electrical

FIGURE 5-9 Autonomic nervous system. The sympathetic nervous system, which originates in the thoracolumbar regions of the spinal cord, has short cholinergic (acetylcholine-releasing) preganglionic fibers and long adrenergic (norepinephrine-releasing) postganglionic fibers. The parasympathetic nervous system, which originates in the brain and sacral region of the spinal cord, has long cholinergic preganglionic fibers and short cholinergic postganglionic fibers. In most instances, sympathetic and parasympathetic postganglionic fibers both innervate the same effector organs. The adrenal medulla is a modified sympathetic ganglion, which releases epinephrine and norepinephrine into the blood. Nicotinic cholinergic receptors are located in the autonomic ganglia and adrenal medulla and respond to ACh released by all autonomic preganglionic fibers. Muscarinic cholinergic receptors are located at the autonomic effectors and respond to ACh released by parasympathetic postganglionic fibers. α_1 , α_2 , β_1 , β_2 adrenergic receptors are variably located at the autonomic effectors and differentially respond to norepinephrine released by sympathetic postganglionic fibers and to epinephrine released by the adrenal medulla.

© Cengage Learning, 2013

activity is spread throughout a smooth or cardiac muscle mass via gap junctions (see p. 66), means that whole organs instead of discrete cells are typically influenced by autonomic activity.

The adrenal medulla, an endocrine gland, is a modified part of the sympathetic nervous system

The *adrenal gland*, which lies above the kidney on each side (*ad*, “next to”; *renal*, “kidney”), is an endocrine gland consisting of an outer portion, the *adrenal cortex*, and an inner portion, the *adrenal medulla*. The **adrenal medulla** is a modified sympathetic ganglion that does not give rise to postganglionic fibers. Instead, on stimulation by the preganglionic fiber that originates in the CNS, it secretes hormones directly into the blood (Figures 5-9 and 5-10). Not surprisingly, the hormones are identical or similar to postganglionic sympathetic neurotransmitters. In mammals, NE ranges from about 2% of the adrenal medullary hormone output in rabbits to almost 50% in pigs, while the output of norepinephrine is as high as 80% in chickens and whales. In all species studied, fetal adrenal tissue contains predominantly NE. The remaining secretion is the closely related substance **epinephrine** (**adrenaline**) (see footnote 1, p. 158). These hormones, in general, reinforce activity of the sympathetic nervous system.

Several different receptor types are available for each autonomic neurotransmitter

Because each autonomic neurotransmitter and medullary hormone stimulates activity in some tissues but inhibits activity in others, the particular responses must depend on the specialization of the tissue cells rather than on properties of the chemicals themselves. Responsive tissue cells have one or more of several different types of plasma membrane receptor proteins for these chemical messengers (“same key, different locks”). Binding of a neurotransmitter to a receptor induces the tissue-specific response, as follows:

1. **Cholinergic nicotinic receptors.** Two types of acetylcholine (*cholinergic*) receptors—*nicotinic* and *muscarinic*—have been identified on the basis of their response to particular drugs (Table 5-4). **Nicotinic receptors** (activated by the tobacco plant derivative nicotine) are found on the postganglionic cell bodies in all autonomic ganglia. Nicotinic receptors respond to acetylcholine released from both sympathetic and parasympathetic preganglionic fibers. Binding of ACh to these receptors brings about opening of nonspecific cation channels in the postganglionic cell that permit passage of both Na⁺ and K⁺. Because of the greater electrochemical gradient for Na⁺ than for K⁺, more Na⁺ enters the cell than K⁺ leaves, depolarizing the postganglionic cell.
2. **Cholinergic muscarinic receptors** (activated by the mushroom poison muscarine) are found on effector cell membranes (smooth muscle, cardiac muscle, and glands). They bind with ACh released from parasympathetic postganglionic fibers. There are five subtypes of muscarinic receptors, all of which are linked to G proteins that activate second-messenger systems that lead to the target cell response.
3. **Adrenergic receptors.** There are two major classes of adrenergic receptors for norepinephrine and epinephrine based on the ability of various drugs to either initi-

ate or prevent responses in the effector organ. These receptors are designated as **alpha (α)** and **beta (β) receptors**, with further subclassifications of α₁ and α₂ and β₁ and β₂ receptors. These various receptor types are distinctly distributed among the effector organs, as shown in Table 5-2. Receptors of the β₂ type bind primarily with epinephrine, whereas β₁ receptors have about equal affinities for norepinephrine and epinephrine, and α receptors of both subtypes have a greater sensitivity to norepinephrine than to epinephrine (Figure 5-10).

All adrenergic receptors are coupled to G proteins, but the ensuing pathway differs for the various receptor types. Activation of both β₁ and β₂ receptors brings about the target cell response by means of the cyclic AMP second-messenger system (see p. 97). Stimulation of α₁ receptors elicits the desired response via the IP₃/Ca²⁺ second-messenger system (see p. 98). By contrast, binding of a neurotransmitter to an α₂ receptor blocks cyclic AMP production in the target cell. Accordingly, activation of α₂ receptors brings about an inhibitory response in the effector organ, such as decreased smooth muscle contraction in the digestive tract. Activation of α₁ receptors, in contrast, usually brings about an excitatory response in the effector organ—for example, arteriolar constriction caused by increased contraction of the smooth muscle in the walls of these blood vessels. The α₁ receptors are present in most sympathetic target tissues. Stimulation of β₁ receptors, which are found primarily in the heart, also causes an excitatory response, namely, increased rate and force of cardiac contraction. The response to β₂ receptor activation is generally inhibitory, such as arteriolar or bronchiolar (respiratory airway) dilation caused by relaxation of the smooth muscle in the walls of these tubular structures. As a quick rule of thumb, activation of the subscript “1” versions of adrenergic receptors leads to excitatory responses and activation of the subscript “2” versions leads to inhibitory responses (Table 5-2).

Autonomic Agonists and Antagonists Because activation of various receptor types brings about different responses to the same autonomic messenger, these receptors can be manipulated fairly selectively by drugs. Drugs are available that

TABLE 5-4 Location of Nicotinic and Muscarinic Cholinergic Receptors

Type of Receptor	Site of Receptor	Respond to Acetylcholine Released from:
Nicotinic Receptors	All autonomic ganglia	Sympathetic and parasympathetic preganglionic fibers
	Motor end plates of skeletal muscle fibers	Motor neurons
	Some CNS cell bodies and dendrites	Some CNS presynaptic terminals
Muscarinic Receptors	Effector cells (cardiac muscle, smooth muscle, glands)	Parasympathetic postganglionic fibers
	Some CNS cell bodies and dendrites	Some CNS presynaptic terminals

© Cengage Learning, 2013

selectively enhance or mimic (agonists) or block (antagonists) (p. 100) autonomic responses at each of the receptor types. Some are only of experimental interest, but others are very important therapeutically. For example, *atropine* blocks the effect of ACh at muscarinic receptors but does not affect nicotinic receptors. Because the ACh released at both parasympathetic and sympathetic preganglionic fibers combines with nicotinic receptors, blockage at nicotinic synapses would knock out both of these autonomic branches. By acting selectively to interfere with ACh action only at muscarinic junctions, atropine effectively blocks parasympathetic effects but does not influence sympathetic activity at all. This principle is used to suppress salivary and bronchial secretions before surgery to reduce the risk of a patient (human or veterinary) inhaling these secretions into the lungs.

Many regions of the central nervous system are involved in the control of autonomic activities

Messages from the CNS are delivered to cardiac muscle, smooth muscle, glands, and other nonskeletal-muscle effectors via the autonomic nerves, but what regions of the CNS regulate autonomic output? Autonomic control of these effectors is mediated by reflexes and through centrally located control centers. Going back one step further, ultimately information carried to the CNS via the visceral afferents is used to determine the appropriate output via the autonomic efferents to the effectors to maintain homeostasis.

1. Some autonomic reflexes, such as urination, defecation, and erection, are integrated at the *spinal cord* (reflex) level, but all these spinal reflexes are subject to control by higher levels (following the basic design of Figure 5-1e).
2. The *medulla* within the brainstem is the region most directly responsible for autonomic output. Centers for

FIGURE 5-10 Comparison of the release and binding to receptors of epinephrine and norepinephrine. Norepinephrine is released both as a neurotransmitter from sympathetic postganglionic fibers and as a hormone from the adrenal medulla. Beta₁ (β_1) receptors bind equally with both norepinephrine and epinephrine, whereas beta₂ (β_2) receptors bind primarily with epinephrine and alpha (α) receptors of both subtypes have a greater affinity for norepinephrine than for epinephrine.

controlling cardiovascular, respiratory, and digestive activity via the autonomic system are located there. Some of these are also subject to higher control (such as breath holding).

3. The *hypothalamus* plays an important role in maintaining stability of the internal environment (e.g., temperature, osmotic, energy homeostasis), and in integrating the autonomic, somatic, and endocrine responses that automatically accompany various emotional and behavioral states. For example, the increased heart rate, blood pressure, and respiratory activity associated with displays of

TABLE 5-5 Comparison of the Autonomic and the Somatic Nervous Systems

Feature	Autonomic Nervous System	Somatic Nervous System
Site of Origin	Brain or lateral horn of spinal cord	Ventral horn of spinal cord for most; those supplying muscles in head originate in brain
Number of Neurons from Origin in CNS to Effector Organ	Two-neuron chain (preganglionic and postganglionic)	Single neuron (motor neuron)
Organs Innervated	Cardiac muscle, smooth muscle, exocrine and some endocrine glands	Skeletal muscle
Type of Innervation	Most effector organs dually innervated by the two antagonistic branches of this system (sympathetic and parasympathetic)	Effector organs innervated only by motor neurons
Neurotransmitter at Effector Organs	May be acetylcholine (parasympathetic terminals) or norepinephrine (sympathetic terminals)	Only acetylcholine
Effects on Effector Organs	Either stimulation or inhibition (antagonistic actions of two branches)	Stimulation only (inhibition possible only centrally through IPSPs on cell body of motor neuron)
Types of Control	Under reflex control; may be voluntarily controlled with biofeedback techniques and training	Subject to both reflex and nonreflex control
Higher Centers Involved in Control	Spinal cord, medulla, hypothalamus, prefrontal association cortex	Spinal cord, motor cortex, basal nuclei, cerebellum, brainstem

aggression or fear are brought about by the hypothalamus acting through the medulla.

The vertebrate somatic system controls skeletal muscles

Now let’s look at the somatic nervous system branch of the PNS. Skeletal muscle is innervated by **motor neurons**, the axons of which constitute this branch. (Sometimes all efferent neurons are referred to as *motor neurons*, but we reserve this term for the efferent somatic fibers that supply skeletal muscle and bring about body movement; *motor* means “movement.”) The cell bodies of these motor neurons are located within the ventral horn of the spinal cord. The only exception is that the cell bodies of motor neurons supplying muscles in the head are in the brainstem. Unlike the two-neuron chain of autonomic nerve fibers, the axon of a motor neuron is continuous from its origin in the spinal cord to its termination on skeletal muscle. Motor-neuron axon terminals release ACh, which brings about excitation and contraction of the innervated muscle fibers. Motor neurons can only stimulate skeletal muscles, in contrast to autonomic fibers, which may either stimulate or inhibit their effector organs. Skeletal muscle activity can be inhibited only within the CNS through activation of inhibitory synaptic input to the cell bodies and dendrites of the motor neurons supplying that particular muscle.

Motor neurons are the final common pathway

Motor neuron dendrites and cell bodies are influenced by many converging presynaptic inputs, both excitatory and inhibitory. Some of these inputs are part of spinal-reflex pathways originating with peripheral sensory receptors. Others are part of descending pathways originating within the brain.

Areas of the brain that exert control over skeletal muscle movements include the motor regions of the cortex, the basal nuclei, the cerebellum, and the brainstem (see p. 174).

Motor neurons are considered the **final common pathway** because the only way any other parts of the nervous system can influence skeletal muscle activity is by acting on these motor neurons. The level of activity in a motor neuron and its subsequent output to the skeletal muscle fibers it innervates depend on the relative balance of EPSPs and IPSPs (see p. 132) brought about by its presynaptic inputs originating from these diverse sites in the brain.

The somatic system is considered under cerebral control, but much of the skeletal muscle activity involving posture, balance, and stereotypic movement is controlled at lower levels, following the logic of a hierarchical system. A vertebrate animal’s cerebrum may make the decision to start walking, but the cerebrum itself does not usually control the alternate contraction and relaxation of the involved muscles, because these movements are coordinated by lower brain centers such as the cerebellum, brainstem, or spine (hence the infamous tales of a chicken running around even after its head has been severed. Similarly, a shark’s body will continue to swim even if its brain is destroyed).

Table 5-5 summarizes the features of the two divisions of the efferent nervous system discussed in this chapter.

5.3 The Vertebrate Nervous System: Central System

As we've discussed, the vertebrate central nervous system (CNS), which consists of the brain and spinal cord, receives input about the external and internal environment from the afferent neurons. The CNS sorts and processes this input, then initiates appropriate directions in the efferent PNS, which carry the instructions to glands or muscles to bring about the desired response—some type of secretion or movement. In general, the nervous system acts by means of its action potentials to control the rapid responses of the body, which are directed toward maintaining homeostasis.

Many cells within the CNS are not neurons but **glial cells** or **neuroglia**, which serve as the connective tissue of the CNS and as such help support the neurons. For unknown reasons, their densities correlate with brain size, making up only a few percent of a nematode worm brain, 25% of a fruit fly brain, 65% of a mouse brain, 90% of a human brain, and 97% of an elephant brain. Despite their large numbers in the human brain, the glial cells occupy only about half the volume because they do not branch as extensively as neurons do.

Glial cells support the interneurons physically, metabolically, and functionally

Unlike neurons, glial cells generally do not initiate or conduct nerve impulses. They are important in the viability of the CNS, however. For much of the time since discovering them in the 19th century, scientists thought the glial cells were passive “mortar” that physically supported the functionally important neurons (*glia* is Greek for *glue*). In the last decade, however, the varied and important roles of these dynamic cells have become apparent. The glial cells serve as the connective tissue of the CNS and as such help support the neurons both physically and metabolically. They homeostatically maintain the composition of the specialized extracellular environment surrounding the neurons within the narrow limits optimal for normal neuronal function. Furthermore, they actively modulate synaptic function and are considered nearly as important as neurons to learning and memory. Certain glial cells can also take up and destroy neurotransmitters released from neighboring neurons. The four major types of glial cells in the CNS are *astrocytes*, *oligodendrocytes*, *ependymal cells*, and *microglia* (Figure 5-11). Let's examine each in turn.

Astrocytes Named for their starlike shape (*astro*, “star”; *cyte*, “cell”) (Figure 5-12), **astrocytes** are the most abundant glial cells. They fill a number of critical functions:

1. As the main “glue” of the CNS, they hold the neurons together in proper spatial relationships.
2. They serve as a scaffold to guide neurons to their proper final destination during fetal brain development.
3. They induce the small blood vessels of the brain to establish the blood–brain barrier, a tight barricade between the blood and brain (soon to be described in greater detail).
4. Through their close association with both local capillaries and neurons, astrocytes help transfer nutrients from the blood to the neurons and store some glycogen.
5. They are important in the repair of brain injuries and in neural scar formation.
6. Astrocytes play a role in neurotransmitter activity. They take up glutamate and gamma-aminobutyric acid (GABA), excitatory and inhibitory neurotransmitters, respectively, thus bringing the actions of these chemical messengers to a halt.
7. Astrocytes take up excess K^+ from the brain ECF when high action-potential activity outpaces the ability of the Na^+/K^+ pump to return the effluxed K^+ to the neurons. (Recall that K^+ leaves a neuron during the falling phase of an action potential; see Figure 4-8.) By taking up excess K^+ , the astrocytes help maintain the proper brain ECF ion concentration to sustain normal neural excitability. If brain ECF K^+ levels were allowed to rise, the resultant lower K^+ concentration gradient between the neuronal ICF and surrounding ECF would reduce the neuronal membrane closer to threshold, even at rest. This would increase the excitability of the brain. In fact, an elevation in brain ECF K^+ concentration may be one of the factors responsible for the brain cells’ explosive convulsive discharge that occurs during epileptic seizures, which occur in some humans and other mammals including some dogs.
8. Astrocytes and other glial cells enhance synapse formation and modify synaptic transmission. Elongated, fine starlike extensions from an astrocyte’s cell body are often wedged between presynaptic and postsynaptic portions of adjacent neurons. Recently scientists learned that an astrocyte can selectively retract these fine processes through actin activity, in a sort of reverse of pseudopod formation in amoeboid movement (see p. 44). Withdrawal of these processes may allow new synapses to form between neurons that were otherwise physically separated by the intervening process. Astrocytes also appear to influence synapse formation and function by chemical means.
9. Astrocytes communicate with neurons and with one another by means of chemical signals in two ways. First, gap junctions (see p. 66) have been identified between astrocytes themselves and between astrocytes and neurons. Chemical signals pass directly between cells through the gap junctions without entering the ECF. Second, astrocytes have receptors for the common neurotransmitter glutamate. Furthermore, the firing of neurons in the brain in some instances triggers the release of ATP along with the classical neurotransmitter from the axon terminal. Binding of glutamate to an astro-

Astrocyte

FIGURE 5-12 Astrocytes. Note the starlike shape of these astrocytes, which have been grown in tissue culture.

Source: Nancy Kedersha, Ph.D., Research Scientist, Cell Biology, ImmunoGen, Inc. (Harvard Medical School).

cyte’s receptors and/or detection of extracellular ATP by the astrocyte leads to calcium influx into this glial cell. The resultant rise in intracellular calcium prompts the astrocyte itself to release ATP, thereby activating adjacent glial cells. In this way, astrocytes share information about action potential activity in a nearby neuron. In addition, astrocytes and other glial cells can also release the same neurotransmitters as neurons do, as well as other chemical signals. These extracellular chemical signals from the glia can affect neuronal excitability and strengthen synaptic activity, such as by increasing neuronal release of neurotransmitter or promoting the formation of new synapses. Moreover, astrocytes secrete *thrombospondin*, a large protein that can trigger synapse formation. Such glial modulation of synaptic activity is likely important in memory and learning.

Scientists are trying to sort out the two-directional chatter that takes place between and among the glial cells and neurons because this dialogue plays an important role in the processing of information in the brain. In fact, some neuroscientists suggest that synapses should be considered “three-party” junctures involving the glial cells as well as the presynaptic and postsynaptic neurons. This point of view is indicative of the increasingly important role being placed on astrocytes in synapse function. Thus, astrocytes have come a long way from their earlier reputation as “support staff” for neurons; these glial cells might turn out to be the “board members” coordinating and/or regulating the neurons.

Oligodendrocytes The insulating myelin sheaths around axons in the CNS are formed by **oligodendrocytes**. An oligodendrocyte has several elongated projections, each of which

is wrapped spirally around a section of an interneuronal axon to form a patch of myelin, similar to that made by *Schwann cells* in the PNS (see Figure 4-13, p. 127, and Figure 5-11).

Ependymal Cells Lining the internal cavities of the vertebrate CNS are **ependymal cells**. As the nervous system develops in an embryo from a hollow neural tube, the original central cavity of this tube is maintained and modified to form the *ventricles* of the brain (Figure 5-13) and the central canal of the spinal cord. The ependymal cells lining the ventricles contribute to the formation of *cerebrospinal fluid*, to be discussed shortly. Ependymal cells are one of the few cell types to bear cilia, whose beating action contributes to the flow of cerebrospinal fluid throughout the ventricles.

Ependymal cells also serve as neural stem cells with the potential of forming not only other glial cells but new neurons as well. Traditional view has long held that new neurons are not produced anywhere in the mature mammalian brain. Then, in the late 1990s, scientists discovered that new neurons are produced in one restricted site, namely in a specific part of the hippocampus, a structure important for learning and memory. The discovery that ependymal cells are precursors for new neurons indicates that the adult brain has more potential for repairing damaged regions than previously assumed.

Microglia The immune defense of the CNS depends on **microglia**, scavengers derived from the same tissue that gives rise to *monocytes*, a type of white blood cell that exits the blood and sets up residence as frontline defense agents in various tissues throughout the body (see Chapter 10). Microglia migrate during embryonic development to the CNS. There they remain stationary until activated by an infection or injury.

In the resting state, microglia are wispy cells with many long branches that radiate outward. Recent evidence suggests that resting microglia are not just waiting watchfully. They release low levels of growth factors, such as *nerve growth factor*, which help neurons and other glial cells survive and thrive. When trouble occurs in the CNS, microglia retract their branches, round up, and become highly mobile, moving toward the affected area to remove any foreign invaders or tissue debris. Activated microglia release destructive chemicals for assault against their target.

Researchers increasingly suspect that excessive release of these chemicals from overzealous microglia may damage the neurons they are meant to protect, thus contributing to the insidious neuronal damage associated with *neurodegenerative diseases*.

The delicate central nervous tissue is well protected

CNS tissue is very delicate. This characteristic, coupled with the fact that damaged nerve cells cannot be replaced because most neurons cannot divide, makes it imperative that this fragile, irreplaceable tissue be well protected. Four major features help protect the vertebrate CNS from injury; we will examine the last two of these in detail:

1. It is enclosed by hard, bony structures: The **cranium (skull)** encases the brain, and the vertebral column surrounds the spinal cord.

2. Three protective and nourishing membranes, the **meninges**, lie between the bony covering and the nervous tissue. From the outermost to the innermost layer, these are the *dura mater*, the *arachnoid mater*, and the *pia mater* (*mater*, “mother”).
3. The brain “floats” in a special cushioning fluid, the *cerebrospinal fluid* (CSF).
4. A highly selective *blood–brain barrier* limits access of blood-borne materials into the vulnerable brain tissue.

The brain floats in its own special cerebrospinal fluid

Cerebrospinal fluid (CSF) surrounds and cushions the brain and spinal cord. The CSF has about the same density as the brain itself, so the brain essentially floats or is suspended in its special fluid environment. A major function of CSF is to serve as a shock-absorbing fluid to minimize damage of the brain when subjected to sudden, jarring movements. Consider the impact on the brain when two combative rams charge into each other.

In addition to protecting the delicate brain from mechanical trauma, the CSF plays an important role in the exchange of materials between the neural cells and the interstitial fluid surrounding the brain. Only the brain interstitial fluid—not the blood or CSF—comes into direct contact with the neurons and glial cells. Because the brain interstitial fluid directly bathes the neural cells, its composition is influenced more by changes in the composition of the CSF than by alterations in the blood. Materials are exchanged fairly freely between the CSF and brain interstitial fluid, whereas only limited exchange occurs between the blood and brain interstitial fluid. Thus, the composition of the CSF must be carefully regulated.

Cerebrospinal fluid is formed primarily as a result of selective transport mechanisms across the membranes of **choroid plexuses** found in particular regions of the ventricle cavities of the brain. Choroid plexuses consist of richly vascularized **pia mater** tissue, which supplies blood to the outer cortex and which dips into pockets formed by ependymal cells. The composition of CSF differs from that of blood. For example, CSF is lower in K^+ and slightly higher in Na^+ , making the brain interstitial fluid an ideal environment for movement of these ions down concentration gradients, a process essential for conduction of nerve impulses. The biggest difference is the near absence of plasma proteins in the CSF. Plasma proteins cannot exit the brain capillaries to leave the blood during formation of CSF.

A highly selective blood–brain barrier carefully regulates exchanges between the blood and brain

The vertebrate brain is carefully shielded from harmful changes in the blood by a highly selective **blood–brain barrier (BBB)**. Throughout a mammal, exchange of materials between the blood and the surrounding interstitial fluid can take place only across the walls of capillaries, the smallest of blood vessels (Chapter 9). Unlike the rather free exchange across most capillaries in the body, permissible exchanges across brain capillaries are strictly limited. Changes in most

FIGURE 5-13 The ventricles of the human brain.

© Cengage Learning, 2013

plasma constituents do not easily influence the composition of brain interstitial fluid because only selected exchanges can be made. For example, even if the K^+ level in the blood is doubled, little change occurs in the K^+ concentration of the fluid bathing the central neurons. This is beneficial because alterations in interstitial fluid K^+ would be detrimental to neuronal function.

The BBB consists of both anatomic and physiologic features. A single layer of endothelial cells forms capillary walls throughout the body. Usually, holes or pores between the cells making up the capillary wall (Figure 9-50) permit free exchange of all plasma components, except the large plasma proteins, with the surrounding interstitial fluid. In the brain capillaries, however, the cells are joined by *tight junctions*, which completely seal the capillary wall so that nothing can be exchanged across the wall by passing between the cells (Figure 5-14). The only possible exchanges are through the capillary cells themselves. Lipid-soluble substances such as O_2 , CO_2 , alcohol, and steroid hormones penetrate these cells easily by dissolving in the lipid plasma membrane. Small water molecules also diffuse through readily, by passing between the phospholipid molecules of the plasma membrane or through aquaporins (water channels, p. 81). All other substances exchanged between the blood and brain interstitial fluid, including such essential materials as glucose, amino acids, and ions, are transported by highly selective membrane-bound carriers. For example, the uptake of glucose is accomplished by primary active transport by a specific glucose transporter. Thus, transport across brain capillary walls *between* the wall-forming cells is prevented *anatomically*, and transport *through* the cells is restricted *physiologically*. Together, these mechanisms constitute the BBB.

By strictly limiting exchange between the blood and brain, the BBB protects the delicate brain from chemical fluctuations in the blood and minimizes the possibility that potentially harmful blood-borne substances might reach the central neural tissue. On the negative side, the BBB limits the use of drugs for the treatment of brain and spinal cord disorders because many drugs are unable to penetrate this barrier. To “fool” the brain, some drugs can be attached to specific delivery vehicles, such as proteins or fatty acids that are nor-

mally transported across the barrier. Once in the brain the protein or fatty acid is metabolized, leaving the drug to pursue its therapeutic task.

Certain areas of the brain are not subject to the BBB, most notably a portion of the hypothalamus. Functioning of the hypothalamus depends on its “sampling” the blood and adjusting its controlling output accordingly to maintain homeostasis. Part of this output is in the form of hormones that must enter hypothalamic capillaries to be transported to their sites of action. Appropriately, these hypothalamic capillaries are not sealed by tight junctions.

The brain depends on delivery of oxygen and glucose by the blood

Even though many substances in the blood never actually come in contact with the brain tissue, the brain, more than any other tissue, is highly dependent on a constant blood supply. Unlike most tissues, which can resort to anaerobic metabolism to produce ATP in the absence of O_2 for at least short periods (see p. 55), most vertebrate brains cannot produce ATP in the absence of O_2 . Scientists recently discovered an O_2 -binding protein, *neuroglobin*, in the brain. This molecule, which is similar to hemoglobin, the O_2 -carrying protein in red blood cells, is thought to play a key role in O_2 diffusion and storage in neurons (see p. 533 for details). Also, in contrast to most tissues, which can use other sources of fuel for energy production in lieu of glucose, the mammalian brain uses only glucose under normal physiological conditions, and glucose plus ketone bodies during starvation. However, except for small amounts of glycogen (a glucose polymer, p. 26) stored in some astrocytes, the brain does not store these nutrients. Therefore, the brain is absolutely dependent on a continuous, adequate blood supply of O_2 and glucose. Accordingly, brain damage results if this organ (particularly in birds and mammals) is deprived of its critical O_2 supply for more than a few minutes or if its glucose supply is cut off for more than 10 to 15 minutes. However, some vertebrates can cope without O_2 for extended periods; for example, some fish and turtles spend the winter living under the ice without O_2 (see Chapter 11). At

FIGURE 5-14 Blood–brain barrier. Unlike most capillaries in the body, the cells forming the walls of brain capillaries are joined by tight junctions that prevent materials from passing between the cells. The only passage across brain capillaries is through the cells that form the capillary walls. With the exception of lipid-soluble substances and water, passage of all other materials through these cells is physiologically regulated by carrier-mediated systems, which are not present in capillaries elsewhere.

© Cengage Learning, 2013

low temperatures their cells consume ATP at a substantially lower rate.

In contrast to birds and mammals, brains in insects and carp store considerably more glycogen, particularly in glial cells, from which it can be transported to nerve cells in the form of alanine (after breakdown of glycogen to glucose to pyruvate and transamination to alanine). In contrast to neurons of honeybees, which lack enzymes to metabolize fatty acids, the brains of moths have a high capacity to oxidize fatty acids as fuel. The extraordinary energy-requiring demands of the moth's long-distance migrations are supported by mobilization of lipid fuel from the fat body and delivered to the brain via the hemolymph.

Brains of virtually all vertebrates display a degree of plasticity

Normally, damaged axons cannot regenerate within the CNS as they can in the peripheral nervous system, because the myelin-forming oligodendrocytes of the CNS release nerve growth-inhibiting proteins. However, the brains of virtually all vertebrates, and many nonvertebrates, display a degree of **plasticity**, that is, an ability to change or be functionally remodeled in response to the demands placed on it. This ability is more pronounced in early development, but even adult animals retain some plasticity. The term *plasticity* is used to describe this ability because plastics can be manipulated into any desired shape to serve a particular purpose. When an area of the brain associated with a particular activity is destroyed, other areas of the brain may gradually assume some or all of the responsibilities of the damaged region. The underlying molecular mechanisms responsible for the brain's plasticity are only beginning to be unraveled. Current evidence suggests that the formation of new neural

pathways between existing neurons in response to changes in experience are mediated in part by alterations in dendritic shape resulting from modifications in certain cytoskeletal elements (see p. 59). Its dendrites undergo **arborization** (*arbor* is Latin for “tree”): more elongated and branched dendrites with small connecting outgrowths called **dendritic spines**, so a neuron can receive and integrate more signals from other neurons. Thus, the precise synaptic connections between neurons are not fixed but can be modified by experience. Conversely, synaptic connections to a particular neuron may be reduced or eliminated if there is a sustained level of reduced input. This mechanism may also be important in seasonally breeding animals, where synaptic connections between differing regions of the brain are believed to change cyclically during the breeding cycle.

Recently, Gerhard Schratt and colleagues found that a microRNA (p. 33) called *miR-134* is expressed only in dendrites of rat hippocampal neurons, and that it stops the growth of dendritic spines. Like most microRNAs, *miR-134* works by blocking translation of specific mRNAs, in this case one for a protein kinase (p. 95) called *Limk1* that enhances spine growth. Stimulated neurons somehow reduce *miR-134* inhibition of *Limk1* translation and thus grow more connections.

Neurogenesis is a normal function of several regions of the brain

Another manifestation of plasticity is **neurogenesis**—the reproduction of neurons. Once thought to be absent in the entire mammalian CNS, cell proliferation and track tracing studies in laboratory rodents demonstrate that there are two main sites of neurogenesis in the adult brain. The first is the *hippocampus* (a key memory center we will encounter later)

Challenges and Controversies

Strokes: Not Always a Deadly Domino Effect

The most common cause of human brain damage is a **cerebrovascular accident (CVA or stroke)**. When a cerebral (brain) blood vessel is blocked by a clot (which accounts for over 80% of strokes in humans) or ruptures, the brain tissue supplied by that vessel loses its vital O_2 and glucose supply. The result of O_2 deprivation is damage and usually death of the deprived tissue. Neural damage (and the subsequent loss of neural function) normally extends well beyond the blood-deprived area as a result of a neurotoxic effect that leads to the death of additional nearby cells. The initial O_2 -deprived cells die by *necrosis* (unintentional cell death), but the doomed neighbors undergo *apoptosis* (deliberate cell suicide; see p. 101). In a process known as **excitotoxicity**, affected cells release excessive amounts of glutamate, the common excitatory neurotransmitter. The excitatory overdose of glutamate from the damaged brain cells binds with and overexcites surrounding neurons. Specifically, glutamate binds with excitatory receptors known as *NMDA receptors* (p. 199), which function as Ca^{2+} channels. As a result of excessive glutamate binding, they remain open for too long, permitting too much

Ca^{2+} to rush into the affected neighboring neurons. This elevated intracellular Ca^{2+} triggers the cells to self-destruct, the mitochondria explosively producing *free radicals* in the process (p. 53). These highly reactive particles contain an unpaired electron, which can damage the DNA and membranes of affected cells. Adding to the injury, researchers speculate that the Ca^{2+} apoptotic signal may spread from the dying cells to abutting healthy cells through gap junctions, which allow Ca^{2+} and other small ions to diffuse freely between cells. These actions kill even more neurons. Thus, most neurons that die following a stroke are originally unharmed cells that commit suicide in response to the chain of reactions unleashed by the toxic release of glutamate from the initial site of O_2 deprivation.

Following the Krogh principle (p. 3) Gillian Renshaw and her colleagues wondered how the epaulette shark, a reef inhabitant in the waters of eastern Australia, could survive lengthy periods of anoxia. At low tides these animals can become trapped in the shallow waters and occasionally are left completely exposed to the air, a situation that would kill nonadapted fish in a matter of minutes. Unlike the situ-

ation in mammals, the epaulette shark employs a unique strategy to survive in these inhospitable conditions. In response to hypoxia (oxygen concentrations below 30% of normal) the shark does the following:

1. It reduces both its heart and respiratory rates.
2. It releases GABA (p. 133), an inhibitory neurotransmitter that counteracts the excitotoxicity of glutamate in nonessential brain areas.
3. It becomes completely inactive but retains its electroreception sense to monitor the presence of any predators or prey.
4. Most importantly, it somehow inhibits the neuronal mitochondria, resulting in a savings in energy. Turning off the mitochondria effectively prevents the production of free radicals once oxygen is restored to the animal.

Unfortunately what works for the shark—GABA effectively blocking the toxic effects of glutamate—does not work in mammals. However, these studies again illustrate how animals can devise unique solutions to survive seemingly inhospitable conditions.

with regard to the formation of spatial memory and the development of cognitive skills. The hippocampus is a highly layered tissue derived by the infolding of the ventricles. These neurons are organized into interconnecting layers, which have a cellular appearance in histological sections and appear *granular*. Adjacent tissue is less organized and termed *agranular*—it is here where most cell proliferation occurs. Throughout the brain ventricular system there are residual stem/progenitor cells capable of regeneration. Like a conveyor belt, cells are generated in the agranular zone of the hippocampus and migrate into the granular zone where they differentiate into functional neurons. These newly differentiated cells undergo arborization to link with existing hippocampal cells, an event associated with the ability to form a memory, as illustrated when test animals are trained to more quickly find a reward in a maze. These inputs eventually result in a local increase in size of a particular region as evidenced by larger hippocampuses in animals that use food caches to store food and must recall their locations. Similarly, the hippocampus of experienced migratory birds is larger than that of comparably sized inexperienced individuals.

These newly derived cells become those most important in memory formation, and are accompanied by cell loss

through apoptosis in the hippocampus, which appears to be required for the subsequent formation of new lineages. If this process is blocked, as occurs, for example, from excessive secretion of adrenal glucocorticoids in chronic stress or adrenal disease, depressive behavior and amnesia result. This can also be exemplified in dominant-subordinate relationships where reduced cognitive abilities, as exemplified by social depression, are associated with the subordinate animal. It is likely that older cells are triggered into apoptosis to provoke neurogenesis from the tissue stem/progenitor pool to maintain normal function. This implies that local signals communicate between cells; thus, there is a negative-feedback control between the differentiated cells and the stem/progenitor pool that ensures regeneration.

The second site of neurogenesis is in the *subventricular zone (SVZ)* associated with the lateral ventricles of the brain where major cell proliferation occurs. These cells migrate in a *rostral* direction (moving forwards in the brain) along defined axonal tracts to reach the olfactory epithelium where they form a regenerative population of sensory cells required for the detection of odors. Besides the hippocampus and SVZ, there is also the *hypothalamus*, where cell division occurs in relation to season and other environmental signals for the generation of long-term cycles, and the *spinal canal*,

Challenges and Controversies

Neural Plasticity: A Song for All Seasons

Songbirds are noteworthy in that there is a constant turnover of neurons in certain regions of their brains. The canary's forebrain (which contains about 7 million neurons), adds approximately 20,000 new neurons each day to replace the ones that die. Within the forebrain the pathway for song production is anatomically distinct from the rest of the brain. Discrete song-responsive nuclei in the high vocal center (HVC) connect to the robust nucleus of the archistriatum (RA), which then connects to the motor neurons controlling the musculature of the syrinx and vocal tract muscles, in conjunction with the respiratory and postural systems. Male canaries sing only during the spring breeding season and then again in the fall as they begin learning a new song repertoire for the subsequent breeding season. During singing, the pattern of firing of neurons in the HVC can be associated with the production of syllables, that is, a group of notes. Each pattern of notes is associated with a stable and unique pattern of neuronal activity. In contrast, the RA exhibits precisely timed bursts of activity that are uniquely associated with note identity.

Canaries are sexually dimorphic, that is, the HVC and the RA are anatomically distinct

between males and females. However, females can be induced to sing if they are administered the hormone testosterone. Associated with song production, both the HVC and RA in the treated females increase in size. Male songbirds with the largest HVC and RA are also the best singers and so are the most likely to attract a mate successfully during the breeding season. In another species, the marsh wren, there is a 40% greater size of the HVC and 30% greater size of the

Lang Elliott

A woodthrush, one of the most melodious of avian singers.

RA nucleus of males living along the west coast of North America compared to males living on the east coast. Associated with this, west coast wrens have song repertoires three times greater than their east coast cousins, most likely related to the greater competition of west coast males for mates.

The neural circuitry associated with song learning is initially formed in response to both listening and practicing of the adult song. The HVC receives auditory input from the primary forebrain auditory nucleus. During this developmental period, neurogenesis is restricted to the song nuclei. Song development normally begins one month after hatch. At this time, the size of the HVC is approximately 10 to 15% of the adult HVC. In the fall, the number of RA-projecting neurons increase as the birds modify their song in preparation for the next breeding season. Even in old birds, new neurons have been shown to project an axon exactly the distance between the HVC and the RA, successfully linking these two brain regions. At the same time, some of the RA-projecting neurons die. This continual turnover of neurons indicates the remarkable plasticity of the songbird brain.

where cell division can sometimes repair neural damage due to injury. A remarkable regeneration of neurons has also been associated with the regulation of the *song control system* of songbirds (see *Challenges and Controversies: Neural Plasticity: A Song for All Seasons*).

Neurogenesis is an area of exciting new research in regenerative medicine. Long gone is the old dogma that there is no neural regeneration in the adult brain. Regeneration is required for normal function—remember, use it or lose it!

Mammalian neural tissue is susceptible to neurodegenerative disorders

Although the mammalian brain and other parts of the CNS are well protected, they can suffer from a number of damaging disorders, including degenerative diseases (in which neural tissue dies) such as Alzheimer's in humans. Among the most perplexing of these diseases are the *transmissible spongiform encephalopathies* (TSE). The TSE family of disease includes *bovine spongiform encephalopathy* (BSE), commonly referred to as “mad cow disease”; *scrapie*, which affects sheep and goats; *transmissible mink encephalopathy* in minks; *feline spongiform encephalopathy* in cats; *chronic wasting disease* in deer and elk; and *kuru*, *classical*, and a *variant Creutzfeldt-Jacob disease* in humans (*vCJD*) that appears to be caused by the BSE agent following ingestion of infected

bovine neural tissue. BSE was first diagnosed in 1986 in Great Britain and first appeared in America in 2004. Chronic wasting disease has been found mainly in central western United States and Canada, especially in Colorado and Wyoming.

The agent responsible for BSE and other TSEs is smaller than the smallest known viruses. It is a highly stable protein called a **prion**, short for *proteinaceous infectious particle*. Like a clicker toy, prions can exist in two stable conformations, one of which is active or dominant while the other is recessive. The neuronal genes that code for prions give rise to the recessive form, which appears to have roles in normal brain functions. For example, mice with their prion genes knocked out (p. 34) cannot make proper myelin sheaths. Also, prionlike proteins may be important to long-term memory formation (as we will discuss later).

However, the recessive form of prions can be converted into the dominant form in the event of an animal consuming food that contains the active form. Once in the dominant form prions initiate a self-perpetuating conversion process that eventually is lethal for the animal. Neurons eventually become clogged with prions, which severely impair their function. Ultimately the assault leads to **spongiform damage**—a stipple of microscopic holes that accumulate as the brain reacts to the infection.

Unfortunately, the BSE agent is extremely resistant to heat and is partially resistant to proteases (enzymes that

degrade other proteins), and does not evoke any detectable immune responses or inflammatory reactions in the infected animal. The incubation period (the time from when an animal becomes infected until it first shows disease signs) ranges from two to eight years. Cattle affected by BSE experience progressive degeneration of the nervous system, which leads to nervousness or aggression, abnormal posture, lack of coordination, and low milk production. Following the onset of clinical signs, the animal's condition steadily declines until it either dies or is destroyed. This period normally takes from two to six months. At present there is no treatment for the disease or vaccine to prevent it.

The BSE agent has been identified only in brain tissue, spinal cord, and retina. In experimentally infected cattle, BSE has been localized in the dorsal root ganglion, trigeminal ganglion, distal ileum, and the bone marrow, although there is no evidence of infection in milk or in muscle tissue.

How are brain capillaries structurally different from systemic capillaries?

Define *neural plasticity*. Other than neurons lining the nasal cavity and those in taste buds, can adult vertebrate neurons divide? Explain.

5.4 Brain Evolution in Vertebrates

At the beginning of this chapter, we discussed brain evolution across the animal kingdom. Here we examine the specific details for vertebrates.

Newer, more sophisticated regions of the vertebrate brain are piled on top of older, more primitive regions

Even though the vertebrate brain is a functional whole, it is organized into several different regions. The parts of the brain can be arbitrarily grouped in various ways based on anatomic distinctions, functional specialization, and evolutionary origin. A vertebrate brain is classically organized into three distinct regions—the hindbrain, midbrain, and forebrain—which form from three successive portions of the embryonic neural tube (Figure 5-15a). But these do not readily follow functional aspects of the brain. Therefore, we use the following regions (Table 5-6):

1. Brainstem
 - a. Medulla oblongata
 - b. Pons
 - c. Midbrain
2. Cerebellum
3. Forebrain (with Limbic System)
 - a. Diencephalon: i. Hypothalamus; ii. Thalamus
 - b. Cerebrum: i. Basal nuclei; ii. Cerebral cortex

The order in which these components are listed generally represents both their anatomic location (from bottom to top in upright animals, or back to front in horizontal animals) and their complexity and sophistication of function (from the least specialized to the most specialized level). As we noted earlier in this chapter, the more sophisticated layers of the brain were added on to the more primitive layers, so the order in the list also represents an evolutionary sequence of oldest to newest. The fundamental regional structure of the brain remains similar between all modern vertebrates, with the exception of jawless vertebrates. The relatively conservative nature of these major brain divisions suggests that much of the organization of these structures must have arisen with the origin of vertebrates or shortly thereafter. Let's examine the brain regions and their evolution in more detail.

Brainstem The **brainstem**, the smallest and least changed region of the vertebrate brain, is continuous with the spinal cord (Table 5-6). It is the most ancient part of the brain, having evolved approximately 500 million years ago. It encompasses the **medulla oblongata** (also called just the *medulla*) and **pons**: brain centers that control many life-sustaining processes, such as breathing and circulation, as well as certain baseline activities of skeletal muscle that are common to all vertebrates. In teleosts (which are the majority of bony fishes), one notable specialization is a region devoted to taste, whereas in electric fishes there is an area that governs activation of the electric organs. The anterior brainstem is the **midbrain**, which helps coordinate reflex responses to sight and sound.

Cerebellum Attached at the top rear portion of the brainstem is the **cerebellum**, another structure that has changed comparatively little with evolution. Only the jawless vertebrates, hagfishes and lampreys, lack a cerebellum. A cerebellum-like structure composed of a central body and paired lobes arose with the origin of the jawed fishes. The cerebellum is concerned with maintaining proper position of the body in space and coordination of motor activity (movement). For example, signals from the balance organs and the auditory and visual systems are integrated in the cerebellum and the information used to orient an animal relative to its surroundings. Flying mammals (such as bats) and birds have a comparatively large cerebellum because of the complexity associated with flight.

Forebrain Using an ice cream cone as an analogy with the brainstem and cerebellum as the “cone,” the **forebrain** sits anteriorly like layered scoops of ice cream. The forebrain has changed more than other regions of the brain during vertebrate evolution (Figure 5-15b). It has two major subdivisions—an inner **diencephalon** and an outer **cerebrum** “scoops.” The diencephalon houses two regions of specific nuclei: the **hypothalamus**, which controls many homeostatic functions important in maintaining stability of the internal environment, and the **thalamus**, which performs some primitive sensory processing and is a relay station for almost all sensory input and for some outgoing commands. In fishes and amphibians, the forebrain is primarily devoted to olfactory input.

The cerebrum, the outermost “scoop,” becomes progressively larger and more highly convoluted (that is, with tortuous ridges delineated by deep grooves or folds) the more

(a) Expansion of the dorsal, hollow nerve cord into more complex, functionally distinct regions in certain lineages

(b)

FIGURE 5-15 Evolutionary trend toward an expanded, more complex vertebrate brain. The trend became apparent after morphological comparisons were made of the brains of some vertebrates. These dorsal views are not to the same scale.

advanced the vertebrate species is. The number of interconnections also increases; for example, in the cortex of the primate brain, each neuron can receive inputs from as many as 10,000 other neurons. The cerebrum is most highly developed in humans, where it constitutes about 80% of the total brain weight. The outer layer of the cerebrum is the highly convoluted **cerebral cortex**, which caps an inner core called the **basal nuclei**. The myriad convolutions of the cerebral cortex in higher mammals give it the appearance of a much-folded walnut (Figure 5-15b). The cortex is perfectly smooth in many lower mammals. Without these surface wrinkles, the primate cortex would take up to three times the area it does, and accordingly, would not fit like a cover over the underlying structures. The **hyperpallium** (formerly referred to as the hyperstriatum) of birds is comparable with the mammalian cerebral cortex and is most highly developed in parrots, crows and passerines. The cortex plays a key role in the most sophisticated neural functions, with three key regions we will explore in depth later: (1) the **motor cortex**, which initiates nonreflex movements; (2) five **sensory cortices**, which deal with sensory perception; and (3) **association cortices**, the

sites of complex memory, integration, and planning, as well as (in some species) self-awareness, language, and personality traits. It is the highest, most complex integrating area of the brain. The forebrain also houses the **limbic system**, an ancient memory and emotional complex consisting of parts of the cerebral cortex, basal ganglia, and diencephalon.

Each of these regions of the vertebrate brain is discussed in turn, following evolution by starting with the lowest level, the spinal cord, and moving to the highest, the cerebral cortex.

Which region of the brain has changed the most over evolutionary time in certain mammals? Why do you think this is so?

TABLE 5-6 Overview of Structures and Functions of the Major Components of the Mammalian Brain (Shown for a Human)

5.5 Spinal Cord

We begin with the oldest component of the CNS, the spinal cord.

The spinal cord retains an inherent segmental organization characteristic of many nonvertebrates

The **spinal cord** is a long, slender cylinder of nerve tissue that extends from the brainstem. Comparable to the organization of segmented ganglia in some nonvertebrates, the spinal cord and its associated nerves have retained a fundamental segmental organization. In humans, it is about 45 cm long (18 inches) and 2 cm in diameter (about the size of your thumb). Exiting through a large hole in the base of the skull, the spinal cord is enclosed by the protective vertebral column as it extends posteriorly through the vertebral canal. Paired *spinal nerves* emerge from the spinal cord through spaces formed between the bony, winglike arches of adjacent vertebrae (Figure 5-16). The actual number of spinal cord segments differs between species, with elongated animals having a greater number of spinal cord segments, whereas short animals have fewer.

The spinal nerves are named according to the region of the vertebral column from which they emerge: Humans have 8 pairs of **cervical** (neck) nerves (that is, C1–C8), 12 **thoracic** (chest) nerves, 5 **lumbar** (abdominal) nerves, 5 **sacral** (pelvic) nerves, and 1 **coccygeal** (tailbone) nerve. The spinal cord extends only to the level of the first or second lumbar vertebra (about waist level in humans), so the nerve roots of the remaining nerves are greatly elongated in order to exit the vertebral column at their appropriate space. The thick bundle of elongated nerve roots within the lower vertebral canal is known as the **cauda equina** (“horse’s tail”) because of its appearance. Thoracic and lumbar regions of the avian spinal cord are highly fused because of their adaptation for flight. For this reason individual vertebrae and their associated ganglia are not numbered.

The white matter of the spinal cord is organized into tracts

Although there are some slight regional variations within a particular species, the cross-sectional anatomy of the spinal cord is generally the same throughout its length (Figure 5-17). However, among different types of vertebrates the

Major Functions

1. Sensory perception
 2. Voluntary control of muscle
 3. Language
 4. Personality traits
 5. Sophisticated mental events, such as thinking, memory decision making, creativity, and self-consciousness
1. Inhibition of muscle tone
 2. Coordination of slow, sustained movement
 3. Suppression of useless patterns of movement
1. Relay station for all synaptic input
 2. Crude awareness of sensation
 3. Some degree of consciousness
 4. Role in motor control
1. Regulation of many homeostatic functions, such as temperature control, thirst, urine output, and food intake
 2. Important link between nervous and endocrine systems
 3. Extensive involvement with emotion and basic behavioral patterns
1. Maintenance of balance
 2. Enhancement of muscle tone
 3. Coordination and planning of skilled voluntary muscle activity
1. Origin of majority of peripheral cranial nerves
 2. Cardiovascular, respiratory, and digestive control centers
 3. Regulation of muscle reflexes involved with equilibrium and posture
 4. Reception and integration of all synaptic input from spinal cord; arousal and activation of cerebral cortex
 5. Role in sleep–wake cycle

© Cengage Learning, 2013

size and number of cord segments is related to the particular locomotory strategies used. For example, species with well-developed limbs show distinct enlargements of the thoracic and lumbar regions, reflecting the greater number of neurons within the spinal cord at these levels. In contrast, snakes (which have no limbs) lack any enlargement in this region of the spinal cord.

Throughout the entire CNS, **gray matter** consists predominantly of densely packaged cell bodies and their dendrites as well as glial cells. Bundles or **tracts** of myelinated nerve fibers (axons) constitute the **white matter**; the white appearance is due to the lipid (fat) composition of the myelin. The gray matter can be viewed as the “computers” of the CNS and the white matter as the “wires” that connect the computers to each other. Integration of neural input and initiation of neural output take place at synapses within the gray matter. The gray matter in the spinal cord forms a butterfly-shaped region on the inside and is surrounded by the outer white matter (Figure 5-17). The tracts are grouped into columns that extend the length of the cord. Each of these begins or ends within a particular area of the brain, and each is specific in the type of information that it transmits. Some are **ascending** (cord to brain) **tracts** that transmit to the brain signals derived from afferent input. Others are **descending**

(brain to cord) **tracts** that relay messages from the brain to efferent neurons (Figure 5-18).

The tracts are generally named for their origin and termination. For example, the **ventral spinocerebellar tract** is an ascending pathway that originates in the spinal cord and runs up the ventral (toward the front) margin of the cord with several synapses along the way until it eventually terminates in the cerebellum (Figure 5-18a). This tract carries information derived from muscle stretch receptors that has been delivered to the spinal cord by afferent fibers for use by the spinocerebellum. In contrast, the **ventral corticospinal tract** is a descending pathway that originates in the motor region of the cerebral cortex, then travels down the ventral portion of the spinal cord, and terminates in the spinal cord on the cell bodies of efferent motor neurons supplying skeletal muscles (Figure 5-18b). Because various types of signals are carried in different tracts within the spinal cord, damage to particular areas of the cord can interfere with some functions while other functions remain intact.

Each horn of the spinal cord gray matter houses a different type of neuronal cell body

The centrally located gray matter is also functionally organized (Figure 5-19). The central canal, which is filled with CSF, lies in the center of the gray matter. Each half of the gray matter is divided into a **dorsal (posterior)** (toward the back) horn, a **ventral (anterior) horn**, and a **lateral horn**. The dorsal horn contains cell bodies of interneurons on which afferent neurons terminate. The ventral horn contains cell bodies of the efferent motor neurons supplying skeletal muscles. Autonomic nerve fibers supplying cardiac and smooth muscle and exocrine glands originate at cell bodies found in the lateral horn.

Spinal nerves contain both afferent and efferent fibers

Spinal nerves (bundles of axons) connect with each side of the spinal cord by a **dorsal root** and a **ventral root** (Figure 5-17). Afferent fibers carrying incoming signals enter the spinal cord through the dorsal root; efferent fibers carrying outgoing signals leave through the ventral root. The cell bodies for the afferent neurons at each level are clustered together in a **dorsal root ganglion**. (A collection of neuronal cell bodies or a group of interneurons in the PNS is called a *ganglion*, whereas a functional collection of cell bodies within the CNS is referred to as a *center* or a *nucleus*.) The cell bodies for the efferent neurons originate in the gray matter and send axons out through the ventral root.

The dorsal and ventral roots at each level join to form a **spinal nerve** that emerges from the vertebral column (Figure 5-17). A spinal nerve contains both afferent and efferent fibers traversing between a particular region of the body and the spinal cord. Note the difference between a *nerve* and a *neuron*. A nerve is a bundle of peripheral neuronal axons, some afferent and some efferent, enclosed by a connective tissue covering and following the same pathway (Figure 5-20). A nerve does not contain a complete nerve cell, only the axonal portions of many neurons. (By this definition, there are no nerves in the CNS! Bundles of axons in the CNS are called *tracts*.) The individual fibers within a nerve generally do not have any direct influence on each other. They travel together for convenience, just as many individual tele-

phone lines are carried within a telephone cable, yet any particular connection can be private without interference or influence from other lines in the cable.

The spinal nerves, along with the cranial nerves that arise from the brain, constitute the peripheral nervous system (PNS) that we discussed earlier. It is important to reiterate that the PNS is not a separate nervous system: Although the

PNS entails axons from sensory and CNS neurons, it is structurally continuous with the CNS. After they emerge, these spinal nerves progressively branch to form a vast network of peripheral nerves that supply the tissues. Each segment of the spinal cord gives rise to a pair of spinal nerves that ultimately supply a particular region of the body with both afferent and efferent fibers.

Dr. R. G. Kessel and Dr. R. H. Kardon/ Visuals Unlimited.

With reference to sensory input, each specific region of the body surface supplied by a particular spinal nerve is called a **dermatome**. These same spinal nerves also carry fibers that branch off to supply internal organs, and sometimes pain originating from one of these organs is “referred” (that is, perceived as arising from the wrong location) to the corresponding dermatome supplied by the same spinal nerve. **Referred pain** originating in the heart, for example, may appear to come from the left shoulder and arm in humans or from the withers region (on the back at the base of the neck) in a ruminant. Pain appears to arise from the withers in response to the penetration of a nail, for example, through the ruminant gut into the pericardium (p. 403), resulting in pericardial inflammation called **traumatic pericarditis**. This is relatively common in cattle allowed to graze in old pastures. The mechanism responsible for referred pain is not completely understood. Presumably, inputs arising from the heart share a pathway to the brain in common with inputs from the upper extremities. The higher perception levels, being more accustomed to receiving sensory input from the withers than from the heart, may interpret the pain input from the heart as having arisen from the withers.

Many reflex responses and patterned movements in vertebrates are integrated in the spinal cord

The spinal cord’s location between the brain and afferent and efferent fibers of the PNS enables the cord to fulfill its two primary functions: (1) serving as a link for transmission of information between the brain and the remainder of the body and (2) integrating reflex activity between afferent input and efferent output without involving the brain. This type of reflex activity is known as a **spinal reflex**. Often neuronal connections that produce patterned or stereotyped movements find their origins in the spinal cord. For example, as we noted earlier, a rudimentary walking rhythm is retained in chickens in the absence of any input from the brain. In fishes, the spinal cord can mediate near-normal swimming and visceral functions. Although the brain can override specific behavioral patterns that originate from the spinal cord, the complexity of the spinal neuron circuitry is sufficient to generate these complex and coordinated behaviors.

As you saw at the beginning of this chapter, a **reflex** is an innate response that occurs without higher neural func-

FIGURE 5-21 The withdrawal reflex. When a painful stimulus activates a receptor in the paw, action potentials are generated in the corresponding afferent pathway, which propagates the electrical signals to the CNS. Once the afferent neuron enters the spinal cord, it diverges and terminates on three different types of interneurons (only one of each type is depicted): (1) excitatory interneurons, which in turn stimulate the efferent motor neurons to the biceps, causing the leg to flex and pull the foot away from the painful stimulus; (2) inhibitory interneurons, which inhibit the efferent motor neurons to the triceps, thus preventing counterproductive contraction of this antagonistic muscle; and (3) interneurons that carry the signal up the spinal cord via an ascending pathway to the brain for awareness of pain, memory storage, and so on.

© Cengage Learning, 2013

tions (anticipation and learning), such as pulling a limb away from a hot object (Figure 5-1e) or the scratch reflex so elegantly performed by a pet dog. Some physiologists suggest that some responses that are acquired, such as hunting or flying skills, should be called conditioned reflexes, as long as they become “automatic.” However, this is misleading, because these learned reactions usually involve higher brain regions such as the motor cortex and cerebellum, and this suggestion ignores the importance of hierarchic control in neural evolution. In some cases, though, some true reflexes through the spine, brainstem, or hypothalamus may improve through *potentiated* synapses, in which case these can be considered true acquired reflexes. We explore potentiation later in the chapter.

Recall that the neural pathway involved in accomplishing reflex activity is the **reflex arc** (Figure 5-1). The spinal cord and brainstem are responsible for integrating basic reflexes, whereas higher brain levels usually process so-called acquired reflexes. The integrating center processes all information available to it from the receptor as well as from all other inputs, then “makes a decision” about the appropriate response. Unlike higher-level behaviors, in which any one of a number of responses is possible, a reflex response is predictable because the pathway between the receptor and effector is always the same.

Withdrawal Reflex Now that you have learned more about vertebrate nervous systems, let us revisit the withdrawal spinal reflex of Figure 5-1e in more detail in Figure 5-21. When an animal touches a hot object (such as an ember following a forest fire), a reflex is initiated to pull the limb away from the object (to withdraw from the painful stimulus). The skin has different receptors for warmth, cold, light touch, pressure, and pain. Even though all information is sent to the CNS by way of action potentials, the CNS can distinguish between various stimuli because specific receptors and consequently different afferent pathways are activated by different stimuli. When a receptor is stimulated sufficiently to reach threshold, an action potential is generated in the afferent neuron. The stronger the stimulus, the greater the frequency of action potentials generated and propagated to the CNS. Once the afferent neuron enters the spinal cord, it diverges to synapse with the following different interneurons (the numbers correspond to those on Figure 5-21).

1. An excited afferent neuron stimulates excitatory interneurons that in turn stimulate the efferent motor neurons supplying the biceps, the muscle in the limb that bends the knee joint. The resultant contraction of this flexor pulls the foot away from the hot ember.

2. The afferent neuron also stimulates inhibitory interneurons that in turn inhibit the efferent neurons supplying the triceps to prevent it from contracting. This extensor is the muscle in the leg that extends (straightens out) the knee joint. When the flexor is contracting, it would be counterproductive for the extensor to be contracting. Therefore, built into the withdrawal reflex is inhibition of the muscle that antagonizes (opposes) the desired response. This type of neuronal connection involving stimulation of the nerve supply to one muscle and simultaneous inhibition of the nerves to its antagonistic muscle is known as **reciprocal innervation**. (Recall from Chapter 4, p. 143, that inhibition here uses GABA, which the tetanus toxin blocks, resulting in locked-up muscles.)
3. The afferent neuron stimulates still other interneurons that carry the signal up the spinal cord to the brain via an ascending pathway. Only when the impulse reaches the sensory area of the cortex is the mammal aware of the pain, its location, and the type of stimulus. (Or at least we assume it is aware, based on their responses being similar to humans'.) Also, when the impulse reaches the brain, the information can be stored as memory, and other actions can be initiated. All this activity at the cortical level is above and beyond the basic reflex.

Stretch Reflex Only one reflex is simpler than the withdrawal reflex: the **stretch reflex**, in which an afferent neuron originating at a stretch-detecting receptor in a skeletal muscle terminates directly on the efferent neuron supplying the same skeletal muscle to cause it to contract and counteract the stretch. This is the **monosynaptic** (*mono*, “one”) reflex of Figure 5-1b, so named because the only synapse in the reflex arc is the one between the afferent neuron and the efferent neuron. The withdrawal reflex and all other reflexes are **polysynaptic** (*poly*, “many”), because interneurons are interposed in the reflex pathway, and, therefore, a number of synapses are involved. The withdrawal reflex is an example of a polysynaptic basic spinal reflex.

Other Reflex Activity Spinal reflex action is not necessarily limited to motor responses on the side of the body to which the stimulus is applied. Assume an animal steps on a sharp rock fragment. The ensuing reflex response includes the same neurons as those used for the withdrawal reflex but also recruits neurons that control extension of the opposite limb. A reflex arc is initiated to withdraw the injured foot from the painful stimulus, while the opposite leg simultaneously prepares to suddenly bear the extra weight so that the animal does not lose balance (Figure 5-22). Unimpeded bending of the injured extremity's knee is accomplished by concurrent reflex stimulation of the muscles that flex the knee and inhibition of the muscles that extend the knee. At the same time, unimpeded extension of the opposite limb's knee is accomplished by activation of pathways that cross over to the opposite side of the spinal cord to reflexly stimulate this knee's extensors and inhibit its flexors. This **crossed extensor reflex** ensures that the opposite limb will be in a position to bear the weight of the body as the injured limb is withdrawn from the stimulus.

Besides protective reflexes such as the withdrawal reflex and simple postural reflexes such as the crossed extensor reflex, basic spinal reflexes also mediate emptying of pelvic organs (for example, urination, defecation, and expulsion of semen).

One final point, concerning the term *reflex*: Not all reflex activity is based on neurons. Simple hormonal and paracrine responses can also be called *reflexes*, as you will see in later chapters.

Reflexes and Higher Regulation Most spinal reflexes can be overridden at least temporarily by higher brain centers. Impulses may be sent down descending pathways to the efferent neurons supplying the involved muscles to override the input from the receptors, actually preventing the muscle from contracting despite a harmful stimulus. As we discussed at the beginning of the chapter, this evolved for higher-level functions such as anticipation (activating a reflex before it is activated by its own sensors) and suppression in learned contexts (such as suppressing the urination reflex when urination is not desired, or, in humans, conscious breath holding while swimming). The mechanisms involved were illustrated in Chapter 4 (Figure 4-20). For example, when a young mammal is suckling its mother's teat, pain receptors may be stimulated, initiating a withdrawal reflex. However, because the animal must be fed, in the mother IPSPs are sent via descending pathways to the motor neurons supplying the musculature of the limb. The activity in these efferent neurons depends on the sum of activity of all their synaptic inputs. Because the neurons supplying the muscles are now receiving more IPSPs from the brain (non-reflex) than EPSPs from the afferent pain pathway (reflex), these neurons are inhibited and do not reach threshold. Therefore, the muscles are not stimulated to contract and the mother remains stationary. In this way, the withdrawal reflex has been overridden.

Activity of command fibers elicits a fixed action pattern

Finally, there is another key example of higher regulation controlling lower neural circuits. Activation of certain **command fibers** located within the CNS of many animals (not just vertebrates) can innately generate *coordinated* behaviors of varying degrees of complexity, that is, **fixed action patterns**. Fixed action patterns are stereotyped behaviors that are generated in response to specific stimuli and, once activated, carry out a complete sequence of movements. They are often characteristic for a particular species or group of animals, and they involve more motions than the simple reflexes we have been considering. Because they are automatic and innate, these patterns are considered reflexes. Examples include mating dances and escape responses. For example, the giant Mauthner neurons (p. 129) in the brains of teleost fish activate muscles in a set sequence via the spine to generate the *startle response*, characterized by a vigorous muscle contraction on one side of the body that move the body quickly out of harm's way. There are two Mauthner cells located on each side of the brain. Tapping the glass of an aquarium creates a mechanical disturbance in the water, which generates sensory input into these cells. The neuron that first receives the signal sends inhibitory input to its counterpart Mauthner cell while at the same time activating muscles on one side of the body, permitting the escape response to occur.

Fixed action patterns are widespread among animals. For example, arthropods and mollusks have a variety of such patterns for feeding, flight, walking and gill ventilation. For example, the crayfish tail flip (in which the tail is repeatedly flipped for rapid swimming) is illustrative of a rapid escape

FIGURE 5-22 The crossed extensor reflex coupled with the withdrawal reflex. (a) The withdrawal reflex, which causes flexion of the injured extremity to withdraw from a painful stimulus. (b) The crossed extensor reflex, which extends the opposite limb to support the full weight of the body.

© Cengage Learning, 2013

behavior. Because the tail flip is generated in specific giant neurons (medial giant and lateral giant neurons), these neurons are considered to function as command fibers. More complex behaviors such as the patterned movements insects use in molting their old exoskeletons are also driven by command fibers. *Ecdysis behavior* of grasshoppers and crickets involves a series of synchronous muscular contractions in each of the body segments, which loosens the old exoskeleton. Subsequently, the large muscles of the body wall contract in a peristaltic fashion from posterior to anterior, which then forces the animal out of the exoskeleton.

What is the difference between a nerve and a neuron?

Compare spinal reflexes and fixed action patterns.

Why is reciprocal innervation important in the withdrawal reflex?

5.6 Brainstem and Cerebellum

Now that we've examined the spine, let's turn to its connections to the brain.

The Brainstem Is a Critical Connecting Link between the Brain and the Spinal Cord All incoming and outgoing fibers traversing between the periphery and higher brain centers

must pass through the brainstem (with exception of the olfactory and optic nerves), with incoming fibers relaying sensory information to the brain and outgoing fibers carrying command signals from the brain for efferent output. A few fibers merely pass through, but most synapse within the brainstem for important processing. The functions of the brainstem include the following:

1. *Sensation input and motor output in the head and neck via cranial nerves.* Twelve pairs of **cranial nerves** arise from the brainstem; most supply structures in the head and neck with both sensory and motor fibers (Figure 5-7). They are important in sight, hearing, taste, smell, sensation of the face and scalp, eye movement, chewing, swallowing, facial expressions, and salivation. An exception is cranial nerve X, the **vagus nerve** (in Figure 5-7), which innervates organs in the thoracic and abdominal cavities. The vagus is the major nerve of the parasympathetic nervous system.
2. *Reflex control of heart, blood vessels, respiration, and digestion.* Collected within the *pons* and *medulla* are integrating neuronal clusters that control these functions primarily for homeostasis (see Chapters 9 and 11).
3. *Modulating the sense of pain* (see p. 260).
4. *Regulation of muscle reflexes involved in equilibrium and posture.*
5. *Receiving and integrating all synaptic input via the reticular formation.* A widespread network of interconnected neurons called the **reticular formation** runs throughout the entire brainstem and into the thalamus. Ascending fibers originating in the reticular formation

carry signals upward to arouse and activate the cerebral cortex (Figure 5-23). These fibers compose the **reticular activating system (RAS)**, which controls the overall degree of cortical alertness and is important in the ability to direct attention. In turn, fibers descending from the cortex, especially its motor areas, can activate the RAS.

6. The centers responsible for *sleep* traditionally have been considered to be housed within the brainstem, although recent evidence suggests that the center promoting slow-wave sleep (see p. 204) lies in the hypothalamus.

The cerebellum is important in balance as well as in coordination of movement

The cerebellum, which is attached to the back of the upper portion of the brainstem, lies behind the occipital lobe of the cortex (Table 5-6 and Figure 5-24). The cerebellum functions as an integrative portion of the brain that consists of circuitry that is functionally similar in all classes of vertebrates that have this region. The surface of the cerebellum is smooth in lower vertebrates but becomes increasingly convoluted in higher vertebrates, increasing available surface area for additional neurons (as in the cerebrum).

More individual neurons are found in the cerebellum than in the entire rest of the brain, indicative of the importance of this structure. In birds and mammals the cerebellum consists of three functionally distinct parts, which are believed to have evolved successively (Figure 5-24). These parts have different sets of inputs and outputs, and, accordingly, each has different functions, although collectively they are concerned primarily with control of motor activity.

- The **vestibulocerebellum** is important for the maintenance of balance and controls eye movement.
- The **cerebrocerebellum** plays a role in planning nonreflex muscle activity by providing input to the cortical motor areas. This is also the cerebellar region that stores *procedural memories* (which we discuss later, p. 195).
- The **spinocerebellum** enhances muscle tone and coordinates skilled, nonreflex movements. This brain region is especially important in ensuring the accurate timing of various muscle contractions to coordinate movements involving multiple joints. This region also receives input from peripheral receptors that appraise it of the body movements and positions that are actually taking place. The spinocerebellum essentially acts as “middle management,” comparing the “intentions” or “orders” of the higher centers (especially the **motor cortex**) with the “performance” of the muscles and then correcting any “errors” or deviations from the intended movement (Figure 5-25). The spinocerebellum even appears able to predict the position of a body part in the next fraction of a second and to make adjustments accordingly.

The motor command for a particular nonreflex activity arises from the motor cortex, but coordination of the actual execution of that activity is accomplished by the cerebellum and certain subcortical regions, which we will examine next. You will learn more about motor control when we cover muscle physiology in Chapter 8.

FIGURE 5-23 The reticular activating system (RAS). The reticular formation, a widespread network of neurons within the brain stem (in red), receives and integrates all synaptic input. The reticular activating system, which promotes cortical alertness and helps direct attention toward specific events, consists of ascending fibers (in blue) that originate in the reticular formation and carry signals upward to arouse and activate the cerebral cortex.

check your understanding 5.6

What are the key functions of the brainstem?

What are the key functions of the cerebellum as a coordinator and predictor?

5.7 Basal Nuclei, Thalamus, Hypothalamus, and Limbic System

We now move up to the **subcortical** (“under the cortex”) **regions** of the brain, which interact extensively with the cortex in the performance of their functions. These regions include the *basal nuclei*, located in the cerebrum, and the *thalamus* and *hypothalamus*, located in the diencephalon. The *limbic system* includes portions of these structures, as well as cortical regions.

The basal nuclei play an important inhibitory role in motor control

The **basal nuclei** (also known as **basal ganglia**) consist of several masses of gray matter located deep within the cerebral white matter (Table 5-6). In the nervous system, a **nucleus** (plural, **nuclei**) refers to a functional aggregation of neuronal cell bodies (thus the term *ganglion* is probably more appropriate, but *nucleus* is unfortunately more widely

FIGURE 5-24 Cerebellum.

Challenges and Controversies

Is the Cerebellum a “Smith Predictor”?

The cerebellum has long been known to be important for smooth, coordinated muscle movements, but scientists still do not entirely understand how it does this. One hypothesis that explains its actions well is that this brain region is a biological version of a Smith predictor. Smith predictors originated in industry for situations with feedback delays, such as a grasping robotic arm in a factory that crushes a soft object before feedback sensors can inform the controller that the object is soft. The Smith predictor has an “internal model” of the action it is about to take

that allows it to initiate certain motions *before* feedback information can inform whether it is correct or not. The cerebellum seems to act this way, particularly once it has learned a skilled motor task. Consider a child throwing a ball. Her higher (prefrontal) center triggers her arm to move forward then waits for feedback to tell it when the arm is in the correct position to release the ball. But by the time the release command arrives at the hand, the arm has moved too far, so the ball goes down at her feet. As the action is learned, though, her spinocerebellum will send the

release command just *before* her hand arrives at the proper angle to prevent this overshooting. Neural recordings suggest that the cerebellum makes such smoothing, coordinating commands even in the absence of feedback from sensors. These ongoing *anticipatory* adjustments are especially important for rapidly changing activities such as climbing, swinging through trees, and running, in which delays in sensory feedback would make the action clumsy. See the Suggested Reading by Miall, Weir, Wolpert, and Stein (1993) at the end of this chapter.

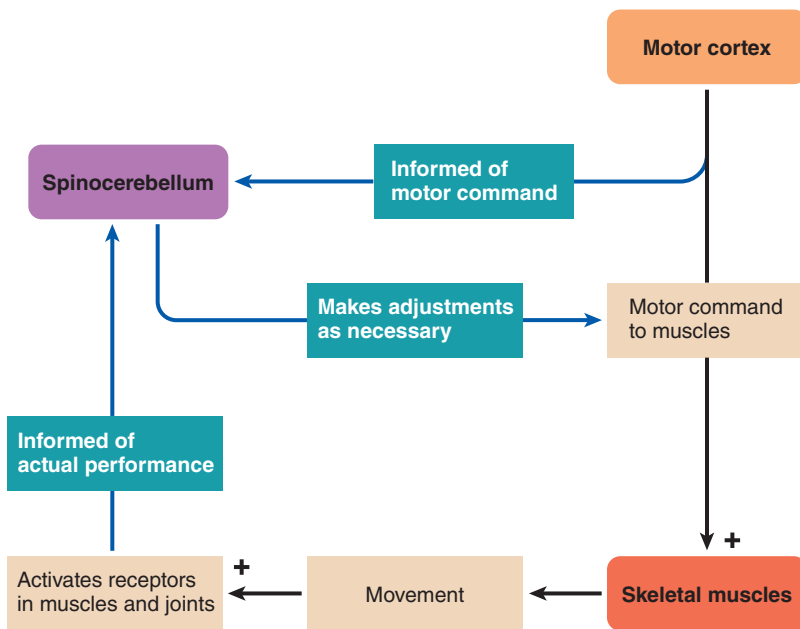

FIGURE 5-25 Role of the spinocerebellum in subconscious control of voluntary motor activity. In coordinating rapid, phasic motor activity, the spinocerebellum compares the “intentions” of higher motor centers with the “performance” of the muscles and corrects any “errors” by making the necessary adjustments to accomplish the intended movement.

used). The basal nuclei play a complex role in the control of movement in addition to having nonmotor functions that are less well understood. In particular, the basal nuclei are important in (1) inhibiting muscle tone throughout the body (proper muscle tone is normally maintained by a balance of excitatory and inhibitory inputs to the neurons that innervate skeletal muscles); (2) selecting and maintaining purposeful motor activity while suppressing useless or unwanted patterns of movement; and (3) helping monitor and coordinate slow, sustained contractions, especially those related to posture and support. The basal nuclei do not directly influence the efferent motor neurons that bring about muscle contraction but act instead by modifying ongoing activity in motor pathways.

To accomplish these complex integrative roles, the basal nuclei receive and send out much information, as is indicated by the tremendous number of fibers linking them to other regions of the brain. One important pathway consists of strategic interconnections that form a complex feedback loop linking the cerebral cortex (especially its motor regions), the basal nuclei, and the *thalamus* (Table 5-6). The thalamus (which we’ll explore further shortly) positively reinforces nonreflex motor behavior initiated by the cortex, whereas the basal nuclei modulate this activity by exerting an inhibitory effect on the thalamus to eliminate antagonistic or unnecessary movements. The basal nuclei also exert an inhibitory effect on motor activity by acting through neurons in the brainstem.

The cerebellum and basal nuclei both monitor and adjust motor activity commanded from the motor cortex, and like the cerebellum, the basal nuclei do not have any direct influence on the efferent motor neurons. Both function indi-

rectly by modifying the output of major motor systems of the brain. Even though the cerebellum and basal nuclei both help to coordinate skeletal motor activity, they play different roles. The cerebellum helps maintain balance; helps coordinate fast, phasic motor activity; and enhances muscle tone. The basal nuclei are important in coordinating slow, sustained movement related to posture and support, and they also function in inhibiting muscle tone.

The thalamus is a sensory relay station and is important in motor control

Deep within the brain near the basal nuclei is the diencephalon, a midline structure that forms the walls of the third ventricular cavity, one of the spaces through which cerebrospinal fluid flows. Recall that its two main parts are the thalamus and the hypothalamus (see Table 5-6 and Figure 5-26).

The **thalamus**, as we noted earlier, serves as a “relay station” and synaptic integrating center for preliminary processing of all sensory input on its way to the cortex. It screens out insignificant signals and routes the important sensory impulses to appropriate areas of the higher sensory cortexes that we will examine later. Along with the brainstem and higher cortical areas, the thalamus is important in an animal’s ability to direct attention to stimuli of interest. For example, mammalian parents can sleep soundly through the noise of wind or rain but be instantly aware of their offspring’s slightest whimper. The thalamus is also capable of crude awareness of various types of sensation but cannot distinguish their location or intensity. As described in the preceding section, the thalamus also plays an important role in motor control by positively reinforcing nonreflex motor behavior initiated by the cortex.

The hypothalamus regulates many homeostatic functions

The **hypothalamus** is a collection of specific nuclei and associated fibers that lie beneath the thalamus. It is an integrating center for many important homeostatic functions that we will explore in later chapters and serves as an important link between the autonomic nervous system and the endocrine system. Specifically, the hypothalamus (1) controls body temperature (although this ability varies considerably among vertebrates, as you will see in Chapter 15); (2) controls thirst and urine output (Chapters 12 and 13); (3) controls food intake (Chapter 15); (4) controls anterior pituitary hormone secretion; (5) produces posterior pituitary hormones (Chapter 7 and others); (6) controls uterine contractions and milk ejection (Chapter 16); (7) serves as a major autonomic nervous system coordinating center, which in turn affects all smooth muscle, cardiac muscle, and exocrine glands; (8) plays a role in emotional and behavioral patterns; and (9) participates in the sleep–wake cycle.

As this list indicates, the hypothalamus (along with the brainstem) is the area of the brain most notably involved in regulating the direct homeostasis of the internal environ-

FIGURE 5-26 Location of the thalamus, hypothalamus, cerebellum, and cerebral cortex in sagittal section.

© Cengage Learning, 2013

ment. For example, when a mammalian body is cold, its hypothalamus initiates internal responses to increase heat production (such as shivering) and to decrease heat loss (such as constricting the skin blood vessels to reduce the flow of warm blood to the body surface, where heat could be lost to the external environment). Other areas of the brain, such as the cerebral cortex, act more indirectly to regulate the internal environment. For example, a cat that feels cold is motivated to seek a warm, sunny place to nap. Even these nonreflex behavioral activities are strongly influenced by the hypothalamus, which, as a part of the *limbic system* (see the next section), functions in conjunction with the cortex in controlling emotions and motivated behavior.

The hypothalamus represents an intermediate level in the distributed hierarchy of neural control and is considered a reflex integrator. That is, it receives input from various internal sensors and sends out effector commands with fewer synapses than would be required if the cerebrum were involved. The hypothalamus is also physically closer to body effectors than is the cerebrum.

The limbic system plays a key role in animal motivation and memory

The **limbic system** is not a separate structure but refers to a ring of forebrain structures that surround the brainstem and are interconnected by intricate neuronal pathways (Figure 5-27). The limbic system includes portions of each of the following: ancient parts of the cerebral cortex, the basal nuclei, the thalamus, and the hypothalamus (although in birds the limbic system remains poorly defined). This complex interacting network is associated with emotions, basic

survival and sociosexual behavioral patterns, motivation, and learning. Two ancient cortical regions we will explore in detail are the *hippocampus*, a vital center for memory processing (see Section 5.9), and the *amygdala*.

The amygdala processes and learns inputs that give rise to the sensation of fear

The **amygdala** of mammalian limbic system is located on the interior underside of the temporal lobe. It is believed to be the homologue of the reptilian and avian **paleostriatum**. It is an especially important region for processing inputs that give rise to the sensation of fear, a sense that normally helps animals avoid danger. Research studies have shown that the amygdala is the region where the link between an *unconditioned* stimulus and a *conditioned* stimulus is formed (see p. 198). For example, when a rat hears a sound and receives a shock, there is a pronounced increase in the firing rate of neurons in the amygdala. This leads to a strengthening of synaptic connections in this region, which, once laid down, are retained for the lifetime of the animal. The amygdala, in turn, activates the animal's fight-or-flight stress system that is controlled by the hypothalamus (p. 310), in anticipation of strenuous escape (or fight) activity. Thus, the next time the rat's ear receives that sound, the amygdala gears up the body for fight-or-flight even before the higher sensory centers "perceive" the sound. After the higher centers process the information, actual fight-or-flight behavior can either be initiated at a high rate (because the body is flooded with oxygen and glucose), or it can suppress the response if the information is judged to be nondangerous.

Normally, in the amygdala the circuits that learn these *emotional memories* are held in check by the release of the

Photo: University of Wisconsin-Madison Comparative Mammalian Brain Collection (Wally Welker)

FIGURE 5-27 Limbic system. This partially transparent view of the brain reveals the structures composing the limbic system.

Source: brainmuseum.org.

inhibitory neurotransmitter GABA (p. 133), so that fight-or-flight responses are activated only by the strongest danger signals. GABA is believed to permit the amygdala to filter out unthreatening stimuli. If, however, the amygdala fails to adequately filter enough incoming information, and, like a leaky valve, permits the entry of too much information, even mildly frightening stimuli can be perceived as terrifying. This syndrome is seen in overly anxious humans and domestic mammals.

The limbic system and higher cortex participate in the control of basic behavioral patterns

Basic innate (inborn) behavioral patterns controlled at least in part by the limbic system include those aimed at survival of the animal (attack, searching for food) and those directed toward perpetuation of the species (sociosexual behaviors conducive to mating). In experimental mammals, stimulation of the limbic system brings about complex and even bizarre behaviors. For example, stimulation in one area can elicit responses of anger and rage in a normally docile animal, whereas stimulation in another area results in placidity and tameness, even in an otherwise vicious animal. Stimulation in yet another limbic area can induce sexual behaviors such as copulatory movements in rodents.

The relationships among the hypothalamus, limbic system, and higher cortical regions regarding emotions and behavior are still not well understood. Apparently the extensive involvement of the hypothalamus in the limbic system governs the internal responses of various body systems in preparation for appropriate action to accompany a particular emotional state. For example, the hypothalamus controls the increased heart rate and respiratory rate, elevation of blood pressure, and diversion of blood to skeletal muscles that occur in anticipation of attack or when angered. These preparatory changes in internal state require no cerebral control (conscious in humans), and as you have seen, emotional memories in the amygdala can trigger them via the hypothalamus.

Role of the Higher Cortex in Basic Behavioral Patterns In executing complex behavioral activities such as attack, flight, or mating, an animal must interact with the external environment. Higher cortical mechanisms are called into play to connect the limbic system and hypothalamus with the outer world so that appropriate overt behaviors are manifested. At the simplest level, the cortex provides the neural mechanisms necessary for implementing the appropriate skeletal muscle activity required to approach or avoid an adversary, participate in sexual activity (mating display), or display emotional expression. For example, the stereotypic sequence of movement for the universal human emotional expression of smiling is apparently preprogrammed in the cortex and can be called forth by the limbic system. One can also voluntarily call forth the smile program, as when posing for a picture. Even individuals blind from birth have normal facial expressions; that is, they do not learn to smile by observation. Smiling means the same thing in every culture, despite widely differing environmental experiences. In contrast, so-called smiling in chimpanzees is actually an innate, limbic-controlled show of fear; but it too can be voluntarily initiated, as chimpanzees in human entertainment shows are trained to do, to make human viewers believe (falsely) that the chimpanzee is happy or amused. Such behavior patterns shared by all members of a species are believed to be more abundant in less advanced animals.

Motivated behaviors are goal directed

An animal tends to reinforce behaviors that have proved gratifying and to suppress behaviors that have been associated with unpleasant experiences. Certain regions of the limbic system have been designated as “reward” and “punishment” centers because stimulation in these respective areas gives rise to pleasant or unpleasant sensations in humans and responses that appear to evoke similar sensations in other mammals. When a self-stimulating device is implanted in a reward center, an experimental rodent will self-deliver up to 5,000 stimulations per hour and will even shun food when starving, in preference for the pleasure derived from self-stimulation. In contrast, when the device is implanted in a punishment center, animals will avoid stimulation at all costs. Reward centers are found most abundantly in regions mediating the highly motivated activities of eating, drinking, and sexual activity.

Motivation is the ability to direct behavior toward specific goals. The concept of animal motivation encompasses many factors, which include subjective emotional feelings and moods (such as rage and fear) that only human subjects can report, plus the overt physical responses that occur in association with these feelings. Animals must continually evaluate the value or worth of a particular stimulus and make decisions weighing the beneficial versus the painful consequences of their choices. These responses include specific behavioral patterns, for example, preparation for attack or defense when approached by an adversary. Evidence (from stimulating or inactivating various brain regions) points to a central role for the brainstem and the limbic system in all aspects of emotion. Some goal-directed behaviors are aimed at satisfying specific identifiable physical needs related to homeostasis. **Homeostatic drives** represent the subjective urges associated with specific bodily needs

that motivate appropriate behavior to satisfy those needs. As an example, the sensation of thirst accompanying a water deficit in the body drives an animal to drink to satisfy the homeostatic need for water. Animal behavior is influenced by experience, learning, and habit, shaped in a complex framework of unique personal gratifications.

Norepinephrine, dopamine, and serotonin are neurotransmitters in pathways for emotion and behavior

The underlying neurophysiological mechanisms responsible for the psychological observations of motivated behavior and emotions largely remain a mystery, although the neurotransmitters norepinephrine (NE), dopamine, and serotonin all have been implicated. NE and dopamine, both chemically classified as *catecholamines*, are known to be transmitters in the regions that elicit the highest rates of self-stimulation in animals equipped with self-administering devices. Imbalances in these are associated with various mental disorders in humans, and possibly other mammals. For example, a functional deficiency of serotonin or NE or both is implicated in **depression**, a disorder characterized by a pervasive unpleasant mood accompanied by a generalized loss of interests and inability to experience pleasure. All effective antidepressant drugs increase the available concentration of these neurotransmitters in the CNS. *Prozac*, the most widely prescribed drug in American psychotherapy, is illustrative. It blocks the reuptake transporters (p. 133) for released serotonin, thus prolonging serotonin activity at synapses. It is often prescribed for humans and companion animals suffering from certain forms of depression and other behavior disorders (see the box, *Concepts and Controversies: Synaptic Solutions to Pet Problems* in Chapter 4, p. 144). Researchers are optimistic that as our understanding of the molecular mechanisms of mental disorders is expanded in the future, many psychological problems can be corrected or managed through drug intervention.

What role do the basal nuclei play in motor control?

Why is the hypothalamus important in the body's homeostatic functions?

Explain the roles that the limbic system has in reactions to fear and sociosexual behaviors related to mating.

5.8 Mammalian Cerebral Cortex

We now turn to the top of the ice cream cone. The cerebrum, by far the largest region of mammalian brains, is divided into two halves, the right and left **cerebral hemispheres**. They are connected to each other by the **corpus callosum**, a thick band consisting of an estimated 300 million neuronal axons traversing between the two hemispheres (Figure 5-26). The corpus callosum is the body's "information highway." The two hemispheres communicate and cooperate with each other by means of constant information exchange through this neural connection.

The cerebral cortex is an outer shell of gray matter covering an inner core of white matter

Each hemisphere consists of a thin outer shell of gray matter, the **cerebral cortex**, covering a thick central core of white matter, the cerebral medulla. The fiber tracts in the white matter transmit signals from one part of the cerebral cortex to another or between the cortex and other regions of the CNS. Such communication between different areas of the cortex and elsewhere facilitates integration of their activity. This integration of neural input is essential for even a relatively simple task such as selecting a food item to eat. Vision and smell of the food is received by one area of the cortex, reception of its palatability takes place in another area, and movement is initiated by still another area. More complex functions may also come into play; for example, a particular food item may have made an animal sick, and its memory therefore may make it reject this particular item even though it might be nutritious. How such complex processing actually works is still poorly understood.

The cerebral cortex is organized into layers and functional columns

The cerebral cortex is organized into six well-defined layers based on varying distributions of the cell bodies and locally associated fibers of several distinctive cell types. These layers are organized into functional vertical columns that extend perpendicularly about 2 mm from the cortical surface down through the thickness of the cortex to the underlying white matter. The neurons within a given column are believed to function as a "team," with each cell being involved in different aspects of the same specific activity—for example, perceptual processing of the same stimulus from the same location.

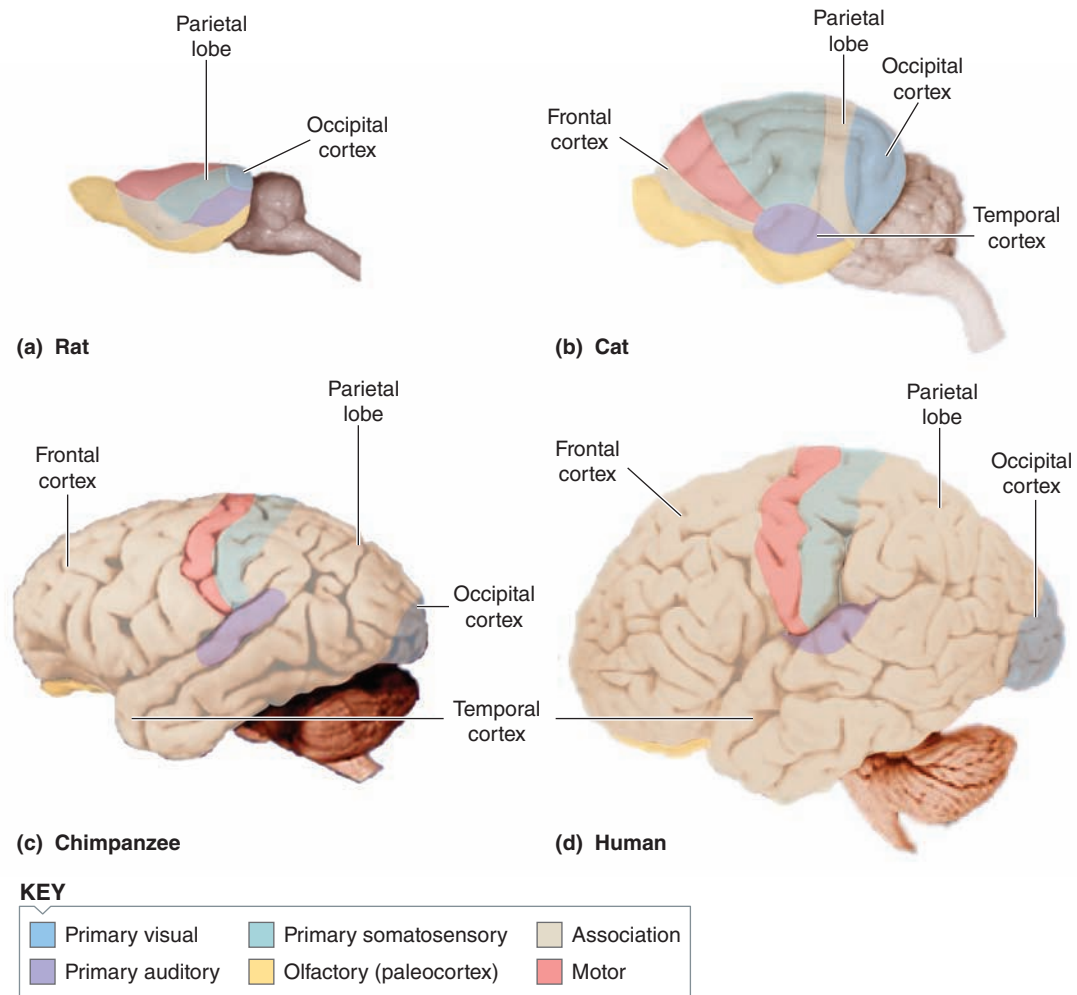

The functional differences between various areas of the cortex result from different layering patterns within the columns and from different input–output connections, not from the presence of unique cell types or different neuronal mechanisms. For example, those regions of the cortex responsible for perception of senses have an expanded layer 4, a layer rich in **stellate cells**, which are responsible for initial processing of sensory input to the cortex. In contrast, the cortical areas that control output to skeletal muscles have a thickened layer 5, which contains an abundance of large **pyramidal cells**. These cells send fibers down the spinal cord from the cortex to terminate on the efferent motor neurons that innervate the skeletal muscles. Pyramidal cells are thought to be the major neurons responsible for higher "decision" events, such as integrating multiple sensory inputs with memory and then outputting appropriate commands.

The four pairs of lobes in the cerebral cortex are specialized for different activities

We now consider the locations of the major functional areas of the mammalian cerebral cortex. Throughout this discussion, keep in mind that even though a discrete activity is ultimately attributed to a particular region of the brain, no part of the brain functions in isolation. Each part depends on complex interplay among numerous other regions for both incoming and outgoing messages.

FIGURE 5-28 Major functional divisions of the mammalian cerebrum, shown for a rat, cat, chimpanzee, and human. Regions devoted to *motor* control are colored red. Regions devoted to processing *sensory* information are colored as indicated in the legend boxes. Regions dedicated to “higher” *associative* functions (those involved in complex memory, planning, and so on) have expanded in certain mammalian groups such as primates.

© Cengage Learning, 2013

The anatomic landmarks used in cortical mapping are certain deep folds that divide each half of the cortex into four major lobes: the *occipital*, *temporal*, *parietal*, and *frontal* lobes (Figure 5-28). Recall that there are three functional types of cortexes: *motor*, *sensory* and *association* (p. 175). Note in Figure 5-28 the relative sizes of these types in various mammals.

During the following discussion of the major activities attributed to various regions of these lobes, refer to the basic functional map of the human cortex in Figure 5-29a. Also think about the typical flow of information, as illustrated in Figure 5-29b for human language. First, as seen in the “Seeing” and “Hearing” images, sensory input arrives at a *sensory* cortex (from the thalamus) for initial perception, then the information goes to a nearby *association* area for processing (e.g., comparing new information with memory, or correlating two or more senses). Wernicke’s area (Figure 5-29a) does this for language. Then information goes to the frontal association area for planning a response (“Thinking” image). Broca’s area (Figure 5-29a) does this for speech. Finally, if action is decided upon, commands go to the *motor* cortex, which initiates muscle activity (“Speaking” image).

Now let’s look at the sensory, motor and associative functions of the lobes. The **occipital lobes**, which are located posteriorly (at the back of the head), are a sensory and association area that carries out the initial perception and

processing of visual input in the cortex. Similarly, auditory (sound) sensation is initially received and processed by the **temporal lobes**, located laterally (on the sides of the head) (Figure 5-29a and b). You will learn more about the functions of these regions in Chapter 6 when we discuss vision and hearing.

The *parietal* lobes and *frontal* lobes, located on the top of the head, are separated by the **central sulcus**, a deep infolding that runs roughly down the middle of the lateral surface of each hemisphere. The parietal lobes lie to the rear of the central sulcus on each side, and the frontal lobes lie in front of it. The **parietal lobes** are primarily responsible for receiving and processing body sensory input (touch, temperature, pain, etc.). The **frontal lobes** contain motor and higher association areas and are responsible for four main functions: (1) nonreflex motor activity, (2) vocal ability (in mammals with this capability), (3) some types of *long-term* memory, and (4) higher mental functions such as planning involving multiple sensory inputs and memory.

Now return to Figure 5-28 and note these lobes and their motor, sensory, and association components in different mammals. Compare, for example, the yellow-colored olfactory cortexes of rat and human (Figure 5-28a versus d), and think about why the differences occur. Note also that the cream-colored association cortexes have expanded more than other regions in primate evolution.

FIGURE 5-29 Functional areas of the human cerebral cortex. (a) Various regions of the cerebral cortex are primarily responsible for various aspects of neural processing, as indicated in this lateral view of the brain. (b) Different areas of the brain “light up” on positron emission tomography (PET) scans as a person performs different tasks. PET scans detect the magnitude of blood flow in various regions of the brain. Because more blood flows into a particular region of the brain when it is more active, neuroscientists can use PET scans to “take pictures” of the brain at work on various tasks.

Courtesy of Washington University School of Medicine, St. Louis.

The parietal lobes are responsible for somatosensory processing

Sensations from the surface of the body, such as touch, pressure, heat, cold, and pain, are collectively known as **somesthetic sensations** (*somesthetic*, “body feelings”). Within the CNS of mammals, this information is “projected” (transmitted along specific neural pathways to higher brain levels) to the **somatosensory cortex**. The somatosensory cortex is located at the front of each parietal lobe immediately behind the central sulcus (Figures 5-28, 5-29a, and 5-30a). It is the site for initial cortical processing and perception of somesthetic input as well as proprioceptive input. **Proprioception** is the awareness of body position. In nonmammalian vertebrates, sensory input generated from proprioceptive receptors are sent to several regions of the brain. For example, in fishes the cerebellum and tectum respond to stimulation initiated from the skin and fins, whereas in turtles and frogs, thalamic nuclei generate *somatotopic* (relation between specific body regions and corresponding areas of the brain) responses.

Each region within the somatosensory cortex receives sensory input from a specific area of the body. The greater the sensory input density from a specific area of the body, the greater the area of the cortex devoted to processing this information. This orderly distribution of cortical sensory processing is depicted for humans in Figure 5-30b. Note that on this so-called **sensory homunculus** in humans (*homunculus*, “little man”), the body is represented upside down on the somatosensory cortex and, more importantly, different parts of the body are not equally represented. For each species, the extent of each body part is indicative of the relative proportion and location of the somatosensory cortex devoted to that area (Figure 5-31). For example, hand and face areas are large in monkeys, mouthparts in rabbits, claws and forelimbs in cats, face in dogs. In cats this cortical representation is referred to a *felunculus* and in dogs it is a *canunculus*. In humans the exaggerated size of the face, tongue, hands, and genitalia is indicative of the high degree of sensory perception and density of nerves associated with these body parts. These cortical maps of the body surface are subject of constant modification in response to changing input from the sensory pathways. Learning, as you will see later, encourages both stronger synaptic connections as well as new synaptic growth.

These maps of the sensory world of an animal were put together by experiments on several species of animals. Electrodes were placed in the cerebral cortex of anesthetized animals, and recordings of clusters of neurons were made in response to visual, auditory, or somatosensory stimulation. For example, tactile stimulation of the animal’s body activated neurons in the rostral regions of the cortex. These studies established that there are maps of the sensory surfaces in the cerebral cortices of all vertebrates. The rhombencephalon of the catfish, for example, contains extensive sensory maps of the taste receptors found on the body surface as well as those from the mouth and pharynx.

The somatosensory cortex on each side of the brain for the most part receives sensory input from the opposite side of the body because most of the ascending pathways carrying sensory information up the spinal cord cross over to the opposite side before eventually terminating in the cortex. Thus, damage to the somatosensory cortex in the left hemisphere produces sensory deficits on the right side of the body, whereas

sensory losses on the left side are associated with damage to the right half of the cortex.

Simple awareness of touch, pressure, or temperature is detected by the thalamus, but the somatosensory cortex goes beyond pure recognition of sensations to fuller sensory perception. The thalamus detects changes in temperature but does not provide information on the intensity. The somatosensory cortex localizes the source of sensory input and perceives the level of intensity of the stimulus. It also is capable of spatial discrimination, so it can discern shapes of objects being held and can distinguish subtle differences in similar objects that come into contact with the skin or outer body surfaces.

The somatosensory cortex, in turn, projects this sensory input via white matter fibers to adjacent higher association areas for even further elaboration, analysis, and integration of sensory information. These higher areas are important in the perception of complex patterns of somatosensory stimulation—for example, simultaneous perception of the texture, firmness, temperature, shape, position, and location of an object the animal is touching. (Note that we can only study perception in humans, who can report to the investigator.)

The primary motor cortex located in the frontal lobes controls the skeletal muscles

The posterior part of the frontal lobe immediately in front of the central sulcus and adjacent to the somatosensory cortex is the **primary motor cortex** (Figures 5-28, 5-29a, and 5-30c). It confers nonreflex control over movement produced by skeletal muscles. As in sensory processing, the motor cortex on each side of the brain primarily controls muscles on the opposite side of the body. Neuronal tracts originating in the motor cortex of the left hemisphere cross over in the medulla oblongata before passing down the spinal cord to terminate on efferent motor neurons that trigger skeletal muscle contraction on the right side of the body. Accordingly, damage to the motor cortex on the left side of the brain produces paralysis on the right side of the body, and the converse is also true.

Stimulation of different areas of the primary motor cortex brings about movement in different regions of the body. Like the sensory homunculus for the somatosensory cortex, the **motor homunculus**, which depicts the location and relative amount of motor cortex devoted to output to the muscles of each body part, is upside down and distorted (Figure 5-30c). For humans, the fingers, thumbs, and muscles important in vocalization, especially those of the lips and tongue, are grossly exaggerated in size, indicative of the fine degree of motor control with which these body parts are endowed. Compare this to how little brain tissue is devoted to the trunk, arms, and lower extremities, which are not capable of such complex movements. Thus, the extent of representation in the motor cortex, as seen in the somatosensory cortex, is proportional to the precision and complexity of motor skills required of the respective part.

The higher motor areas are important in motor control

Even though signals from the primary motor cortex terminate on the efferent neurons that trigger nonreflex skeletal muscle contraction, the motor cortex is not the only region of the brain involved with motor control. First, as you have

seen, lower brain regions and the spinal cord control reflex skeletal muscle activity, such as the maintenance of posture. The cerebellum also plays an important role in monitoring and coordinating nonreflex motor activity that the primary motor cortex has set in motion. Second, although fibers originating from the motor cortex can activate motor neurons to bring about muscle contraction, the motor cortex itself does not *initiate* nonreflex movement. The motor cortex is activated by a widespread pattern of neuronal discharge, the **readiness potential**, which occurs about 750 msec before specific electrical activity is detectable in the motor cortex. Three higher motor association areas of the brain are involved in this decision-making period. These areas, which all command the primary motor cortex, include the *supplementary motor area*, the *premotor cortex*, and the *posterior parietal cortex* (Figure 5-29a). Furthermore, the cerebellum appears to play an important role in the anticipatory planning and timing of certain kinds of movement by sending input to the motor areas of the cortex.

These three association motor areas of the brain are important in programming and coordinating complex movements involving simultaneous contraction of many muscles. Even though electrical stimulation of the primary motor cortex brings about contraction of particular muscles, no purposeful coordinated movement can be elicited, just as pulling on isolated strings of a puppet does not produce any meaningful movement. A puppet displays purposeful movements only when a skilled puppeteer manipulates the strings in a coordinated manner. In the same way, these other regions (and perhaps other areas as yet undetermined) develop a **motor program** for the specific nonreflex task and then “pull” the appropriate pattern of “strings” in the primary motor cortex to bring about the sequenced contraction of appropriate muscles to accomplish the desired complex movement.

The cerebral hemispheres have some degree of specialization

The cortical areas described thus far appear equally distributed in both the right and left hemispheres (except for human language areas, which are found only on one side, usually the left). The left side is also most commonly the dominant hemisphere for fine motor control, at least in primates. Thus, most humans are right-handed because the left side of the brain controls the right side of the body. In contrast, most parrots are left-footed, with the right side of the brain controlling the left side of the body. Each hemisphere is somewhat specialized in the types of mental activities it carries out best. In humans, the **left cerebral hemisphere** excels in the performance of logical, analytical, sequential, and verbal tasks, such as math, language forms, and philosophy. In contrast, the **right cerebral hemisphere** excels in nonlanguage skills, especially spatial perception and artistic and musical endeavors. Whereas the left hemisphere tends to process information in a fragmentary way, the right hemisphere views the world in a big-picture, holistic way. Normally, much sharing of information occurs between the two hemispheres so that they complement each other, but in many individuals the skills associated with one hemisphere are more strongly developed. Left cerebral-hemisphere dominance tends to be associated with “thinkers,” whereas the right-hemispheric skills dominate in “creators.”

Avian intelligence evolved differently than mammalian intelligence

So far, we have been discussing advanced brain functions only in mammals. The story for birds illustrates the flexibility of natural selection. Birds have long been thought to be inferior in intelligence to mammals because they have a smooth cerebrum (Figure 5-28b) with a small cortex lacking the computer-like columnar network of the mammalian cerebrum. But we now know that many birds exhibit signs of intelligence up to the primate level, including both sound and visual communication in many species (including some language abilities in parrots), tool use (sticks) by crows, learning by watching other birds, and even self-awareness in magpies. It appears that limbic-like structures have evolved in bird brains into advanced associative neural clusters—in other words, *nuclei*—of the *hyperpallium* (p. 175), rather than a folded columnar system. Thus, the chance mutations that became favored in the evolution of intelligence began differently in birds, and the resulting brains not only rival those of mammals in sophistication but may also have greater plasticity and regenerative abilities (p. 173).

What are the functions of sensory, motor, and association cortices?

Somatosensory projections in the cortex of mammals are distorted. What factors determine the extent of innervation to each body part?

5.9 Learning, Memory, and Sleep

As we have repeatedly noted, one reason for the evolution of a complex CNS is the ability to *learn*. **Learning** is the acquisition of abilities or knowledge as a consequence of experience, instruction, or both. It is widely believed that rewards and punishments are integral parts of many types of learning, at least in higher vertebrates (and perhaps cephalopods). If an animal is rewarded on responding in a particular way to a stimulus, the likelihood increases that it will respond in the same way again to the same stimulus as a consequence of this experience. Conversely, if a particular response is accompanied by punishment, the animal is less likely to repeat the same response to the same stimulus. When behavioral responses that give rise to pleasure are reinforced or those accompanied by punishment are avoided, learning has taken place. Housebreaking a puppy is an example. If the puppy is praised when it urinates outdoors but scolded when it wets the carpet, it soon learns the acceptable place to empty its bladder. Wild mammals, except those specifically marking territorial boundaries, have no such training experience, but they can learn about other aspects of their environments through reward (such as finding and remembering a source of tasty food) and punishment (such as encountering and remembering the den of a predator).

TABLE 5-7 Comparison of Short-Term and Long-Term Memory

Characteristic	Short-Term Memory	Long-Term Memory
Time of Storage after Acquisition of New Information	Immediate	Later; must be transferred from short-term to long-term memory through consolidation; enhanced by practice or recycling of information through short-term mode
Duration	Lasts for seconds to hours	Retained for days to years
Capacity of Storage	Limited	Very large
Retrieval Time (Remembering)	Rapid retrieval	Slower retrieval, except for thoroughly ingrained memories, which are rapidly retrieved
Inability to Retrieve (Forgetting)	Permanently forgotten; memory fades quickly unless consolidated into long-term memory	Usually only transiently unable to access; relatively stable memory trace
Mechanism of Storage	Involves transient modifications in functions of preexisting synapses, such as altering amount of neurotransmitter released	Involves relatively permanent functional or structural changes between existing neurons, such as formation of new synapses; synthesis of new proteins plays a key role

© Cengage Learning, 2013

(Note again that the perception of “reward” and “punishment” are derived solely from human subjects; we infer similar feelings in some animals because of similar reactions.) Thus, learning is a change in behavior that occurs as a result of experiences. It is highly dependent on the animal’s interaction with its environment. The only limits to the effects that environmental influences can have on learning are the biological constraints imposed by species-specific and individual genetic endowments.

Memory comes in two forms—declarative and procedural—and is laid down in stages

Memory is the storage of acquired knowledge or abilities for later recall. It is widely recognized that there are at least two categories of memory: (1) **declarative** or **explicit** memory—the learning of events, places, and so on [sometimes subdivided into **semantic memories** (memories of facts) and **episodic memories** (memories of events)]; and (2) **procedural** or **implicit** memory—the learning of skilled motor movements. Learning and both types of memory form the basis by which animals adapt their behaviors to their particular external circumstances. Without these mechanisms, planning for successful interactions and intentional avoidance of predictably disagreeable circumstances would be impossible.

Not all forms of learning provide well for this flexibility, however, as evidenced by the phenomenon of **imprinting**, in which newborns are programmed to learn that situations and objects encountered early in life are both normal and important for life. For example, many newly hatched birds are programmed to learn that the first moving object they encounter is a parent. Konrad Lorenz first demonstrated this programmed learning by exposing newly hatched goslings to a substitute mother. Rather than follow their biological parent, the goslings could be induced to follow a variety of inanimate objects or another animal, including a human. In birds and some species of mammals there is a narrowly defined period in which the nervous system is responsive to this form of learning. For example, foals exposed to a variety of handling and grooming procedures within 24 hours after

birth are less fearful of these procedures later in life (such as the vibration and sound of clippers, and rhythmic palpation of both the inside and outside of the ears, nostrils, mouth, anus, genitals). If properly desensitized, these animals are more easily examined and treated by veterinarians and other professionals dealing with horses. Conversely, infant chimpanzees raised in highly stressful situations have hair-trigger fight-or-flight responses for the rest of their lives.

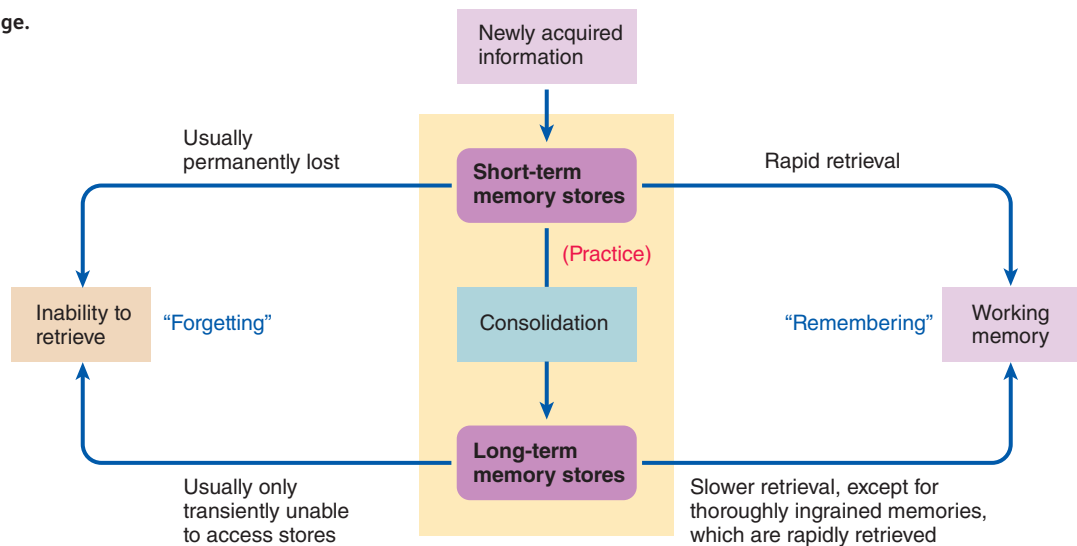

The neural change responsible for retention or storage of knowledge is known as the **memory trace**. Generally concepts, not *verbatim* information, seem to be stored. As you read this page, you are storing the concept discussed, not the specific words. Later, when you retrieve the concept from memory, you will convert it into your own words. It is possible, however, to memorize bits of information word by word.

Storage of acquired information is accomplished in at least two stages: short-term memory and long-term memory (Table 5-7 and Figure 5-32). **Short-term memory** lasts for seconds to hours, whereas **long-term memory** is retained for days to years. The process of transferring and fixing short-term memory traces into long-term memory stores is known as **consolidation**. Stored knowledge is of no use unless it can be retrieved and used to influence current or future behavior.

A recently developed concept is that of a **working memory**, or what has been called “the erasable blackboard of the mind” (Figure 5-32). Working memory involves comparing current sensory data with relevant stored knowledge and manipulating that information, as in being able to plan a future action based on a current situation coupled with past experience. Newly acquired information is initially deposited in short-term memory, which has a limited capacity for storage. Information in short-term memory has one of two eventual fates. Either it is soon forgotten (for example, forgetting a telephone number after you have looked it up and finished dialing), or it is transferred into the more permanent long-term memory mode through *active practice*. The recycling of newly acquired information through short-term memory increases the likelihood of long-term memory consolidation.

FIGURE 5-32 Memory storage.

© Cengage Learning, 2013

(Therefore, when you cram for an exam, your long-term retention of the information is poor!)

Short-term memory has very limited capacity; indeed, there is evidence that all vertebrates have only about 7 to 10 distinct short-term “registers.” That is, a vertebrate brain cannot deal with more than 7 to 10 distinct items on a short-term basis (think about how many numbers you can remember briefly, as in a telephone number). Prey fish that school are thought to take advantage of this. A predator such as a barracuda approaching a school of prey herring may initially focus on one individual to pursue. But by initiating certain stereotypical maneuvers (such as the flash expansion, in which the fish move outward radially with each individual moving off at a unique angle from the predator), the barracuda’s brain seems to become confused by having too many moving targets for its short-term memory to cope with.

The storage capacity of the long-term declarative memory bank in mammals is much larger than the capacity of short-term memory. Different informational aspects of long-term declarative memory traces seem to be processed and codified, then stored in conjunction with other memories of the same type; for example, visual memories are stored separately from auditory memories. This organization facilitates future searching of memory stores to retrieve desired information.

Because long-term memory stores are larger, it often takes longer to retrieve information from long-term declarative memory than from short-term memory. *Remembering* is the process of retrieving specific information from memory stores; *forgetting* is the inability to retrieve stored information or to erase it. Information lost from short-term memory is permanently forgotten, but information in long-term storage is frequently forgotten only transiently. Forgetting short-term memory is important, to make room for new information. There is evidence that short-term memories are in fact actively erased: There are neuromodulators, especially **anandamide** (also spelled *anandimide*), that reset short-term memory neurons to their unpotentiated state, particularly after some stressful events. (The active ingredient in marijuana, *tetrahydrocannabinol*, is an anandamide agonist, explaining why this drug interferes with short-term memory.)

Memory traces are present in multiple regions of the brain

What parts of the CNS govern memory? We here focus primarily on vertebrates but consider other animals for some aspects of memory later. There is no single “memory center” in the vertebrate brain. Instead, the neurons involved in memory traces are widely distributed throughout the subcortical and cortical regions of the brain. The regions of the brain implicated in memory include the hippocampus and other parts of the limbic system, and associated structures of the medial (inner) temporal lobes, the prefrontal cortex, the cerebellum and other regions of the cerebral cortex.

The Hippocampus and Declarative Memories The **hippocampus** (“horse-headed sea monster”), the elongated, seahorse-shaped medial portion of the temporal lobe that is part of the limbic system (see Figure 5-27), plays a vital role (as we noted on p. 172) in short-term declarative memory involving the integration of various related stimuli, and is also crucial for consolidation into long-term memory. The hippocampus is believed to store new long-term memories only temporarily and then transfer them to other cortical sites for more permanent storage. The sites for long-term storage of various types of memories are only beginning to be identified by neuroscientists, but they include the prefrontal cortex and medial temporal lobes.

Use of declarative memory requires active recall. Accessing and manipulating these long-term stores, as well as comparing them to current information and short-term memories, appear to be carried out by the *working memory* of the *prefrontal cortex* (see Figure 5-29). Consider what happens, for example, when your prefrontal cortex is planning to tell your motor cortex to initiate walking across a street. As you look right and then left down the street, your working memory uses (1) the current state of the street to the left, (2) the short-term hippocampal memory of the street a second ago when you looked to the right, and (3) long-term memories about the danger of moving vehicles. A monkey planning to descend from a tree might go through a similar sequence as it scans the ground for predators.

The Cerebellum and Procedural Memories The cerebellum and some motor cortical regions play an essential role in the “how to” *procedural memories* involving motor skills gained through repetitive training. In contrast to declarative memories, which are recollected from previous experiences by the “highest” brain centers (that is, consciously in humans), procedural memories can be brought forth without the involvement of those centers (that is, subconsciously in humans). As you saw earlier, learned skilled motor behaviors may be initiated by higher brain centers (that is, the prefrontal or premotor cortex), but after that they are taken over by the lower centers that have learned the detailed movements. This generally makes the behavioral movements much smoother (see the box on the cerebellum as a Smith predictor, p. 185).

Short-term and long-term memory involve different molecular mechanisms

Another question besides the “where” of memory is the “how” of memory. Obviously, some change must take place within the neural circuitry of the brain to account for the altered behavior that follows learning. Recent research shows that simple short-term memories can reside in a single neuron, but more complex memories are thought to reside in changes in the pattern of signals transmitted across synapses within a neuronal *network*. However, different mechanisms are responsible for short- and long-term memory. Short-term memory involves transient modifications in the function of preexisting synapses, such as a temporary alteration in the amount of neurotransmitter released in response to stimulation within affected nerve pathways. Long-term memory, in contrast, involves relatively permanent functional or structural changes between existing neurons in the brain. Let’s look at each of these types of memory in more detail.

Short-term memory involves transient changes in synaptic activity

To investigate short-term memory, we depart from vertebrates for the moment. Following the Krogh principle (p. 3), ingenious experiments were undertaken by Eric Kandel using the giant marine snail *Aplysia* (Figure 5-33), for which he was awarded the Nobel Prize in Physiology or Medicine in 2000. *Aplysia* were selected as a model for the study of memory for several reasons: (1) they have comparatively large neurons which can be easily identified and recorded, (2) their nervous systems are relatively small (only about 20,000 neurons), and (3) they exhibit simple behaviors with rudimentary learning. The experiments have shown that two forms of short-term memory—*habituation* and *sensitization*—are due to modification of different membrane channel proteins in presynaptic terminals of specific afferent neurons. This modification in turn brings about changes in transmitter release.

These studies have exploited the defensive withdrawal reflexes of the external organs of the mantle cavity. This reflex is analogous to vertebrate withdrawal responses. In mollusks, the mantle cavity is a respiratory chamber housing the gill (Figure 5-33). Surrounding the cavity is a protective covering, the *mantle shelf*, which terminates in a fleshy spout, the *siphon*. When the siphon or mantle shelf is stimulated by

touch, the siphon and gill are vigorously withdrawn into the mantle cavity under the shelf. Afferent neurons responding to touch of the siphon or mantle shelf directly synapse on efferent motor neurons controlling gill withdrawal. This simple reflex can be modified by experience in two ways:

- **Habituation** represents a decreased responsiveness to repetitive presentations of an indifferent stimulus—that is, one that is neither rewarding nor punishing. The snail becomes habituated when its siphon is repeatedly touched; that is, it learns to ignore an indifferent stimulus and no longer withdraws its gill in response. (A natural example would be an ocean current.)
- **Sensitization** refers to increased responsiveness to mild stimuli following a strong or noxious stimulus; after having been subjected to a threatening stimulus an animal responds more attentively to almost any other stimulus. Sensitization, a more complex form of learning, takes place in *Aplysia* when it is given an electric shock to the tail followed immediately by a touch on the siphon, or repeated shocks to the tail (a natural analogue might be a fish nibbling on the tail). Subsequently, the snail withdraws its gill more vigorously in response to even mild stimuli it once failed to react to. The animal in effect has learned that something truly dangerous such as a biting fish is in the vicinity.

Interestingly, these different forms of learning affect the same site—the synapse between a siphon afferent and a gill efferent—in opposite ways. Habituation depresses this synaptic activity, whereas sensitization enhances it. These transient modifications persist for as long as the time course of the memory.

Mechanism of Habituation Habituation in *Aplysia* develops after about 10–15 nonharmful stimulations. Scientists have found that this is based on *prolonged closing of Ca^{2+} channels*, reducing Ca^{2+} entry into the presynaptic terminal, which leads to a decrease in quantity of neurotransmitter released. As a consequence, the postsynaptic potential is reduced compared to normal, resulting in a decrease or absence of the gill withdrawal controlled by the postsynaptic efferent neuron (Figure 5-33, left-hand chart). Thus, the memory for habituation in *Aplysia* is stored in the form of modification of specific Ca^{2+} channels. With no further training, this reduced responsiveness lasts an hour or more. The synaptic events responsible for habituation are also observed in other species studied. This suggests that Ca^{2+} channel modification may be a general mechanism of habituation, although in advanced species the involvement of intervening interneurons makes the process somewhat more complicated. Habituation is probably the most common form of learning; by learning to ignore indifferent stimuli, the animal is free to focus on other more important stimuli.

Mechanism of Sensitization Sensitization in *Aplysia* has also been shown to involve channel modification, although a different channel and mechanism are involved. In contrast to what happens in habituation, *Ca^{2+} entry into the presynaptic terminal is enhanced* in sensitization. The *nociceptors* (pain receptors) activated by the electric shocks to the tail connect with the presynaptic terminal of the sensory touch neuron in the gill-withdrawal reflex pathway. The subsequent increase in the release of excitatory neurotransmitter

FIGURE 5-33 Gill of a sea hare (*Aplysia*), a gastropod, and habituation and sensitization. (a) The gill lies within the mantle cavity, into which it is withdrawn in response to a gentle tap on the siphon or mantle. (b) Researchers have shown that in the sea snail *Aplysia* two forms of short-term memory—habituation and sensitization—result from opposite changes in neurotransmitter release from the same presynaptic neuron, caused by different transient channel modifications. See text for details.

from the touch neuron strengthens the synaptic potential in the motor cell. Sensitization thus elicits a larger postsynaptic potential (EPSP) in the motor neuron, which results in a more vigorous gill-withdrawal response. Sensitization does not have a direct effect on the presynaptic Ca²⁺ channels. Instead, it indirectly enhances Ca²⁺ entry via presynaptic facilitation (see p. 140), that is, enhanced neurotransmitter release from the terminals of the sensory touch neurons. Sensitization thus involves a more complex response at the molecular level. For this form of learning to occur, noxious stimulation of the tail (unconditioned stimulus) must be either repeated or paired with stimulation of the touch neurons in the siphon or mantle shelf (conditioned stimulus). The conditioned stimulus normally produces only a small response, whereas a noxious or unconditioned stimulus generates a powerful response. After pairing of these two stimuli, the gill withdrawal response to stimulation of the siphon is enhanced. The conditioned stimulus must *precede* the unconditioned stimulus by a narrow critical period of 0.5 sec. Biochemical events initiated in the sensory touch neuron are then exaggerated by neurotransmitter (serotonin) released from the pain pathway. This results in an increase in the release of the excitatory neurotransmitter glutamate from the touch neuron onto the motor neuron innervating the gill. Here is a summary of the events associated with sensitization (Figure 5-33, right-hand chart):

1. Arrival of an action potential in the touch neuron within 0.5 sec of activation of the nociceptor (pain) pathway. Release of *serotonin* by an interneuron in the pain pathway.
2. Binding of serotonin to a specific receptor in the sensory touch neuron and activation of adenylyl cyclase and generation of *cAMP* from ATP (see p. 97).
3. Activation of a *cAMP-dependent protein kinase*, *protein kinase A* (see p. 97).
4. Protein kinase phosphorylation of a specific class of K⁺ channels, which reduces the efflux of K⁺ from the touch neuron,

- prolonging the action potential and permitting the Ca^{2+} channels to remain open for an extended period of time.
5. A greater quantity of glutamate release from the sensory touch neuron.
 6. Ca^{2+} activation of the protein *calmodulin*, priming adenylyl cyclase to generate additional cAMP.
 7. Duration of the action potential increased by 20%, which leads to a more vigorous withdrawal of the gill for a prolonged period.

Thus, existing synaptic pathways may be functionally interrupted (habituated) or enhanced (sensitized) during simple learning. Habituation and sensitization persist for about an hour in *Aplysia*, the time it takes for cAMP concentrations to return to normal. However, if noxious stimuli (four to five tail shocks) are repeatedly administered to *Aplysia*, behavioral sensitization can last from one to several days. This phenomenon is known as **long-term potentiation (LTP)**—a prolonged increase in the strength of existing synaptic connections in activated pathways following brief periods of repetitive stimulation. That is, this connection gets stronger the more often it is used. Sensitization alerts animals to predators and other potentially harmful stimuli and so is critical for their survival. Researchers speculate that much of short-term memory in vertebrates is similarly a temporary modification of already existing processes. The cyclic AMP cascade, particularly the activation of protein kinase, plays an important role in elementary forms of learning and memory, to which we now turn our attention.

Mechanism of Long-Term Potentiation in Mammals LTP has been shown to last for days or even weeks in vertebrates—long enough for this short-term memory to be consolidated into more permanent long-term memory, which you may recall is the role of the hippocampus (p. 172), where LTP is especially prevalent. When LTP occurs, simultaneous activation of both the presynaptic and the postsynaptic neurons at a given excitatory synapse results in long-lasting modifications that enhance the ability of the presynaptic neuron to excite the postsynaptic neuron (Figure 5-34). Because both the presynaptic neuron and the postsynaptic neurons must be activated at the same time, the development of LTP is restricted to the pathway that is stimulated. With LTP, signals from a given presynaptic cell to a postsynaptic neuron become stronger with repeated use. Keep in mind that strengthening of synaptic activity results in the formation of more EPSPs in the postsynaptic neuron, ultimately resulting in more action potentials being sent along this postsynaptic cell to other neurons.

Enhanced synaptic transmission could theoretically result from either changes in the postsynaptic neuron (such as increased responsiveness to the neurotransmitter) or in the presynaptic neuron (such as increased release of neurotransmitter). The underlying mechanisms for LTP are still the subject of much research and debate. Most likely, multiple mechanisms are involved in this complex phenomenon. It appears that there are several forms of LTP, some arising from changes only in the postsynaptic neuron and others also having a presynaptic component. Based on current scientific evidence, the following is a plausible mechanism for LTP involving both a postsynaptic change and a presynaptic modification.

LTP begins when a presynaptic neuron releases the common excitatory neurotransmitter glutamate in response

to an action potential (step 1). Glutamate binds to two types of receptors on the postsynaptic neuron: *AMPA receptors* and *NMDA receptors* (step 2). An **AMPA receptor** is a chemically mediated receptor-channel that opens on binding of glutamate (step 3) and permits net entry of Na^+ ions, leading to formation of an EPSP at the postsynaptic neuron (step 4; see p. 132). This is the ordinary receptor at excitatory synapses about which you already learned. An **NMDA receptor** is a receptor-channel that permits Ca^{2+} entry when it is open. This receptor-channel is unusual because it is both chemically gated and voltage dependent. It is closed by both a gate and by a magnesium ion (Mg^{2+}) that physically blocks the channel opening at resting potential. Two events must happen almost simultaneously to open an NMDA receptor-channel: presynaptic glutamate release and postsynaptic depolarization by other inputs. The gate opens on binding of glutamate, but this action alone does not permit Ca^{2+} entry. Additional depolarization of the postsynaptic neuron beyond that produced by the EPSP resulting from glutamate binding to the AMPA receptor is needed to depolarize the postsynaptic neuron enough to force Mg^{2+} out of the channel (step 5). The postsynaptic cell can be sufficiently depolarized to expel Mg^{2+} in two ways: by repeated input from this single excitatory presynaptic neuron, resulting in temporal summation of EPSPs from this source (see p. 136), or by additional excitatory input from another presynaptic neuron at about the same time. When the NMDA receptor channel opens as a result of simultaneous gate opening and Mg^{2+} expulsion, Ca^{2+} enters the postsynaptic cell (step 6). The entering Ca^{2+} activates a Ca^{2+} second-messenger pathway in this neuron. This second-messenger pathway leads to the physical insertion of additional AMPA receptors in the postsynaptic membrane (step 7). Because of the increased availability of AMPA receptors, the postsynaptic cell exhibits a greater EPSP response to subsequent release of glutamate from the presynaptic cell. This heightened sensitivity of the postsynaptic neuron to glutamate from the presynaptic cell helps maintain LTP.

Furthermore, at some synapses activation of the Ca^{2+} second-messenger pathway in the postsynaptic neuron causes this cell to release a **retrograde** (“going backward”) paracrine that diffuses to the presynaptic neuron (step 8). Here, the retrograde paracrine activates a second-messenger pathway in the presynaptic neuron, ultimately enhancing the release of glutamate from the presynaptic neuron (step 9). This positive feedback strengthens the signaling process at this synapse, also helping sustain LTP. Note that in this mechanism, a chemical factor from the postsynaptic neuron influences the presynaptic neuron, just the opposite direction of neurotransmitter activity at a synapse. The retrograde paracrine is distinct from classical neurotransmitters or neuropeptides. Most investigators believe that the retrograde messenger is *nitric oxide*, a chemical that performs a wide array of other functions (see p. 93).

The modifications that take place during the development of LTP are sustained long after the activity that led to these changes has ceased. Therefore, information can be transmitted along this same synaptic pathway more efficiently when activated in the future. That is, the synapse “remembers.” Note that LTP develops in response to frequent activity across a synapse as a result of repetitive, intense firing of a given input (as with repeatedly practicing a

FIGURE 5-34 Possible pathways for long-term potentiation.

© Cengage Learning, 2013

particular display) or to the linking of one input with another input firing at the same time. For example, consider a zoo animal whose mouth waters in anticipation of the imminent arrival of dinner when hearing a food cart. Earlier in its life, only the taste and feel of food in the mouth could trigger salivation. However, through experience, neurons in the pathway that control salivation link input arising from the sound of the cart with input from food in its mouth. After the sound-input pathway is strengthened through development of LTP and ultimate consolidation into long-term storage, the sound alone can cause salivation.

The *ethanol* in alcoholic beverages blocks the NMDA receptors, which is likely the reason people have difficulty remembering what happened during a time of heavy drinking. Ethanol also enhances the actions of GABA, the major inhibitory neurotransmitter in the brain, thus depressing the overall activity of the CNS (dampening reaction speed, for example).

Studies suggest a regulatory role for the cAMP second-messenger pathway in the development and maintenance of LTP in addition to the Ca^{2+} second-messenger pathway. Participation of cAMP may hold a key to linking short-term memory to long-term memory consolidation.

Can intelligence and memory be changed by single genes? We have discussed a number of proteins and genes (as well as neuropeptides) associated with learning and memory. Thus, many researchers have believed that complex higher brain functions such as intelligence are the result of many interacting genes (as well as environmental influences) and thus cannot be readily manipulated. But others believe that single genes may have profound influences on memory and perhaps intelligence. Many studies are being done to test these ideas. Some focus on changes in gene expression during learning. For example, one research team put rats to a standard learning task, and used a gene chip (p. 25) to analyze gene expression in the hippocampus at various times before, during, and after the task. They found that learning was associated with significant changes in expression of about 30 genes. The roles of these genes are mostly still uncertain, but one of them, *Fibroblast Growth Factor (FGF) 18*, was tested further because it increased at every stage of learning. Significantly, injections of FGF-18 into rats improved the ability of rats to learn a new task.

Other studies approach the problem by genetically engineering rodents with ex-

cess genes suspected of being involved in learning, or by knocking out such genes. One study engineered mice to overexpress growth-associated protein *GAP-43*, a target of the second-messenger transducer protein kinase C, and which is suspected of being crucial to the growth of new synapses during learning. Another study engineered mice that had enhanced synaptic release of glutamate. In both cases, mice exhibited significantly greater long-term learning abilities.

Yet another study knocked out a gene called *NR1*, which codes for part of the *NMDA* receptor associated with memory formation. The gene was knocked out in the hippocampus of mice, and the mice indeed could not learn very well. The next study engineered overexpression with another *NMDA* gene, called *NR2B*, that is active only in the forebrain. The mice's forebrains then had an *NMDA* receptor with a major difference: The channel of the receptor stayed open (during learning) about 2.5 times longer than normal (250 msec instead of 100 msec). These mice were smarter—they solved problems such as mazes about 40% faster than normal mice—and their memories were better.

Other such studies have focused on drugs that target genes and proteins involved in learning. For example, a drug that enhances *CREB* activity (see main text below) led to dramatic improvement in learning in mice with cognitive impairments. Another study involved hamsters with learning impairments caused by a lack of circadian rhythm (p. 283); their mutation resulted in constant release of the inhibitory neurotransmitter GABA (p. 133) in hippocampus memory neurons. A drug that blocked GABA binding restored their learning abilities. Such studies are aimed at the development of drugs that might help with certain human mental disorders.

The idea of drugs or genetic manipulations to increase human learning may be appealing, but there may harmful trade-offs (p. 2). Humans who are born with “photographic memories” (people who, for example, can read a long text just once and then can recite it verbatim) often have other cognitive problems, for example, problems with *understanding* a text because of an overwhelming focus on details. Simple pharmaceutical or genetic manipulations of human learning may thus not work as planned.

Long-term memory involves formation of new, permanent synaptic connections

Whereas short-term memory involves transient strengthening of preexisting synapses, long-term memory storage requires the activation of specific genes that control protein synthesis. These proteins, in turn, are needed for the formation of new synaptic connections. Thus, long-term memory storage involves permanent physical changes in the brain.

Studies comparing the brains of experimental rodents reared in a sensory-deprived environment with those raised in a sensory-rich environment demonstrate readily observable microscopic differences. The animals afforded more environmental interactions—and, therefore, more opportunity to learn—have greater branching, “spine” formation and elongation of dendrites in nerve cells in regions of the brain involved with memory storage. Greater dendritic surface area presumably provides more sites for synapses. Thus, long-term memory may be stored at least in part by a particular pattern of dendritic branching and synaptic contacts.

We have seen that sensitization in *Aplysia* increases concentrations of cAMP and protein kinase A in synapses. But what happens after repeated bouts of noxious stimuli? Repeated learning trials causes protein kinase A to move to the nucleus, where it activates a regulatory protein, cAMP

response-element binding protein (CREB-1), which binds to a promoter (the cAMP response element) (Figure 5-35a). This is the molecular switch that activates (turns on) a group of genes, the **immediate early genes (IEGs)**, which play a critical role in memory consolidation. These genes govern the synthesis of the proteins that encode long-term memory. If the action of CREB-1 is somehow blocked (e.g., by the use of specific repressors), then the long term strengthening of these synaptic connections is prevented. Consolidation of procedural as well as declarative memories depends on CREB-1. CREB-1 serves as a common molecular switch for converting both these categories of memory from the transient short-term to the permanent long-term mode. Recently, researchers have found another protein kinase *PKM*, which is somehow activated during sensitization. Blocking *PKM* with an injected inhibitor prevents long-term memory formation. *PKM* is unique in that, once activated, it cannot be shut off, thus insuring memory persistence.

Interestingly, protein kinase A recruits another kinase, called **MAP kinase**, which also migrates to the nucleus and *inactivates* a second form of the CREB protein. In contrast to CREB-1, which activates gene expression, **CREB-2** suppresses gene expression. The shifting balance between positive and repressive factors is believed to ensure that only information relevant to the animal, not everything encountered,

(a) Short- vs long-term stimulation and CREB

FIGURE 5-35 The role of CREB and CPEB in long-term memory in *Aplysia*. (a) Left panel: a summary of short-term sensitization (see Figure 5-33 and main text). Right panel: prolonged stimulation leads to gene activation via *cAMP response-element binding protein 1* (CREB-1), with the resulting growth changes shown.

is put into long-term storage. Thus, formation of enduring memories involves not only the activation of positive regulatory factors (CREB-1, PKM) that favor memory storage but also the turning off of inhibitory, constraining factors (CREB-2) that prevent memory storage. In life-threatening situations, sufficient MAP kinase molecules are presumably sent to the nucleus rapidly enough to inactivate the CREB-2 molecules, so that protein kinase A activates sufficient CREB-1 molecules to ensure that the animal recalls the details of this experience for future reference.

Initially, proteins synthesized in the nucleus are shipped to the activated synapses where they initiate synaptic growth. However, for the growth of new synapses to be sustained,

locally synthesized proteins are now required. For this to occur dormant mRNA synthesized in the nucleus must be activated at these particular synapses by a novel protein, CPEB (cytoplasmic polyadenylation element-binding protein), which regulates local protein synthesis (Figure 5-35b). Of note, CPEB is a *prion*-like protein (p. 173), that is, it self-perpetuates: Once activated at a particular synapse, it remains active for as long as the memory persists. And it is serotonin that is responsible for the activation of CPEB.

Returning to mammals, most investigation of learning and memory has focused on changes in synaptic connections within the brain's gray matter. To complicate the issue even further, scientists now have evidence that white matter also

(b) Long-term memory and the prion-like CPEB protein. As a result of a prior stimulus, the sensory cell's nucleus has sent dormant messenger RNA (mRNA) to all axon terminals (1). Five pulses of serotonin at one terminal convert a prion-like protein (CPEB) that is present at all synapses into a dominant, self-perpetuating form (2). Dominant CPEB can convert recessive CPEBs to the dominant form (3). Dominant CPEB activates dormant messenger RNA (4). The activated messenger RNA regulates protein synthesis at the new synaptic terminal, stabilizes the synapse, and perpetuates the memory.

changes during learning and memory formation as more myelin surrounds axons, especially during adolescence, speeding up transmission between connected neurons. Apparently neurons produce chemical signals such as **neuregulin** that regulate the extent to which myelin-forming cells wrap themselves around the axon. The amount of neuregulin produced is correlated with the extent of action potential propagation within the axon. Accordingly, researchers propose that conduction velocity can be increased by means of further myelination in more active pathways, and that these changes support learning and memory. In addition to a probable role of white matter, numerous hormones and neuropeptides have also been shown to affect learning and memory processes. We discussed one of these, anandamide, earlier (p. 196).

Complex memories and learning may reside in neuronal networks

Although we have seen how the beginnings of learning and memory probably begin with changes in synaptic functions and connections, we have not addressed the larger question of how such changes actually encode a retrievable complex

memory such as an image of an object or the location of a home den or lair. This question about neuronal function remains largely unsolved. Working hypotheses and models that have made some headway in explaining complex learning are based on **neuronal networks** (not to be confused with nerve nets, p. 150). These are largely computer models that simulate a number of neurons with synaptic connections that excite, inhibit, modulate, and change with usage. Crude forms of image recognition and other simple learning have been demonstrated in these models. Whether these represent the way a real nervous system works is still under investigation.

Now let's turn to another incompletely understood phenomenon that may be intimately tied to memory and learning: **sleep**.

Sleep is a nearly universal phenomenon, and has two states in birds and mammals

Sleep is a widespread phenomenon characterized by several features: (1) periods of minimal movement; (2) reduced responsiveness to external stimuli; (3) rapid reversibility (as opposed to hibernation, which is not); and often (4) a

characteristic body posture. For example, bats are noted for their ability to sleep upside down with talons locked onto a cave roof or tree branch (this allows them to drop off to take flight, since bats have trouble taking off from an upright roosting position like birds). However, despite its apparent quiescent nature, sleep is an *active* process, not just the absence of wakefulness. Sleep, at least in mammals, is not accompanied by a reduction in neural activity (that is, the brain cells are not “resting”), as once was suspected, and overall metabolic rate drops by only about 10%. Indeed, during certain stages of sleep, O₂ uptake by the brain is even increased above normal waking levels. Rather sleep involves a profound *change* in neural activity. A certain length of sleep per day seems to be important, since deprivation is normally followed by longer “rebound” sleep.

Some form of sleep probably occurs in most types of animals except sponges, although the phenomenon has not been studied in many phyla. In some species true neurological sleep states can be difficult to ascertain and the behavioral indices of minimal movement and reduced responsiveness to external stimulation may be used to define the sleep state. For example, researchers in Australia attached small tracking devices to box jellies (Cnidaria), and found that at night, they sank to the seafloor and ceased swimming. Thus, sleep, or sleeplike states, are widespread. Why is that? Before we tackle that question, let’s look at some key aspects of sleep in more detail.

Neural aspects of sleep are often determined by electrical recordings. Extracellular current flow arising from electrical activity within the vertebrate cerebral cortex can be detected by placing recording electrodes on the head to produce a graphic record known as an **electroencephalogram**, or EEG. These “brain waves” for the most part are not due to action potentials but instead represent the momentary collective postsynaptic potential activity (that is, EPSPs and IPSPs; see p. 132) in the cell bodies and dendrites located in the cortical layers under the recording electrode. Electrical activity can always be recorded from the living brain, even during sleep and unconscious states, but the waveforms vary, depending on the degree of activity in the cerebral cortex. Interestingly, some cetaceans and some birds can sleep with one half of the brain while the other half is awake, so-called **unihemispheric slow-wave sleep**. This may be so that they keep a lookout for predators. In the case of cetaceans, this may also allow them to regularly surface to breathe, while for migrating birds, this might let them keep flying on long transoceanic migrations without stopping.

In birds and mammals two types of sleep can be characterized by different EEG patterns as well as different behaviors: *slow-wave sleep* and *paradoxical*, or *REM*, *sleep*. **Slow-wave sleep** is characterized by slow, large EEG waves and by considerable muscle tone with frequent body shifts. **Paradoxical** or **REM sleep** has rapid small EEG waves similar to the wake state, but with muscle tone absent and little movement except for breathing and rapid eye movements (hence the term *REM*). Reptiles such as the Mexican giant tortoise and spiny-tailed iguana exhibit two distinct sleep phases with similar characteristics. Although still speculative, recent studies suggest that these forms of sleep serve different purposes. Birds and nonhuman mammals have cycles of non-REM and REM sleep comparable to humans, though birds’ cycles are much shorter. Short bouts of REM sleep concomitant with unihemispheric sleep enable some species of birds to sleep

“on the wing.” Horses and other herbivorous ungulates can sleep while standing, but must necessarily lie down for brief periods when shifting from slow-wave to REM sleep.

The function of sleep is unclear

Now let’s turn to the big question: why sleep? Despite considerable research, why sleep occurs largely remains a mystery. Let’s look at the major hypotheses.

1. *Restoration and recovery*: One widely accepted proposal holds that sleep provides “catch-up” time for the brain to restore biochemical or physiological processes that have progressively degraded during wakefulness. The most direct evidence supporting this proposal is the role of *adenosine* as a neural sleep factor. Adenosine, the backbone of adenosine triphosphate (ATP), the cell’s energy currency, is generated during the awake state by metabolically active neurons and glial cells. Thus, the brain’s extracellular concentration of adenosine continues to rise the longer an animal has been awake. Adenosine, which acts as a neuromodulator, has been shown experimentally to inhibit the arousal centers (the brainstem RAS and hypothalamus). This action can bring on slow-wave sleep, during which restoration and recovery activities are believed to take place. Adenosine levels diminish during sleep, presumably because the brain uses this adenosine as a raw ingredient for replenishing its limited energy stores. Thus, the need for sleep may stem from the brain’s periodic need to replenish diminishing energy stores. Because adenosine reflects the level of brain cell activity, the concentration of this chemical in the brain may serve as a gauge of how much energy has been depleted.

Another “restoration and recovery” proposal suggests that slow-wave sleep provides time for the brain to repair the damage caused by the toxic free radicals produced as by-products of the stepped-up metabolism during the waking state. A possible “restoration and recovery” function of REM sleep is to let some of the neural pathways regain full sensitivity. When an animal is awake, the brain neurons that release the neurotransmitters norepinephrine and serotonin are maximally and continuously active. Release of these neurotransmitters ceases during REM sleep. Studies suggest that constant release of norepinephrine and serotonin can desensitize their receptors. Perhaps REM sleep is needed to restore receptor sensitivity for optimal functioning during the next period of wakefulness.

In support of these ideas is the observation that smaller, high-metabolic-rate mammals need much more sleep than large, low-metabolic-rate ones (a *scaling* phenomenon; see p. 10). For example, in hours per day, a brown bat sleeps 20, a house cat 13.5, a human 8, and an Asiatic elephant 3.1. The correlation is not perfect—a lion, for example, may sleep as much as a house cat—but overall the trend is quite striking.

2. *Memory processing*: Another leading theory has nothing to do with restoration and recovery. Instead, other researchers believe that sleep is necessary to allow the brain to “shift gears” to accomplish the long-term structural and chemical adjustments necessary for learning and memory. This theory might explain the observation

that young mammals tend to sleep for a larger proportion of each 24-hour day than adults (although some dolphins and orcas do not sleep at all during the first weeks of life, likely because of their vulnerability to predators). Young mammals' highly plastic brains are rapidly undergoing profound synaptic modifications in response to environmental stimulation. In contrast, neural changes in older animals are less dramatic. Some evidence suggests that the different types of sleep might be involved in consolidation, editing and even elimination of different kinds of memories, with declarative memories being processed during slow-wave sleep and procedural memories during REM sleep. A recent memory-related theory is that sleep, especially slow-wave sleep, is a time for replaying the events of the day, not only to help consolidate memories but perhaps to make recent experiences more meaningful by catching information missed on first pass and by "connecting the dots" between new pieces of information. Also, some evidence shows that recent memories deemed irrelevant are deleted (forgotten), an essential action to prevent what might become an overwhelming amount of stored "data." Recall that the neuromodulator *anandamide* is involved in this process in some memory regions (p. 196).

Even the nematode worm *Caenorhabditis elegans* has a sleeplike period during its early development. Importantly, this occurs when its nervous system is undergoing its most rapid changes in synaptic growth and pruning.

3. *Energy conservation* is another theory of why animals need sleep. This may indeed be the case for less complex animals such as box jellies; but this proposal is not as widely accepted for vertebrates because of the level of neural activity during sleep.

These various hypotheses are not mutually exclusive. Sleep might serve multiple purposes.

The term *consciousness* refers to a subjective awareness of the world and self

This ends our coverage of nervous system evolution and mechanisms. There is one final topic of complex brain function we have not analyzed: *consciousness*. This term refers to subjective awareness of the external world and self. Even though it is clear that the final level of awareness resides in the cerebral cortex, and although there is evidence that a crude sense of awareness depends on the thalamus, conscious experience depends on the integrated functioning of many parts of the nervous system. The cellular and molecular basis underlying consciousness remains one of the greatest unanswered questions in neuroscience. Although consciousness is a thorny topic, some researchers believe that many primates (in addition to humans), African parrots, elephants, and dolphins have a sense of self and personal experience over time. For example, these animals and humans (but not other animals that have been tested) recognize themselves in mirrors. Perhaps other animals have a personal self-image as well.

The following states of consciousness are listed in decreasing order of arousal level, based on the extent of interaction between peripheral stimuli and the brain:

- maximum alertness
- wakefulness
- sleep (several different types)
- coma

Maximum alertness depends on attention-getting sensory input that "energizes" the RAS and subsequently the activity level of the CNS as a whole. At the other extreme, coma is the total unresponsiveness of a mammal to external stimuli, caused either by brainstem damage that interferes with the RAS or by widespread depression of the cerebral cortex, such as accompanies O₂ deprivation.

How Nervous Systems Contribute to the Body as a Whole

To interact in appropriate ways with the external environment to sustain an animal's viability, such as in the acquisition of food, and to make the internal adjustments needed to maintain homeostasis, the animal's body must be informed about any changes taking place in the external and internal environment and must be able to process this information and send messages to various effectors to accomplish the desired results. The nervous system, one of the body's two major control systems, plays a central role in this life-sustaining communication. The central nervous system (CNS) receives information about the external and internal environment by means of afferent peripheral nerves. After sorting, processing, and integrating this input, the CNS sends commands by means of efferent peripheral nerves to bring about appropriate muscular contractions, glandular secretions, and other effector functions. Electrical signaling allows for rapid responses.

Much neural regulation is aimed toward maintaining homeostasis, whereas some is for regulated changes. For example, when informed by the afferent nervous system that blood pressure has fallen in a mammal, the CNS sends appropriate commands to the heart and blood vessels to increase the blood pressure to normal. When a predator is detected through the eyes, and recognized in the brain, commands may be sent to initiate rapid running. Were it not for this processing and integrative ability of the CNS, coordinated regulation of multiple organs in complex animals would be impossible.

The autonomic nervous system in vertebrates plays a major role in the following range of homeostatic activities:

- Regulation of blood pressure.
- Control of digestive juice secretion and of digestive tract contractions that mix ingested food with the digestive juices.
- Control of sweating to help maintain body temperature.

The somatic nervous system of vertebrates, the efferent branch that innervates skeletal muscle, contributes to homeostasis by stimulating the following activities:

- Skeletal muscle contractions that enable the body to move in relation to the external environment contribute to homeostasis by, for example, moving the body toward food or away from harm.
- Skeletal muscle contraction also accomplishes breathing to maintain appropriate levels of O_2 and CO_2 in the body.
- Shivering is a skeletal muscle activity important in the maintenance of body temperature.

Nervous systems have become progressively more complex during evolution, with more sophisticated control of homeostasis and regulated change. However, more primitive regions retain many controls necessary for survival. For example, in vertebrates, the spinal cord integrates many basic

protective and evacuative reflexes that do not require higher levels, such as withdrawal from a painful stimulus and emptying of the urinary bladder. The newer levels piled on top of the older ones progressively modify, enhance, or nullify actions coordinated by lower levels in a hierarchy of command, using new capabilities such as complex perceptual awareness of the external environment, initiation of nonreflex skeletal muscle movements, memory and anticipation, and consciousness. Learning and both types of memory form the basis by which animals adapt their behaviors to their particular external circumstances. Without these mechanisms, planning for successful interactions and intentional avoidance of predictably disagreeable circumstances would be impossible.

Chapter Summary

- Nervous systems evolved from simple reflex arcs to centralized brains with distributed, hierarchic regulation.
- Sponges have no nerves but can respond to stimuli using electrical signals.
- Nerve nets are the simplest nervous systems and are found in most animals. Simple ganglia and nerve rings evolved for more complex behavior.
- There has been an evolutionary trend for the most anterior region of the CNS to be larger and contain sizable clusters of neurons, which contributed to the evolution of a so-called superganglion or brain.
- The logarithm of brain weight as a function of body weight is typically linear for a variety of vertebrates, with a positive slope indicating that the overall size of an animal is related to its relative brain size.
- As with bilateral animals in general, the nervous system of vertebrates is organized into a central nervous system (CNS) and a peripheral nervous system (PNS).
- Three classes of neurons make up the nervous system: afferent neurons, efferent neurons, and interneurons.
- The autonomic efferent division of the PNS is the communication link by which the CNS controls the activities of muscles, glands, and other effector organs that carry out actions, such as making feedback correction. Each autonomic nerve pathway extending from the CNS to an innervated organ consists of a two-neuron chain.
- The sympathetic system promotes responses that prepare a vertebrate animal for strenuous physical activity in the face of emergency or other stressful situations, such as a physical threat from the environment. The parasympathetic system, in contrast, dominates in quiet, relaxed situations. Sympathetic and parasympathetic preganglionic fibers release the same neurotransmitter, ACh (acetylcholine), but the postganglionic endings of these two systems release different neurotransmitters that influence the effector organs. Dual innervation of organs with nerve fibers whose actions oppose each other enables precise control over an organ's activity.
- Responsive tissue cells have one or more of several different types of plasma membrane receptor proteins for the respective neurotransmitters released from the presynaptic terminal. Binding of a neurotransmitter to a receptor induces the tissue-specific response.
- About 90% of the cells within the CNS are not neurons but glial cells, which serve as the connective tissue of the CNS and as such help support the neurons both physically and metabolically.
- A highly selective blood–brain barrier carefully regulates exchanges between the blood and brain. The brain floats in a cushioning cerebrospinal fluid.
- Neurogenesis is a normal function of several regions of the brain. Brains of virtually all vertebrates display a degree of plasticity.
- Newer, more sophisticated regions of the vertebrate brain are piled on top of older, more primitive regions. A vertebrate brain is classically organized into three distinct regions—the hindbrain, midbrain, and forebrain. The forebrain has changed more than other regions of the brain during vertebrate evolution.
- The spinal cord is strategically located between the brain and afferent and efferent fibers of the PNS; this location enables the spinal cord to fulfill its two primary functions: (1) serving as a link for transmission of information between the brain and the remainder of the body and (2) integrating reflex activity between afferent input and efferent output without involving the brain.
- The brainstem is a critical connecting link between the remainder of the brain and the spinal cord. The cerebellum is important in balance as well as in planning and execution of nonreflex movements, coordinating by anticipating needed motions.
- The basal nuclei play a complex role in the control of movement in addition to having nonmotor functions that are less well understood.
- The thalamus serves as a “relay station” and synaptic integrating center for preliminary processing of all sensory input on its way to the cortex.
- The hypothalamus is a collection of specific nuclei and associated fibers that lie beneath the thalamus. It is an integrating center for many important homeostatic functions and serves as an important link between the autonomic nervous system and the endocrine system.
- The cerebrum, by far the largest region of mammalian brains, is divided into two halves, the right and left hemispheres. Functionally, it has sensory, motor, and associative cortices.
- Sensations from the surface of the body, such as touch, pressure, heat, cold, and pain, are collectively known as somesthetic sensations. Within the CNS of mammals, this information is transmitted along specific neural pathways to higher brain levels to the somatosensory cortex.

- The primary motor cortex located in the frontal lobes controls the skeletal muscles. The motor cortex is activated by a widespread pattern of neuronal discharge, the readiness potential.
- The limbic system controls basic emotions, responses to fear, and primitive memory.
- Learning is the acquisition of abilities or knowledge as a consequence of experience, instruction, or both. Memory comes in two forms—declarative and procedural—and is laid down in stages.
- Two forms of short-term memory—habituation and sensitization—are due to modification of different membrane channel proteins in presynaptic terminals of specific afferent neurons, which in turn brings about changes in transmitter release. In habituation, repeated stimulation leads to closing of the Ca^{2+} channels, reducing Ca^{2+} entry into the presynaptic terminal, which leads to a decrease in quantity of neurotransmitter released. In contrast, Ca^{2+} entry into the presynaptic terminal is enhanced in sensitization.
- Whereas short-term memory involves transient strengthening of preexisting synapses, long-term memory storage requires the activation of specific genes that control protein synthesis. These proteins, in turn, are needed for the formation of new synaptic connections.
- In birds and mammals, two types of sleep can be characterized by different EEG patterns as well as different behaviors: slow-wave sleep and paradoxical, or REM, sleep. Sleep's role is unclear, but may serve for restoration and recovery and/or to process memory.

Review, Synthesize, and Analyze

1. What factors determine the complexity of a nervous system?
2. Would you expect the self-perpetuating form of CPEB (which maintains protein synthesis in a particular neuron) to be capable of reverting back to its inactive state? Support your reasoning.
3. If tight junctions limit transport of substances through brain capillaries, how can veterinarians treat disorders of the brain?
4. Why is plasticity an important feature of neural function?
5. What is the relationship between the basal nuclei and the thalamus?
6. Describe the process by which a permanent memory is made.
7. Are genes that encode suppressor proteins for converting short-term to long-term memory set at a low or high threshold? Explain your reasoning.
8. Compare the evolution of intelligence in birds and mammals.

The great white shark, *Carcharodon carcharias*. Like other sharks, it has electrical sensors in its snout that allow it to find prey even in murky waters and when its eyes are covered by protective flaps during an attack.

Sensory Physiology

6.1 Evolution and Roles of Senses

In Chapter 1, you learned that organisms must gather information about their environments and internal states if they are to successfully achieve regulated changes and homeostasis. The shark above, for example, finds its prey by detecting sound waves, light patterns, chemicals in the water, the flow of water, and electrical fields. This multifaceted information allows its nervous system to regulate muscles for swimming toward, and subsequently locating and consuming, the prey. In turn, prey consumption aids in internal energy homeostasis. In animals, the ability to gather such information is typically done by **sensory cells**, each of which responds to a specific **stimulus**—defined as any agent detectable by an organism—such as light, vibration, and so on. In this chapter we will examine how these cells work.

Sensory cells have ion channels and receptor proteins with specific modalities

Animal nervous systems transmit information by electrical signals (graded and action potentials, Chapter 5). Thus, sensory cells must be specialized to perform **transduction**: the conversion of one form of energy—an external stimulus—into electrical energy that can be interpreted by a nervous system. The process of transduction is inextricably linked to the opening and closing of *ion channels*, often due to the actions of *receptor proteins* in plasma membranes, which bind specific chemicals. As you saw in Chapters 3 and 4, ion channels and receptor proteins are universal components of living systems, found even in prokaryotes. Recall that channels fall into two broad types: **leak channels** (which are always open) and **gated channels**, that is, ones that open and/or close in response specific stimuli (p. 81). The

latter come in four forms (p. 94): (1) *mechanically gated*, (2) *chemically gated*, (3) *voltage-gated*, and (4) *thermally gated* channels. Let's begin with a look at the evolution of receptor proteins and ion channels in sensory functions.

1. *Mechanically gated* were probably the first gated ion channels to evolve. Sensitive to stretch, they may have served as osmotic stress sensors in prokaryotes, opening when a cell was deformed by changes in cell volume. By opening, such channels *transduce* mechanical deformation into an ion current. In turn, the current triggers compensatory processes.
2. *Chemically gated* channels are also ancient, probably arising initially for sensing chemicals in the environment. Such sensing by single cells often involves *chemoreceptor proteins* rather than, or in addition to, gated channels. A key example is found in **chemotaxis**: movement

of an organism toward or away from a chemical substance. For example, bacteria and protozoa residing in ruminant stomachs are attracted to “desirable” molecules such as sugars, amino acids, and small peptides, which are associated with the arrival of a fresh bolus of food. They also can move away from toxins. Both responses follow the binding of the molecules to surface-membrane receptor proteins, which transduce the signal to the cell interior to alter flagellar motions. In many bacteria, these chemoreceptor proteins are strategically localized at the forward-moving pole of the cell.

Receptor-based chemoreception is at the heart of the evolution of multicellularity, as evidenced by *inter-cellular communication* in the slime mold (*Dictyostelium discoideum*). Starvation induces the single-celled amoeba to secrete cAMP (p. 97) into the environment, which serves as a chemoattractant for neighboring amoeba. Chemotaxis leads the amoebas to aggregate into large-bodied slugs, which can move to a new food source or turn into a reproductive stage to spread spores to new habitats. Activation of the membrane-bound cAMP receptor protein triggers a G-protein-linked biochemical cascade (p. 97), which leads to the developmental changes. As you will see, this mechanism was retained by animals in various forms of chemosensing.

3. *Voltage-gated channels* are also ancient, but their ancestral functions are unclear. For example, in the common gut and laboratory bacterium *Escherichia coli*, two types of membrane channels have been identified, one of which responds to deformation, and another that is voltage gated (and with an uncertain function, though it may be involved in sugar transport). Voltage-gated K⁺ channels are also found in the plasma membranes of yeast cells and various plant cells. For example, these channels are essential to the opening of stomata, the pores of leaves that allow for gas exchange. Moreover, K⁺- and Ca²⁺-based action potentials are generated in response to touch in fast-moving plants such as the insectivorous Venus flytrap. However, Na⁺ channels are found only in animals and a few protists, where they are essential to long-range signaling involved in both sensory input and effector control (Chapters 4 and 5).
4. *Thermally gated channels* are widespread in animals and are also found in some animal-like protists including *Paramecium* (protozoa with swimming cilia that cover much of the cell; p. 25). However, the evolution of these channels is poorly known outside of animals.

Paramecium are of great interest to animal physiologists because they can actually be considered free-swimming sensory cells with most of the sensory capabilities of animals. That is, they can respond to a variety of environmental stimuli—not only thermal but also mechanical, chemical, *photoc* (light), and ionic—through changes in their membrane potentials. They have multiple types of ion-selective membrane channels that are voltage, chemically, mechanically, and thermally gated, and they have receptor proteins that react to certain chemicals that indirectly affect membrane potential via second messenger. They respond behaviorally by changing either their cell shape or the pattern of ciliary beating. Thus, much of the machinery associated with the function of sensory neurons arose long before the evolution of nervous systems.

The four types of gated channels, some leak channels, and various receptor proteins provide the basic transduction mechanisms for animal sensory cells. Animal physiologists recognize six to eight types of such sensors based on their **modalities**—the kind of stimulus they react to. (Note again that the term *receptor* can refer both to a protein and to a whole sensory cell; in this chapter, we will refer to the proteins as *receptor proteins* or *sites*, while calling the cells *receptors*, *receptor cells* or *sensors* interchangeably.)

- **Mechanoreceptors** are sensitive to mechanical energy through various mechanically gated channels. Examples include touch and pressure sensors in the skin; skeletal muscle sensors sensitive to stretch; sound, motion, and balance sensors in the mammalian ear; and osmosensors and baroreceptors in vertebrate bloodstreams.
- **Chemoreceptors** are sensitive to specific chemicals due primarily to chemical receptor proteins and chemically gated channels. Chemoreceptors include those for smell and taste, as well as those that detect O₂ and CO₂ concentrations in the blood and the chemical content of the digestive tract. Leak and voltage-gated channels are involved in sensing ions, for example, in salty food or as the primary component of the osmotic concentration of blood.
- **Thermoreceptors** are sensitive to heat and cold by having thermally gated channels.
- **Photoreceptors** are sensitive to photic energy, including ultraviolet and infrared wavelengths. They have light-activated receptor proteins which in turn control chemically gated channels.
- **Electroreceptors** are responsive to electric fields by poorly known mechanisms, most likely involving leak channels or voltage-gate channels.
- **Magnetoreceptors** are responsive to magnetic fields. These may use a special type of mechanical gating.

In addition, one other type of stimulus is sometimes classified separately:

- **Nociceptors, or pain receptors**, are sensitive to tissue damage such as pinching or burning, to distortion of tissue, or to harmful chemicals. These are thought to be types of chemo- and mechanoreceptors. Intense stimulation of almost any sensor is also perceived as painful, at least to mammals.

Animal senses can be classified into three roles: sensing the external environment, the internal environment, and body motion and position

In complex animals, the number and types of sensory cells are quite extensive, far more than the classic “five senses” frequently taught. In addition to categorizing sensors by modality (above), physiologists recognize three primary *roles* of receptor cells:

- **Interoceptors** detect information about the internal body fluids usually crucial to homeostasis, such as blood pressure and the concentration of O₂.
- **Proprioceptors** send information about movement and the position of an animal’s body or certain parts such as limbs.
- **Exteroceptors** are the “classic” senses that detect external stimuli such as light, chemicals (for taste, smell), touch, temperature, electromagnetic fields, and sound.

In vertebrates, interoceptors are located at numerous sites, mainly in association with blood vessels and gut fluids. Proprioceptors are located mainly in the muscles, tendons, and joints, and also in the inner ear. Finally, exteroception information is sometimes categorized as (1) **somesthetic sensation** arising mainly from the body surface (touch, pressure, temperature, pain, and electrical fields), and (2) **special senses**, including *vision*, *hearing*, *taste*, and *smell*. Somesthetic sensors, found diffusely in many organs but most notably in the integument, provide information about an animal's interaction with the environment across its entire surface and about some internal physical stresses. In contrast, each of the special senses has highly localized, extensively specialized sensors (usually in a distinct, dedicated sensory organ) that respond to unique environmental stimuli. Each animal group has evolved specific senses that are essential for survival in its particular environment.

The peripheral nervous system (PNS) carries information about body position and motions and about internal and external environments from the sensory cells to the central nervous system (CNS: spine and brain in vertebrates). For example, the incoming pathway for information derived from visceral interoceptors is called a **visceral afferent**. Processing of sensory input by the CNS, followed by efferent activation of appropriate effectors, is essential for interaction with the environment for basic survival (for example, food procurement and defense from predators).

Perception is not reality

If the sensory information from the PNS reaches the brain, it may be *perceived* by the animal. **Perception** is an animal's interpretation of the external world as created by the brain from a pattern of nerve impulses delivered to it from sensory cells. This is primarily a human concept because we cannot know what another animal truly perceives.

unanswered Questions | Do fish perceive pain?

Recent studies with fish illustrate the difficulties in demonstrating perception in nonhuman animals. Bony fish (teleosts) have skin sensors that are similar to pain sensors in mammals, whereas earlier evolved fish (cartilaginous fishes, lampreys) do not. To investigate the possible perception of pain in fish, researchers injected acetic acid or bee venom (irritants) or saline (a control) into the lips of trout. The trout with acetic acid exhibited complex nonreflex behaviors, such as rubbing their lips on the aquarium walls, which indicated a perception of pain. Similar experiments in more primitive fish did not induce such behaviors. Other researchers attached tiny heaters to goldfish after some were injected with pain-suppressing morphine and others with saline. After heat exposure, the fish without painkillers retreated to one spot in their tank where they remained, as if they were fearful or wary of their environments. This suggested some perception of pain occurred. However, other researchers note that fish lack the neocortical centers associated with pain perception in mammals, and their responses in these studies could be avoidance behaviors triggered as reflexes in the absence of

true perception. Thus, it is still not certain whether any fish actually perceive pain. See the Suggested Readings by Rose (2002), Sneddon et al. (2003), and Nordgreen et al. (2009). <<

Is the environment, as we humans and other animals perceive it, reality? The answer is a resounding no. Perception is different from what is really “out there” for several reasons. Humans, for example, have sensors that detect only a limited number of existing energy forms. We perceive sounds, colors, shapes, textures, smells, tastes, and temperature but are not informed of magnetic and electric forces and polarized and ultraviolet light waves (stimuli that some animals can sense), because we lack sensors for the latter energy forms. Our response range is limited even for the energy forms for which we do have sensors. For example, dogs can hear a dog whistle pitched above our level of detection. Second, the information channels to our brains are not high-fidelity recorders. During precortical processing of sensory input, many features of stimuli are *filtered*: Some features are accentuated, and others are suppressed or ignored. For example, the retina of mammals, horseshoe crabs, and many other animals actively enhances *contrast*, making fuzzy boundaries appear as sharp edges. Furthermore, the mammalian retina also enhances light signals from any object that is moving relative to the background light.

Third, the cerebral cortex further manipulates the data, comparing the sensory input with other incoming information as well as with memories of past experiences to extract the significant features—for example, sifting out a friend's words from the hubbub of sound in a school cafeteria. In the process, the cortex often fills in or distorts the information to abstract a logical perception; that is, it “completes the picture.” Human brains, for example, are primed to detect faces even with limited input; as a result, we easily “see” faces where there are none, such as in natural stone formations and a mountain on Mars (or Figure 6-1a). Our brains are also primed to recognize that an object will appear smaller the further away it is. Many optical illusions, used by artists, architects, and photographers, can use this expectation to make objects look smaller or larger than they are (Figure 6-1b). Chimpanzees are also subjected to such optical illusions, and at least one other animal may actually exploit one. Consider the male great bowerbird of Australia, which builds tunnel-like nests to attract females for mating. Remarkably, he selects stones of various sizes and lays them out from the backside of the tunnel in increasing size, to form a “courtyard” (Figure 6-1c). This array of stones may trick the female brain (as it does the human brain) into perceiving that the courtyard is much smaller than it is, since normally a courtyard would have paving stones of equal size that should appear to get smaller with distance. The illusion may cause the male sitting in the small-appearing courtyard to look much larger than he is. When John Endler and colleagues, who discovered the illusion, reversed the stone array, the male bird dutifully restored it to the original pattern, showing that it was deliberate.

Optical illusions illustrate how the brain interprets reality according to its own rules. Thus, perceptions do not replicate reality. Species equipped with different types and sensitivities of sensors and numbers of sensors, with different neural processing, presumably would perceive a markedly different, but nevertheless filtered, world from ours.

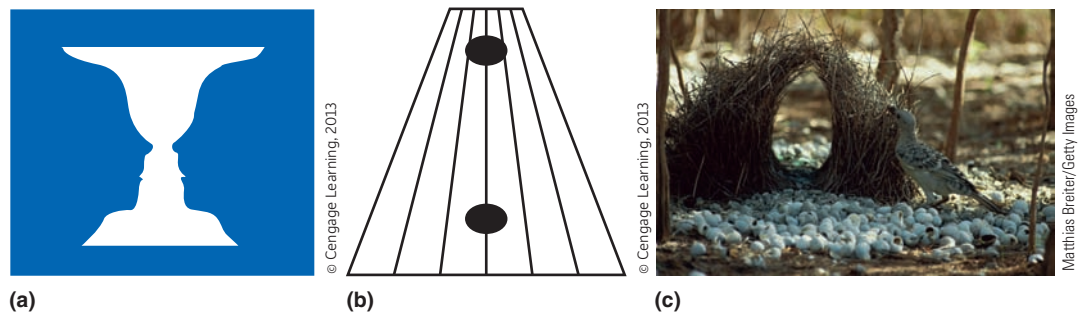

FIGURE 6-1 Optical Illusions. (a) Do you see two faces in profile, or a wineglass? Can you see both at once? (b) Forced perspective illusion. The two ovals are identical in size, but the upper one appears larger. The drawing simulates a path receding into the distance, and our brains expect that “distant” objects should appear small. (c) Forced perspective illusion. A male great bowerbird builds a tunnel-like nest and “courtyard” of small to large stones that possibly make him look bigger to a female entering the nest (see main text).

check your understanding 6.1

List and describe the receptor types according to their modalities and roles.

Describe the ancient roles of receptors and ion channels in sensing.

6.2 Receptor Cell Physiology

As we’ve discussed, stimuli exist in a variety of modalities, such as heat, sound, and chemical changes. Sensory cells must detect these different forms of energy using their ion channels and/or receptor proteins.

Receptors have differential sensitivities to various stimuli

Each type of receptor (sensory cell) is specialized to respond more readily to one type of stimulus, called its **adequate stimulus**, than to other stimuli. For example, receptors in the eye are most sensitive to light, certain receptors in the ear to sound waves, and warmth receptors in the skin to heat energy. An animal cannot “see” with its ears or “hear” with its eyes because of this differential sensitivity of receptors, a principle Johannes Müller formulated in 1835 and entitled the **doctrine of specific nerve energies**. Some receptors can respond weakly to stimuli other than their adequate stimulus, but even when activated by a different stimulus, a receptor still gives rise to the sensation usually detected by that receptor type. As an example, the adequate stimulus for eye receptors (photoreceptors) is light, to which they are exquisitely sensitive, but these receptors can also be activated to a lesser degree by mechanical stimulation. When hit in the eye, a person often “sees stars” because the mechanical pressure stimulates the photoreceptors, and the brain interprets the action potentials as light. Thus, the sensation perceived depends on the type of receptor stimulated rather than on the type of stimulus.

Some sensations in humans are compound sensations in that their perception arises from central integration of sev-

eral, simultaneously activated, primary sensory inputs. For example, the perception of wetness comes from touch, pressure, and thermal receptor input; there appears to be no such thing as a “wet receptor.”

Uses for Information Detected by Receptors The information detected by receptors is conveyed via afferent neurons to the CNS to be used for a variety of purposes:

- Afferent input is essential for control of efferent output, both for regulating motor behavior in accordance with external circumstances and for coordinating internal activities to maintain homeostasis.
- Central processing of sensory information gives rise to an animal’s perceptions of the environment in the higher brain centers. In humans at least, it can also evoke emotional responses.
- Processing of sensory input by the reticular activating system in the vertebrate brain stem is critical for cortical arousal and consciousness (see p. 184).
- Finally, selected information delivered to the CNS may be learned for future reference.

Next let’s examine how adequate stimuli initiate action potentials that ultimately are used for these purposes.

A stimulus alters the receptor’s permeability, leading to a graded receptor potential

A receptor may be located either (1) on an afferent neuron with a specialized dendrite or (2) a separate cell closely associated with a dendrite of an afferent neuron (Figure 6-2). As we noted earlier, stimulation of a receptor alters its permeability to selective ion(s). The means by which this permeability change takes place is individualized for each receptor type. Because the electrochemical driving force is greater for Na^+ than for other small ions at resting potential, the predominant channel is an Na^+ one, leading to an inward flux of Na^+ that depolarizes the receptor membrane. (There are exceptions; for example, vertebrate photoreceptors are hyperpolarized on stimulation, as you will see later.)

This local depolarizing change in potential is known as a **receptor potential** in the case of a separate receptor cell or as a **generator potential** if the receptor is a specialized afferent

(a) Receptor potential in specialized afferent ending

1 In sensory receptors that are specialized afferent neuron endings, stimulus opens stimulus-sensitive channels, permitting net Na^+ entry that produces receptor potential.

2 Local current flow between depolarized receptor ending and adjacent region opens voltage-gated Na^+ channels.

3 Na^+ entry initiates action potential in afferent fiber that self-propagates to CNS.

(b) Receptor potential in separate receptor cell

1 In sensory receptors that are separate cells, stimulus opens stimulus-sensitive channels, permitting net Na^+ entry that produces receptor potential.

2 This local depolarization opens voltage-gated Ca^{2+} channels.

3 Ca^{2+} entry triggers exocytosis of neurotransmitter.

4 Neurotransmitter binding opens chemically gated receptor-channels at afferent ending, permitting net Na^+ entry.

5 Resultant depolarization opens voltage-gated Na^+ channels in adjacent region.

6 Na^+ entry initiates action potential in afferent fiber that self-propagates to CNS.

FIGURE 6-2 Conversion of receptor and generator potentials into action potentials. (a) Specialized afferent ending as sensory receptor. Local current flow between a depolarized receptor ending undergoing a receptor potential and the adjacent region initiates an action potential in the afferent fiber by opening voltage-gated Na^+ channels. (b) Separate receptor cell as sensory receptor. The depolarized receptor cell undergoing a receptor potential releases a neurotransmitter that binds with chemically gated channels in the afferent fiber ending. This binding leads to a depolarization that opens voltage-gated Na^+ channels, initiating an action potential in the afferent fiber.

© Cengage Learning, 2013

neuron. For convenience, from here on we refer to both receptor and generator potentials as *receptor potentials*. The receptor potential is graded (see p. 113) with an amplitude and duration that can vary, depending on the strength and the rate of application or removal of the stimulus. That is, *the stronger the stimulus, the greater the permeability change and the larger the receptor potential*. As is true of all graded potentials, receptor potentials have no refractory period (p. 124), so summation in response to rapidly successive stimuli is possible. Because the receptor region lacks voltage-gated action-potential channels, the receptor potential must be converted into action potentials for long-distance transmission.

Receptor potentials may initiate action potentials in the afferent neuron

If of sufficient magnitude, a receptor potential can initiate an action potential in the afferent neuron membrane adjacent to the receptor cell or dendritic region by triggering the opening of voltage-gated Na^+ channels in this region. The means by which the Na^+ channels are opened differ depending on whether the receptor is a separate cell or a specialized afferent ending.

- In the case of a specialized afferent ending (Figure 6-2a), local current (from the receptor potential) flows between the activated receptor and the nearby *trigger zone* (p. 121), opening voltage-gated Na^+ channels.
- In the case of a separate receptor, such as in the retina, a receptor potential triggers the release of a chemical messenger—a *neurotransmitter*—that diffuses across a synapse between the receptor and an afferent neuron

(Figure 6-2b). Binding of the neurotransmitter with specific protein receptors on the afferent neuron opens chemically gated Na^+ channels (see pp. 130–132). The subsequent graded current travels to the trigger zone of the afferent and opens voltage-gated Na^+ channels.

In either case, if the magnitude of the resulting ionic flux is sufficient to bring the trigger-zone membrane to threshold, action potentials are initiated that self-propagate along the afferent fiber to the CNS. Of course, not all stimuli result in action potentials. For example, mosquitoes can land so lightly on the skin of a mammal that the receptor potentials generated in touch sensors do not reach threshold.

Note that in an afferent neuron the trigger zone differs from that in an efferent neuron or interneuron. In the latter two types of neurons, the trigger zones are located in the axon hillock at the beginning of the axon adjacent to the cell body (see p. 121). By contrast, action potentials are initiated at the peripheral end of an afferent nerve fiber adjacent to the receptor region, often a long distance from the cell body (Figure 6-3).

A larger receptor potential does not bring about a larger action potential (recall the all-or-none law, p. 125), but will induce a more rapid firing of action potentials. This is one way stimulus strength is coded: The *stronger* the stimulus, the greater the *frequency* of action potentials (Figure 6-4). Stimulus strength is also reflected by the *size of the area* stimulated. Stronger stimuli usually affect larger areas, so a correspondingly greater population of receptors responds. For example, a light touch does not activate as many pressure receptors in the skin as a more forceful touch applied to the same area. Stimulus intensity is therefore distinguished both by the frequency of action potentials generated in the afferent neuron (**frequency code**) and by the number of receptors activated within the area (**population code**).

Receptors may fire continuously or adapt slowly or rapidly to sustained stimulation

Stimuli of the same intensity do not always bring about receptor potentials of the same magnitude from the same receptor. Some receptors can diminish the extent of their depolarization despite sustained stimulus strength, a phenomenon called **adaptation** (see p. 17 for caveats regarding this term). That is, the receptor “adapts” to the stimulus by decreasing its response to it or not responding at all.

Tonic and Phasic Receptors The two types of receptors—*tonic* and *phasic* receptors—differ in speed of adaptation. **Tonic receptors** do not adapt at all, or adapt slowly (Figure 6-5a). These receptors are important in situations where maintained information about a stimulus is valuable. Examples are muscle stretch proprioceptors, which monitor muscle length, and joint proprioceptors, which measure the degree of joint flexion. To maintain posture and balance, the CNS must continually be informed about the degree of muscle length and joint position. It is important, therefore, that these receptors do not adapt to a stimulus but continue to generate action potentials to relay this information to the CNS.

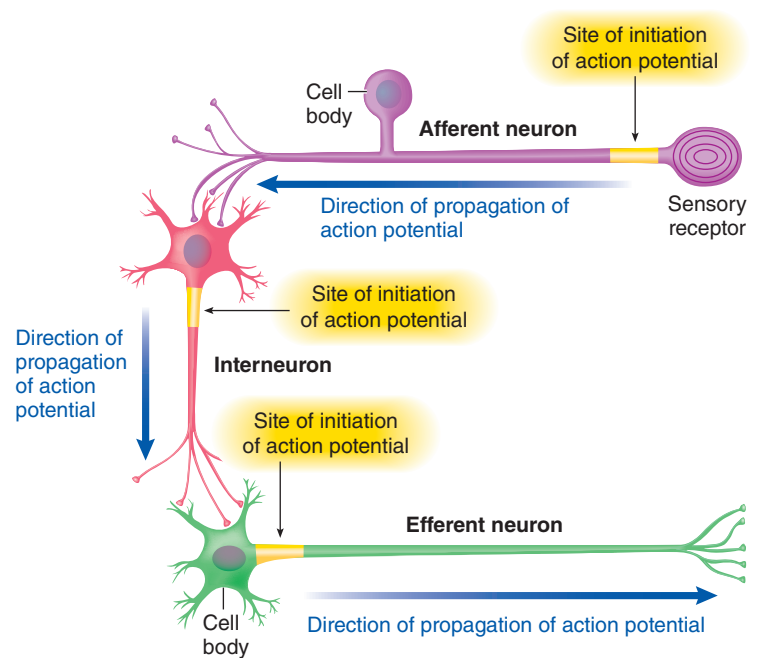

FIGURE 6-3 Comparison of the site of initiation of an action potential in the three types of neurons.

© Cengage Learning, 2013

Phasic receptors, in contrast, adapt rapidly; that is, they quickly stop responding to a maintained stimulus. Some of these receptors respond with a slight depolarization when the stimulus is removed, the **off response** (Figure 6-5b). Rapidly adapting receptors include *tactile (touch)* receptors in the skin that signal changes in pressure on the skin surface. Because these receptors adapt rapidly, a horse does not remain conscious of a saddle on its back or a bit in its mouth. You, for example, are not continually conscious of wearing your watch, rings, and clothing. When you put something on, you soon become accustomed to it because of these receptors' adaptation. When you take the item off, you are aware of its removal because of the off response.

Thus, phasic receptors essentially ignore continuous information. Why is this useful to survival? There are two interrelated reasons. (1) Often it is important to pay attention to a *change* in stimulus rather than status quo information. A sudden change in an environmental stimulus may signify danger, the arrival of prey, and so on, whereas, after a short time, if the stimulus continues and is of no threat or use, it can be ignored. (2) Brains have limited sensory processing capabilities. Ignoring an unimportant continuous stimulus prevents the brain from being overloaded with too much information. While this is useful, it can also be a problem in some situations. Many predators make use of this phenomenon in, for example, stalking or ambushing behaviors. Consider a lioness stalking a gazelle as she moves at a slow even pace, or freezes in position for an extended time. Until she makes her final running attack, the gazelle may stop paying attention to her as she gradually gets closer. Also, brain scans reveal that when a person is doing a visual task akin to driving a car while talking (even hands-free) on a mobile phone, his or her brain significantly reduces attention to the visual task of driving to focus on the conversation and so increases the odds of an accident.

FIGURE 6-4 Magnitude of receptor potential, frequency of action potentials in afferent fiber, and rate of neurotransmitter release at afferent terminals as a function of stimulus strength.

© Cengage Learning, 2013

receptor potential of a magnitude that reflects the intensity of the stimulus. As the stimulus continues, the pressure energy is dissipated because it causes the layers to slip (just as steady pressure on a peeled onion causes its layers to slip). Because this physical effect removes the steady component of the applied pressure, the underlying neuronal ending no longer responds with a receptor potential. Also contributing to adaptation is the electrochemical component, which involves changes in ionic movement across the receptor membrane. In the corpuscle, for reasons unknown, the Na^+ channels that opened in response to the stimulus are slowly inactivated, thus reducing the inward flow of Na^+ ions that was responsible for the receptor potential. With prolonged depolarization, the voltage-gated Na^+ channels cannot open, regardless of stimulus intensity.

Intrinsic Mechanism of Adaptation in Olfactory Receptors Olfactory (smell) receptors can also adapt, as you might recall from the last time you entered a musty room—at first you notice the musty odor, but after a few minutes you do not. As you will see later, binding of an odorant molecule to a receptor leads to the opening of Ca^{2+} channels. Evidence suggests that ions entering these open channels slowly activate a protein that in turn closes the ion channels. Importantly, some olfactory cells—particularly those that detect odors of dangerous substances—do not adapt. Rotting food, for example, produces sulfurous odors that do not lead to adaptation. (Similar odors are added by gas companies to natural gas—which is odorless—so that people will not ignore gas leaks.) The skunk takes advantage of this by producing a defensive cocktail of seven compounds, six of them based on sulfur. The cocktail slowly reacts with water to release more of the strong-smelling substances. Potential predators sprayed with this cocktail are continually bothered by a noxious smell until the odor molecules themselves decay.

The proximate mechanism by which adaptation is accomplished varies for different receptors and has not been fully elucidated for all receptor types. The known mechanisms fall into the two regulatory categories of *intrinsic* (local) and *extrinsic* (p. 19). Intrinsic mechanisms occur in the receptor cell itself and are not controlled by the brain. Extrinsic ones, on the other hand, are accomplished by the brain and so can be turned on or off rapidly. Let's look at examples.

Intrinsic Mechanisms of Adaptation in the Pacinian Corpuscle One receptor type that has been extensively studied is the mammalian **Pacinian corpuscle**, a rapidly adapting skin receptor that detects pressure and vibration. A comparable sensory receptor, the **Herbst corpuscle**, is the most widely distributed receptor in the skin of birds and can be found in the bills of some aquatic species. Adaptation in a Pacinian corpuscle is believed to involve both mechanical and electrochemical intrinsic components. The mechanical component depends on the physical properties of this receptor. A Pacinian corpuscle is a specialized receptor ending that consists of concentric layers of connective tissue resembling layers of an onion wrapped around the peripheral terminal of an afferent neuron (Figure 6-6). When pressure is first applied to the Pacinian corpuscle, the underlying terminal responds with a

receptor potential of a magnitude that reflects the intensity of the stimulus. As the stimulus continues, the pressure energy is dissipated because it causes the layers to slip (just as steady pressure on a peeled onion causes its layers to slip). Because this physical effect removes the steady component of the applied pressure, the underlying neuronal ending no longer responds with a receptor potential. Also contributing to adaptation is the electrochemical component, which involves changes in ionic movement across the receptor membrane. In the corpuscle, for reasons unknown, the Na^+ channels that opened in response to the stimulus are slowly inactivated, thus reducing the inward flow of Na^+ ions that was responsible for the receptor potential. With prolonged depolarization, the voltage-gated Na^+ channels cannot open, regardless of stimulus intensity.

Extrinsic Mechanism of Adaptation in Hearing In contrast to the preceding examples, reception of sound can be dampened by the brain in mammals (i.e., extrinsically). Sound vibrations are detected by *hair cells* in the inner ear (which we will discuss later). In turn, these hair cells release neurotransmitter onto an afferent neuron. The brain has an efferent neuron connecting to this synapse that releases GABA, thus suppressing the signal. This is what your brain does when it chooses to ignore so-called white noise like the hum of a constant fan motor. However, unlike the intrinsic

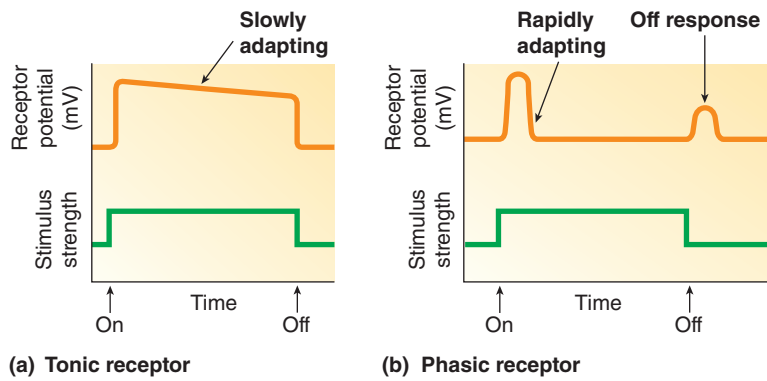

FIGURE 6-5 Tonic and phasic receptors. (a) A tonic receptor does not adapt at all or adapts slowly to a sustained stimulus and thus provides continuous information about the stimulus. (b) A phasic receptor adapts rapidly to a sustained stimulus and frequently exhibits an off response when the stimulus is removed. Thus, the receptor signals changes in stimulus intensity rather than relaying status quo information.

© Cengage Learning, 2013

mechanisms of smell (which you cannot consciously reactivate), you can instantly hear the fan noise if someone calls your attention to it (as your brain shuts off its GABA neuron). This important mechanism allows, for example, an animal to ignore the sound of running water when that information is useless (freeing up the brain to listen for prey or predators), or to instantly hear it if it is thirsty.

Adaptation should not be confused with *habituation* (see p. 197). Although both these phenomena involve decreased neural responsiveness to repetitive stimuli, they operate at different points in the neural pathway. Adaptation is a receptor adjustment in the PNS, whereas habituation involves a modification in synaptic effectiveness in the CNS.

Each somatosensory pathway is “labeled” according to modality and location

On reaching the spinal cord of vertebrates, afferent information has two possible destinations: (1) It may become part of a reflex arc, bringing about an appropriate effector response, and/or (2) it may be relayed upward to the brain via ascending pathways for further processing (and possible conscious awareness). Pathways conveying sensory information consist of discrete chains of neurons, or **labeled lines**, synaptically interconnected in a particular sequence to accomplish progressively more sophisticated processing of the sensory information.

Labeled Lines Sensory signals begin in the periphery and are carried by the PNS either to the spinal cord or the medulla, depending on which sensory pathway is involved. There a secondary neuron has an axon that synapses in the *thalamus* “relay station” (p. 186), which in turn sends an axon to the appropriate *sensory cortex* (see Figure 5-26a). With each step, the input may be enhanced or filtered. In sum, a particular sensory modality detected by a specialized receptor type is sent over a specific afferent and ascending pathway to excite a defined area in the cortex. Thus, different types of incoming information are kept separated within specific labeled lines between the periphery and the cortex. In this way, even though all information is propagated to the CNS via the same type of signal (action potentials), the brain can decode the type and location of the stimulus, following Müller’s doctrine of specific nerve energies (p. 211). The mechanism of perception in the specific sensory cortexes is not understood, but if one experimentally stimulates one of them (for example, by an electrode in the optical cortex), a human subject will report the perception of that cortex’s speciality (e.g., light). Table 6-1 summarizes how the CNS is informed of the type (what?), location (where?), and intensity (how much?) of a stimulus.

Acuity is influenced by receptive field size and filtered by lateral inhibition

Let’s look at sensory enhancement and filtering more closely, using skin senses as an example. Each sensory neuron responds to stimulus information only within a circumscribed region of the skin surface surrounding it; this region is known as its **receptive field**. The size of a receptive field varies inversely with the density of receptors in the region; the more closely receptors of a particular type are spaced, the smaller the area of skin each monitors. The smaller the receptive field in a region, the greater its **acuity** or **discriminative ability**. Compare the tactile (touch) discrimination in your fingertips with that in your elbow by “feeling” the same object with both. For example, you can discern more precise information about the object with your richly innervated fingertips because the receptive fields there are small; as a result, each neuron signals information about small, discrete portions of the object’s surface. An estimated 17,000 tactile mechanoreceptors are present in the fingertips and palm of each human hand, whereas the skin over the elbow is served by relatively few sensory endings with larger receptive fields. Thus, within each large receptive field, subtle differences in pressure cannot be discriminated. The

TABLE 6-1 Coding of Sensory Information

Stimulus Property	Mechanism of Coding
Type of Stimulus (Stimulus Modality)	Distinguished by the type of receptor activated and the specific pathway over which this information is transmitted to a particular area of the cerebral cortex
Location of Stimulus	Distinguished by the location of the activated receptor field and the pathway that is subsequently activated to transmit this information to the area of the somatosensory cortex representing that particular location
Intensity of Stimulus (Stimulus Strength)	Distinguished by the frequency of action potentials initiated in an activated afferent neuron and the number of receptors (and afferent neurons) activated

© Cengage Learning, 2013

distorted cortical representation of various body parts in the *sensory homunculus* (see Figure 5-30b) corresponds precisely with the innervation density; more cortical space is allotted for sensory reception from areas with smaller receptive fields and, accordingly, greater tactile discriminative ability.

Besides receptor density, a second factor influencing acuity is **lateral inhibition**, which enhances *contrast*. You can appreciate the importance of this phenomenon by slightly indenting the surface of your skin with the point of a pencil (Figure 6-7a). The receptive field is excited immediately under the center of the pencil point where the stimulus is most intense, but the surrounding receptive fields are also stimulated, only to a lesser extent because they are less distorted. If information from these marginally excited afferent fibers in the fringe of the stimulus area were to reach the cortex, localization of the pencil point would be blurred. To facilitate localization and sharpen contrast, lateral inhibition occurs within the CNS (Figure 6-7b). The most strongly activated signal pathway originating from the center of the stimulus area inhibits the less excited pathways from the fringe areas. This occurs via inhibitory interneurons that pass laterally between ascending fibers serving neighboring receptive fields. Blocking further transmission in the weaker inputs increases the contrast between wanted and unwanted information so that the pencil point can be precisely localized.

As we noted earlier, perception is not reality. The reality is that the pencil distorts more of your skin than just at the point. The perception, however, is just of the point itself, which is presumably more useful information. The extent of lateral inhibition within sensory pathways varies for different modalities. Those with the most lateral inhibition—touch and vision—bring about the most accurate localization. As we mentioned earlier, retinas enhance the contrast of edges, making blurry boundaries appear sharp, by using lateral inhibition.

Now we turn to the major organs and modalities of senses, primarily the extero- and proprioceptors. The roles of most interoreceptors are discussed in later chapters.

(a) Activity in afferent neurons

(b) Lateral inhibition

FIGURE 6-7 Lateral inhibition. (a) The receptor at the site of most intense stimulation is activated to the greatest extent. Surrounding receptors are also stimulated but to a lesser degree. (b) The most intensely activated receptor pathway halts transmission of impulses in the less intensely stimulated pathways through lateral inhibition. This process facilitates localization of the site of stimulation.

6.3 Mechanoreception: Touch, Pressure, and Proprioception

Detection of physical forces in the environment is possibly the most ancient sense, as we noted earlier. Virtually all single-celled motile organisms react to surface contact with an external object. In animals, this mode of sensing is found in integuments and some internal organs for detecting the somesthetic senses of touch and pressure. Mechanoreception is also used in proprioception and hearing. Though all of these senses are presumed to use mechanically gated ion channels, only a few of the channels involved have been identified.

Animal integuments may have both touch and pressure receptors

Touch and pressure receptors in integuments are typically in sensory dendrites (Figure 6-8a). Researchers have investigated these channels in the exoskeleton of insects, specifically the sensors located at the hinge of leg bristles. The channel proteins have external protein fibers attached to them, and when these fibers are stretched or distorted (as when vertebrate skin is touched, or when the insect bristle moves), they essentially pull open the gate of the ion channel. Such external fibers attached to channels may also act as levers, amplifying very small movements into large ones at the channel. Cations entering the sensory dendrite then create a receptor potential and, if the signal is strong enough, action potentials.

The fruit fly channel is called *TRP-N1*, a mechanically gated Ca^{2+} channel. Of note is that *TRP-N1* belongs to the superfamily of *transient receptor-potential (TRP)* proteins involved in sensory transduction in eukaryotes from yeast to mammals (as you will see later).

The skin of vertebrates has three or more types of touch and pressure mechanoreceptors. Earlier we saw the Pacinian corpuscle, which detects deep pressure. Closer to the skin surface are highly sensitive touch sensors consisting of

© Larry Lipsky/Index Stock Imagery/Photo Library

late very precise movements of the small limbs of arthropods. However, as you recall, these signals cannot travel long distances.

The stretch receptors in vertebrates are **muscle spindles**, **Golgi tendon organs**, and other such sensors, discussed in Chapter 8. In humans, these sensors provide feedback to the brain in the so-called **kinesthetic sense**, a conscious “sixth sense” that lets you know where your limbs are even when you have your eyes closed. These sensors also provide feedback to the cerebellum while it is learning motor skills to produce smooth coordination (p. 184).

The statocyst is the simplest organ that can monitor an animal’s position in space

Numerous groups of animals have gravity receptors known as **statocysts** (Greek *statos*, “standing”; *kystis*, “bag”) (Figure 6-9), which are considered the simplest organs of equilibrium. This sense organ is particularly important in animals that are essentially neutrally buoyant, such as fish, because they do not get information about gravity from other sensory sources. (Notably, insects lack this special sense organ and instead rely on visual and joint proprioceptors to orient themselves.) A statocyst is essentially a hollow chamber lined with ciliated mechanoreceptors that contain dense, movable objects, the **statoliths**. For example, the statoliths of lobsters are sand grains glued together by mucus. In other animals, the statoliths consist of calcium carbonate fused together to resemble tiny marbles. When a body movement tilts the statocyst, the statoliths contained inside it move in the same direction, bending the sensory hairs, opening mechanically gated channels and thus generating action potentials. On reception and integration of the neural signals in the brain, motor neurons are activated, which can restore the animal to its equilibrium position.

FIGURE 6-9 A statocyst, an organ of equilibrium. Shown here is the organ in a lobster’s antennule.

© Cengage Learning, 2013

numerous dendrites with a large surface area, which can act as levers when pushed. There are also touch mechanoreceptors at the base of hairs, much like those associated with insect bristles (Figure 6-8b).

Proprioceptors in the muscles, tendons, and joints give information on limb position and motion

Another major use of mechanoreception is the detection of motion and position. This sense is critical to most animals’ ability to navigate and orient properly in the environment and to move in a coordinated manner. Examples of these mechanoreceptors include the stretch and related sensors associated with muscle movement. In fruit flies and the nematode *C. elegans*, the TRP-N1 channel has been identified (by fluorescent labeling, p. 34) in proprioceptor neurons. Mutant flies and worms with nonfunctional TRP-N1 genes had uncoordinated muscle control, and the flies could neither walk nor fly. In arthropod limbs, many of these receptors are **nonspiking** neurons, that is, ones that do not generate action potentials. Rather they transmit information in strictly *graded* (rather than frequency) fashion. This may allow for a continuous range of corrective signals (as opposed to the quantized nature of frequency coding) to regu-

The lateral line system of amphibians and fish detects motion in the surrounding water

In fish, a specialized somesthetic and proprioceptive mechanoreceptor system extends the length of the animal’s body. Information about the fish’s orientation with respect to gravity, its swimming velocity and details about water currents and vibrations are collected by a string of **neuromast cells** (Figure 6-10a and b), the basic sensory unit of the **lateral line system**. Fish behavior linked to lateral line function includes object and predator avoidance and the ability to school. Cave and deep-sea fishes, as well as species active at night, rely on highly sensitive lateral line systems for detecting both prey and predators.

Neuromasts evolved in early vertebrate ancestors and persist in bony fish, lampreys, sharks, and aquatic amphibians. As you will see shortly, derivatives are also found in the inner ear of reptiles, birds, and mammals for proprioception

and hearing. Neuromasts may occur free on the skin's surface, in small pits called *pit organs*, or may be lined up in rows within fluid-filled grooves or canals. The lateral line system in fish runs along the sides of the body onto the head, where it divides into three branches, two to the snout and one to the lower jaw. In many species of fish the lateral, often-pigmented rows of canal pores give rise to the name of the organ. Each neuromast is dome shaped, with up to several hundred mechanoreceptor sensory **hair cells** clustered at its base. Microvillar processes called **stereocilia** (Figure 6-10b) are the actual sensory transducers that protrude from the sensory hair cells into a jellylike substance (at the base of the dome). The cilia of the hair cells may actually extend up to 50 microns into the surrounding water, usually embedded in an overlying caplike, gelatinous layer, the **cupula**. Stereocilia are arranged together into ciliary bundles and are oriented according to size. The tallest row of stereocilia lies closest to an elongated cilium, the **kinocilium** (Figure 6-10b). Signals are sent to the brain in response to the bending of the kinocilium and stereocilia, using a mechanism identical to that of the mammalian inner ear, which we describe shortly.

A swimming fish sets up a pressure wave in the water that can be detected by the lateral line systems of other fishes. It also sets up a bow wave in front of itself, the pressure of which is higher than that of the wave flow along its sides. These minute differences in pressure are detected by its own lateral line system. As the fish approaches a solid object, such as a rock or the glass wall of an aquarium, the pressure waves around its body are distorted enough that the lateral line system registers these changes and results in the fish swerving away. Schooling fish also coordinate their motions by detecting pressure and flow changes, allowing precise movements.

Hair cells transduce movement using externally gated mechanical channels (thought to be TRP channels, p. 217). The stereocilia of each hair cell are organized into rows of graded heights ranging from short to tall in a staircase pattern (Figure 6-11a). Importantly, external **tip links**, which are CAMs (cell adhesion molecules, p. 65), link the tips of stereocilia in adjacent rows (Figure 6-11a). In neuromasts, as well as all the inner-ear senses of reptiles, birds, and mammals, hair cells normally send out continuous bursts of nerve impulses when they are at rest (that is, the cilia are unbent; Figure 6-11b left). This is because the mechanically gated channels in the ciliary tips are partly open. When a force causes the cilia to bend (by pressure waves, sound waves, or gravity) towards the tallest stereocilium (sometimes called the kinocilium), the tip links stretch, tugging open the cation channels to which they are attached (Figure 6-11b middle). When more cation channels are pulled open, more positive ions enter the hair cell, depolarizing it. When a force moves the cilia in the opposite direction, the hair bundle bends away from the tallest stereocilium, slackening the tip links and closing all the channels. As a result, ion entry ceases, hyperpolarizing the hair cell (Figure 6-11b right).

In fish neuromasts, the ion channels are for Ca^{2+} . In the mammalian hearing organ (the *cochlea*, which we will describe shortly), the stimulating ion is unusual because of the unique composition of the special ECF (*endolymph*) that bathes the stereocilia. In sharp contrast to ECF elsewhere, endolymph has a higher concentration of K^+ than found inside the hair cell. Some cation channels are open in a resting

hair cell, allowing low-level K^+ entry down its concentration gradient.

The vestibular apparatus of vertebrates detects position and motion of the head and is important for equilibrium and coordination of head, eye, and body movements

The advanced vertebrate inner ear has two specialized sensory components using hair cells: the **cochlea** (from the Greek *kochlias*, “snail”), a tightly coiled structure in mammals and

**(a)** Tip link pulling open mechanically gated channel

a curved tube in birds and reptiles, which is used in hearing; and the **vestibular apparatus**, which provides proprioceptive information essential for the sense of equilibrium and for coordinating head movements with eye and postural movements. The vestibular apparatus consists of two sets of structures lying within a tunneled-out region of the temporal bone near the cochlea—the *semicircular canals* and the *otolith organs*

(the *utricle* and *sacculle*) (Figure 6-12a). Vertebrates without a cochlea (fish and amphibians) also use the vestibular apparatus for hearing. The vestibular hair cells have synapses with afferent neurons whose axons join with those of the other vestibular structures to form the **vestibular nerve**. This nerve in turn unites with the **auditory nerve** from the cochlea to form the **vestibulocochlear nerve**.

Semicircular Canals Let's first examine the vestibular senses. The **semicircular canals** (Figure 6-12a) detect *rotational or angular acceleration or deceleration of the head*, such as when starting or stopping, spinning, diving, or turning the head. Each ear contains three semicircular canals arranged three-dimensionally in planes at right angles to each other. The receptive hair cells of each semicircular canal lie on top of a ridge located in the **ampulla**, a swelling at the base of the canal (Figures 6-13a and b). The hairs are embedded in a cupula (as in a neuromast), which protrudes into the endolymph within the ampulla. The cupula sways in the direction of fluid movement, much like seaweed leaning in the direction of the prevailing tide.

Acceleration or deceleration during rotation of the head in any direction causes endolymph movement in at least one of the semicircular canals because of their three-dimensional arrangement (Figure 6-13a and b). As the head starts to move, the bony canal and the ridge of hair cells embedded in the cupula move with the head. Initially, however, the fluid within the canal, not being attached to the skull, does not move in the direction of the rotation but lags behind because of its inertia. (Because of inertia, a resting object remains at rest, and a moving object continues to move in the same di-

rection unless acted on by some external force.) Thus, the endolymph that is in the same plane as the head movement is shifted in the opposite direction from the movement (like your body tilting rightward as the car in which you are riding suddenly turns left). This relative fluid movement causes the cupula to lean in the opposite direction from the head movement, resulting in the bending of its embedded sensory hair. If the head movement continues at the same rate in the same direction, the endolymph catches up and moves in unison with the head so that the hairs return to their unbent position. When the head slows down and stops, the reverse occurs. The endolymph briefly continues to move in the direction of the rotation while the head decelerates to a stop. When the endolymph gradually comes to a halt, the hairs straighten again. Thus, the semicircular canals detect *changes* in the rate of rotational movement of the head. They do not respond when the head is motionless or during circular motion at a constant speed. (However, think about why you get dizzy if you spin around repeatedly.)

The size of the semicircular canals has changed greatly with evolutionary adaptation. In primates that swing through trees and flying vertebrates, the canals are very large, evolved for processing complex motion in three

**FIGURE 6-13** Activation of the hair cells in the semicircular canals.

dimensions. They are of moderate size in terrestrial animals, including extinct terrestrial ancestors of whales (whose canals can be reconstructed from fossil skulls). Modern whales, in contrast, have very small canals, perhaps to reduce their sensitivity, to prevent seasickness, or because they do not make rapid head motions.

Otolith Organs Whereas the semicircular canals provide the CNS with information about rotational changes in head movement, the **otolith organs** provide information about the position of the head relative to gravity and changes in rate of linear motion. The otolith organs, the **utricle** and **sacculus**, are saclike structures housed within a bony chamber situated between the semicircular canals and the cochlea (see Figure 6-12a). The cilia of the hair cells in these organs also protrude into an overlying gelatinous sheet, whose movement displaces the cilia and results in changes in hair cell potential. Many tiny crystals of calcium carbonate—the **otoliths** (“ear stones”)—similar to the statoliths associated with statocysts in many nonvertebrates—are suspended within the gelatinous layer, making it heavier and giving it more inertia than the surrounding fluid (Figure 6-14). When an animal is in an upright position, the hairs within the utricles are oriented vertically and the saccule hairs are lined up horizontally.

Let’s look at the utricle as an example. Its otolith-embedded, gelatinous mass shifts positions and bends the hairs in two ways, described as follows.

1. When the head is tilted in any direction other than vertical (that is, other than straight up and down), the hairs are bent in the direction of the tilt because of the gravitational force exerted on the top-heavy gelatinous layer

(Figure 6-14b). Within the utricles on each side of the head, some of the hair cell bundles are oriented to depolarize and others to hyperpolarize when the head is in any position other than upright. The CNS thus receives different patterns of neural activity, depending on head position with respect to gravity.

2. The utricle hairs are also displaced by any change in horizontal linear motion (such as moving straight forward, backward, or to the side). As an animal starts to walk forward (Figure 6-14c), the top-heavy otolith membrane at first lags behind the endolymph and hair cells because of its greater inertia. The hairs are thus bent to the rear, in the opposite direction of the forward head movement. If the walking pace is maintained, the gelatinous layer soon catches up and moves at the same rate as the head so that the hairs are no longer bent. When the animal stops walking, the otolith sheet continues to move forward briefly as the head slows and stops, bending the hairs toward the front. Thus, the hair cells of the utricle detect horizontally directed linear acceleration and deceleration, but they do not provide information about movement in a straight line at constant speed.

The saccule functions similarly to the utricle, except that it responds selectively to the tilting of the head away from a horizontal position (such as diving) and to vertically directed linear acceleration and deceleration (such as leaping up and down). An interesting variation occurs in flatfish such as flounders (*Pleuronectiformes*): Fry (immature fish), which have body forms and orientation similar to most fish, metamorphose into adults that lie and swim on one side. Although one eye migrates across the top of the head, leav-

(c)

ing the bottom side eyeless, the vestibular system does not change in orientation, and so functions at 90 degrees relative to that of other fish. Ichthyologists believe the saccule replaces the utricle in posture regulation, suggesting that central nervous pathways have reorganized.

Signals arising from the various components of the vestibular apparatus are carried through the vestibulocochlear nerve to the cerebellum and the **vestibular nuclei**, a cluster of neuronal cell bodies in the brain stem. Here, the vestibular information is integrated with input from the skin surface, eyes, joints, and muscles for (1) maintaining balance and desired posture; (2) controlling the external eye muscles so that the eyes remain fixed on the same point, despite head

movement; and (3) perceiving motion and orientation (Figure 6-15).

6.4 Mechanoreception: Ears and Hearing

Hearing is the neural perception of sound energy, which travels as **sound waves** through a medium—liquid, gas, or solid (but unlike light, not in a vacuum). Waves are traveling vibrations of air or liquid that consist of regions of high pressure caused by compression of molecules, alternating with regions of low pressure caused by rarefaction of the molecules. Detection of sound waves is less common than photoreception and touch; for example, there is no evidence for sound sensing in single-celled organisms. But many animals do detect sound, especially vertebrates and arthropods, using some form of mechanoreceptor, often organized into complex organs called *ears*. Like light and smell, but unlike taste and touch, sound is a long-range “early warning” signal used to detect predators, competitors, physical threats, potential prey, and mating calls.

Fishes hear with lateral lines and otolith organs, aided by the gas bladder in some species

Fishes can hear noises for some of these purposes, such as the intense “whistle” of the male toadfish used as a mating call during the breeding season. Because sound waves are waves of pressure, the lateral lines in some species are used to detect very-low-frequency sounds of 100 Hz or less. Researchers think fish and amphibians also detect sounds that penetrate the body using hair cells of otolith organs in their inner ears. Some fish (such as minnows and catfish) have a **Weberian apparatus** (Figure 6-16), consisting of bone and fluid sacs that transfer sound from the *gas* (or

FIGURE 6-16 Weberian apparatus for fish hearing, which includes Weber's bones and two fluid sacs connecting the swim bladder with the otolith organs.

swim) bladder (p. 539) to the inner ear. This is advantageous because the gas bladder is much more sensitive to sound vibrations than are the otolith organs. Whether directly stimulated by sound waves or indirectly by the gas bladder, otoliths in motion result in a shearing action on the cilia of the sensory hair cells and thus in generation of action potentials. Many fishes (such as cod, *Gadus morhua*) also can localize sound, although the precise mechanism is not known.

FIGURE 6-17 Anatomy of the mammalian ear.

© Cengage Learning, 2013

Many terrestrial vertebrates and insects receive sound initially with a tympanic membrane, aided by other external features in some groups

Compared to animals in aquatic habitats, animals living in air evolved different structures capable of receiving and processing sounds traveling through the air. In terrestrial vertebrates and many insects, initial sound reception involves a **tympanic membrane** (eardrum) or comparable structure that vibrates as sound hits it. As we will explore later, many insects have such structures on their abdominal segments or legs. Among vertebrates, amphibians and some reptiles have a tympanic membrane located at the back of the animal's head on the skull surface. In other reptiles, including birds and in mammals, there is a canal leading from the external environment to the tympanic membrane. Snakes lack external ears, but recent research shows that their *jaws* can pick up sound vibrations in the ground and transmit them to their inner ears.

Vertebrates typically have two ears, which allows for localization of sounds. Whether a sound is approaching from the right or left is determined by two cues. First, the sound wave reaches the ear closer to the sound source slightly before it arrives at the farther ear. Second, the sound is less intense as it reaches the farther ear, because the head acts as a sound barrier that partially disrupts the propagation of sound waves. The auditory cortex integrates all these cues to determine the location of the sound source.

Let's look at mammals in more detail. In mammals the **external ear** (Figure 6-17) consists of the *pinna* (ear), exter-

nal auditory meatus (ear canal), and tympanic membrane. Unique to mammals, the **pinna**, a prominent skin-covered flap of cartilage, collects sound waves and channels them down the external ear canal, improving hearing acuity. Most mammals (dogs, for example) can cock their ears in the direction of sound to collect more sound waves, but human ears are relatively immobile. Because of its shape, the pinna partially shields sound waves that approach the ear from the rear and thus helps an animal distinguish whether a sound is coming from directly in front or behind.

Among nonmammalian vertebrates, birds have the most highly evolved auditory system. The avian external ear is inconspicuous, although ear-flaps or specialized feathers may reflect or amplify sound, as in the barn owl (*Tyto alba*). In some species of owls, the external openings in their left and right ears differ in height and direction on the head in order to more accurately locate a particular sound source. Remarkably, barn owls can successfully hunt prey (such as a field mouse making a faint noise) in total darkness. In

the owl's midbrain, certain cells fire only when sounds are received from a particular spot in the external environment. In principle, this could give the owl the ability to "see" (that is, visually perceive) its prey's location using sound!

Recall that the inner ear of terrestrial vertebrates evolved a separate sound-sensing organ, the *cochlea*. We explore this and *middle ear* structures in more detail below.

Sound is characterized by its intensity (loudness), pitch (tone), and timbre (quality)

Let us look first at the transmission and properties of sound in the environment. Sound waves can travel through air, solids and liquids. Because water is less compressible than air, sound attenuation is not as great. Thus, in water, sound travels at an average of 1,500 m/sec, compared to 340 m/sec in air. However, both the temperature of the water and the hydrostatic pressure can affect the measured speed. The greater the depth, the heavier the column of water above, and the faster sound waves are propagated.

Sound waves have three features—*intensity*, *pitch*, and *timbre*—all of which are important to the sense of hearing (see Figure 6-18).

Intensity The intensity, or loudness, of a sound depends on the *amplitude* of the sound waves, or the pressure differences between a high-pressure region of compression and a low-pressure region of rarefaction. Loudness is expressed in decibels (dB), which are a logarithmic measure of intensity compared with the faintest sound that can be heard—the

Collared scops owl (*Otus lettia*). This bird hunts at night and has enhanced two major sensory systems to aid in this behavior. First, it has a specialized auditory system that amplifies sounds and localizes prey in three dimensions (see text). Second, it has large eyes with a reflective layer, the tapetum lucidum, behind the retina. This layer reflects photons back into the retina that were not detected initially (see p. 245).

hearing threshold. Because of the logarithmic relationship, every 10 decibels indicates a 10-fold increase in loudness. Within the hearing range, the greater the amplitude, the louder the sound. An animal’s ear may detect a wide range of sound intensities, from the slightest rustle of a leaf (about 10 dB) to the comparatively loud roar of a waterfall (perhaps 100 dB, a 100 million times louder than the leaf rustling).

Pitch The pitch or tone of a sound (for example, whether it is a C or a G note) is determined by the *frequency* of vibrations. The greater the frequency of vibration, the higher the pitch. Human ears can detect sound waves with frequencies from 20 to 20,000 cycles per second (Hertz, Hz) but are most sensitive to frequencies between 1,000 and 4,000 Hz (or 1 to 4 kilohertz, or kHz). In contrast, goldfish (*Carassius auratus*) detect frequencies between 50 to 3,000 Hz with the

best sensitivity between 200 to 1,000 Hz. Dogs, on the other hand, can hear sound frequencies up to 40 kHz. These higher frequencies, or **ultrasound**, consist of frequencies greater than those audible by the human ear, whereas **infrasound** consists of sounds below the range of frequencies audible by humans (20 Hz).

Infrasound is subject to very little attenuation in the environment and so can function in long-distance communication, and it travels well in the ground as well as in air and water. Salts in seawater more rapidly absorb high-frequency sounds, whereas low-frequency acoustic waves are not affected by the molecular structure of the salts and may travel for thousands of kilometers. Infrasound communication is particularly useful for animals separated by great distances. For example, whales and elephants use such infrasound for such communication. Baleen whales such as humpbacks may broadcast mating calls or the location of feeding

FIGURE 6-18 Properties of sound waves.

© Cengage Learning, 2013

grounds over hundreds of kilometers using frequencies less than 60 Hz. Elephants use frequencies in the range of 14 to 25 Hz, which can travel in the ground over distances as great as several kilometers. This is valuable because once every four years and for only four days, a female elephant makes a special call that signals mature elephant bulls in the area that she is in estrus. Movement of separate elephant herds can also be coordinated by this form of communication. (Interestingly, research suggests that elephants can pick up these sound wave vibrations in the ground through their feet!)

Ultrasound, in contrast to infrasound, is useful because its numerous small (i.e., high frequency) waves can reflect well off very small features, making it ideal for **echolocation**: the use of sound echoes to detect objects in the environment. Echolocation (also called **biosonar** in reference to the human invention SONAR for SOUNd Navigation And Ranging) is particularly useful for animals active at night or living in dark waters. Consider insectivorous bats, which locate prey at night by emitting successive pulses of ultrasound; the duration of each varies from about 10 to 15 ms (5 pulses per second) and consists of a descending frequency spectrum that varies from approximately 100 kHz to 20 kHz. It has been shown that varying the frequency spectrum this way aids in discriminating details of echo patterns. Faint reflections (echoes) from the insect are then detected by enlarged pinnae on the bat (see p. 400), and its brain uses the information to compute location, size, and speed of the insects. Like the owl, bats may actually visualize their environments using sound.

Other vertebrates that can obtain information from echoes of the sounds they produce include toothed whales, shrews, and several species of birds such as cave swiftlets. Toothed whales (Odontoceti) such as dolphins generate patterned arrangements of clicks with sound frequencies between 200 Hz to 32 kHz for echolocating prey items (such as squid) and other objects in the environment. (They also use sounds of many frequencies for communication.) In dolphin echolocation, physiologists think click sounds (1) are produced by *lips* near the blowhole; (2) become focused by the *melon*, a fat-filled organ in the forehead, much as a lens focuses light; (3) travel until they hit a sound-reflecting object (such as another animal); (4) reflect back (“echo”) to-

ward the dolphin; and (5) are received in the *lower jaw* where a *fat body* focuses the waves into (6) the inner ear. The dolphin’s brain then computes the distance of the object by the time delay of the echo, and by making repeated clicks (like bats) can judge the size and speed of the object. Again, actual visualization through sound is thought to occur in dolphin brains.

Timbre The **timbre**, or **quality**, of a sound depends on its **overtones**, which are additional frequencies superimposed on top of the fundamental pitch or tone. A tuning fork has a pure tone, but most sounds lack purity. For example, complex mixtures of overtones impart different sounds to different instruments playing the same note (a C note sounds different on a trumpet from the way it sounds on a piano). Over-

tones are likewise responsible for the characteristic differences in voices. Timbre enables the listener to distinguish the source of sound waves because each source produces a different pattern of overtones. Moreover, an echolocating dolphin can learn about an object’s composition, because the timbre of reflected sounds differs depending on that composition.

The external ear and middle ear convert airborne sound waves into fluid vibrations in the inner ear

Now we turn to the fate of sound waves that reach an animal, focusing primarily on mammals. The specialized receptors for sound are located in the fluid-filled inner ear in terrestrial vertebrates. Airborne sound waves must therefore be channeled toward and transferred into the inner ear while at the same time compensating for the loss in sound energy that naturally occurs as sound waves pass from air into water. This function is performed by the external ear (described earlier) and the *middle ear*.

Recall the **tympanic membrane (eardrum)**, stretched across the entrance to the middle ear, vibrates when struck by sound waves. The alternating higher- and lower-pressure regions of a sound wave cause the exquisitely sensitive eardrum to bow inward and outward in unison with the wave’s frequency. For the membrane to be free to move as sound waves strike it, the resting air pressure on both sides of the tympanic membrane must be equal. The outside of the eardrum is exposed to atmospheric pressure through the ear canal. The inside of the eardrum facing the middle-ear cavity is also exposed to atmospheric pressure via the **Eustachian (auditory) tube**, which connects the middle ear to the **pharynx** (back of the throat) (see Figure 6-17). The Eustachian tube is normally closed, but it can be pulled open by yawning, chewing, and swallowing, permitting air pressure within the middle ear to equilibrate with atmospheric pressure. Infections originating in the throat sometimes spread through this tube to the middle ear.

Middle Ear The **middle ear** of mammals transfers the vibratory movements of the tympanic membrane to the fluid of the inner ear. This transfer is facilitated by a movable chain

of three small bones or ossicles (the **malleus**, **incus**, and **stapes**) that extend across the middle ear (Figure 6-19a). The first bone, the malleus, is attached to the tympanic membrane, and the last bone, the stapes, is attached to the **oval window**, the entrance into the fluid-filled cochlea. As the tympanic membrane vibrates in response to sound waves, the chain of bones is set into motion at the same frequency, transmitting this frequency of movement from the tympanic membrane to the oval window. The resulting pressure on the oval window with each vibration produces wave-like movements in the inner ear fluid at the same frequency as the original sound waves. To create the greater pressure required to set cochlear fluid in motion, two mechanisms related to the ossicular system come into play. First, because the surface area of the tympanic membrane is much larger than that of the oval window, pressure is increased as force exerted on the tympanic membrane is conveyed to the oval window ($\text{pressure} = \text{force}/\text{unit area}$). Second, the lever action of the ossicles provides an additional mechanical advantage. Together, these mechanisms increase the force exerted on the oval window by 20 times what it would be if the sound wave struck the oval window directly. This additional pressure is sufficient to set the cochlear fluid in motion.

The tympanic membrane of anuran amphibians and reptiles (including birds) is connected to the inner ear by a single, bony ossicle, the **columella**, homologous to the stapes of mammals. Both embryological and fossil evidence show that the malleus, incus, and stapes evolved from jaw structures. Indeed, in 2011, a reptilian-like mammalian fossil was found in which there was a connection between the middle ear bones and a support bone arising from the jaw.

FIGURE 6-19 Middle ear and cochlea. (a) Gross anatomy of the middle ear and cochlea, with the cochlea “unrolled.” (b) Cross section of the cochlea. (c) Enlargement of the organ of Corti. The stereocilia (hairs) from the hair cells of the basilar membrane are embedded in the overlying tectorial membrane. These hairs are bent when the basilar membrane is deflected in relation to the stationary tectorial membrane. This bending opens channels, leading to ion movements that result in a receptor potential.

Several tiny muscles in the middle ear contract reflexively in response to loud sounds (over 70 dB in humans), tightening the tympanic membrane and limiting movement of the ossicular chain. This reduced movement of middle ear structures diminishes the transmission of loud sound waves to the inner ear, to protect the delicate sensory apparatus from damage. This reflex response is relatively slow, however, happening at least 40 msec after exposure to a loud sound. It thus provides protection only from prolonged loud sounds, not from sudden sounds like an explosion. Taking advantage of this reflex, World War II anti-aircraft guns were designed to make a loud prefiring sound, to protect the gunner's ears from the much louder boom of the actual firing.

The cochlea of the inner ear contains the organ of Corti, the sense organ for hearing

The cochlear portion of the mammalian inner ear is a coiled tubular system lying deep within the temporal bone (see Figure 6-17). It is easier to understand the functional components of the mammalian cochlea by “uncoiling” it somewhat, as shown in Figures 6-19a and 6-20a. The cochlea is divided throughout most of its length into three fluid-filled longitudinal compartments. A blind-ended **cochlear duct**, or **scala media**, constitutes the middle compartment. It tunnels lengthwise through the center of the cochlea, almost but not quite reaching its end. The upper compartment, the **scala vestibuli**, follows the inner contours of the spiral, while the **scala tympani**, the lower compartment, follows the outer contours (Figure 6-19a and b). The fluid within the scala vestibuli and scala tympani is called **perilymph**. The cochlear duct contains a slightly different fluid, the **endolymph** (Figure 6-20a). The region beyond the tip of the cochlear duct where the fluid in the upper and lower compartments is continuous is called the **helicotrema**. The scala vestibuli is sealed from the middle ear cavity by the oval window, to which the stapes is attached. Another small membrane-covered opening, the **round window**, seals the scala tympani from the middle ear. The thin **vestibular membrane** forms the ceiling of the cochlear duct and separates it from the scala vestibuli. The **basilar membrane** forms the floor of the cochlear duct, separating it from the scala tympani. The basilar membrane is especially important because it bears the **organ of Corti**, the sense organ for hearing (Figure 6-19c).

Hair cells in the organ of Corti transduce fluid movements into neural signals

The organ of Corti, which rests on top of the basilar membrane throughout its full length, contains hair cells that are the receptors for sound. The hair cells (15,000 within each human cochlea) are arranged in four parallel rows along the length of the basilar membrane: one row of **inner hair cells** and three rows of **outer hair cells** (Figure 6-19c). Protruding from the surface of each hair cell are about 100 stereocilia, which you saw earlier (p. 219). These stereocilia are mechanically embedded in the **tectorial membrane**, an awning-like projection overhanging the organ of Corti throughout its length (Figure 6-19b and c).

The cochlea of other terrestrial vertebrates is a curved tube. In birds, the organ has short and tall (rather than inner and outer) hair cells embedded in the tectorial membrane. In

contrast, the hair cells of non-avian reptiles project into the endolymph without an overlying tectorial membrane, and amphibians lack both tectorial and basilar membranes.

Returning to mammals, the pistonlike action of the stapes against the oval window sets up pressure waves in the upper compartment. Because fluid is incompressible, pressure is dissipated in two ways as the stapes causes the oval window to bulge inward: (1) displacement of the round window and (2) deflection of the basilar membrane (Figure 6-20a). In the first of these pathways, the pressure wave pushes the perilymph forward in the upper compartment, then around the helicotrema, and into the lower compartment, where it causes the round window to bulge outward into the middle-ear cavity to compensate for the pressure increase. As the stapes rocks backward and pulls the oval window outward toward the middle ear, the perilymph shifts in the opposite direction, displacing the round window inward. This pathway does not result in sound reception; it just dissipates pressure.

Pressure waves of frequencies associated with sound reception take a “shortcut.” Pressure waves in the upper compartment are transferred through the thin vestibular membrane, into the cochlear duct, and then through the basilar membrane into the lower compartment, where they cause the round window to alternately bulge outward and inward. The main difference in this pathway is that *transmission of pressure waves through the basilar membrane causes this membrane to vibrate in synchrony with the pressure wave*. Because the organ of Corti rides on the basilar membrane, the hair cells also move up and down as that membrane oscillates.

Role of the Inner Hair Cells The inner and outer hair cells differ in function. The inner hair cells are the ones that “hear”: They transform the mechanical forces of sound (cochlear fluid vibration) into the electrical impulses of hearing (action potentials propagating auditory messages to the cerebral cortex). Because the stereocilia of these receptor cells contact the stiff, stationary tectorial membrane, they are bent back and forth when the oscillating basilar membrane shifts their position in relationship to the tectorial membrane (Figure 6-19c). This back-and-forth mechanical deformation of the hairs alternately opens and closes mechanically gated cation channels (see Figure 6-11) in the hair cell, resulting in alternating depolarizing and hyperpolarizing potential changes—the receptor potential—at the same frequency as the original sound stimulus. The inner hair cells communicate, via a chemical synapse, with the terminals of afferent nerve fibers making up the **auditory (cochlear) nerve**. Thus, sound waves are translated into neural signals that the brain can perceive as sound sensations (Figure 6-21).

Role of the Outer Hair Cells Whereas the inner hair cells send auditory signals to the brain over afferent fibers, the outer hair cells do not signal the brain about sounds. Instead, the outer hair cells actively and rapidly elongate in response to changes in membrane potential, a function known as *electromotility*. These changes in length are believed to amplify or accentuate the motion of the basilar membrane. An analogy is a person deliberately pushing the pendulum of a grandfather clock in time with its swing, to accentuate its motion. Researchers speculate that such modi-

Fluid movement within the perilymph set up by vibration of the oval window follows two pathways:

- Pathway 1** : Through the scala vestibuli, around the helicotrema, and through the scala tympani, causing the round window to vibrate. This pathway just dissipates sound energy.
- Pathway 2** : A “shortcut” from the scala vestibuli through the basilar membrane to the scala tympani. This pathway triggers activation of the receptors for sound by bending the hairs of hair cells as the organ of Corti on top of the vibrating basilar membrane is displaced in relation to the overlying tectorial membrane.

(b) The numbers indicate the frequencies in cycles per second with which different regions of the basilar membrane maximally vibrate.

(c)

FIGURE 6-20 Transmission of sound waves in the mammalian ear. (a) Fluid movement within the perilymph set up by vibration of the oval window follows two pathways, one dissipating sound energy and the other initiating the receptor potential. (b) Different regions of the basilar membrane vibrate maximally at different frequencies. (c) The narrow, stiff end of the basilar membrane nearest the oval window vibrates best with high-frequency pitches. The wide, flexible end of the basilar membrane near the helicotrema vibrates best with low-frequency pitches.

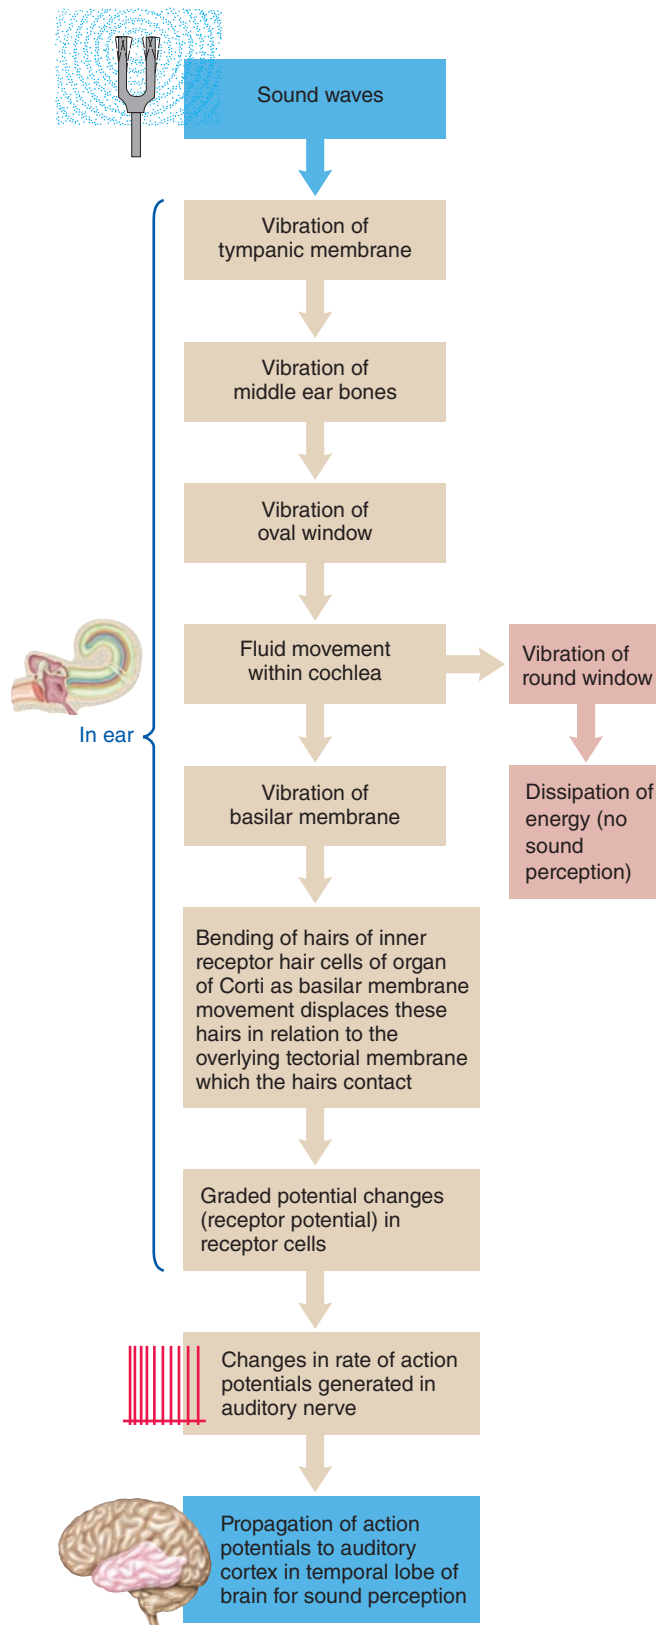

FIGURE 6-21 Pathway for sound transduction.

© Cengage Learning, 2013

fication of basilar membrane movement improves and tunes the stimulation of the inner hair cells. Thus, the outer hair cells enhance the response of the inner hair cells, making them exquisitely sensitive to sound intensity and highly discriminatory between various pitches of sound.

Pitch discrimination depends on the region of the basilar membrane that vibrates

Pitch discrimination (that is, the ability to distinguish between various frequencies of incoming sound waves) depends on the shape and properties of the basilar membrane. Different regions of the basilar membrane naturally vibrate maximally at different frequencies; that is, each frequency displays peak vibration at a different position along the membrane. The *narrow* end nearest the oval window, which is narrow and stiff, vibrates best with *high-frequency* pitches, whereas the *wide* end nearest the helicotrema, which is wide and flexible, vibrates maximally with *low-frequency* tones (Figure 6-20c; note again that the cochlea has been diagrammatically “unrolled” in this figure to aid understanding, but the real cochlea does not do this!). The pitches in between are sorted out along the length of the membrane from higher to lower frequency. As a sound wave of a particular frequency is set up in the cochlea by oscillation of the stapes, the wave travels to the region of the basilar membrane that naturally responds maximally to that frequency. The energy of the pressure wave is dissipated with this vigorous membrane oscillation, so the wave dies out at the region of maximal displacement.

The hair cells in the region of peak vibration of the basilar membrane undergo the most mechanical deformation and accordingly are the most excited. You can think of the organ of Corti as a piano with 15,000 strings (represented by the 15,000 hair cells). In a piano, the resonant frequency of each string is determined by its width and stiffness; similarly, each part of the basilar membrane has a resonant frequency based on its width and stiffness of its connective protein fibers such as collagen. Each hair cell is also “tuned” to an optimal sound frequency, determined by its location on the organ of Corti. Since different sound waves promote maximal movement of different regions of the basilar membrane, they activate differently tuned hair cells (that is, different sound waves vibrate different “piano strings”). This information is propagated to the CNS, which interprets the pattern of hair cell stimulation as a sound of a particular frequency. Modern techniques have determined that the basilar membrane is so fine-tuned that the peak membrane response to a single pitch probably extends no more than the width of a few hair cells, possibly due to *lateral inhibition* (see Figure 6-7).

Overtone of varying frequencies cause many points along the basilar membrane to vibrate simultaneously but less intensely than the fundamental tone, enabling the CNS to distinguish the timbre of the sound (**timbre discrimination**).

Loudness discrimination depends on the amplitude of vibration

Intensity (loudness) discrimination depends on the amplitude of vibration. As sound waves originating from louder sound sources strike the eardrum, they cause it to vibrate more vigorously (that is, bulge in and out to a greater extent) but at

Molecular Biology and Genomics

The Smell and Taste of Evolution

Until the advent of modern genetic techniques, the receptor proteins involved in many senses were unknown. But with these new methods, genes can be found once a single receptor's structure has been found by searching the genome for similar codes and then seeing where (if anywhere) those genes are expressed (see Chapter 2). In several studies that searched animal genomes for codes related to a known taste receptor, researchers have found that there are many (not one) genes for variants of bitter receptors, ranging from about 50 in a frog, 30 to 40 in various mammals including humans, to fewer than 10 in zebra fish and pufferfish. Multiple sweet receptors have also been found. Furthermore, the researchers found that these genes were being expressed in the mouse tongue. The sense of taste may be more sophisticated than originally thought, particularly for bitter substances, which can be dangerous and which have evolved into an enormous array of defense molecules in plants.

The most recent studies on taste involve “knocking out” genes (p. 34) for taste receptors. In one study, mice were

engineered by knocking out a sweet-receptor gene (called *T1R2*) and replacing it with the human equivalent. The mice were highly attracted to the artificial sweetener *aspartame*, which humans taste as sweet but which mice normally do not detect.

Genomic database searches have revealed odorant receptors of humans, dogs, mice, catfish, salamanders, many bird species, and insects. A surprisingly large family of vertebrate odor receptors (OR) has been found, with approximately 50 OR genes in fish to about 1,000 in mammals (though not all are functional). OR genes in birds are quite variable, estimated to range from 107 in galah cockatoos to 600 in kiwis. In mice, animals highly reliant on their sense of smell, 80% of the 1,000 or so OR genes are functional; the other 20% have mutated into unusable pseudogenes. In comparison, the proportion of OR pseudogenes in chimpanzees is about 30%, and in humans it is 60%! This is an excellent example of *vestigial structures* (p. 2), which, like remnant hindlimbs in snakes and whales, provide some of the strongest evidence for the theory of evolution. The loss

of 60% of functional OR genes in humans accords with what people have long known about human sense of smell: It has clearly degenerated in comparison to other mammals. Yoav Gilad and colleagues have found that the percentage of OR pseudogenes correlates among humans and Old World and New World primates with the degree of reliance on color vision.

Finally, the first insect taste-receptor genes have been recently isolated in *Drosophila* (fruit flies). Here again, the fly genome was scanned for codes of known taste receptors, and the results were about 75 potential taste genes. Many of these were found to be expressed in the fly's taste organ, the proboscis **labellum**. The researchers in this study hope the information will allow the design of baiting (to an insect) chemicals for use in repelling pests that eat crops and damage trees.

Clearly, genomic analysis continues to produce many surprising and exciting results for physiologists. Many long-standing mysteries such as sensory mechanisms are now becoming amenable to further physiological analysis.

the same frequency as a softer sound of the same pitch. The greater tympanic membrane deflection is converted into a greater amplitude of basilar membrane movement in the region of peak responsiveness. The CNS interprets greater basilar membrane oscillation as a louder sound.

The auditory cortex is mapped according to tone

Just as various regions of the basilar membrane are associated with particular tones, the **primary auditory cortex** (see Figure 5-17a) in the temporal lobe is also *tonotopically* organized. Each region of the basilar membrane is linked to a specific region of the primary auditory cortex. Accordingly, specific cortical neurons are activated only by particular tones; that is, each region of the auditory cortex becomes excited only in response to a specific tone detected by a selected portion of the basilar membrane.

The neural pathway between the organ of Corti and the auditory cortex, beginning with the auditory nerve, involves several synapses en route, including the *brainstem* (which uses the auditory input for alertness and arousal) and the *thalamus*, which sorts and relays the signals upward. Unlike signals in the visual pathways, auditory signals from each ear are transmitted to both temporal lobes because the fibers partially cross over in the brainstem. For this reason, a dis-

ruption of the auditory pathways on one side beyond the brain stem does not affect hearing in either ear to any extent.

The primary auditory cortex appears to perceive discrete sounds, whereas the surrounding *associative* auditory cortex integrates the separate sounds into a coherent, meaningful pattern. Consider the complexity of the task accomplished by the auditory system in sorting out a myriad of noises in the environment. An animal's ability to discriminate the sound of an approaching predator from that of background noises can be a matter of survival.

Insect ears are derived from the respiratory tracheal system

Let's conclude our examination of hearing with the most successful group of all animals. Insects use auditory information for a variety of behaviors, including social dominance as well as communication with the opposite sex. In crickets the prothoracic walking leg contains a specialized auditory organ, which is derived from a modified trachea. In contrast, locusts' ears are located on the first abdominal segment and consist of modified spiracles (see Figure 11-3e, p. 496). Sensory cells are aggregated into clusters directly coupled to the **tympanum**, a structure similar in appearance to the frog tym-

panic membrane. The tympanum is exposed to air on both sides of the membrane. Thus, as in mammals, any changes in air pressure induced by sound waves causes the tympanum to vibrate. Vibration of the tympanum activates specific receptors, generating action potentials, which are sent to the central nervous system. Depending on the source of the sound, differences in the time it takes the sound waves to reach the right or left tympani can be used to establish the source. In addition, because the tracheal system is interconnected, sounds arriving at one tympanum are conducted throughout the animal and cause the opposite tympanum to move from the inside. Interestingly, rather than the ability to discriminate pitch, as in the case of vertebrates, insects' hearing organs are specialized for determining patterns, duration, and intensity of sound waves.

check your understanding 6.4

What is responsible for the pitch, intensity, and timbre of a sound? How are these different sound components used by various animals?

Describe the function of each of the following parts of the mammalian ear: pinna, ear canal, tympanic membrane, ossicles, oval window, and the various parts of the cochlea. Include a discussion of how sound waves are transduced into action potentials.

6.5 Chemoreception: Taste and Smell

As we noted earlier, detection of chemicals in the environment is a very ancient sense. Animal sensors for taste and smell, plus numerous interoceptors, are chemoreceptors, detecting chemicals to generate neural signals, often (but not always) following binding of particular chemicals in their environment to specific receptor proteins. The functions of interoceptors, such as those monitoring blood chemistry, are discussed in other chapters. Here we focus on the exteroceptors for **gustation** (**taste**, or detection of molecules in objects in solids or liquids in contact with the body) and **olfaction** (**smell** or detection of individual molecules released from a distant object) exteroceptors. Chemoreception can take place on the skin or in special organs such as antennae of insects and the tongue in the mouth and olfactory bulbs in nasal cavities of air-breathing vertebrates.

Taste and smell have numerous roles such as sensing food, kin, mates, and direction

Animal chemical senses have many functions. Clearly, taste and smell provide a “quality control” checkpoint for substances available for ingestion. The sensations of taste and smell in association with food intake in some species can influence the flow of digestive juices and affect appetite. Furthermore, stimulation of taste or smell receptors induces pleasurable or objectionable sensations (at least in humans). In many species of animals these senses also permit finding direction, seeking prey or avoiding predators, detection of damaged and diseased tissue, social recognition of kin, and sexual attraction to a mate. For example, carnivorous cone

snails (p. 34) detect prey by their odor molecules; mosquitoes find their human “prey” by smelling CO₂ and octenol, a volatile chemical in sweat; barnacle larvae settle on intertidal rocks chosen in part by smelling chemicals released by adult barnacles; mice sniff for potential mates while avoiding those that are infected with parasites; and hermit crabs find buried snail shells in part by smelling calcium leaching from them. Crabs can detect virtually all classes of biologically available molecules, including petroleum hydrocarbons and the odors of decaying flesh.

Taste and smell senses are highly variable in sensitivities among species. For example, cats cannot taste sweets because their sweet-receptor gene (presumably not useful in these meat-eaters) has become a pseudogene (p. 3). Smell is a relatively poor sense in humans (see *Molecular Biology and Genomics: The Smell and Taste of Evolution*) and is much less important in influencing our behavior compared to most mammals. Bird species are also variable. Some species of pelagic birds, which until recently ornithologists thought had no sense of smell at all, can detect the odor of *dimethyl sulfide* (DMS) from up to 4 kilometers away. White-chinned petrels, bloodhounds of the Antarctic skies, rely on the odor of DMS to locate zooplankton (such as krill, shrimplike crustaceans) on which to feed. DMS is produced when zooplankton feed on phytoplankton (single-celled algae), which contain an *osmolyte* (p. 617) called *dimethylsulfoniopropionate* that breaks down into the globally important gas DMS (see Chapter 1, p. 14). Vultures and kiwis also locate food sources by smell and have unusually large proportions of their brains devoted to the sense of smell.

The intraspecies roles of olfaction are largely mediated by *pheromones* (p. 92). In the social insects, including ants, honeybees, and termites, olfactory communication maintains the very fabric of their complex societies. Exocrine glands located on the bodies of these insects release volatile pheromones into the environment. These lightweight chemical compounds made of 5 to 20 carbon atoms are passed from one animal to another and trigger a characteristic behavioral or physiological response. Among the specific behaviors attributed to pheromones in insects include alarm reactions, orientation, swarming, food source tracking, fighting, and recognizing members of a colony. (We will examine pheromones in vertebrates shortly.) The first pheromone to be identified was **bombykol**, a pheromone released from sexually receptive female moths to attract the male. Chemoreceptors of insects can be exquisitely sensitive to their ligands: The binding of only one pheromone molecule to a receptor on the antennae of the male gypsy moth (*Lymantria dispar*) is sufficient to trigger an action potential. Relying on this remarkable degree of sensitivity, the male flies “upwind” in pursuit of the flightless, sexually receptive female.

Next, we examine the mechanism of taste (gustation) in detail and then turn our attention to smell (olfaction).

Taste sensation is coded by patterns of activity in various taste receptors

In insects, **sensilla**—specialized projections from the cuticle—permit molecules to reach their internal sensory endings through minute pores. In flies and moths, for example, these chemoreceptors are located in sensory hairlike projections

FIGURE 6-22 Location and structure of human taste buds. Taste buds are located primarily along the edges of moundlike papillae on the upper surface of the tongue. The receptor cells and supporting cells of a taste bud are arranged like slices of an orange.

© Cengage Learning, 2013

on the terminal segment of the leg as well as in the tip of the proboscis, which is used for feeding and drinking. Appropriate stimuli result in extension of the proboscis and elicitation of feeding or drinking behavior. Dendrites, containing the sensory receptors, project to the apex of each sensillum. In some species of insects (such as ants, bees, and wasps), taste organs are also located on the antennae. Insects rely on their chemical senses for feeding and mating behavior, habitat selection, and parasite–host relationships.

In higher vertebrates the chemoreceptors for taste (**gustatory**) sensation are packaged in **taste buds** (Figure 6-22), about 10,000 of which are present in the human oral cavity and throat, with the greatest percentage on the upper surface of the tongue. This compares to over 15,000 in pigs and rabbits, 550 in lizards, and only 24 in chickens. Recent studies on mammals have found that the digestive tract also contains taste receptors involved in regulation of digestion (see Chapter 14), and the lung contains bitter taste receptors that trigger relaxation of the airways, perhaps to aid in coughing out toxins. In other vertebrates, such as catfish, taste buds may be located over the entire surface of the animal's body and number over 100,000. In most species of bony fish, taste buds are located in the mouth, pharyngeal region, and gill arches. The extraoral taste receptors help in detecting and capturing the foodstuff, whereas the function of the intraoral taste system is similar to that of air-breathing animals.

A typical mammalian taste bud consists of about 50 long, spindle-shaped receptor cells packaged with supporting cells in an arrangement like slices of an orange. Each taste bud has a small opening, the **taste pore**, through which fluids in the mouth come into contact with the surface of its receptor cells.

Vertebrate taste receptor cells are modified epithelial cells with many surface folds—**microvilli**—that protrude slightly through the taste pore, greatly increasing the surface area exposed to the oral contents. The plasma membrane of the microvilli contains receptor sites that bind selectively with chemical molecules in the environment. Only chemicals

in solution—either ingested liquids or solids that have been dissolved in saliva—can attach to receptor cells and evoke the sensation of taste. Binding of a taste-provoking chemical, a **tastant**, with a receptor cell ultimately alters the cell's ionic channels to produce a depolarizing receptor potential. This receptor potential, in turn, initiates action potentials within terminal endings of afferent nerve fibers with which the receptor cell synapses.

Most receptors are carefully sheltered from direct exposure to the environment, but the taste receptor cells, by virtue of their task, frequently come into contact with potent chemicals. Unlike the eye or ear receptors, which are irreplaceable, taste receptors have a limited life span—about 10 days in humans. Epithelial cells surrounding the taste bud differentiate first into supporting cells and then into receptor cells to constantly renew the taste bud components.

Terminal afferent endings of several cranial nerves synapse with taste buds in various regions of the mouth. Signals in these sensory inputs are conveyed via synaptic stops in the brain stem and thalamus to the **cortical gustatory area**, a region in the parietal lobe adjacent to the “tongue” area of the somatosensory cortex. Unlike most sensory input, the gustatory pathways are primarily uncrossed. The brain stem also projects fibers to the hypothalamus and limbic system, presumably to add affective dimensions, such as whether the taste is pleasant or unpleasant, and to process behavioral aspects associated with taste and smell.

Mammalian taste is based on five (and perhaps more) primary tastes

Mammals can discriminate among thousands of different taste sensations, yet most tastes are thought to be varying combinations of just five tastant categories, the **primary tastes**: **salty** (*sodium*), **sour** (or acidic), **sweet**, **bitter**, and **umami**, a meaty or savory taste. Each receptor cell responds in varying degrees to all the primary tastes but is generally preferentially responsive to one of the taste modalities. (You may have learned that specific areas of your tongue respond

to specific tastes; for example, sweet taste is sometimes shown as located at the tip of your tongue. Recent studies show that these common taste maps are erroneous. Human taste types are scattered over most of the tongue, and the map varies from individual to individual.)

As with all biological features, understanding these tastes requires both proximate and evolutionary explanations. In terms of evolution, each uniquely aids survival. In terms of mechanisms, receptor cells use different pathways to bring about a receptor potential in response to each of the five primary tastant categories (Figure 6-23):

- **Salty taste** is stimulated by chemical salts, especially Na^+ (as in table salt, NaCl). This is important to survival because obtaining sufficient dietary NaCl is critical for osmotic balance (Chapter 13) and electrical signals (Chapter 4). Salty taste is particularly prominent in herbivores, whose plant diet is low in sodium. Transduction is direct, due to entry of positively charged Na^+ ions through specialized Na^+ channels in the receptor cell membrane of rats, hamsters, and primates. There are at least two types of channels, including a very specific one called *ENaC* (for epithelial Na^+ channel; Figure 6-23). It may be a simple leak channel, though there is some evidence it might be gated. This ion movement reduces the cell's internal negativity and is believed to be responsible for receptor potential. Salty taste transduction is different among species; e.g., frog taste cells have nonspecific cation channels whereas mammalian taste cells are highly specific for Na^+ .
- **Sour taste** is caused by acids, which contain a free hydrogen ion, H^+ . The citric acid content of lemons, for example, accounts for their distinctly sour taste. Moderate sourness taste is pleasant, perhaps because it favors ingestion of acidic vitamin C. Strong acid taste may warn against spoiled food or unripe fruit. Depolarization of the receptor cell by sour tastants may occur directly by H^+ entry (see Figure 6-23), or when H^+ blocks K^+ channels in the receptor cell membrane. The resultant decrease in the passive movement of positively charged K^+ ions out of the cell reduces the internal negativity.
- **Sweet taste** is evoked by the particular configuration of small sugar molecules (Figure 6-23). Clearly this pleasant taste favors intake of this primary energy form (glucose, sucrose and so forth) in most animals. Depending on the species of animal, other organic molecules, such as saccharin, aspartame, and other artificial sweeteners, can also interact with sweet receptor binding sites. Signaling begins with the binding of glucose or another chemical to a **G-protein coupled receptor**, which leads to either (1) the cAMP second-messenger pathway, or (2) (in some species) the IP_3 pathway (see pp. 97–98). The second-messenger pathway results in either (1) phosphorylation and blockage of K^+ channels in the receptor cell membrane, leading to a depolarizing receptor potential; or (2) IP_3 -induced release of Ca^{2+} from the endoplasmic reticulum, leading to neurotransmitter release.
- **Bitter taste** is elicited by a more chemically diverse group of tastants than the other taste sensations because there are many different bitter receptors (see the box, *Molecular Biology and Genomics: The Smell and Taste of Evolution*, p. 232). This is largely a negative taste

FIGURE 6-23 Transduction pathways in taste bud cells. For convenience, pathways for salt, acid, sweet, bitter, and umami are shown in one cell, but a real taste bud receptor would have only one type.

© Cengage Learning, 2013

that helps avoid noxious or toxic molecules. For example, alkaloids (such as caffeine, nicotine, strychnine, morphine, and other toxic plant derivatives) as well as many poisonous plant compounds all taste bitter. Each bitter-taste receptor cell has multiple receptors and possibly multiple signaling pathways for detecting this wide array of potentially harmful chemicals. Most or all involve G proteins (Figure 6-23). Indeed, the first G protein in taste—**gustducin**—was identified in one of the bitter-signaling pathways. Interestingly, this G protein is structurally very similar to the visual G protein, *transducin* (see p. 248).

Interestingly, humans and laboratory animals can learn to like certain bitter tastes, a phenomenon called **acquired taste**. For example, most wines and beer contain bitter compounds that are distasteful upon first drinking to humans and laboratory mice. However, as the brain learns to associate the pleasure induced by alcohol with these drinks, the associative sensory cortex somehow reverses its perception of the bitter taste.

- **Umami** (Japanese for “yummy”) taste is triggered by amino acids such as glutamate. The presence of amino acids serves as a marker for a nutritionally protein-rich food. First named by a Japanese researcher in 1908, umami was not widely accepted as a fifth taste until the 1990s, and the actual receptor was not confirmed until 2009. Glutamate binds to this G-protein coupled receptor and activates a second-messenger system (Figure 6-23).

This list of five tastes may soon be outmoded. A new sixth taste sensation has also been proposed—**fatty**. Scientists have recently identified a potential sensor in the mouth for long-chain fatty acids in humans and rodents. This makes sense for survival, because all three major food groups—carbohydrates (sweet), protein (umami), and fats—are essential. Mice have recently been found to have a seventh taste modality with a unique receptor for *calcium* (humans may also have it). Calcium is essential for so many functions—bone formation, exocytosis, muscle contraction—that a taste for it makes evolutionary sense as well.

FIGURE 6-24 Location and structure of the mammalian olfactory receptors.

© Cengage Learning, 2013

The richness of fine taste discrimination beyond these five (or more) primary tastes depends on subtle differences in the stimulation patterns of all the taste buds in response to various substances, as well as to the complementary sense of smell. (As you know if you have tasted food while your nose was plugged up due to a cold, much of what humans call food's "taste" is actual a smell sensation, in part from chemicals released during chewing that enter the nasal cavity from the nostrils or the back of the mouth.) Other factors affecting taste include temperature and texture of the food as well as psychological factors associated with past experiences with the food. How the cortex accomplishes the complex perceptual processing of taste sensation is currently not known.

We now turn to the sensation of smell.

The olfactory receptors in the nose are specialized endings of renewable afferent neurons

The **olfactory mucosa** of vertebrates, located in the **nasal fossae** (upper tract of the respiratory airways), contains three cell types: *olfactory receptors*, *supporting cells*, and *basal cells* (Figure 6-24). The **supporting cells** (also called **Bowman's glands**) secrete mucus, which coats the nasal passages. The **basal cells** are precursors for new olfactory receptor cells, which are replaced about every two months in humans. This is remarkable because, unlike the other special sense receptors, **olfactory receptors** are specialized endings of afferent neurons, not separate cells. The entire neuron, including its afferent axon projecting into the brain, is replaced. These are the only mammalian neurons that undergo cell division (although recent evidence suggests that new neurons can be produced in the hippocampus, a part of the brain important in forming long-term memory; see p. 171).

The receptor portion of the olfactory receptor cells consists of an enlarged knob bearing several long cilia that extend like a tassel to the surface of the mucosa. These cilia contain the binding sites for attaching **odorants**, molecules that can be smelled. During quiet breathing in air breathers, odorants typically reach the sensitive receptors only by diffusion because the olfactory mucosa is above the normal path of airflow. The act of sniffing enhances this process by drawing the air currents upward within the nasal cavity so that a greater percentage of the odoriferous molecules in the air contact the olfactory mucosa. As we noted earlier for taste, odorants also reach the olfactory mucosa during eating by wafting up to the nose from the mouth through the nostrils or pharynx (back of the throat).

The nasal cavity in both fish and aquatic amphibians is generally a pit or saclike structure on either the dorsal or ventral surface of the snout. In aquatic vertebrates water is drawn across the olfactory epithelium and odor signals become absorbed in the mucous layer, where they bind to specific receptor sites on the surface membranes of olfactory cilia in the outer mucous layer.

To be smelled, a substance must be (1) sufficiently volatile (easily vaporized or dissolved) that some of its molecules can enter the nose in the inspired air or water; and (2) sufficiently soluble that it can dissolve in the mucus layer coating the olfactory mucosa. Many thousands of odors can be distinguished by the sense of smell, although it has been difficult to categorize particular odors based on their chemical structure. Some odors quickly dissipate in the atmosphere, such as alarm substances released by ants, whereas others are intended to persist for long periods of times. For example, lipid added to the territorial scent markings of lions and tigers extends the release time of the pheromonal message released by the anal sacs.

Various parts of an odor are detected by different olfactory receptors and sorted into “smell files”

The human nose contains 5 million olfactory receptors, about 10-fold less than in rodents and dogs. Genomics reveal that most vertebrates have many more different types of odor receptor (OR) genes than genes for other senses. Although chemoreception is important in all animals, mammals can sample a larger repertoire of the environment compared to other vertebrates because they have more OR proteins (though some ORs are pseudogenes; see the box, *Molecular Biology and Genomics: The Smell and Taste of Evolution*, p. 232). Also, number of olfactory neurons in mammals is greater, varying from 60 million in rats, to 100 million in rabbits, to almost a billion in the German shepherd dog.

Like many tastants, sensing of an appropriate scent molecule begins with binding to a G-protein coupled receptor, triggering a cascade of intracellular reactions that leads to opening of Ca^{2+} or Na^{+} channels. The resultant ion movement brings about a depolarizing receptor potential that generates action potentials in the afferent fiber. For unknown reasons, some members of the olfactory receptor family are also expressed in the mammalian tongue, sperm cells (p. 799), and developing rat heart, as well as in the avian notochord (non-neuronal embryonic tissue which induces formation of the neural tube).

Smell detection “dissects” an odor into various components. Each receptor responds to only one discrete component of an odor rather than to the whole odorant molecule. Accordingly, different receptors detect the various parts of an odor, and a given receptor can respond to a particular odor component shared in common by different scents, ultimately permitting spatial summation. Basically the gustatory sense determines whether the food is good or not (that is, is it safe?), whereas the olfactory sense is more discriminatory and picks up the selected differences in food items.

The afferent fibers arising from the receptor endings in the nose pass through tiny holes in the flat bone plate separating the olfactory mucosa from the overlying brain tissue (Figure 6-25). They immediately synapse in the **olfactory bulb**, a complex neural structure containing several different layers of cells that are functionally similar to the retinal layers of the eye. In humans, the twin olfactory bulbs, one on each side, are about the size of small grapes. Each olfactory bulb is lined by small, ball-like neural junctions known as **glomeruli** (“little balls”) (Figure 6-25). Comparatively, fish are noted for having few glomeruli. Within each glomerulus, the terminals of receptor cells carrying information about a particular scent component synapse with the next cells in the olfactory pathway, the **mitral cells**. Because each glomerulus

FIGURE 6-25 Processing of scents in the mammalian olfactory bulb. Each of the glomeruli lining the olfactory bulb receives synaptic input from only one type of olfactory receptor, which, in turn, responds to only one discrete component of an odorant. Thus, the glomeruli sort and file the various components of an odiferous molecule before relaying the smell signal to the mitral cells and higher brain levels for further processing.

© Cengage Learning, 2013

receives signals only from receptors that detect a particular odor component, the glomeruli serve as “smell files.” The separate components of an odor are sorted into different glomeruli, one component per file. Thus, the glomeruli, which serve as the first relay station for processing olfactory information, play a key role in organizing scent perception.

The mitral cells on which the olfactory receptors terminate in the glomeruli refine the smell signals and relay them to the brain for further processing. Fibers leaving the olfactory bulb travel in two different routes (Figure 6-26):

1. A *subcortical route* going primarily to regions of the limbic system, especially the lower medial sides of the temporal lobes (considered to be the **primary olfactory cortex**). This route is for close coordination between smell and primitive memory, as well as behavioral reactions associated with feeding, mating, and direction orienting.
2. A *thalamic-cortical route*. This route, which includes hypothalamic involvement, permits conscious perception and fine discrimination of smell.

FIGURE 6-26 Mammalian olfactory pathways. See Figures 6-24 and 6-25 for a location reference point.

Odor discrimination is coded by patterns of activity in the olfactory bulb glomeruli

Because each given odorant activates multiple receptor proteins and glomeruli in response to its various odor components, odor discrimination is based on different patterns of glomeruli activated by various scents. In this way, the cortex can distinguish about 20,000 different scents with a 1,000 or fewer different receptor proteins. This mechanism for distinguishing different odors is very effective, even in humans, who have a poor sense of smell compared to other species. (By comparison, dogs' sense of smell is hundreds of times more sensitive than that of humans). A noteworthy example is our ability to detect methyl mercaptan at a concentration of 1 molecule per 50 billion molecules in the air! This is the substance is added to odorless natural gas to enable us to detect potentially lethal gas leaks (p. 214).

The olfactory system adapts quickly, and odorants are rapidly cleared

Although the olfactory system is sensitive and highly discriminating, it is also quickly adaptive. Sensitivity to most new odors diminishes rapidly after a short period of exposure to it, even though the odor source continues to be present. This reduced sensitivity or habituation involves both intrinsic receptor adaptation (as we noted earlier, p. 214) and some sort of extrinsic adaptation in the CNS. Adaptation is specific for a particular odor, and responsiveness to other odors remains unchanged.

What clears the odorants away from their binding sites on the olfactory receptors so that the smell does not "linger" after the source is removed? Several "odor-eating" enzymes have recently been discovered in the olfactory mucosa that may serve as molecular janitors, clearing away odoriferous molecules so they do not continue to stimulate olfactory receptors. Interestingly, these odorant-clearing enzymes are very similar chemically to detoxification enzymes in the liver. (These liver enzymes inactivate potential toxins absorbed from the digestive tract; p. 685). This resemblance

may not be coincidental. Researchers speculate that these enzymes may serve the dual purpose of clearing the olfactory mucosa of old odorants and transforming potentially harmful chemicals into harmless molecules. Such detoxification would be very useful, considering the open passageway between the olfactory mucosa and the brain.

The vomeronasal organ detects pheromones

In addition to the olfactory mucosa, the vertebrate nose may contain another sense organ: the **vomeronasal organ (VNO)** in mammals, including humans, and non-avian reptiles, where it is sometimes called **Jacobson's organ** (note most aquatic vertebrates and birds lack this organ). The VNO is located just inside the nose next to the vomer bone, hence its name. The VNO is called the "sexual nose" for its role in governing reproductive and social behaviors, such as identifying and attracting a mate, by reception of pheromones. For example, male ungulates, such as stallions, put their lips into the urine of an estrous mare and curl their upper lip in the **Flehman position** ("horse's laugh"), which partially blocks the nostril opening. Breathing deeply carries the urine into the VNO, where the stallion determines sexual receptivity of the mare by the concentration of pheromone. Sex pheromones are also produced in the urine of female elephants about to ovulate, which initiates the Flehman response in reproductively active males. Males first identify the urine through the sense of smell and then detect the pheromone by placing urine from the tip of their trunk to the opening of ducts leading to the VNO. Interestingly, this pheromone, (*Z*)-7-dodecenyl acetate, is identical to a substance used by more than a hundred species of moths as one of their major sex pheromones.

Males also make pheromones. For example, male mice produce an unusual protein called *darcin*, which, in their urine, makes them attractive to female mice. One of the few other mammalian pheromones that has been characterized is *androstene*, a steroid in the saliva of male pigs and human male sweat. Release of this potent pheromone in pigs causes sows to assume the **lordosis** (mating) position. Androstene elicits this behavior only in estrous sows, which suggests that in some species, the response to a **releaser** pheromone is context dependent and not necessarily automatic.

Although the role of the VNO in human behavior has not been validated, researchers suspect it governs spontaneous "feelings" between people, either "good chemistry," such as "love at first sight," or "bad chemistry," such as "getting bad vibes" from someone you just met. Evidence from individuals whose VNO has been surgically removed supports the existence of a subtle role for the VNO in group behavior, sexual activity, and compatibility with others,

similar to the role they play in other animals. Because messages conveyed by the VNO are believed to bypass the cortex (using the limbic path of Figure 6-26), the response to the largely odorless pheromones, if real, would be largely subconscious.

Recent studies in mice have found that the VNO also has receptor proteins for the detection of damaged or infected tissues. These presumably help animals assess the health status of potential mates, and perhaps even to avoid potential disease carriers in general.

Describe the structure and activation of the taste receptors and why each different primary taste aids survival.

Discuss the location and activation of olfactory receptors (including the VNO) and how the brain distinguishes tens of thousands of odors from 1,000 or fewer receptor proteins.

6.6 Photoreception: Eyes and Vision

Light is one of the most useful signals in the environment, and the ability to detect it can be critical for survival. Indeed, over 90% of known animal species have some type of light sensors. In some animals (such as birds) vision may be the dominant sense in day-to-day life (and in some species vision is considered responsible for an evolutionary decline in acuity in the olfactory system, as we noted earlier).

Light detection uses universal photopigments in ciliary or rhabdomeric receptor cells

Even though organisms may be sensitive to light, their sensitivities and acuities can vary tremendously. At the most primitive level, light detection is based on structures not dedicated solely to this purpose. For example, *chromatophores* (pigment-containing skin cells, p. 154) in many phyla of nonvertebrates and classes of lower vertebrates are directly sensitive to light, responding with color and shade changes in the skin. Even a single-celled *Amoeba* responds to a flash of light by ceasing to move. However, special organs dedicated to light detection have evolved numerous times in a variety of structures. Yet even though the light-capturing organ of an animal may be structurally very different (as you will see shortly), the initial chemical pathways that transduce the light energy are similar, beginning with a highly conserved group of *photopigment molecules* (see *Molecular Biology and Genomics: The Eyes Have It*, p. 241). Furthermore, most organisms use light energies in a narrow spectral band between 400 and 700 nm (nanometers, or billions of a meter between wave peaks), matching the major output frequencies of the sun as well as the biochemical limits of the pigments, because too little energy would not excite the pigments, whereas energy frequencies that are too high would potentially break down the constituents necessary for phototransduction. However, as you will see, a number of animals have expanded the range into the ultraviolet (UV) region of the spectrum below 400 nm.

Only two types of photoreceptor cells have evolved:

1. **Ciliary** photoreceptors have a large single cilium (see p. 60) with a highly folded membrane, often internal, that contains the photopigments. A key example is the *rod cell* of vertebrates, to be discussed later; ciliary types are also found in Cnidaria, flatworms, and some mollusks.
2. **Rhabdomeric** photoreceptors increase their surface area with numerous parallel microvilli (p. 63). These are found in arthropod compound eyes, also to be discussed later, and in most other bilateral animals with the notable exception of vertebrates. Note that this means that some phyla, including flatworms and mollusks, have both ciliary and rhabdomeric types. Why did both of these evolve? One hint comes from recent studies on the marine annelid, the ragworm *Platynereis dumerilii*. Considered a “living fossil” for its ancient features, this worm’s head has two large rhabdomeric eyes for image formation and two simple ciliary *eyespots* (see below) dedicated to detecting light for regulation of *circadian rhythms* (p. 276). Thus, the two types of photoreceptor cells may have first evolved for independent functions.

Dedicated light-sensing organs range from simple eyespots to complex eyes

Considerable evolutionary inventiveness exists in the light-detecting organs that house the photoreceptors (Figure 6-27), though remarkably, most if not all share common genetic features (see the box, *Molecular Biology and Genomics: The Eyes Have It*). Scientists have discovered at least 10 different categories of eyelike structures. **Eyespots**, the simplest form, consist of a small number of photoreceptor cells (less than 100) lining an open cup or pit (Figure 6-27a). Each pit samples a relatively large area of the visual world. Representatives with these simple photoreceptor plates that have received study include planarian flatworms (Platyhelminthes), jellies (Cnidarians), and seastars (Echinoderms); but similar less-studied structures are found in many animal phyla. These photoreceptors are lined by photopigment on one side and receive light from only one direction. The pigment cells enclose the dendritic endings of the sensory neurons; the neuronal axons are bundled into nerves that travel from each cup, usually to integrating nerves such as a ganglion or brain. This particular arrangement permits the animal to locate a light source and, in some cases, to orient movement. For example, butterflies sense light with their genitalia. These extraocular photoreceptors determine whether the ovipositor (external appendage that transmits the egg) in females is sufficiently pushed out from the abdominal tip on oviposition (process of egg laying) or the deposited eggs will not be properly attached to the leaf surface. In males the photoreceptors confirm correct coupling with the female during mating.

However, recognition of predator/prey movement requires a more complex optical system that permits formation of an image—a true eye. By reducing the size of the cup aperture to produce a **pinhole eye**, an eye can actually form an image, even though it may not be very discriminatory. The evolution of a clear focusing orb called a **lens** in some animals enhances the light-gathering power of the eye, forming what is called a **camera eye** (Figure 6-27b, c). This familiar arrangement appears in many phyla; the most ancient

version is probably that evolved by the Cubozoa (box jellies), a surprisingly advanced structure for a Cnidarian (Figure 6-27d). More complex camera eyes are the optical solution evolved by vertebrates and cephalopods (the most intelligent nonvertebrates). The major alternative evolutionary solution is the **compound eye**, with densely packed units called *ommatidia*, each having its own lens and pigment-shielded photoreceptors (Figure 6-27e). Fossil evidence of ommatidia is very ancient, found in arthropods such as trilobites living during the mid-Cambrian period. Although compound eyes provide comparatively poor image formation, they are superior for detecting movement and have a wider field of view than do camera eyes.

A final improvement in eye evolution was the origin of two or more different photoreceptors sensitive to different wavelengths, a fundamental condition for color vision. Many vertebrates, for example, have this adaptation to at least some degree. Let's now examine the vertebrate eye in detail, and then take a look at some non-vertebrate eyes.

The vertebrate eye is a fluid-filled sphere enclosed by three specialized tissue layers

Camera eyes capture patterns of illumination in the environment as an “optical picture” on a layer of light-sensitive cells, the **retina**, much as a camera captures an image on film. Just as film can be developed into a visual likeness of the original image, the coded image on the retina is transmitted through a series of progressively more complex steps of visual processing until it is finally perceived in the visual associative cortex as a likeness of the original image. The retina of all vertebrates is structurally and functionally similar.

Each eye (Figure 6-28a) is a spherical, fluid-filled structure enclosed by three layers. From outermost to innermost, these layers are (1) the *sclera* and *cornea*; (2) the *choroid*, *ciliary body*, and *iris*; and (3) the *retina*. Most of the eyeball is covered by a tough outer layer of connective tissue, the **sclera**, which forms the visible white part of the eye (Figure 6-28b). Anteriorly (toward the front), the outer layer consists of the transparent **cornea** through which light rays pass into the interior of the eye. The middle layer underneath the sclera is the highly pigmented **choroid**, which contains many blood vessels that nourish the retina. The choroid layer becomes specialized anteriorly to form the **ciliary body** and **iris**, which are described shortly. The innermost coat under the choroid is the retina, which consists of an outer pigmented layer and an inner nervous tissue layer. The latter contains the **rods** and **cones**, the photoreceptors that convert light energy into nerve impulses. Like the black walls of a photographic stu-

dio, the pigment in the choroid absorbs light after it strikes the retina to prevent reflection or scattering of light within the eye.

The interior of the eye consists of two fluid-filled cavities, separated by the lens, all of which are transparent to permit light to pass through the eye from the cornea to the retina. The anterior (front) cavity between the cornea and lens contains a clear, watery fluid, the **aqueous humor**, and the larger posterior (rear) cavity between the lens and retina contains a semifluid, jellylike substance, the **vitreous humor** (Figure 6-28a). The vitreous humor is important in maintaining the spherical shape of the eyeball. The aqueous humor carries nutrients for the cornea and lens, both of which lack a blood supply. Blood vessels in these structures would impede the passage of light to the photoreceptors.

Molecular Biology and Genomics

The Eyes Have It

Genomic studies have revealed remarkable commonalities among animal eyes. Photopigments are almost universally the protein *opsin* and the vitamin-A derivative *retinene*. We will examine these in detail later, but it is worth noting that opsins are ancient. David Plachetzki and colleagues have recently used genomic analysis to find an opsin gene in hydras, simple freshwater Cnidarians. Though lacking eyes, hydras will react when exposed to a sudden bright light by withdrawing. Blocking the phototransduction pathway (which is active in some hydra neurons) abolishes this reaction. Remarkably, genetic sequences show that human and hydra opsins evolved from a common ancestor.

Moreover, despite the diversity of eyes at the organ level, scientists have found a striking similarity in their development. The formation of all these eyes (at least all that have been tested) is initiated by a common “master” regulatory gene, called *Pax6* in vertebrates, first discovered in mutated form in humans born either without eyes or severely deformed ones. Nearly identical genes have been found in a variety of eyes across the animal kingdom. These genes are active in embryonic stages just before eye formation, which does not occur if the gene is nonfunctional. Remarkably, these related genes are interchangeable. A fruit

fly with its *Pax6* homolog knocked out will not form eyes, but if a mouse or a squid *Pax6* gene is engineered into it, it will form normal fly eyes! Apparently early in the evolution of animals, this gene became the master switch that turns on a cascade of other genes to construct eyes. However, this does not mean that eyes arose only once. *Pax6* also regulates other developmental pathways in other body regions, such as mammalian pancreas and squid olfactory organ, so perhaps it is a general organ-development switch that was selected independently in different groups for initiation of eye development.

FIGURE 6-28 Structure of the mammalian eye. (a) Internal sagittal view. (b) External front view.

© Cengage Learning, 2013

The mammalian retina is comparatively well vascularized, but the presence of blood vessels in the retina interferes with visual acuity. In contrast, reptiles have retinas that completely lack blood vessels. These groups rely on a *pecten* (birds) or a very similar *conus papillaris* (non-avian reptiles) to provide oxygen and nutrients to the retina by diffusion through the vitreous body. The avian *pectens* are thin, comblike projections from the choroid into the vitreous humor. Their comblike folds of endothelial cells enhance surface area available for nutrient exchange. In nocturnal birds the *pecten* tends to be simplified in structure, whereas in diurnal birds it is elongated and more elaborate. Because these vessels do not lie within the retina, the eyes of birds are

capable of greater visual resolution than a mammal's due to more space for photoreceptors (1,000,000/mm² in some hawks, versus 200,000 in humans). Thus, a sharp-eyed hawk can spot a field mouse from hundreds of meters away, something a mammal cannot do. Birds in general have the largest eyes relative to body size among all animals.

The amount of light entering many vertebrate eyes is controlled by the iris

Not all the light passing through the cornea reaches the light-sensitive photoreceptors, because of the *iris*, a thin, pigmented, smooth muscle that forms a visible ringlike

FIGURE 6-29 Control of pupillary size.

© Cengage Learning, 2013

structure within the aqueous humor (Figures 6-28 and 6-29). The pigment in the iris governs eye color. The round opening in the center of the iris, through which light enters the interior portions of the eye, is the **pupil**. The size of this opening can be adjusted by variable contraction of the iris muscles to admit more or less light as needed, much as the shutter controls the amount of light entering a camera. The mammalian iris contains two sets of smooth muscle networks, one **circular** (muscle fibers run in a ringlike fashion within the iris) and the other **radial** (fibers project outward from the pupillary margin like bicycle spokes) (Figure 6-29). Because muscle fibers shorten when they contract, the pupil gets smaller when the **circular (or constrictor) muscle** contracts and forms a smaller ring while the radial muscles relax. This reflex pupillary constriction occurs in bright light to decrease the amount of light entering the eye. When the **radial (or dilator) muscle** shortens, the size of the pupil increases and the circular muscles now relax. Such pupillary dilation occurs in dim light to allow more light to enter.

Iris muscles are controlled by the autonomic nervous system. Parasympathetic nerve fibers innervate the circular muscle, and sympathetic fibers supply the radial muscle. Acting via the autonomic nervous system, conditions other than light can induce changes in pupillary size (Figure 6-29). For example, dilation of the pupils accompanies generalized discharge of the sympathetic nervous system in response to actual or perceived danger.

The cornea and lens refract the entering light to focus the image on the retina

Light is a form of electromagnetic radiation consisting of particle-like individual packets of energy, called **photons**, that travel in a wavelike fashion. The distance between two wave peaks is known as the **wavelength**. So-called visible light (a term based on human vision) lies between 400 (violet) and 700 nm (red), which most animal eyes can sense, with some species also detecting ultraviolet wavelengths

down to 310 nm. Light of different wavelengths in this frequency band is perceived as different **color** (hue) sensations, at least by humans. In addition to having variable wavelengths, light energy also varies in **intensity**; that is, in the amplitude, or height, of the wave. Dimming a bright red light does not change its color; it just becomes less intense or less bright.

Light waves *diverge* (radiate outward) in all directions from every point of a light source. The forward movement of a light wave in a particular direction is known as a *light ray*. Divergent light rays reaching the eye must be bent inward to be focused back into a point on the light-sensitive retina to provide an accurate image of the light source (Figure 6-30a). The bending of a light ray (**refraction**) occurs when the ray passes from a medium of one density into a medium of a different density. Light travels faster through air than through other transparent media such as water and glass. When a light ray enters a medium of greater density, it slows down (the converse is also true).

Two factors contribute to the degree of refraction: the comparative *densities* of the two media (the greater the difference in density, the greater the degree of bending) and the *angle* at which the light strikes the second medium (the greater the angle, the greater the refraction). *The two structures most important in the eye's refractive ability are the cornea and the lens*. The curved corneal surface, the first structure light passes through as it enters the eye, contributes extensively to the refractive ability of a terrestrial animal's eye because the difference in density at the air/corneal interface is much greater than the differences in density between the lens and the fluids surrounding it. In contrast, the refractive power of the fish cornea is negligible because the surrounding medium of the fish cornea is water and not air. Thus, in fish, most of the refractive power is present in the lens.

With a curved surface such as a lens, the greater the curvature, the greater the degree of bending and the stronger the lens. When a light ray strikes the curved surface of any object of greater density, the direction of refraction depends

FIGURE 6-30 Focusing with a convex lens. Diverging light rays must be bent inward to be focused. (a) The rays from a distant (far) light source (more than 6 meters from the eye) are parallel by the time the rays reach the eye. (b) The rays from a near light source (less than 6 meters from the eye) are still diverging when they reach the eye. A longer distance is required for a lens of a given strength to bend the diverging rays from a near light source into focus compared to the parallel rays from a distant light source. (c) To focus both a distant and a near light source in the same distance (the distance between the lens and retina), a stronger lens must be used for the near source.

© Cengage Learning, 2013

on the angle of the curvature (Figure 6-30b, c). A lens with **convex** surfaces converges light rays, bringing them closer together, a requirement for bringing an image to a focal point. Refractive surfaces of the eye are therefore convex. (A lens with *concave* surfaces diverges light rays.)

The transparent state of the lens is due to proteins called **crystallins**, a term originating from the ancient Greeks who considered the lens to be icelike in appearance (*krusallinos*, “ice crystal”). Young lens cells contain organelles when they first form from stem cells in a fetus, but the structures are destroyed during early development, leaving a cytoplasm consisting of an usually thick solution of these crystallins. Strangely enough, the genes for crystallins evolved from the duplicated genes of various small enzymes such as *lactate dehydrogenase* of anaerobic glycolysis (p. 55). Vertebrates have multiple families of crystallins, whereas cephalopods have only a single family, the S-crystallins, which descended from a liver enzyme. For a lens to be transparent, crystallins must stay folded and evenly dispersed in order to create a glassy state.

Many vertebrate lenses in color-sensing eyes are *multi-focal*, having concentric rings of different refractive indices such that the more peripheral region has a lower refractive index (a decreased ability to bend light) than does the more central region. Seeing clearly underwater also requires a special spherical lens with this property. Blue light refracts more than red light does, so having different zones of refractive index allows the lens to focus all color wavelengths properly on the retina. This gradation, from the lens’s center outwards, is accomplished with progressively lower concentrations of crystallins. Animals such as humans and pigs lack multifocal lenses and so suffer from *chromatic aberration*; that is, they cannot focus on, for example, a blue and a red object at the same distance simultaneously. This problem is minimal in bright light when narrowed pupils allow light only into the lens center, where refraction is minimal; so multifocal lenses are mainly found in color-seeing nocturnal species and those fish residing in dim waters or with non-closing pupils.

In primates, there may be yellow pigment in the lens that acts as a filter, absorbing wavelengths below 400 nm to eliminate ultraviolet light. In contrast, the lens of animals that perceive ultraviolet wavelengths is clearer and permits the transmission of wavelengths as low as 310 nm. The lens thus absorbs only the more destructive region of the spectrum (nucleic acids and proteins begin to absorb light strongly at wavelengths shorter than 310 nm). In some species of fish the cornea is pigmented, which can also limit the penetration of short-wavelength light. In some species of fishes, reptiles including birds, and amphibians, colored oil droplets effectively limit the passage of short wavelengths to the photoreceptors. These oil droplets lie in the inner segments of the cone receptors.

Occasionally the crystallin fibers of the lens in older animals are progressively broken down and become so opaque that light rays cannot pass through, a condition known as a **cataract**. Cataracts often appear to have a white or crushed ice appearance and are the most common cause of blindness in dogs, in which either a genetic predisposition or diabetes is the cause. However, in the vast majority of dogs over six years of age the lens develops the more normal condition of **nuclear sclerosis**, which appears as a slight graying of the lens. It usually appears in both eyes at the same time and occurs because of compression of the crystallin fibers of the lens.

If an image is focused before it reaches the retina, or is not yet focused when it reaches the retina, it will be blurred. Light rays originating from near objects are more divergent when they reach the eye than are rays from distant sources. By the time they reach the eye, rays from light sources more than 6 meters away are considered parallel. For a given refractive ability of the eye, a near source of light requires a greater distance behind the lens for focusing than does a distant source because the near-source rays are still diverging when they reach the eye (Figure 6-30a, b).

In species where the distance between the lens and the retina always remains the same, in order to bring both near and distant light sources into focus on the retina (that is, in the same distance) a stronger lens must be used for the near source (Figure 6-30c). The strength of the lens can be adjusted through the process of *accommodation*, to which we now turn.

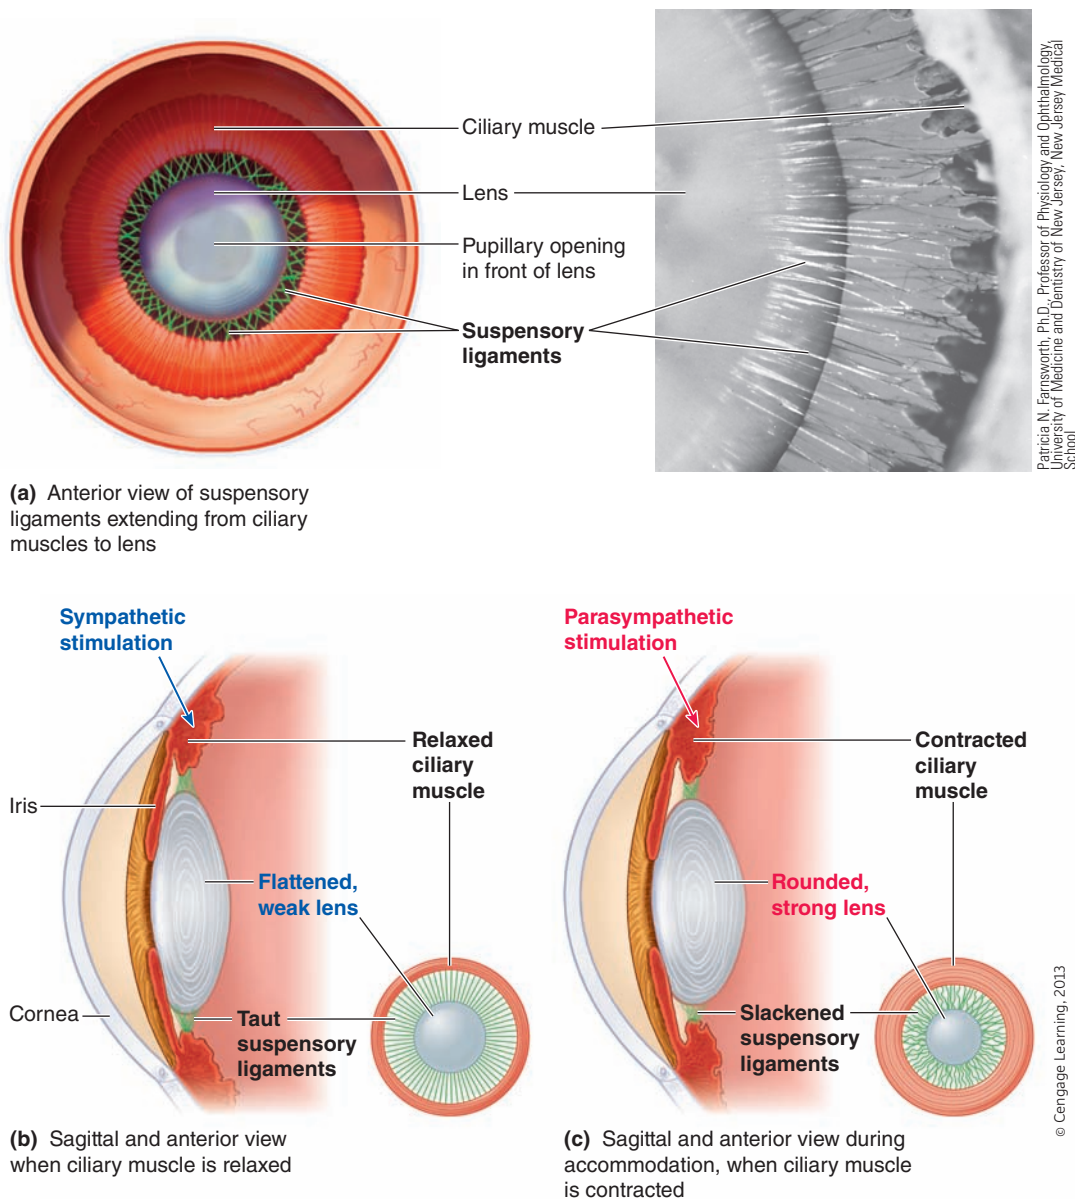

FIGURE 6-31 Mechanism of accommodation. (a) Suspensory ligaments extend from the ciliary muscle to the outer edge of the lens. (b) When the ciliary muscle is relaxed, the suspensory ligaments are taut, putting tension on the lens so that it is flat and weak. (c) When the ciliary muscle is contracted, the suspensory ligaments become slack, reducing the tension on the lens, allowing it to assume a stronger, rounder shape because of its elasticity.

Accommodation increases the strength of the lens for near vision

The ability to adjust lens strength to focus both near and distant sources of light on the retina is called **accommodation**. This occurs in three ways. (1) The strength of the lens depends on its shape, which in turn is regulated in mammals and some species of reptiles (including all birds) by the *ciliary muscle*. (2) However, the fish lens is extremely dense (overall a high refractive index), so it has a fixed focal length, and focusing is accomplished by physical movement of the lens back and forth. (3) Moving the photoreceptor layer also works if the lens shape cannot be changed. For example, some species of annelids can increase or decrease

the fluid volume within the optic chamber to alter distance between the lens and the photoreceptors.

In mammals, the **ciliary muscle** is part of the ciliary body, an anterior specialization of the choroid layer. The ciliary body has two major components: the ciliary muscle and the capillary network that produces the aqueous humor (Figure 6-28). The ciliary muscle is a ring of smooth muscle attached to the lens by suspensory ligaments (Figure 6-31), and it works somewhat counter intuitively. When the ciliary muscle is *relaxed*, the suspensory ligaments are taut, and they *pull* the lens into a flattened, weakly refractive shape. As the muscle *contracts*, its circumference decreases, *slackening* the tension in the suspensory ligaments (Figure 6-31). When the lens is subjected to less tension by the suspensory

ligaments, it assumes a more spherical shape because of its inherent elasticity. The greater curvature of the more rounded lens increases its strength, bending light rays more strongly.

In the normal mammalian eye, the ciliary muscle is relaxed and the lens is flat for distant vision, but the muscle contracts to let the lens become more convex and stronger for near vision. Sympathetic nerve fibers induce relaxation of the ciliary muscle for distant vision, whereas the parasympathetic nervous system causes the muscle's contraction for near vision. The lens of birds is softer than that of mammals and so exhibits a more rapid accommodation rate. Of note, the lens of the chameleon is remarkable for its ability to cause light to diverge rather than focus it. Studies have shown that the process of accommodation in chameleons is much greater than that of other vertebrates. First, the chameleon cornea overfocuses the image, which the lens corrects for by diverging the image just sufficiently enough to cast a magnified image on the retina.

Light must pass through several retinal layers in vertebrates before reaching the photoreceptors

The major function of the eye is to focus light rays from the environment on the *rods* and *cones*, the photoreceptor cells of the retina. The photoreceptors then transform the light energy into electrical signals for transmission to the CNS.

The receptor-containing portion of the vertebrate retina is actually an extension of the CNS and not a separate peripheral organ. During embryonic development, the retinal cells “back out” of the nervous system, so the retinal layers, surprisingly, are facing backward! The neural portion of the retina consists of three layers of excitable cells (Figure 6-32): (1) the outermost layer (closest to the choroid) containing the *rods* and/or *cones*, whose light-sensitive ends face the choroid (away from the incoming light); (2) a middle layer of *bipolar cells*; and (3) an inner layer of *ganglion cells*. **Rods** and **cones** were named for their appearance under a light microscope. In lower vertebrates, rods and cones converge via chemical synapses onto the same **bipolar neuron**, in contrast to the separate rod bipolar and cone bipolar pathways of higher vertebrates. Axons of the **ganglion cells** join together to form the **optic nerve**, which leaves the retina slightly off center. The point on the retina at which the optic nerve leaves and through which blood vessels pass is the **optic disc** (Figures 6-28a and 6-33). This region is often called the **blind spot**; no image can be detected in this area because it lacks rods and cones. We are normally not aware of the blind spot, because a combination of information from two eyes, rapid eye movements, and central processing “fills in” the missing spot. You can discover your own blind spot by a simple exercise (Figure 6-34).

The backwards nature of vertebrate retinas may be an accident of evolution that, while seeming to be illogical (see the cephalopod eye, p. 255), works well enough. However, it does create at least three problems: (1) the blind spot that required the evolution of corrective mechanisms; (2) susceptibility to *retinal detachment* (a serious problem in many mammals including dogs and humans, in which the neural layer separates from the pigment layer); and (3) light having to pass through nonsensory cell layers first, with potential distortion. Recent research has found that certain glial cells in the overlying nonsensory layer have *waveguide* properties

that direct light into the photoreceptors, compensating for problem 3. Whether this ability favored the evolution of the “backwards” layout of the retina, or evolved later to compensate for an accidentally flawed layout, is not known. The glial cells do not solve problems 1 and 2, however.

Light must pass through the ganglion and bipolar layers before reaching the photoreceptors in all areas of the retina except the **fovea**. In the primate fovea, which is a pinhead-sized depression located in the exact center of the retina (Figure 6-28a), the bipolar and ganglion cell layers are pulled aside so that light strikes the photoreceptors directly. This feature, coupled with the fact that *only* cones (which have greater acuity or discriminative ability than do rods) are found here, makes the fovea the point of greatest visual acuity (most distinct vision). Thus, you turn your eyes so that the object at which you are looking is focused on the fovea. The area immediately surrounding the fovea, the **macula lutea**, also has a high concentration of cones and fairly high acuity (Figure 6-34). Fovea are present in teleost fishes, some snakes, and birds. Dogs (and wolves) lack a fovea per se and instead have a **visual streak**, which serves as the region of highest visual acuity. In addition to a dense central area, the visual streak extends into the temporal and nasal portions of the retina. Physiologists believe these extensions enable animals to scan the horizon with enhanced visual acuity. The visual streak also contains a higher density of ganglion cells. For example, the density of ganglion cells is generally greater in wolves than in domesticated canines (12,000 to 14,000/mm² versus 6,400 to 14,000/mm²). Survival pressures that maintain the elevated density of ganglion cells are likely evolutionary factors in wolves, whereas breeding programs in dogs place little selective pressure on maximizing visual acuity.

Some species of birds may have as many as two or three foveas. The **central fovea** of birds lies on the nasal side of the optic nerve and, in species that need high stereoscopic vision (hawks and eagles), produces (as we noted earlier) a resolving power approximately eight times greater than that of humans. The density of ganglion cells in this region reaches approximately 65,000/mm², far surpassing foveal values from mammals with high acuity (human, 38,000/mm²; macaque, 33,000/mm²). A second **lateral fovea** is located above the optic nerve and a third area, the so-called **linear area**, extends horizontally across the central portion of the retina. Nocturnal predators, such as owls, must summate light from both eyes under dim conditions and are characterized by a single temporal fovea.

In conditions of dim light, a layer of reflecting material, the superiorly located **tapetum lucidum**, enhances the ability of many animal species to locate and detect distant objects. In dogs the tapetum lucidum is a highly cellular structure enriched in zinc and cysteine that is between 9 and 20 layers thick at its center. Physiologists believe the tapetum reflects light that has previously passed through the retina back through it a second time, giving photoreceptors a second opportunity to capture the light stimuli. For example, the feline eye reflects approximately 130 times more light than does the human eye. However, there is a price for reflecting this light: The ability of the eye to accurately resolve the details of an image is somewhat compromised by the scattering of light during this process. This reflecting layer accounts for the eye shine you can see in animals staring back into a source of light.

FIGURE 6-32 Retinal layers (mammalian eye). The retinal visual pathway extends from the photoreceptor cells (rods and cones, whose light-sensitive ends face the choroid *away from* the incoming light) to the bipolar cells to the ganglion cells. The horizontal and amacrine cells act locally for retinal processing of visual input.

The tapetum of cats and lemurs is rich in riboflavin, which can absorb light in the shorter wavelengths (blue, 450 nm) and then emit fluorescent light at a longer wavelength (520 nm) more closely approximating the maximal sensitivity of *rhodopsin* in the rod photoreceptors. This shift in wavelength would brighten the appearance of a blue-black background and enhance the contrast between objects in the environment and the background.

(a) Structure of rods and cones

Phototransduction by opsin and retinene in retinal cells converts light stimuli into neural signals

Photoreceptors consist of three parts (Figure 6-35a): (1) an *outer segment*, which lies closest to the eye's exterior, facing the choroid, and detects the light stimulus; (2) an *inner segment*, which lies in the middle of the photoreceptor's length and contains the metabolic machinery of the cell; and (3) a *synaptic terminal*, which lies closest to the eye's interior, facing the bipolar cells, and transmits the signal generated in the photoreceptor on light stimulation to these next cells in the visual pathway.

The outer segment, which is rod-shaped in rods and cone-shaped in cones (Figure 6-35a), consists of stacked, flattened, membranous discs containing an abundance of photopigment molecules. Each retina has about 150 million photoreceptors, and over a billion photopigment molecules may be packed into the outer segment of each photoreceptor.

Photopigments within the photoreceptor undergo chemical alterations when activated by light. A photopigment consists of an enzymatic protein called **opsin** combined with **retinene**, a derivative of vitamin A. **Rhodopsin**, the vertebrate rod photopigment, cannot discriminate between various wavelengths in the visible spectrum; it absorbs all visible wavelengths, though with a peak around 500 nm. Therefore,

rods provide vision only in shades of gray by detecting different intensities, not different colors. Some fish and amphibian rods also have the photopigment **porphyropsin**, named in part because it is more purple in hue than rhodopsin. (Porphyropsin is also found in some insect eyes, which we will consider later.)

The cone photopigments in vertebrates, called **scotopsins**, are found in five types—**red, green, yellow, blue, and ultraviolet**. (We will look at insect color vision later.) These respond selectively to various wavelengths of light according to their names, making color vision possible. Birds can have up six different photopigments, one in the rods and one in each of five types of cones. Most mammals have one to three (one rod type and zero to two for color), though most primates have four (three for color). Retinene is identical in all types of photopigments, but the photoreceptors' opsins vary slightly, altering the electron resonance of the retinene so it can differentially absorb various wavelengths of light.

Phototransduction, the mechanism of excitation, is basically the same for all vertebrate photoreceptors (Figure 6-35b). It begins when a retinene molecule absorbs a photon, causing retinene to shape from a *cis* to a *trans* conformation. This change triggers the enzymatic activity of opsin. Through a series of steps, this light-induced breakdown and subsequent activation of the protein bring about a hyperpolarizing receptor potential that *reduces* transmitter release from the synaptic terminal of the photoreceptor. Ultimately, as you will see next, phototransduction both a *graded* response and a *hyperpolarization*, and as such, is distinctly different from the “all-or-none” depolarization response of typical nerves.

Photoreceptor Activity in the Dark The plasma membrane of a photoreceptor's outer segment contains chemical-messenger-gated Na^+ channels. Unlike other chemical-gated channels that respond to external chemical messengers, these channels respond to an internal second messenger, **cyclic GMP** or **cGMP** (cyclic guanosine monophosphate). Binding of cGMP to these Na^+ channels keeps them open. In the absence of light, the concentration of cGMP is high (Figure 6-36a). Unlike most receptors, therefore, the Na^+ channels of a vertebrate photoreceptor are open in the absence of stimulation, that is, in the dark. The resultant passive inward Na^+ leak depolarizes the photoreceptor. The passive spread of this depolarization from the outer segment (where the Na^+ channels are located) to the synaptic terminal (where the photoreceptor's neurotransmitter is stored) keeps the synaptic terminal's voltage-gated Ca^{2+} channels open. Calcium entry triggers the release of the neurotransmitter glutamate from the synaptic terminal while in the dark.

Photoreceptor Activity in the Light On exposure to light, the concentration of cyclic GMP is decreased through a series of biochemical steps triggered by retinene-opsin activation (Figure 6-36b). Rod and cone cells contain a G protein (see p. 97) called **transducin**. The activated opsin activates transducin, which in turn activates the enzyme **phosphodiesterase**. This enzyme degrades cyclic GMP, thus decreasing the concentration of this second messenger in the cell. This reduction in cyclic GMP permits the chemically gated Na^+ channels to close, which stops the depolarizing Na^+ leak and hyperpolarizes the membrane. This hyperpolarization,

which is the receptor potential, passively spreads from the outer segment to the synaptic terminal of the photoreceptor. Here the potential change leads to *closure* of the voltage-gated Ca^{2+} channels and reduction in glutamate release from the synaptic terminal. Thus, photoreceptors are inhibited by their adequate stimulus (hyperpolarized by light) and excited in the absence of stimulation (depolarized by darkness). The hyperpolarizing potential and subsequent decrease in transmitter release are graded according to the intensity of light. The brighter the light, the greater the hyperpolarizing response and the greater the reduction in glutamate release.

The short-lived active form of the photopigment quickly dissociates into opsin and retinal. The retinal is converted back into its *cis* form. In the dark, enzyme-mediated mechanisms rejoin opsin and this recycled retinal to restore the photopigment to its original inactive conformation (Figure 6-35b).

Conversion into Action Potentials How does the retina signal the brain about light stimulation through such an inhibitory response? The photoreceptors synapse with bipolar cells. These cells in turn terminate on the ganglion cells, whose axons form the optic nerve for transmitting signals to the brain. The answer to our seeming paradox lies in the fact that the transmitter released from the photoreceptors' synaptic terminal has an *inhibitory* action on the bipolar cells. The reduction in transmitter release that accompanies light-induced receptor hyperpolarization decreases this inhibitory action on the bipolar cells. Removing inhibition has the same effect as directly exciting the bipolar cells. The greater the illumination on the receptor cells, the greater the removal of inhibition from the bipolar cells and the greater in effect the excitation of these next cells in the visual pathway to the brain.

Bipolar cells display graded potentials similar to the photoreceptors. Action potentials do not originate until the ganglion cells, the first neurons in the chain that must propagate the visual message over long distances to the brain.

Now let us turn to the differences between rods and cones.

Rods provide indistinct gray vision at night, whereas cones provide sharp color vision during the day

The earliest mammals are believed to have been nocturnal and thus characterized by a pure rod retina, comparable to that found in living nocturnal animals such as the American flying squirrel (*Glaucomys volans*). In the human retina there are 20 times more rods than cones (120 million rods compared to 6 million cones per eye). In species with a mixture of both rods and cones, the rods are most abundant in the periphery (away from the macula/fovea). Recall that cones, if present, are most abundant in the macula/fovea regions, although the proportion of cones in this region varies between species. For example, in this region of the canine retina there are fewer than 10% cones, whereas diurnal squirrels have an all-cone region. Diurnal birds have a greater number of cones, as well as a greater cone density, than do humans.

Greater Sensitivity of Rods versus Cones The outer segments are longer in rods than in cones, so they contain more photopigments and thus can absorb light more readily. Also, as you will see shortly, the way in which rods connect with other neurons in their processing pathway further increases the sensitivity of rod vision. Because rods have high sensitivity, they can respond to the dim light of night. Cones by contrast have lower sensitivity to light, being activated only by bright daylight. Thus, as we noted earlier, rods are specialized for night vision and cones for day vision. Diurnal animals use cones for day vision, which is in color and distinct.

An astonishing discovery in 2009 revealed a totally unexpected mechanism to enhance rod sensitivity. In most cells, including rods of diurnal mammals, active unwound DNA is in the center of the nuclei, with dense-packed inactive DNA in the periphery. Irina Solovei, Jochen Guck, and colleagues found that in animals that prefer low-light conditions—including cats, rats, mice, opossums and deer—the situation is reversed. Amazingly, the nuclei appear to be lenses! With loose DNA on the outside and dense DNA in the center, the refractive index of these nuclei are predicted by biophysical simulations to focus light in the rods like a tiny lens. (Whether this actually works to improve night vision remains to be tested.)

Greater Acuity of Cones versus Rods The pathways by which cones are “wired” to the other retinal neuronal layers confer high acuity (sharpness; ability to distinguish between two nearby points). Thus, cones provide sharp vision with high resolution for fine detail. By contrast, the wiring pathways of rods provide low acuity, so you can see at night with your rods but at the expense of distinctness. Let us see how the wiring patterns influence sensitivity and acuity.

Little convergence of neurons takes place in the retinal pathways for cone output (see p. 141). Each cone generally has a private line connecting it to a particular ganglion cell. In contrast, much convergence occurs in rod pathways. Each human retina has about 1 million ganglion cells, which receive the output from around 125 million photoreceptors, 120 million of which are rods. Thus, output from more than 100 rods may converge via bipolar cells on a single ganglion cell.

Before a ganglion cell can have an action potential, the cell must be brought to threshold through influence of the graded potentials in the photoreceptors to which it is wired. Because a single-cone ganglion cell is influenced by only one cone, only bright daylight is intense enough to induce a sufficient receptor potential in the cone to ultimately bring the ganglion cell to threshold. The abundant convergence in the rod visual pathways, in contrast, offers good opportunities for summation of subthreshold events in a rod ganglion cell (see p. 136). Whereas a small receptor potential induced by dim light in a single cone would not be sufficient to bring its ganglion cell to threshold, similar small receptor potentials induced by the same dim light in multiple rods converging on a single ganglion cell would have an additive effect to bring the rod ganglion cell to threshold. Because rods can bring about action potentials in response to small amounts of light, they are much more sensitive than cones. However, because cones have private lines into the optic nerve, each cone transmits information about an extremely small recep-

tive field on the retinal surface. Cones are thus able to provide highly detailed vision at the expense of sensitivity. With rod vision, acuity is sacrificed for sensitivity. Because many rods share a single ganglion cell, once an action potential is initiated, it is impossible to discern which of the multiple rod inputs were activated to bring the ganglion cell to threshold. Objects appear fuzzy when rod vision is used because of this poor ability to distinguish between two nearby points.

The sensitivity of eyes can vary markedly through dark and light adaptation

The eyes' sensitivity to light depends on the amount of photopigment present in the rods and cones. When you go from bright sunlight into darkened surroundings, you cannot see anything at first, but gradually you begin to distinguish objects as a result of both pupil dilation and the process of **dark adaptation**. Breakdown of photopigments during exposure to sunlight tremendously decreases photoreceptor sensitivity. For example, a reduction in rhodopsin content of only 0.6% from its maximum value decreases rod sensitivity about 3,000 times. In the dark, the photopigments broken down during light exposure are gradually regenerated. (An hour is required for canine rhodopsin to regenerate itself after exposure to light, whereas in humans it regenerates much more quickly.) As a result, the sensitivity of your eyes gradually increases so that you can begin to see in the darkened surroundings.

Conversely, when you move from the dark to the light (for example, leaving a movie theater and entering the bright sunlight), your eyes are very sensitive to the dazzling light at first. With little contrast between lighter and darker parts, the entire image appears bleached. In addition to pupil constriction, as the intense light rapidly breaks some of the photopigments down, the sensitivity of the eyes decreases and normal contrasts can once again be detected, a process known as **light adaptation**. The rods are so sensitive to light that sufficient rhodopsin is broken down to essentially “burn out” the rods in bright light; that is, the rod photopigments, having already been broken down by the bright light, are no longer able to respond to the light. Furthermore, a central neural adaptive mechanism switches the eye from the rod system to the cone system on exposure to bright light. Researchers estimate that human eyes' sensitivity can change as much as 1 million times with each change event as they adjust to various levels of illumination through dark and light adaptation.

Because retinene, one of the two key photopigment components, is a derivative of vitamin A, adequate amounts of this nutrient must be available for the ongoing resynthesis of photopigments. **Night blindness** occurs because of dietary deficiencies of vitamin A. This can occur for example in cattle lacking green food, such as those being fed old hay or grazing on very dry pastures. Although photopigment concentrations in both rods and cones are reduced in this condition, there is still enough cone photopigment to respond to the intense stimulation of bright light, except in the most severe cases. However, even modest reductions in rhodopsin content can decrease the sensitivity of rods so much that they cannot respond to dim light. Such an animal can see in the day using cones but cannot see at night because the rods are no longer functional.

Color vision depends on the ratios of stimulation of the various cone types

Certain objects in the environment such as the sun, fire, and bioluminescent organisms emit light. But how does an animal see most objects (e.g., trees, rocks), which do not emit light? Molecules in various objects selectively absorb particular wavelengths of light transmitted to them from light-emitting sources, and the unabsorbed wavelengths are *reflected* from the objects' surfaces. It is these reflected light rays that enable animals to see the objects and their color. In the open ocean, for example, water molecules absorb the longer red wavelengths of light and scatter the shorter blue wavelengths back to the observer, which can be absorbed by the photopigment in the eyes' blue cones, thereby activating them.

Color vision occurs in most vertebrates and insects. We will explore species differences later; for now, recall that each cone type is most effectively activated by a particular wavelength of light in the range of color indicated by its name. Many primates including humans have **trichromatic**, or three-color, vision, as illustrated in Figure 6-37. Cones that are most sensitive to wavelengths in the region of 560 nm are termed **long (L) cones** and contribute to the perception of red. Cones that respond best to more intermediate wavelengths of 530 nm are termed **middle (M) cones**, and contribute to the perception of green; whereas cones that respond to short wavelengths of light in the region of 420 nm are termed **short (S) cones** and contribute to the perception of blue. Animals that can perceive ultraviolet waves have a fourth type of cone, the **ultraviolet (UV) cone**, with a peak response in the region of 360–380 nm. However, cones also respond in varying degrees to other wavelengths (Figure 6-37). An animal's perception of the many colors of the world depends on the cone types' various *ratios of stimulation* in response to different wavelengths. A wavelength perceived as blue does not stimulate red or green cones at all but excites blue cones maximally (the percentages of maximal stimulation for red, green, and blue cones, respectively, are 0:0:100). The sensation of yellow, in comparison, arises from a stimulation ratio of 83:83:0, red and green cones each being stimulated 83% of maximum, whereas blue cones are not excited at all. The ratio for green is 31:67:36, and so on, with various combinations giving rise to the sensation of all the different colors. (Televisions and other video equipment make use of this phenomenon with so-called **RGB** technology, e.g., red, green, and blue pixels on a computer monitor, and RGB output cables from some video players.) **White** is a mixture of all wavelengths of light, whereas **black** is the absence of light.

The extent that each of the cone types is excited is coded and transmitted in separate parallel pathways to the brain. A distinct color vision center in the primary visual cortex has recently been identified. This center combines and processes these inputs to generate the perception of color, taking into consideration the object in comparison with its background.

Color discrimination abilities vary greatly among types of animals

Now let's compare animal color vision in more detail. Generally, the level of color discrimination correlates well with an animal's lifestyle and habitat light features. As previously

FIGURE 6-37 Sensitivity of the different types of cones to different wavelengths. Graph shows the trichromatic eye for Old World primates (including humans), with blue (S), green (M), and red (L) cones. The ratios of stimulation of the three cone types are shown for three sample colors (see main text).

discussed, many strictly nocturnal animals such as some species of bats have only rods. Other illustrative patterns include the following:

- **Fish:** Many shallow-water bony fish such as trout are trichromatic, with L, M, and S cones as in humans. However, most deep-sea fish (and other animals) have lost the L (red) cones, because red light from the sun does not penetrate into the depths. Remarkably, one species of deep-sea fish, the predatory dragonfish *Malacosteus niger*, has re-evolved L cones with a novel phototransduction using bacterial *chlorophyll* instead of retinene to absorb red light! This is adaptive because these fish have bioluminescent organs—*photophores*—that produce red light, which they use to illuminate prey (in contrast, most bioluminescent marine organisms make blue or green light). This allows the dragonfish's light to be virtually invisible to all but itself (a “sniper scope”). Some fish such as salmon have UV cones (we will explore the use of UV vision shortly). In at least one fish, the salmon *Oncorhynchus gorbuscha*, the UV cones switch to S (blue) types with age. This is likely because young salmon live in shallow water where UV penetrates, whereas adults go deeper where blue dominates but UV is absent. This discovery by Christiana Cheng and Iñigo Flamarique was the first to document cone-switching as a way to modulate color vision as an animal changes habitat.
- **Non-avian reptiles:** Most diurnal snakes and lizards have cones but no rods; many can see UV. Curiously, nocturnal geckos (p. 4), which evolved from diurnal ancestors, have only UV, L, and M cones (again, no rods). It is not certain

how these work at night, but of note is that the cones have evolved rodlike morphologies and have been behaviorally shown to work very well in dim light.

- **Birds:** Most birds except some nocturnal species have excellent color vision, some having four (**tetrachromatic**) or five (**pentachromatic**) cone types! For example, the pigeon *Columba livia* has UV and yellow cones in addition to L, M, and S cones.
- **Mammals:** Most orders of mammals have been shown to have color vision in that they can discriminate based on color, with most (such as mice, dogs and cats) being *dichromatic* (with M, or medium-long “LM,” cones and either S or UV cones). In contrast, Old World primates including humans, and some female New World monkeys, are trichromatic; for example, baboons have primarily green M (63%) and the recently evolved red L (33%) cones, whereas only 4% are blue S. Genomic analysis shows that the L opsin evolved from a few simple mutations from the M opsin. This may have been favored to help pick out ripe red fruit from among green leaves and/or to see bright colors on the faces or genitals of potential mates (as in baboons). Remarkably, mice engineered with the human L-opsin gene gained the ability to distinguish new colors at the red end of the spectrum!
- **Arthropods:** Many species of insects can distinguish color, including UV and polarized light (see the following section). Most are thought to be dichromatic, but flies and honeybees are trichromatic, while the Japanese swallowtail butterfly is tetrachromatic. The mechanism by which insects perceive color is less well understood than in vertebrates but is believed to result from expressing retinal receptors with differing sensitivities to light of different wavelengths. Flies and honeybees have UV, blue, and yellow receptors but cannot see red. The world champion in terms of color vision appears to be the mantis shrimp (see Figure 6-27e). Some species have up to 16 different photoreceptors, 12 for color (**dodedachromatic!**), and 4 for polarized light. Such vision may be important in mating but also in feeding. These highly colorful animals hide in burrows or reef crevices looking for specific prey that often have unique color patterns, such as fish and snail shells; these must be discriminated from the complex colorful reef background. The shrimp attack using powerful, extremely fast claws as stunning and shell-cracking weapons. (The claws are fast due to storage and release of spring energy; see Chapter 8, p. 350).

unanswered Questions | Why did whales lose the blues?

Whales and seals are **monochromatic**, with rods and only a medium-long “LM” cone; their blue S cones have been lost due to mutation of the S-opsin gene into a pseudogene. This is counterintuitive, since blue light is so dominant in the oceans, yet it seems to have occurred independently in whales and seals. One reason suggested by Leo Peichl and colleagues (who discovered the widespread occurrence of this phenomenon) is that the mutation occurred in a coastal semiterrestrial ancestor that foraged in murky shallow waters, which are browner (redder) and much less blue than the open sea. However, we do not know this for certain. <<

Some animals can see ultraviolet and/or polarized light

Many arthropods and some species of birds, fish, marsupial mammals, bats, and rodents have UV cones (although there are not necessarily all four types of cones in any one species). The detection of UV wavelengths may give birds and fish spatial cues that they can use in orientation and navigation during migration. Short-wavelength gradients vary depending on the sun’s angle in the sky. These gradients increase in saturation as the sun moves from directly overhead to an angle of 90 degrees (that is, UV light is a greater proportion of the incoming sunlight at twilight). Some species of birds as well as some salmon migrate over thousands of kilometers and appear to rely on UV-color gradients in the sky to locate the position of the sun on days when clouds obscure it.

Territorial markings and food detection are other uses of ultraviolet sensing. Mice and voles, for example, have M and UV cones, with the latter possibly used to mark trails and see territorial scent markings (urine and feces), which are visible in UV light. In turn, kestrels—raptorial birds with UV cones—can use this information to locate areas of prey abundance. Because fresh vole urine and feces absorb UV sunlight, to a kestrel, the marks would look like dark streaks on a field. Recently, researchers have shown that a flower bat (*Glossophaga soricina*) senses ultraviolet; although it cannot distinguish colors, it may be able to see flowers better at twilight, when ultraviolet radiation is relatively more prevalent. Some pollinating insects also find desirable flowers base on their UV reflectance.

Among arthropods, honeybees have been best studied. They can detect the pattern of not only UV itself but also **polarized** light, which has electromagnetic waves all oriented at the same angle. That angle changes with respect to the movement of the sun in the sky, and the bees can use this information to communicate the location of a food source to the other bees in the hive. (This form of communication can be eliminated experimentally by using filters that block the passage of specific light forms to determine the role of those forms in animal behavior.)

Polarized light can also be used to find potential mates, prey, and predators by the pattern of polarized light reflected from the body surfaces. For example, researchers have recently shown that one species of butterfly can detect patterns of polarized light reflecting off the wings of others of its kind, a signal used in mating. And the African dung beetle uses the polarization of moonlight to orient itself so that it can move along a straight line. Once the beetle has located a food source, it quickly forms a ball of dung and rolls it rapidly away in order to avoid any aggressive encounters for food in the dung pile.

Finally, let us return to the visual champions, mantis shrimp. Recently it was found that at least two mantis shrimp species—as well as one shiny colorful scarab beetle—can see **circularly polarized light** (CPL), in which the angle of the waves rotates continuously as the light travels. CPL can be produced when light reflects off of certain surfaces (e.g., reflections off helical proteins in scarab beetle carapaces are CPL). It is not known what these arthropods use this ability for, but it may give them private communication signals that no other animal can perceive.

Visual information is separated and modified within the visual pathway before it is integrated into a perceptual image of the visual field by the vertebrate cortex

The field of view that can be seen without moving the head is known as the **visual field**. In vertebrates, the information that reaches the visual cortex in the occipital lobe is not a replica of the visual field for several reasons.

1. The image detected on the retina at the onset of visual processing is upside down and backward because the light rays bend (Figure 6-38). Once projected to the brain, the animal interprets the inverted image as being correctly oriented.
2. The information transmitted from the retina to the brain is not merely a point-to-point record of photoreceptor activation. Before the information reaches the brain, the retinal neuronal layers beyond the rods and cones reinforce selected information and suppress other information to enhance contrast. One mechanism of retinal processing is *lateral inhibition* (see Figure 6-7, p. 216), which increases the dark–bright contrast to enhance the sharpness of boundaries.

Another mechanism of retinal processing involves differential activation of two types of ganglion cells, **on-center** and **off-center ganglion cells** (Figure 6-39). The receptive field of a cone ganglion cell is determined by the field of light detection by the cone with which it is linked. On-center and off-center ganglion cells respond in opposite ways, depending on the relative comparison of illumination between the center and periphery (surroundings) of their receptive fields. Think of the receptive field as a doughnut. An on-center ganglion cell increases its rate of firing when light is most intense at the center of its receptive field (that is, when the doughnut hole is lit up). In contrast, an off-center cell increases its firing rate when the periphery of its receptive field is most intensely illuminated (that is, when the doughnut itself is lit up). This is useful for enhancing the difference in light level between one small area at the center of a receptive field and the illumination immediately around it. By emphasizing differences in relative brightness, this mechanism helps define contours of images, but in so doing, information about absolute brightness is sacrificed.

3. Various aspects of visual information such as form, color, depth, and movement are separated and projected in parallel pathways to different regions of the cortex. Only when these separate bits of processed information are integrated by higher visual regions is a reassembled picture of the visual scene perceived. This is similar to the blobs of paint on an artist's palette versus the finished portrait; the separate pigments do not represent a portrait of a face until they are appropriately integrated on a canvas.

FIGURE 6-38 Inversion of the image on the retina.

4. Because of the pattern of wiring between the eyes and the visual cortex, the left half of the cortex receives information only from the right half of the visual field as detected by both eyes, and the right half receives input only from the left half of the visual field of both eyes.

As a result of refraction, light rays from the left half of the visual field fall on the right half of the retina of both eyes (the medial or inner half of the left retina and the lateral or outer half of the right retina) (Figure 6-40). Similarly, rays from the right half of the visual field reach the left half of each retina (the lateral half of the left retina and the medial half of the right retina). Each optic nerve exiting the retina carries information from both halves of the retina it serves. The human optic nerve contains 1.2 million nerve fibers; compare this to 167,000 in canines and 116,000 to 165,000 in cats. This information is separated as the optic nerves meet at the **optic chiasm** (*chiasm* means “cross”) located underneath the hypothalamus. Within the optic chiasm, the fibers from the medial half of each retina cross to the opposite side, but those from the lateral half remain on the original side. The reorganized bundles of fibers leaving the optic chiasm are known as **optic tracts**. Each optic tract carries information from the lateral half of one retina and the medial half of the other retina. Therefore, this partial cross-over brings together from the two eyes fibers that carry information from the same half of the visual field. Each optic tract, in turn, delivers to the half of the brain on its same side information about the opposite half of the visual field.

The thalamus and visual cortices elaborate the visual message

The first stop in the mammalian brain for information in the visual pathway is the **lateral geniculate nucleus** in the thalamus (Figure 6-40) (**optic tectum** in fish and amphibians). It separates information received from the eyes and relays it via fiber bundles known as **optic radiations** to different zones in the cortex, each of which processes different aspects of the visual stimulus (for example, color, form, depth, movement). This sorting process is no small task, because each human optic nerve contains more than 1 million fibers carrying information from the photoreceptors in one retina. This is more than all the afferent fibers carrying

Both types of cells are weakly stimulated by uniform light on both center and surround.

(a) Receptive fields of on-center and off-center cells

(b) Outcome of retinal processing by on-center and off-center cells

FIGURE 6-39 Example of the outcome of retinal processing by on-center and off-center ganglion cells. (a) On-center cells are excited and off-center cells are inhibited by bright light in the centers of their receptive fields. (b) Retinal processing by on-center and off-center ganglion cells is largely responsible for enhancing differences in relative (rather than absolute) brightness, which helps define contours. Note that the gray circle surrounded by black appears brighter than the one surrounded by white, even though the two circles are identical (same shade and size).

somatosensory input from all the regions of the body! Researchers estimate that hundreds of millions of neurons, occupying about 30% of the human cortex, participate in visual processing, compared to 8% devoted to touch perception and 3% to hearing. Yet the connections in the visual pathways are precise. The lateral geniculate nucleus and each of the zones in the cortex that process visual information have a topographic map representing the retina point for point. As with the somatosensory cortex, the neural maps of the retina are distorted. The fovea, the retinal region capable of greatest acuity, has much greater representation in the neural map than do the more peripheral regions of the retina. Interestingly, in animals born with immature visual systems such as the ferret and cats, during the first three to four weeks after birth while their eyes remain closed, the retinal ganglion cells are still developing connections among themselves as well as to other retinal cells. The long axons of the ganglion cells grow along the optic tract to each lateral geniculate nucleus of the thalamus. These ganglion cells eventually grow into layers in the lateral geniculate nucleus, although axons from each eye remain separate from each other.

Depth Perception Although each half of the visual cortex receives information simultaneously from the same part of the *visual field* as received by both eyes, the messages from

the two eyes are not identical. Depending on the species of animal, there is a potential area of overlap (Figure 6-41). The overlapping area seen by both eyes at the same time is known as the **binocular** (“two-eyed”) **field of vision**, which is important for **depth perception**. Binocular vision is achieved in part by routing axons from one eye together with axons from the other eye to synapse in the same layers of the lateral geniculate nucleus. The brain uses the slight disparity in the information received from the two eyes to estimate distance, allowing an animal to perceive three-dimensional objects in spatial depth.

Depending on placement of the eyes in the skull, both the extent of the visual field and the amount of binocular overlap can vary considerably. For example, there is no evidence for binocular vision in teleost fish, where eyes are located on opposite sides of the head. Dog eyes are laterally directed approximately 20 degrees from the midline, and human and owl eyes look straight ahead. Thus, with each eye, the average dog has a monocular field of view from 135 to 150 degrees, approximately 60 to 70 degrees greater than that of humans. Although this gives dogs a greater ability to scan the horizon, the degree of binocular overlap is much less (about 30 to 60 degrees compared to 130 in cats and 140 degrees in humans). Interestingly, in some species of birds the effect of two or more foveas enables each eye to have completely separate visual fields. Such an arrangement increases the total visual field and may also permit some binocular vision.

Hierarchy of Visual Cortical Processing Within the cortex, visual information is first processed in the primary visual cortex, then is projected to *associative* visual areas for even more complex processing and abstraction. The cortex contains a hierarchy of visual cells that respond to increasingly complex stimuli. The visual cortex is precisely organized into vertical columns extending from its outer surface to the white matter. Each column is made up of cells that process the same bit of visual input. There are three types of columns: One type is devoted to input from the left or the right eye for binocular interaction and depth perception; a second type perceives form and movement; and a third type processes color. Unlike a retinal cell, which responds to the amount of light, a cortical cell fires only when it receives a particular pattern of illumination for which it is programmed. For example, the types that process form and movement come in three subtypes called **simple**, **complex**, and **hypercomplex** cells. Simple and complex cells are found within the columns of the primary visual cortex, whereas hypercomplex cells are found in the higher visual associative areas. Some simple cells fire only when a bar is viewed vertically in a specific location, others when a bar is horizontal, and others at various oblique orientations. Movement of a critical axis of orientation is important for response by some of the complex cells. Hypercomplex cells add a new dimension by responding only to particular edges, corners, and curves. Other aspects of visual input, such as color, are processed simultaneously through a similar hierarchical organization. In this way, the dotlike pattern of photoreceptors stimulated in the retinal image is transformed in the cortex into information about depth, color, position, orientation, movement, contour, and length. How and where the entire image is finally put together is still unresolved.

FIGURE 6-40 The mammalian visual pathway and visual deficits associated with lesions in the pathway.

(a) Note that the left half of the visual cortex in the occipital lobe receives information from the right half of the visual field of both eyes (in green), and the right half of the cortex receives information from the left half of the visual field of both eyes (in red). (b) Each visual deficit illustrated is associated with a lesion at the corresponding numbered point of the visual pathway in part (a).

Visual input goes to other areas of the vertebrate brain not involved in vision perception

Not all fibers in the visual pathway terminate in the visual cortex. Some are projected to other regions of the brain for purposes other than direct vision perception. Examples of nonsight activities dependent on input from the rods and cones include (1) contribution to cortical alertness and attention, (2) control of pupil size, (3) setting the biological “clock,” and (4) control of eye movements. For setting the clock, 3% of the ganglion cells are not involved in visual processing. Instead, they make **melanopsin**, a light-sensitive pigment that leads to signals through a non-optic nerve that connects the retina to the clock center of the hypothalamus (p. 282). For eye movement, each eye is equipped with a set of six **external eye muscles** that position and move the eye so that it can better locate, see, and track objects in response to retinal signals.

Cephalopod camera eyes have light-sensing cells on top of neural cells

Let’s now contrast the vertebrate eye with advanced ones in other animals. The cephalopod eye is particularly instructive in terms of **convergent evolution** (that is, the independent evolution of similar structures in different species without a common ancestral structure). The backward structure of the vertebrate retina, as you saw earlier (p. 247), causes problems. Comparative studies suggest that there is no inherent advantage for this design, because the sophisticated cephalo-

FIGURE 6-42 Comparison of cephalopod and vertebrate eye formation. Development proceeds from top to bottom. The cephalopod eye forms from the epidermis through a series of invaginations, while the vertebrate eye emerges from the internal brain and induces the overlying epidermis to form the lens. Thus, their respective retinas end up in opposite arrangements.

Source: W.A. Harris (1997). Pax-6: Where to be conserved is not conservative. *Proceedings of the National Academy of Sciences* 94: 2098–2100.

pod eye has evolved a reversed arrangement. The eye of the squid, octopus, cuttlefish (or cuttles), and nautiloids is remarkably similar to the vertebrate eye in having a cornea, lens, and retina, but there the resemblance ends. In these eyes, the pigment (sensory) cells are on top of the retina and receive light directly from the lens (Figure 6-42). There is no blind spot since the optic nerve leaves from the backside. Studies on the image-resolving power of squid and cuttlefish eyes reveal that they work as well or better than eyes of many mammals, allowing them to discriminate distant prey in the ocean and intricate signaling color patterns generated by the skin chromatophores (p. 154) of their conspecifics. Some cuttles can also see polarized light (p. 252). The difference between cephalopod and vertebrate retinas seems to be an accident of

that make up a newspaper photograph. Due to these separate units, compound eyes form an upright retinal image, in contrast to the inverted image displayed on the vertebrate retina. Compound eyes have lower visual acuity than do vertebrate eyes because while vertebrate photoreceptors sample approximately 0.02 degrees of the visual field, each ommatidium views as much as 2 to 3 degrees. Consequently, the visual fields of adjacent ommatidia overlap. However, because most adult insects have a pair of compound eyes that bulge out of each side of the head, the *field of vision* can be markedly greater compared to vertebrates. For example, in the water bug *Notonecta*, the field of view for the two eyes provides binocular vision in front (almost 250 degrees in the horizontal plane), above and below the head.

evolution, arising from the different ways in which this sensory system first evolved out of the nervous system.

Compound eyes of arthropods and some annelids and bivalves consist of multiple image-forming units

Now let's turn to the most successful group of animals, the arthropods. As we noted earlier, they have *compound*, or *faceted*, eyes. The functional unit of the compound eye is termed the rhabdomeric **ommatidium** (Figure 6-43). Each ommatidium consists of an optical, light-gathering part as well as a sensory portion, which transduces light into an action potential. The number of ommatidia can vary from one, as in the worker ant *Ponera punctatissima*, to over 10,000 in the eye of a dragonfly. Generally, in animals with only a few ommatidia the *facets* (external surface of an individual compound eye unit or ommatidium) are circular in appearance, whereas with increased numbers the facets are more densely packed together and assume a hexagonal shape for optimal packing (Figure 6-44a). Each of these optical units focuses on a separate portion of the visual field, with the conglomerate image appearing as a mosaic rather than the sharp visual image perceived by vertebrates (Figure 6-44b), much like ink dots

FIGURE 6-43 Anatomy of the compound eyes of the horseshoe crab, *Limulus polyphemus*.

The lens of arthropod compound eyes forms from the cuticle as a biconvex corneal lens at the outer end of each ommatidium. Normally this cuticle forming the lens is transparent and colorless. In addition to having its own lens, each ommatidium contains a cluster of at least eight **retinular** or **photoreceptor cells** (Figures 6-43b and 6-44a). The retinular cells are arranged in a circle with the periphery lined with pigment to shield against leakage of light from neighboring ommatidia. At the center of the circle lies a dendrite from a

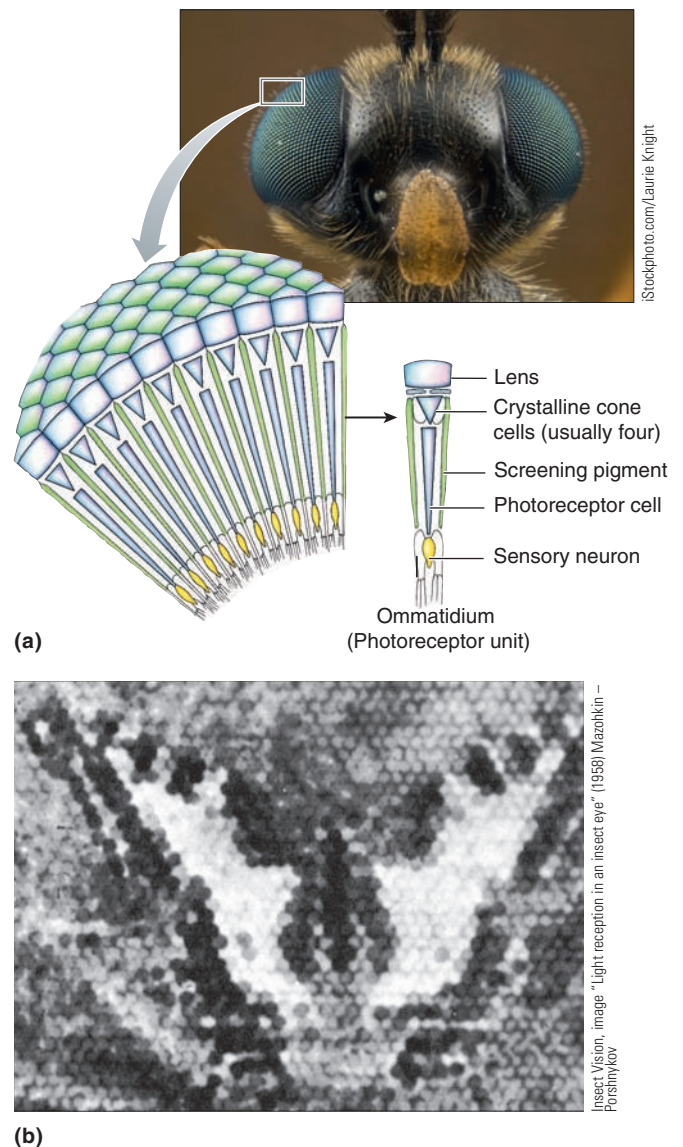

FIGURE 6-44 Insect compound eyes. (a) Eyes of a soldier fly. The lens of each photosensitive unit (ommatidium) directs light onto a crystalline cone, which focuses light on photoreceptor cells below it. (b) An approximation of light reception in an insect eye. This image of a butterfly formed after a researcher took a photograph through the outer surface of a compound eye that had been detached from an insect. It might not be what the insect “sees,” because integration of signals sent to the brain from photoreceptors might produce a sharper image. But this representation is useful insofar as it suggests how the separate ommatidia sample the overall visual field.

single, modified retinular cell, the so-called **eccentric cell**. The photopigment *rhodopsin* is localized in a specialized region of the retinular cell called the **rhabdome** (Figure 6-43c). Normally the rhabdomeres of each retinular cell are tightly packed along this central region of the ommatidium. Structurally, rhabdomeres appear as microvilli that increase the surface area available for light absorption. This elongated region of photosensitive microvilli, with contributions from each of the eight or more rhabdomeres, is termed the

rhabdom of the ommatidium (Figure 6-43c). The body of the eccentric cell lies on the periphery of the ommatidium, with the dendrite making direct connections with the rhabdom.

To enhance visual contrast at a light–dark edge, the eccentric cells interact with each other by the process of lateral inhibition that we noted earlier for touch (see Figure 6-7) and the vertebrate eye. Lateral inhibition also diminishes the apparent difference in brightness between areas that are uniformly illuminated, whereas in darkness the ommatidia are less stimulated by light but are comparatively less inhibited by their neighbors. Each eccentric cell sends collaterals, which make inhibitory synaptic contacts with its neighbor cells lying approximately three to five ommatidia away. In this manner, a strongly activated cell directly receiving a light stimulus generates impulses, which *decrease* impulse generation in its comparatively weakly stimulated neighbors. At the boundary between light and dark illumination, the net effect is to enhance discrimination between the two zones because the eccentric cells lying in this region receive different degrees of inhibition from the two sides. Thus, ommatidia lining the border of a light–dark edge and not receiving a light stimulus to activate them are strongly inhibited by their neighboring cells, which are better illuminated. The net effect is that the activity in these cells is comparatively low compared to ommatidia lying in either the light or dark zones.

Two basic types arthropod compound eyes have evolved. Most diurnal insects have **apposition eyes**, characterized by ommatidium that are optically isolated from each other. Thus, each ommatidium receives light from a comparatively narrow region of the visual field. However, a wide, optically clear zone between the rhabdoms and the lens characterizes **superposition eyes**, which nocturnal arthropods have. Light from different ommatidia can mix together so that when the light finally reaches the rhabdom it represents a composite from many ommatidia. The adaptive value of this arrangement lies with its ability to receive light energy striking the eye surface to focus on a single rhabdom at the expense of acuity.

In addition to arthropods, compound eyes occur in some annelids such as featherduster worms (see Figure 11-5) and bivalve mollusks called ark clams. These have very poor resolution and seem to serve mainly as sentinels for danger, warning the animal of a potential predator approaching so that it can withdraw into its tube (worm) or close up (clam).

Phototransduction in rhabdomeric eyes uses rhodopsin but otherwise differs from that in vertebrate eyes

Although compound eyes use rhodopsin and G proteins as do camera eyes, the rest of the process of phototransduction differs remarkably from that found in vertebrates. Recall that vertebrate Na^+ channels *close* in response to an increase in light, leading to hyperpolarization in rods and cones. In contrast, rhabdomeric photoreceptors *depolarize* in response to light. Rhodopsin, via a G protein, activates phospholipase C, which in turn leads to an increased production of inositol triphosphate (IP_3) and diacylglycerol (DAG) (see p. 98). The increase in IP_3 triggers release of Ca^{2+} ions from intracellular stores. Together these two second messengers, intracellular

Ca^{2+} and DAG, govern the opening of cation channels and thus generate a depolarizing potential. Graded potentials generated in the reticular cells spread through gap junctions into the dendrite of the eccentric cell. The eccentric cell thus depolarizes and an action potential is conducted through the optic nerve to the optic lobe of the brain.

Insects use the same set of photoreceptors for vision at all light intensities. Comparative studies of photoreceptor K^+ conductance have shown that rapidly moving diurnal species such as blowflies have fast photoreceptor responses that consume considerable amounts of ATP in order to restore rapidly changing ion gradients. In contrast, species such as crane-flies that are nocturnal and fly slowly have slow (and less costly) photoreceptors. Interestingly, locusts (*Schistocerca*) are diurnal but migrate at night. In this species changes in K^+ conductance are associated with the functioning of the photoreceptors as they switch between a day state, with high acuity and low sensitivity, to a night state, with low acuity and high sensitivity.

6.7 Thermoreception

The ability to detect environmental temperature has clear survival value, given that biological processes are often highly temperature sensitive (Chapter 15) and thermal extremes can quickly become lethal, particularly elevated body temperatures, which can rapidly impair protein function. Vertebrates have at least three kinds of thermoreceptors, best studied in mammals and the rattlesnake: *cold* sensors, *warmth* sensors, and *infrared* sensors.

Warmth and cold thermoreceptors give information about the temperature of the environment near the body

Mammalian skin and tongue (technically an extension of the skin) have two distinct kinds of sensors for temperature. One responds to increased temperature (warmth sensors), primarily above the skin's temperature, whereas the other responds to decreasing temperature (cold sensors) below skin temperature. (Skin temperatures tend to be lower than body temperatures, around 30 to 33°C in humans.) These are used primarily for thermoregulation, informing the brain about possible disturbances to core temperature (there are also pain sensors that respond to extreme heat or cold; see the section on nociception that follows). These sensors are *anticipatory* feedback components: They inform the brain of an oncoming disturbance *before* the core temperature is ac-

tually altered, allowing corrective measures to be activated with little or no time delay (Chapter 1, pp. 16–17, and Chapter 15, p. 748).

The molecular receptors for these senses have proven remarkably elusive until recently. However, distinct mammalian heat-gated and cold-gated ion channels have now been discovered, and their genes cloned. They are of the TRP Ca-channel family (p. 217) and thus related to mechanoreceptors. At least three heat-gated channels are known, called TRPV1, -2, and -3. TRPV3 starts firing at about 33°C, likely providing the signal for thermoregulation. But TRPV1 only fires above 42°C, a point at which heat starts to become painful. As you will see later, this receptor also reacts to spicy food! And TRPV2 fires at 52°C and higher, also clearly for pain response rather than thermoregulation. These channels appear to be directly gated by thermal changes. (In contrast, thermosensing neurons in the nematode *C. elegans* have a thermally activated receptor that activates cGMP as a second messenger, as in vertebrate phototransduction.)

Two cold-gated channels are known, called TRPA1 and TRPM8 (which is also activated by menthol, the “cooling” chemical of mint). TRPA1 only opens at ice-cold temperatures and is associated with pain. TRPA1 also appears to signal temperature changes in fruit flies and nematodes. In contrast, TRPM8 opens between 8° and 28°C in mammals and seems to be the receptor for thermoregulation. Interestingly, the amphibian TRPM8 channel operates over a lower temperature range, reflecting these animals’ lower basal body temperatures than mammals’.

Recently, researchers have discovered thermal sensors in sharks. The sensory cells are those that have long been known as electroreceptors, the topic of the next section, where we return to this discovery.

Infrared thermoreceptors give pit vipers the ability to detect prey and desirable thermal habitats

A very different use of thermal stimuli has evolved in at least two groups of animals, the pit vipers (Viperidae, which includes rattlesnakes), and some pythons and boas. These

have extraordinarily sensitive receptors that respond to **infrared radiation**, the low-energy radiation that carries heat energy. The receptor cells are simply branched dendrites of neurons, located in small pits in the skin (Figure 6-45a), on either side of the head in pit vipers (anterior to and below the eyes), and along the jaws of pythons. Behavioral studies (in which a rattlesnake’s eyes are covered with black tape) show that these pits allow detection of warm mammalian prey (such as rodents; Figure 6-45b). The snake’s brain may construct a visual image from the thermal data, although measurements and calculations of sensory resolution show that the snake would see only blurry images. A mouse that is 10°C warmer than the background environment can be detected at about half a meter away. The sensors are particularly important for use in the first rapid strike to capture the prey. Because there are two pits on vipers, a type of binocular infrared vision is possible, allowing a rattlesnake to determine prey distance.

Physiologists are not sure how these receptor cells detect infrared radiation, but recent work shows they have a very heat-sensitive TRPA1 channel (76% identical to the TRPA1 that signals “ice-cold” pain in mammals; see above). Remarkably, neurophysiological recordings suggest that different sensors respond to different infrared wavelengths. Thus, the snakes may be able to see infrared light in colors! Recent behavioral studies suggest that pit vipers can also use thermal information to find desirable thermal habitats and to avoid undesirable ones. These animals, like all ectotherms, cannot regulate body temperature by internal mechanisms, and instead must rely on the environment (see Chapter 15).

Compare uses and mechanisms of cold, warmth, and infrared receptors.

Are warmth or cold receptors more important to an animal? Why?

6.8 Nociception: Pain

Pain is primarily a protective mechanism meant to bring to awareness (or the higher brain centers) the fact that tissue damage is occurring or is about to occur. Unlike other somatosensory modalities, the perception of pain can be influenced by other past or present experiences, for example, heightened pain perception in a dog that has been abused, or lowered pain signaling induced by stress responses in an injured animal. (Recall, though, that perception is only reportable by humans; we infer perception in other animals by their reactions, but cannot know what, if anything, they actually perceive.)

Stimulation of mammalian nociceptors elicits two types of pain signals

There are three categories of pain receptors or *nociceptors*:

- **Mechanical nociceptors** respond to mechanical damage such as cutting, crushing, or pinching.
- **Thermal nociceptors** respond to temperature extremes, especially heat.
- **Polymodal nociceptors** respond equally to all kinds of damaging stimuli, including irritating chemicals released from injured tissues.

None of the nociceptors have specialized receptor organs; they are all naked nerve endings. At least in mammals, to some extent pain occurs in two phases with two signaling pathways: (1) a quick response to direct damage (the **fast pain pathway**, which may subside), followed by (2) a slower, prolonged chemical response to inflammation and cell contents released by damage (the **slow pain pathway**). Think about the last time you cut or burned your finger. You undoubtedly felt a sharp twinge of pain at first that stopped, followed by a more diffuse, disagreeable, persistent pain shortly thereafter. Pain impulses originating at nociceptors are transmitted to the mammalian CNS via one of two types of afferent fibers.

Fast Pain The fast initial pain has the following features:

- Arises from specific mechanical or heat nociceptors.
- Transmitted over large, myelinated **A-delta fibers** at rates of up to 30 meters/sec.
- Easily localized, but may be fast adapting giving only a brief signal

Slow Pain The subsequent slow, dull, aching sensation that persists has these properties:

- Arises from mechanical and thermal nociceptors, activated by chemicals such as **bradykinin**, a normally inactive substance that is activated by enzymes released into the ECF from damaged tissue. (It is also involved in inflammation; see p. 469).
- Transmitted by small, unmyelinated **C fibers** at a slower rate of 12 meters/sec.
- Poorly localized, but because of value to survival, does not quickly adapt to sustained stimulation. The persistence of bradykinin might explain the long-lasting, aching pain that continues after removal of the mechanical or thermal stimulus that caused the damage.

Researchers have isolated some mammalian pain receptor proteins. As you saw earlier in the section on thermoreception, one of the fast pain receptors is the thermally gated TRPV2, which fires at 52°C and higher. This channel appears to be directly gated by the “heat” stimulus. One nociceptor protein responsible for the slow burning pain associated with inflammation is called *TRPV1* (p. 259), also known as “the chili pepper receptor” because it is also activated by **capsaicin**, the chemical of seed-bearing fruits of pepper plants that causes burning sensation in the mouth (see *A Closer Look at Adaptation: Why Are Hot Spices Hot?*). Interestingly, the TRPA1 channel that we noted earlier as a “cold pain” sensor has also been found to be activated by chemicals of damaged tissues as well as by wasabi, horseradish, garlic, and mustard oil.

All nociceptors in mammals can be sensitized by **prostaglandins**, which greatly enhance the receptor response to noxious stimuli (that is, it hurts more when prostaglandins are present). Prostaglandins are fatty acid derivatives released as paracrine in tissue injury (see p. 468). Aspirin-like drugs inhibit the synthesis of these paracrine, accounting at least in part for the analgesic (pain-relieving) properties of these drugs (p. 470).

Higher-Level Processing of Pain Input Multiple structures are involved in mammalian pain processing. The primary afferent pain fibers synapse with specific second-order excitatory interneurons in the dorsal horn of the spinal cord. The two best-known neurotransmitters here are *substance P* and *glutamate*. **Substance P** activates ascending pathways that transmit nociceptive signals to higher levels for further processing (Figure 6-46a). Ascending pain pathways go first to the brainstem’s *reticular formation*, which increases the level of alertness associated with the noxious encounter. The next stop is the *thalamus* relay station, and then to cortical *somatosensory* areas, which localize the pain. (Pain can still be perceived in the absence of the cortex, presumably at the level of the thalamus.) Next, associative cortical areas participate in other conscious components of the pain experience, such as deliberation (at least in humans) about the incident. Interconnections from the thalamus and reticular formation to the *hypothalamus* and *limbic system* elicit the behavioral and emotional responses accompanying the painful experience. The limbic system appears to be especially important in perceiving the unpleasant aspects of pain.

Recall that glutamate is a major excitatory neurotransmitter (p. 172). In pain afferents, it acts on two different plasma membrane receptors on the dorsal horn excitatory interneurons, with two different outcomes. First, binding of glutamate with its *AMPA receptors* (see p. 199) ultimately results in the generation of action potentials in the dorsal horn cells, transmitting the pain message to higher centers. Second, binding of glutamate with its *NMDA receptors* leads to Ca^{2+} entry into these neurons. Ca^{2+} initiates second-messenger systems that make the dorsal horn cells more excitable than usual (see p. 199). This hyperexcitability contributes in part to the exaggerated sensitivity of an injured area to subsequent exposure to painful or even normally nonpainful stimuli, such as a light touch. Think about how highly sensitive your sunburned skin is, even to clothing. This exaggerated sensitivity is presumably useful to discourage activities that could cause further damage or interfere with healing of the injured area.

A Closer Look at Adaptation

Why Are Hot Spices Hot?

Most mammals find capsaicin highly irritating, and thus avoid eating the fruit. But many birds eat them with impunity. Why? Recall that all biological phenomena have both proximate and evolutionary explanations (Chapter 1). The proximate explanation has been recently revealed: Whereas one mammalian pain receptor is triggered by capsaicin, the equivalent receptors in

birds are completely insensitive. Thus, birds do not sense the painful burning that mammals do on eating peppers. In evolutionary terms, researchers speculate that the plants evolved this chemical to prevent mammals from eating their fruits, while allowing birds to do so and thus disperse their seeds. The seeds pass unharmed through a bird's digestive tract, and their flight capa-

bilities ensure a more widespread dispersal than mammalian dispersal would. Of course, many humans learn to like the taste of capsaicin-laden food. This may be because the pain triggers euphoria in response to *endogenous opiate* release (see the main text below), leading to the process of *acquired* taste (p. 235).

The mammalian brain has a built-in analgesic system

In addition to the chain of neurons from peripheral nociceptors to higher CNS structures for pain perception, the mammalian CNS also contains a built-in pain-suppressing or **analgesic system** that suppresses transmission in the pain pathways as they enter the spinal cord. One major brainstem region involved is the **periaqueductal gray matter** (gray matter surrounding the cerebral aqueduct, a narrow canal that connects the third and fourth ventricular cavities), which stimulates particular neurons whose cell bodies lie in nuclei in the *medulla* and *reticular formation*. Electrical stimulation of any of these parts of the brain produces profound analgesia. From the nuclei, neurons terminate on inhibitory interneurons in the dorsal horn of the spinal cord (Figure 6-46b). These inhibitory interneurons release *enkephalin*, which binds with **opiate receptors** at the afferent pain-fiber terminal.

People have long known that **morphine**, a component of the opium poppy, is a powerful analgesic. Researchers considered it very unlikely that mammals have been endowed with opiate receptors only to interact with chemicals derived from a flower! They therefore began to search for the substances that normally bind with these opiate receptors. The result was the discovery of **endogenous opiates** (morphine-like substances)—the *endorphins*, *enkephalins*, and *dynorphin*—which are important in the body's natural analgesic system. These endogenous opiates serve as analgesic neurotransmitters. Binding of enkephalin from the dorsal-horn inhibitory interneuron with the afferent pain-fiber terminal suppresses the release of substance P via presynaptic inhibition, thereby blocking further transmission of the pain signal (see Figure 4-22, p. 140). Morphine binds to these same opiate receptors, which accounts in large part for its analgesic properties. Furthermore, injection of morphine into the periaqueductal gray matter and medulla causes profound analgesia, suggesting that endogenous opiates also are released centrally to block the descending pain-suppressing pathway.

Describe the built-in analgesic system of the mammalian brain.

6.9 Electoreception and Magnetoreception

Many non-visual systems have evolved for environmental navigation and object sensing in situations where light is not adequate. Examples include predators tracking prey scent trails, a harbor seal's sensitive whiskers tracking the turbulent wake of a fish, and an echolocating bat. An alternative sensory mechanism in light-limited areas evolved in a number of bony and cartilaginous fishes and at least two mammals: **electoreception** which allows for **electrolocation**—the directional detection of external electric fields.

Electoreception can be passive or active, and can be used for navigation, prey detection, and communication

Passive electoreception is the ability to detect extraneous electric fields, not an animal's own electrical currents, and is used primarily for electrolocation. **Ampullary electoreceptors** (found in almost all nonteleost fishes and in some teleosts, as well as in several amphibian species) respond to low-frequency electric signals that are typical of electrical output from animal nerves and hearts as well as the electrical discharge used in electric fish courtship. (Most animals emit a direct current or DC field in seawater because of ion currents in their excitable tissues, and a wound or even a scratch can markedly alter these electrical fields). In elasmobranchs (sharks, skates, and rays) and certain teleosts, the **ampullae of Lorenzini**, a modified group of neuromasts (p. 218), act as **electoreceptors** and are used to locate prey even if it is located below the sediment surface (Figure 6-47a). For example, a shark or skate can easily detect the faint potentials associated with the gill muscles (from minute leakage of ions) of

(a) Substance P pain pathway

(b) Analgesic pathway

FIGURE 6-46 Substance P pain pathway and analgesic pathway. (a) When activated by a noxious stimulus, some afferent pain pathways release substance P, which activates ascending pain pathways that provide various brain regions with input for processing different aspects of the painful experience. (b) Endogenous opiates released from descending analgesic (pain-relieving) pathways bind with opiate receptors at the synaptic knob of the afferent pain fiber. This binding inhibits the release of substance P, thereby blocking transmission of pain impulses along the ascending pain pathways.

a buried flounder. The ampullae are filled with a clear, salty gel (a glycoprotein complex) that readily transmits minute electrical currents. New studies show that very small temperature changes induce voltage changes in the gel, suggesting that it serves in both electrosensing and thermosensing.

Passive electroreception has been also demonstrated in the platypus, which uses sensors in its “duckbill” to find electrical currents of prey hidden at the bottom of streams. Also, the aptly named star-nosed mole, a blind animal living in burrows, is suspected of having electroreception in its odd nose, which sprouts numerous fingerlike tentacles.

In contrast, **active electroreception** resembles echolocation in that the animal assesses its environment by actively emitting signals and receiving the feedback signal. Found in some freshwater fishes in the murky Amazon and some (also murky) African rivers, this system uses an **electric organ** in the tail section of the fish’s body that discharges a current field, which emanates from its anterior body and then converges on the tip of the tail (Figure 6-47b), a transepidermal current flow. (We will describe these organs in more detail shortly.) Momentarily, the tip of the tail becomes negatively charged so that an electric current is produced in the surrounding water. This momentary change is induced repeatedly, at a high frequency. **Tuberous electroreceptors**, more numerous than ampullary electroreceptors, lie on the anterior body surface in the lateral line system and monitor changes in the local transepidermal current flow. These receptors respond to the high-frequency signals from the fish’s *electric organ discharge* (which we will describe later in detail). Their distribution over the body surface provides a somatotopically organized view of the electrosensory world that resembles what might be presented to the visual system by an extended retina without a lens. These electroreceptors terminate in somatotopically organized maps in an area of the brain known as the *electrosensory lateral line lobe* (ELL), with much of the ELL circuitry dedicated to detecting small changes in amplitude associated with prey.

The reception is used in both *electrolocation* and *electrocommunication* with conspecifics. Active electroreceptive fish test the conductivity of the water around them and locate perturbations by detecting distortions produced in their own electric field. Any object that differs in impedance from the surrounding water distorts the electric field and alters the pattern of transepidermal current intensities in the area of body surface closest to the object (Figure 6-47c). The South American electric fish *Eigenmannia* generates electric organ discharges at frequencies from 250 to 600 Hz. When two fish with similar discharges meet, they shift their frequencies away from each other in order to create a larger frequency difference and to avoid “jamming” or interfering with their conspecific neighbor’s own discharge pattern.

In marine fish, the electroreceptors (mainly ampullary) are connected to the body surface via long, low-resistance channels, whereas the ducts of freshwater fish receptors (mainly tuberous) are comparatively short. Because the skin resistance of freshwater fish is much higher than that of marine fish, transepidermal voltage differences are greater, which means that current flow can be detected with the much shorter ducts. When current enters an electroreceptor cell of a fish, the resulting depolarization opens voltage-gated Ca^{2+} channels in the membrane, which triggers the efflux of neurotransmitter from the receptor cell. Conse-

quently, the frequency of action potentials in the sensory fiber that innervates the receptor is increased. Although one important disadvantage of having an electric sense is its very limited range (only several meters), electrolocation permits an animal to actively function in darkness or in murky waters.

Electric organs use specialized electrocytes to generate electric organ discharges

Electric organs, located within active electroreceptive animals, produce **electric organ discharges** (EODs), currents outside the animal’s body. The organs are derived from muscle tissue and consist of thin, waferlike cells called **electrocytes** stacked in columns of several thousand surrounded by a gelatinous insulating material (one side of the electrocyte is “smooth” and highly innervated, whereas the other is “rough” and consists of deep folds). The increased surface area due to the folding markedly increases the capacitance of each cell. These modified muscle cells have lost the ability to contract and are instead specialized for generating an ion current flow. When the organ is at rest, the *opposite* faces of the generating cells are at the same positive potential (that is, the extracellular fluid is positive on opposite surfaces of the electrocyte at approximately +80 mV). However, when the potential on one side of the electrocyte is reversed, current flows in a circuit that involves the two membranes, the cell cytoplasm and the external medium (Figure 6-47d). During a discharge, the potential on the innervated side is briefly reversed. The electrocytes are excited in synchrony by spinal nerves that generate small individual voltage gradients around each electrocyte (approximately 150 mV). Because the electrocytes are stacked in series and surrounded by insulating material, the voltage adds arithmetically, in a similar manner to batteries connected in series. A pacemaker potential whose command center is in the medulla drives the electric organ. Gap junctions assure precision in the firing of the electrocytes, maximizing signal intensity to achieve close electrotonic coupling of the medullary and spinal neurons. An additional factor that determines signal intensity is the number of columns of electrocytes capable of generating current.

In most electric fish species, EODs are limited in range to millivolts to volts and may be emitted continually for electrolocation and social communication. In contrast, a few species such as the electric eel (*Electrophorus*) can produce EODs up to several hundred volts *outside* their bodies. Such strong EODs are emitted to stun or kill prey. Because the conductivity of seawater is so high, the electric field produced by a strong discharge is essentially short-circuited and thus limited in range.

Production of EODs is energetically costly, and the South American longtail knifefish (*Sternopygus macrurus*) has evolved a clever solution. It uses its electrical sense at night, while during the day, it turns down signal generation. Neural and hormonal signals have been found to regulate the rapid insertion and removal of Na^+ channels in electrocyte membranes in a night-day (circadian) rhythm. Reducing Na^+ currents in this way saves considerable energy. Moreover, during unexpected social encounters, a surge of neural-hormonal signals can also trigger rapid insertion of channels. This system may be the fastest in the animal kingdom for regulating the number of ion channels in a membrane.

The Pacific electric ray, *Torpedo californica*, which can stun its prey with 45 volts of electricity generated by electrocytes in its wings.

Paul Yancey

Some animals can detect magnetic fields for long-range navigation, possibly by magnetic induction, magnetic minerals in receptors, or magnetochemical reactions

A final sensory mode provides a form of internal “compass.” A variety of organisms, including some bacteria, mollusks, crustaceans, insects, fish, amphibians, reptiles, birds, and mammals (mole rats, at least), can detect *magnetic fields* and are capable of using this information for orientation. The lines of Earth’s field are vertical at the poles and horizontal at the equator. Migratory birds are known to be able to use this magnetic field to help locate established nesting sites thousands of miles away from the wintering grounds. Similarly, sea turtles have been shown in the laboratory to respond to artificial magnetic fields, orienting their swimming directions in response.

How do these animals detect the field? Since magnetic fields penetrate bodies, no discrete sense organ is necessary, and the mechanisms have remained elusive. Three possible mechanisms have been identified (of which an animal might have more than one); but the receptors remain unknown.

1. *Magnetic induction*: The highly sensitive electroreceptors of elasmobranchs are suspected to detect Earth’s magnetic field. Movement of any conductive object such as a fish body across magnetic field lines produces electric currents (a process called *magnetic induction*); these may be monitored by the electroreceptors in the ampullae of Lorenzini. This mechanism only works for animals with such sensitive receptors.

2. *Magnetic minerals* (magnetite crystals, Fe_3O_4) have been identified in various magnetically sensitive organisms including bacteria, honeybees (thorax), homing pigeons (beak), salmon (brain), rainbow trout (noses at terminal end the *trigeminal* nerve, which responds to magnetic fields), robins (nostrils), and mole rats (cornea). For magnetic sensing, magnetic crystals are arranged in a chain called a **magnetosome** within a bacterium or an animal cell. Single crystals of magnetite (50 nm in size) do not interact strongly enough with Earth’s magnetic field to overcome the randomizing effects of thermal buffeting. However, once arranged in chains, their individual movements add together such that they can align with a magnetic field and interact with the receptor. How this leads to cellular signals is unknown, although moving magnetic particles could be linked to the opening of mechanically gated channels.
3. *Magnetochemical reactions*: Some chemical reactions involve free-radical formation that can be affected by magnetic fields. One class of biological candidates involve **cryptochromes**, ancient blue-light receptors used in nonvisual and nonphotosynthetic light responses as diverse as light-oriented plant growth, moonlight-induced coral spawning, and setting of circadian rhythms in animals with eyes (where the cryptochromes are located; see p. 284). Light absorption by cryptochrome does indeed cause magnetically sensitive free-radical reactions. Fruit flies lacking their cryptochrome gene lost the ability to react to magnetic fields. Some experiments with birds suggest that their cryptochrome-containing retinas can detect magnetic fields, leading to the possibility that they can visualize the Earth’s fields!

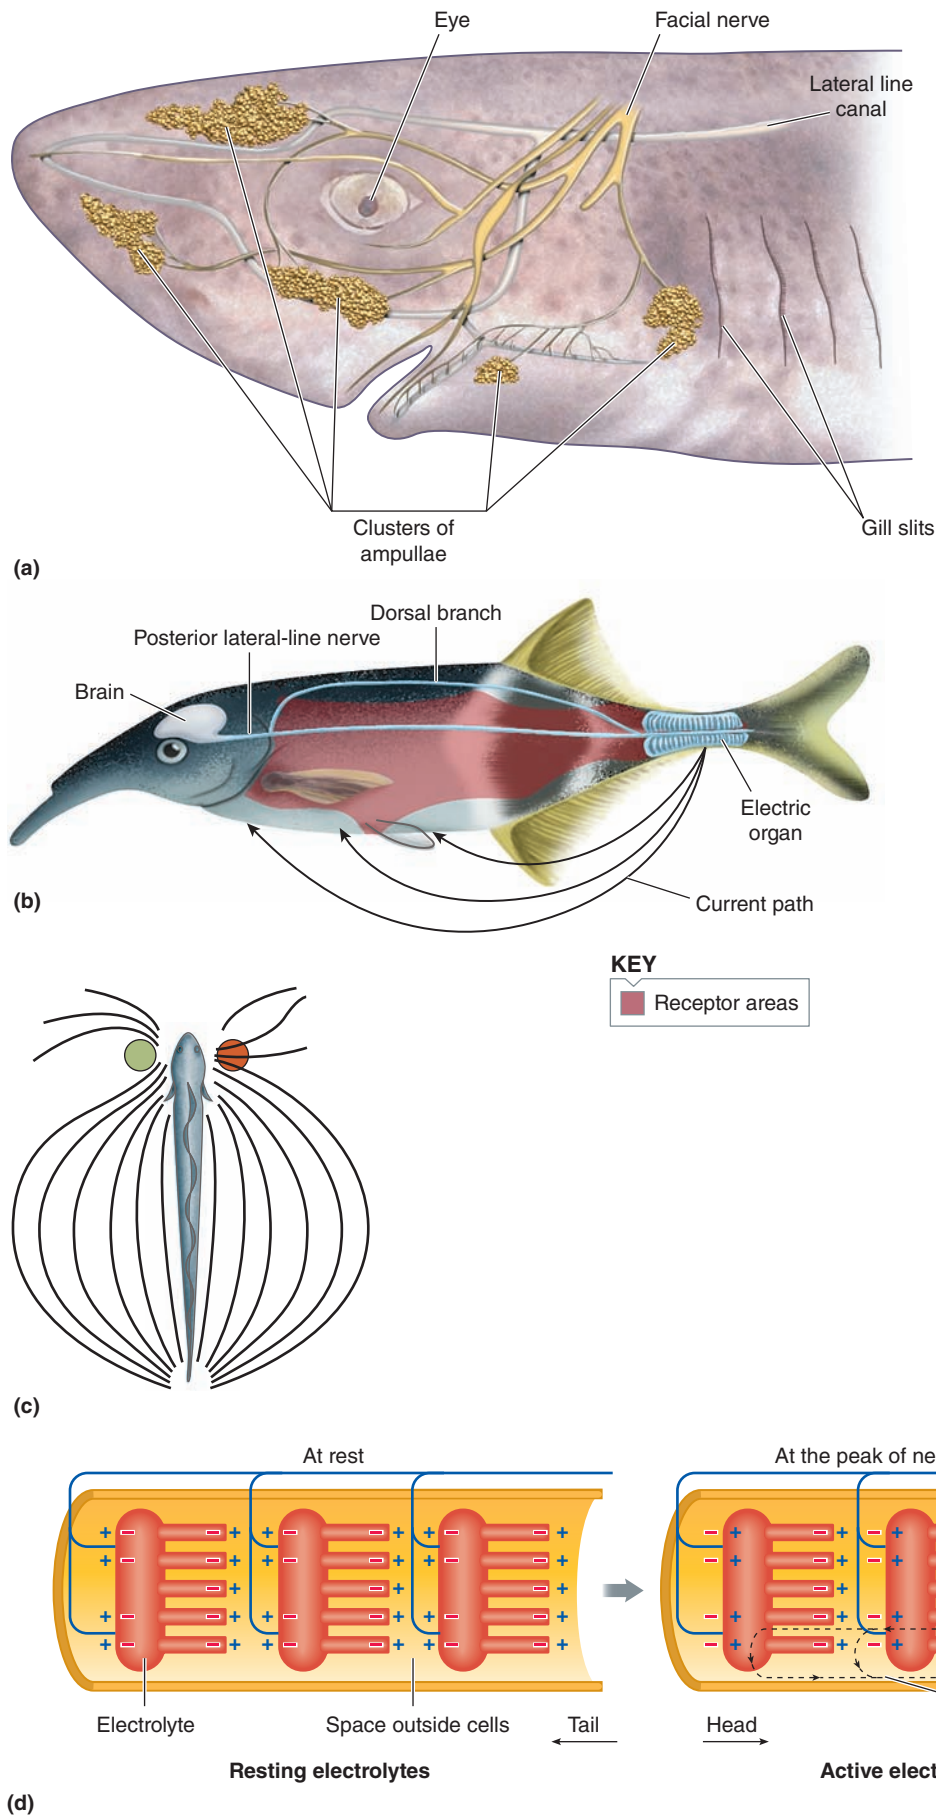

FIGURE 6-47 Electoreception and electrical discharge. (a) Ampullary electoreceptors in a shark. Sensory nerve endings in the ampullae detect electrical currents produced by other animals; they also appear to be sensitive to changes in temperature and salinity. (b) Active electoreception in a weakly electric fish (*Gymnotus*). An electric field is set up by an organ in the tail and received by sensors in the head. (c) An external object (round circle) in the electric field distorts the field (in this case, a nonconductive object diverts the field around it), allowing the fish to detect it (a conductive object such as another animal would concentrate the field lines). (d) Transmembrane potentials in modified muscle cells to produce an EOD (electric organ discharge). The cells have smooth sections (left parts) and rough projections (right parts). At rest (left), the cells are negatively charged internally. Only the smooth part is innervated. When stimulated (right), ion channels permit Na^+ to flow into the smooth part, making it positive inside, but the rough part remains negative. This allows for a large external current to flow. By having cells in series, the currents in some electric fish can add up to very large voltages, which can stun prey.

How Senses Contribute to the Body as a Whole

As you saw in Chapter 1, biological regulation begins with the sensing of a regulated state or of a potential threat to that state. In other words, to maintain a life-sustaining sta-

ble internal environment, animal nervous systems must be able to sense the myriad external and internal factors that continuously threaten to disrupt homeostasis, such as external exposure to cold, the impending attack of a predator, or internal acidity (pH) changes. Regulated (nonhomeostatic) changes such as reproduction also involve senses such as in finding a mate.

Sensory information is sent to the central nervous system (CNS), the integrating and decision-making component of the nervous system in “advanced” animals. The CNS in turn commands appropriate effector responses in organ systems to maintain the body's viability. Almost every system in an animal body can be involved in regulatory responses, including physiological (such as altering respiration in response to sensing an abnormal blood CO₂ concentration) and behavioral effector processes (such as running rapidly on sensing of a predator).

Chapter Summary

- Sensory cells have ion channels and receptor proteins with specific modalities: mechano-, chemo-, photo-, thermo-, electro-, and magnetoreception; and nociception (pain). Each receptor responds best to a single adequate stimulus (e.g., light). Receptors fall into three roles: interoceptors for internal states, proprioceptors for body position and motion, and exteroceptors for the environment.
- Perception is not reality because sensory systems enhance (as in lateral inhibition for contrast enhancement) or filter information before it reaches the brain.
- A stimulus alters the receptor's permeability, leading to a graded receptor potential. Receptor potentials may initiate action potentials in an afferent neuron. Receptors may fire continuously or adapt slowly or rapidly to sustained stimulation. Each sensory pathway is “labeled” according to modality and location, so the brain “knows” what and where it is.
- Animal integuments may have both touch and pressure receptors. Proprioceptors in the muscles, tendons, and joints give information on limb position and motion. The statocyst is the simplest organ that can monitor an animal's position in space, with mineral crystals that move and open ion channels. The lateral line system of amphibians and fish detects motion in the surrounding water with hair cells, which transduce movement using externally gated mechanical channels on cilia.
- The vestibular apparatus of vertebrate inner ears detects position and motion of the head for equilibrium and coordination of head, eye, and body movements. These use otolith minerals like statocysts, which move and push on hair cells. Fishes hear with otolith organs, aided by the gas bladder in some species. Many terrestrial vertebrates and insects receive sound initially with a tympanic membrane, aided by other external features in some groups such as the mammalian pinna. Insect ears are derived from the respiratory tracheal system.
- Sound is characterized by its intensity (loudness), pitch (tone), and timbre (quality). Pitch, for example, can be varied, with low frequencies for long-distance signals and high frequencies for echolocation. The vertebrate external ear (typanum) and middle ear bones convert airborne sound waves into fluid vibrations in the inner ear. The cochlea of the inner ear contains the organ of Corti, the sense organ for hearing. Hair cells in that organ transduce fluid movements into neural signals. Pitch discrimination depends on the region of the organ's basilar membrane that vibrates. The auditory cortex is mapped according to tone.
- Taste and smell have numerous roles such as sensing food, kin, mates, and direction. Taste sensation is coded by patterns of activity in various taste receptors. Mammalian taste is based on five (and perhaps more) primary tastes, labeled for discrimination in the brain.
- The olfactory receptors in the nose are specialized endings of renewable afferent neurons. Various parts of an odor are detected by different olfactory receptors and sorted into “smell files.” Odor discrimination is coded by patterns of activity in the olfactory bulb glomeruli. The olfactory system adapts quickly, and odorants are rapidly cleared. The vomeronasal organ detects pheromones.
- Light detection uses universal photopigments in ciliary or rhabdomeric receptor cells. Dedicated light-sensing organs range from simple eyespots to complex eyes. The vertebrate eye is a fluid-filled sphere with the amount of light entering controlled by the iris. The eye refracts the entering light to focus the image on the retina. Accommodation increases the strength of the lens for near vision. Light must pass through several retinal layers in vertebrates before reaching the photoreceptors.
- Phototransduction by retinal cells converts light stimuli into neural signals via hyperpolarization. Rods provide indistinct gray vision at night, whereas cones provide sharp color vision during the day. The sensitivity of eyes can vary markedly through dark and light adaptation. Color vision depends on the ratios of stimulation of the various cone types. Color discrimination abilities vary greatly among types of animals. Some animals can see ultraviolet and/or polarized light.

- Visual information is separated and modified within the visual pathway before it is integrated into a perceptual image of the visual field by the cortex. The thalamus and visual cortices elaborate the visual message. Visual input goes to other areas of the vertebrate brain not involved in vision perception.
- Cephalopod camera eyes have light-sensing cells on top of neural cells. Compound eyes of arthropods and some annelids and bivalves consist of multiple image-forming units. Phototransduction in rhabdomeric eyes uses rhodopsin but otherwise differs from that in vertebrate eyes, causing depolarization.
- Warmth and cold thermoreceptors give information about the temperature of the environment near the body. Infrared thermoreceptors give pit vipers the ability to detect prey and desirable thermal habitats.
- Stimulation of mammalian nociceptors elicits two types of pain signals: fast signals for quick warning and slow, persisting signals to maintain awareness of an injury. The mammalian brain has a built-in analgesic system (e.g., endorphins) to shut off excessive pain signals.
- Electoreception can be passive or active and can be used for navigation, prey detection, and communication. Electric organs use specialized electrocytes to generate signals.
- Some animals can detect magnetic fields for long-range navigation, possibly by magnetic induction, magnetic minerals in receptors, or magnetochemical reactions.

Review, Synthesize, and Analyze

1. Compare the transduction mechanisms of touch, cold, vision, hearing, taste, smell, and temperature.
2. In what ways is perception not reality, and is that harmful, beneficial, or both?
3. Humans have circular pupils, whereas cats' pupils are more slitlike. For simplicity in calculation, assume the cat pupil is rectangular. (a) Calculate by what percentage the amount of light allowed into the eye decreases if a human's round pupil contracts by half, and if a cat's rectangular pupil contracts by half along one axis only. (b) Comparing these values, do humans or cats have more precise control over the amount of light falling on the retina?
4. Humans with certain nerve disorders are unable to feel pain. Why is this a problem?
5. Receptor cells that are neurons with sensory dendrites are faster than receptor cells that are separate from neurons. Why is that, and why might that be important in, for example, the sense of touch versus vision?
6. Compare the evolution and development steps for vertebrate and cephalopod eyes and the implications for their functions.
7. In what ways are vertebrate eyes superior to compound eyes? And vice versa?
8. What factors might favor the evolution of UV vision? Of pentachromatic vision?
9. Explain how humans and some other mammals can learn to like certain bitter-tasting substances and painful chemicals in food.
10. Electric fish detect time differences between different parts of their body surface within 0.5 microseconds. Provide an example of how mammals and birds similarly exploit time differences with one of their senses.

Hillar Klendorf

The northern gannet (*Sula bassanus*). Diving into the cold waters of the North Sea precluded the development of a brood patch in this species. Rather, the females cradle their eggs in the webbing of their feet during incubation, achieving temperatures close to 37°C.

Endocrine Systems

7.1 Introduction: Principles of Endocrinology

The ability of cells to “communicate” with each other is ancient, preceding the evolution of multicellularity. Protozoan cells, for example, communicate through the release of chemical signals into the environment in order to mate. Recall that chemicals that elicit specific behavioral responses in other individuals of the same species are termed **pheromones** (p. 92). In animals, pheromones and internal signal molecules used locally within a tissue (that is, paracrine action, p. 91) appear in all phyla, as do signal molecules used by neurons at synapses except in the sponges. With the evolution of internal body cavities and circulatory systems, which provided an effective route for delivering signal molecules to distant tissues, there arose **endocrine systems**, which consist of ductless glands, often scattered throughout an animal’s body as both discrete endocrine organs and as subsets of other organs having nonendocrine functions (as shown in Figure 7-1 for a mammal). The glands secrete **hormones** (signal molecules delivered by circulatory

fluids), providing a second mechanism (in addition to nervous systems) for regulating and coordinating distant organs. The endocrine and nervous systems are specialized for controlling different types of activities. In general, the nervous system coordinates rapid, precise responses and is especially important in mediating interactions with the external environment. The endocrine system, by contrast, primarily controls activities that require duration rather than speed as well as coordinating diverse tissues (e.g. liver, muscle, and gut). In the course of animal evolution, there has been an increase in the number and complexity of processes that have come under hormonal regulation. Moreover, the two systems are often intimately linked in *neuroendocrine* interactions, in which neurons secrete neurohormones into a body fluid for transport. In vertebrates, this is reflected in a classification of glands into **central** ones linked to the central nervous system, and **peripheral** ones that are not.

Endocrinology is the study of the evolution and physiological function of hormones. We begin this chapter by examining general principles of endocrinology,

and then we examine specific hormones in nonvertebrates (primarily insects) and vertebrates.

Hormones are chemically classified into three categories: peptides and proteins, amines, steroids

Hormones are not all similar chemically, but instead fall into three distinct classes according to their biochemical structure (Table 7-1; compare this table to the list of all chemical messengers on p. 93):

1. The **peptide and protein hormones** consist of specific amino acids arranged in a chain of varying length; the shorter chains are peptides and the longer ones are categorized as proteins. For convenience, we refer to this entire category as *peptides*. The majority of animal hormones fall into this class; an example is *insulin*, which regulates blood glucose in vertebrates.

FIGURE 7-1 The mammalian endocrine system.

© Cengage Learning, 2013

2. The **amines** are derived from the amino acid tyrosine and include the hormones secreted by the vertebrate thyroid gland and adrenal medulla. The catecholamine hormones are specifically known as **catecholamines**.
3. The **steroids** are neutral lipids derived from cholesterol. These include the hormones secreted by the molting glands of arthropods and the vertebrate adrenal cortex and gonads (sex steroids such as *estradiol* and *testosterone*), as well as some mammalian placental hormones. Insects cannot synthesize the core steroid molecule and so must ingest suitable precursors in order to synthesize their primary steroid hormone *ecdysone*.

These signal types are apparently quite ancient. Several amines and peptides identical to signal molecules found in animals have been detected as pheromones in protozoa. A peptide closely related to human insulin (with a corresponding receptor) has been found in some Porifera (sponges), although its function is unclear. In recent years, all three signal types have been found in Cnidaria. For example, estradiol and testosterone have been found in some corals, in which estradiol levels surge during mass spawning events, suggesting a regulatory role in reproduction.

Minor differences in chemical structure between hormones within each category often result in profound differences in biological response. For example, note the subtle difference between testosterone, the male sex hormone responsible for inducing the development of masculine characteristics, and estradiol, a form of estrogen, which is the feminizing female sex hormone (Figure 7-2).

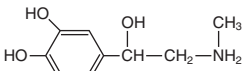

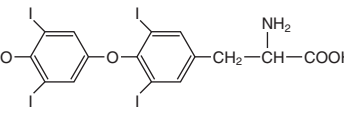

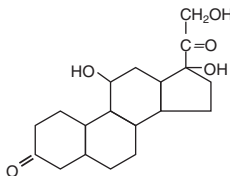

FIGURE 7-2 Comparison of two steroid hormones, testosterone and estradiol.

Solubility Characteristics of Hormone Classes The structural classification of hormones is of more than biochemical interest. The chemical properties of a hormone, most notably its solubility, determine the means by which the hormone is synthesized, stored, and secreted; the way it is transported in the blood; and the mechanism by which it exerts its effects at the target cell, and typically, the type of processes regulated (rapid versus long-term) and their half-lives (turnover) in the circulation. The following differences

TABLE 7-1 Chemical Classification of Vertebrate Hormones

Properties	Amines			
	Peptides	Catecholamines	Thyroid Hormone	Steroids
Structure	Chains of specific amino acids, for example: $\begin{array}{c} \text{Cys}^1 - \text{s} - \text{s} - \text{Cys}^6 - \text{Pro}^7 - \text{Arg}^8 - \text{Gly}^9\text{NH}_2 \\ \qquad \qquad \\ \text{Tyr}^2 \qquad \text{Asn}^5 \\ \qquad \qquad \\ \text{Phe}^3 \qquad \text{Gln}^4 \end{array}$ (Vasopressin)	Tyrosine derivative, for example:  (Epinephrine)	Iodinated tyrosine derivative, for example:  (Thyroxine, T ₄)	Cholesterol derivative, for example:  (Cortisol)
Solubility	Hydrophilic (lipophobic)	Hydrophilic (lipophobic)	Lipophilic (hydrophobic)	Lipophilic (hydrophobic)
Synthesis	In rough endoplasmic reticulum; packaged in Golgi complex	In cytosol	In colloid, an inland extra-cellular site	Stepwise modification of cholesterol molecule in various intracellular compartments
Storage	Large amounts in secretory granules	In chromaffin granules	In colloid	Not stored; cholesterol precursor stored in lipid droplets
Secretion	Exocytosis of granules	Exocytosis of granules	Endocytosis of colloid	Simple diffusion
Transport in Blood	As free hormone	Half bound to plasma proteins	Mostly bound to plasma proteins	Mostly bound to plasma proteins
Receptor Site	Surface of target cell	Surface of target cell	Inside target cell	Inside target cell
Mechanism of Action	Channel changes or activation of second-messenger system to alter activity of preexisting proteins that produce the effect	Activation of second messenger system to alter activity of preexisting proteins that produce the effect	Activation of specific genes to produce new proteins that produce the effect	Activation of specific genes to produce new proteins that produce the effect
Hormones of This Type	All hormones from the hypothalamus, anterior pituitary, posterior pituitary, pineal gland, pancreas, parathyroid gland, gastrointestinal tract, kidneys, liver, thyroid C cells, heart	Only hormones from the adrenal medulla	Only hormones from the thyroid follicular cells	Hormones from the adrenal cortex and gonads plus most placental hormones (vitamin D is steroid-like)

© Cengage Learning, 2013

in the solubility of the various types of hormones are critical to their function (Table 7-1):

- All peptides and catecholamines are *hydrophilic* (water loving); that is, they are highly H₂O soluble and have low lipid solubility.
- All steroid and thyroid hormones are *lipophilic* (lipid loving); that is, they have high lipid solubility and are poorly soluble in H₂O.

We are first going to consider the different ways in which these hormone types are processed at their site of origin, the endocrine cell, before comparing their means of transport and mechanisms of action.

The mechanisms of hormone synthesis, storage, and secretion vary according to the class of hormone

Because of their chemical differences, the means by which the various classes of hormones are synthesized, stored, and secreted differ as follows.

Peptide Hormones Peptide hormones are synthesized by the same method used for the manufacture of any protein that is to be exported (see Figure 2-10, p. 40). Because they are destined to be released from the endocrine cell, the synthesized hormones must be segregated from intracellular proteins by being sequestered in a membrane-enclosed compart-

ment until they are secreted. Briefly, synthesis of peptide hormones requires the following steps:

1. Large precursor proteins, or **preprohormones**, are synthesized by ribosomes on the rough endoplasmic reticulum. The preprohormones then migrate to the Golgi complex in membrane-enclosed vesicles that pinch off from the smooth endoplasmic reticulum.
2. During their journey through the endoplasmic reticulum and Golgi complex, the large preprohormone precursor molecules are pruned first to **prohormones** and finally to **active hormones**. The peptide “scraps” that remain after the large preprohormone molecule is cleaved to form the classic hormone are often stored and cosecreted along with the hormone. This raises the possibility that these other peptides may also exert biological effects that differ from the traditional hormonal product; that is, the cell may actually be secreting multiple hormones, but the functions of the other peptide products are for the most part unknown. A known example involves the large precursor molecule **pro-opiomelanocortin (POMC)** in vertebrates. Before secretion, several diverse cell types produce POMC and slice it in unique ways, depending on the processing enzymes they possess, to yield different active products. In particular, POMC can be cleaved into *adrenocorticotrophic hormone (ACTH)*, *melanocyte-stimulating hormones (MSH)*, and a morphinelike substance, *β -endorphin*, along with peptide “scraps” that have no known function. We’ll examine the roles of each active product later.
3. The Golgi complex concentrates the finished hormones, then packages them into secretory vesicles that are pinched off and stored in the cytoplasm until an appropriate signal triggers their secretion. By storing peptide hormones in a readily releasable form, the gland can respond rapidly to any demands for increased secretion without first needing to increase hormone synthesis.
4. On appropriate stimulation, the secretory vesicles fuse with the plasma membrane and release their contents to the outside by the process of exocytosis (see p. 42). Such secretion usually does not go on continuously; it is triggered only by specific stimuli. The blood subsequently picks up the secreted hormone for distribution.

Steroid Hormones All steroidogenic (steroid-producing) cells perform the following steps to produce and release their hormonal product:

1. Cholesterol is the common precursor for all steroid hormones; however, numerous species cannot synthesize cholesterol and must obtain it from their diet. Vertebrate steroidogenic cells can synthesize some cholesterol on their own, although most is derived from low-density lipoproteins (LDLs) from the blood (see p. 389). Unused cholesterol may be chemically modified and stored in large amounts as lipid droplets within steroidogenic cells. Utilization of LDLs and conversion of stored cholesterol into free cholesterol for use in steroid hormone production can be closely coordinated with the animal’s overall need for the hormone product.
2. Synthesis of the various steroid hormones from cholesterol requires a series of enzymatic reactions that modify the type and position of side groups attached to the

cholesterol framework or the degree of saturation within the rings (Figure 7-3). Each conversion from cholesterol to a specific steroid hormone requires enzymes found in the mitochondria or endoplasmic reticulum. Accordingly, each steroidogenic organ can produce only the steroid hormones for which it has a complete set of appropriate enzymes. For example, a key enzyme necessary for the production of *cortisol* is found only in the adrenal cortex. The steroid molecule is therefore shuttled back and forth between different compartments within the steroidogenic cell for step-by-step modification until the final secretory product is formed.

3. Unlike peptide hormones, steroid hormones cannot be stored after their formation. Once formed, the lipid-soluble steroid hormones immediately diffuse through the steroidogenic cell’s lipid plasma membrane to enter the circulatory system. Only the hormone precursor cholesterol is stored in significant quantities within steroidogenic cells. Accordingly, the rate of steroid hormone secretion is controlled entirely by the rate of hormone synthesis. In contrast, peptide hormone secretion is controlled primarily by regulating the release of presynthesized, stored hormone.
4. After their secretion into the circulation, some steroid hormones undergo further interconversions within the blood or other organs, where they are converted into more potent or different hormones.

Amines The amine hormones of vertebrates—thyroid hormone and catecholamine hormone—have unique synthetic and secretory pathways that are thoroughly described when each of these hormones is specifically addressed. However, in brief, the amines share the following features:

- They are derived from the naturally occurring amino acid tyrosine.
- Both types of amines are stored until they are secreted.
- Thyroid hormone also undergoes further processing once in the peripheral circulation.

Hydrophilic hormones are transported dissolved in the plasma, whereas lipid-soluble hormones are almost always transported bound to plasma proteins

All hormones are carried by the blood, but they are not all transported in the same manner:

1. The hydrophilic peptide hormones are transported simply dissolved in the plasma or, in some cases, bound to a specific carrier protein.
2. Lipophilic steroids and thyroid hormone (in vertebrates), which are poorly soluble in water, cannot dissolve in the aqueous plasma in sufficient quantities to account for their known plasma concentrations. Instead, most of these hormones circulate to their target cells reversibly bound to plasma proteins. Some plasma proteins are designed to carry only one type of hormone, whereas other plasma proteins, such as albumin, indiscriminately pick up any “hitchhiking” hormone.

Only the small, unbound, freely dissolved fraction of a lipophilic hormone is biologically active (that is, free to

none, which increases the rate of O_2 consumption and the metabolic activity of almost every cell of mammals and birds, is an example of a nontropic hormone.

Complexity of Endocrine Function The following factors add to the complexity of an endocrine system:

- A single endocrine gland may produce multiple hormones. The mammalian anterior pituitary, for example, secretes six different hormones, usually made by different specialized cells in that gland; each hormone is under different control mechanisms and has different functions, some being tropic and others nontropic.
- A single hormone may be secreted by more than one endocrine gland. For example, the vertebrate hypothalamus and pancreas both secrete the hormone *somatostatin*. In amphibians *thyrotropin-releasing hormone* is synthesized in the hypothalamus and the skin as well as other organs. The functional significance of this arrangement has not been established.
- Frequently, a single hormone has more than one type of target cell and therefore can induce more than one type of effect. This is the “same key, different locks” concept that we discussed in Chapter 3 (p. 93). As an example, *vasopressin* from the posterior pituitary promotes H_2O reabsorption by mammalian kidney tubules by binding with V_2 receptors on the distal and collecting tubular cells and vasoconstriction of arterioles throughout the body by binding with V_1 receptors on arteriolar smooth muscle. Sometimes hormones that have multiple target-cell types can coordinate and integrate the activities of various tissues toward a common end. For example, the effects of *insulin* from the pancreas on muscle, liver, and fat all act in concert to store nutrients after absorption of a meal.
- The secretion rate of some hormones varies considerably over the course of time in a cyclic pattern. Therefore, endocrine systems also provide temporal (time) coordination of function. This is particularly evident in the endocrine control of reproductive cycles, such as the estrous cycle, in which normal function requires highly specific patterns of change in the secretion of various hormones.
- A single target cell may be influenced by more than one hormone. Some cells contain an array of receptors for responding in different ways to different hormones. To illustrate, *insulin* promotes the conversion of glucose into *glycogen* (a storage polymer) within vertebrate liver cells by stimulating one particular hepatic enzyme, whereas another hormone, *glucagon*, by activating a different set of hepatic enzymes, enhances the degradation of glycogen into glucose within liver cells.
- The same chemical messenger may be either a hormone or a neurotransmitter, depending on its source and mode of delivery to the target cell. A prime example is norepinephrine, which is secreted as a hormone by the vertebrate adrenal medulla and released as a neurotransmitter from sympathetic postganglionic nerve fibers. The effects of the identical hormone and neurotransmitter are generally different, again illustrating the “same key, different locks” principle (p. 93).
- Some organs are exclusively endocrine in function (they specialize in hormonal secretion alone, the anterior pituitary and thyroid glands being examples), whereas other organs of the endocrine system perform nonendocrine

functions in addition to secreting hormones. For example, vertebrate testes produce sperm and also secrete the male sex-hormone *testosterone*.

- Nonnative or hormonelike substances termed **endocrine-disrupting chemicals (EDCs)**, whose structures are similar to hormones, can sometimes disrupt endocrine communication by altering hormone secretion, transport or action. These compounds are derived from the by-products of manufactured organic compounds.

This has been a brief overview of the general functions of the endocrine system. Certain hormones are introduced elsewhere and are not discussed in this chapter; these (in vertebrates) are the *gastrointestinal hormones* (Chapter 14), the renal hormones (*erythropoietin* in Chapter 9, and *renin* in Chapter 13), *atrial natriuretic peptide* from the heart (Chapter 12), and *thymosin* (Chapter 10). Most of the remainder of the major hormones are described in greater detail in this chapter.

Hormones produce their effects by altering intracellular proteins through ion fluxes, second messengers, and transcription factors

To induce their effects, hormones must bind with target cell receptors specific for them. Each interaction between a particular hormone and a target-cell receptor produces a highly characteristic response that differs among hormones and among different target cells influenced by the same hormone.

General Mechanisms of Hydrophilic and Lipophilic Hormone Action The location of the receptors within the target cell, and the mechanism by which binding of the hormone with the receptors induces a response, both vary, depending on the hormone's solubility characteristics. Receptor–hormone interactions can be grouped into two broad categories based on the location of their receptors (Table 7-1):

1. **Membrane receptors.** The hydrophilic peptides and catecholamines, which are poorly soluble in lipid, cannot pass through the lipid membrane barriers of their target cells. Instead, they bind with specific receptors located on the outer plasma membrane surface of the target cell. In turn, these receptors either alter the conformation (shape) of adjacent ion channels already present in the membrane (p. 94), or activate second-messenger systems within the target cell. Second messengers directly alter the activity of preexisting intracellular proteins, usually enzymes, to produce the desired effect.
2. **Internal receptors.** The lipophilic steroids and thyroid hormone (in the free form, not bound with a plasma protein carrier) easily pass through the surface membrane to bind with specific receptors located *inside* the target cell. The receptors inside the cell are typically *transcription factors* that regulate specific genes in the target cell that code for the formation of new intracellular proteins (pp. 31 and 94). Some lipophilic hormones also have specific receptors in the plasma membrane and cytosol of target tissues.

Membrane receptors were covered in Chapters 2 and 3; however, the lipophilic mechanism of hormonal action warrants further examination.

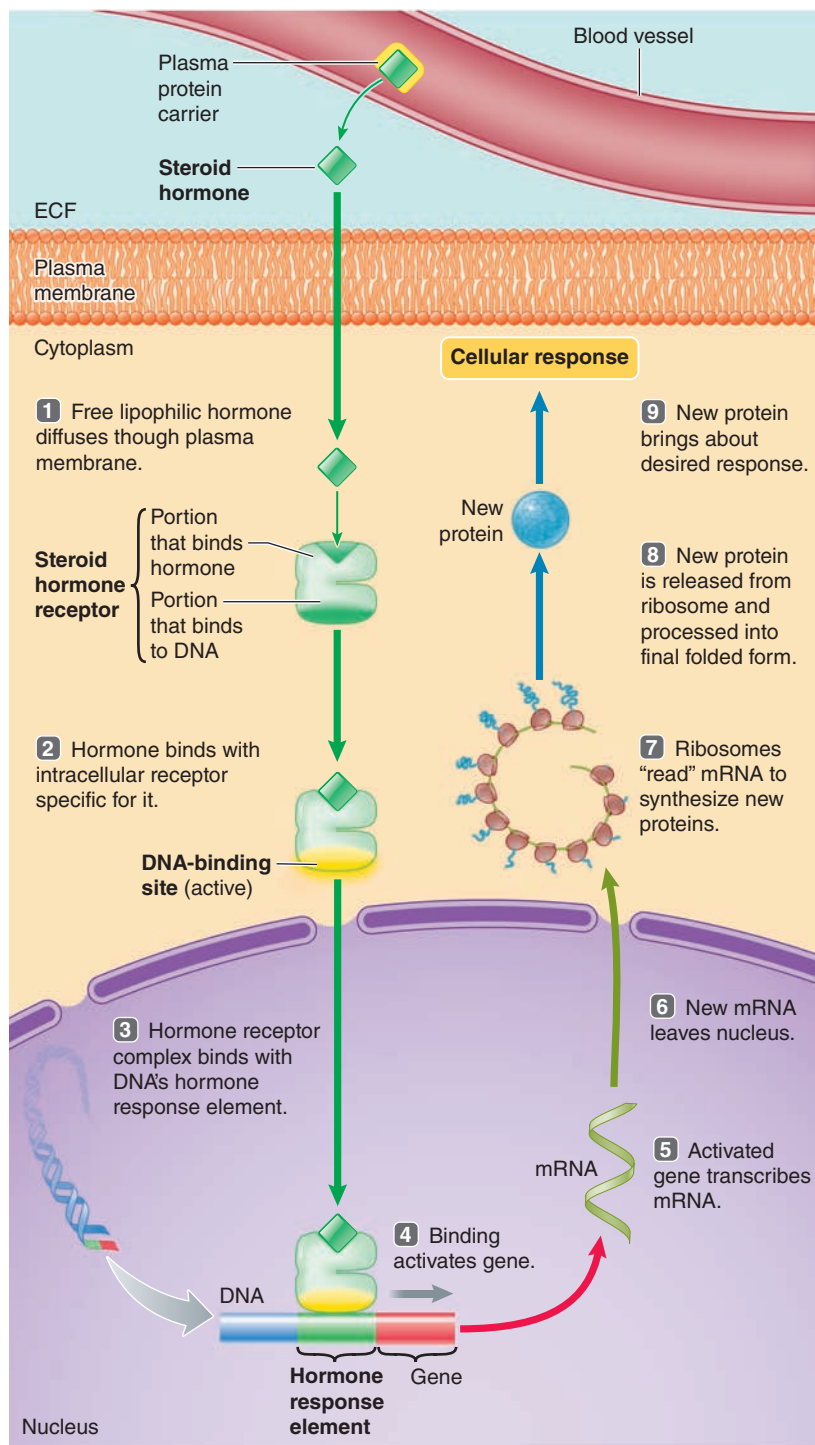

FIGURE 7-4 Mechanism of action of lipophilic hormones.

© Cengage Learning, 2013

By stimulating genes, lipophilic hormones promote synthesis of new proteins

All lipophilic hormones (steroids and thyroid hormone) bind with intracellular receptors in their target cells by activating specific genes that cause the synthesis of new proteins, as summarized in Figure 7-4.

Free lipophilic hormone (hormone not bound with its plasma-protein carrier) diffuses through the plasma mem-

brane of the target cell (step 1 in Figure 7-4) and binds with its specific receptor inside the cell, either in the cytoplasm or in the nucleus (step 2). Each receptor has a specific region for binding with its hormone and another region for binding with DNA. The receptor cannot bind with DNA unless it first binds with the hormone. Once the hormone is bound to the receptor, the hormone receptor complex binds with DNA at a specific attachment site on the DNA known as the **hormone response element (HRE)** (step 3). Different steroid hormones and thyroid hormone, once bound with their respective receptors, attach at different HREs on DNA. For example, the estrogen receptor complex binds at DNA's estrogen response element.

Binding of the hormone receptor complex with DNA "turns on" or activates a specific gene within the target cell (step 4). This gene contains a code for synthesizing a given protein. The code of the activated gene is transcribed into complementary messenger RNA (mRNA) (step 5). The new mRNA leaves the nucleus and enters the cytoplasm (step 6), where it binds to a ribosome, the "workbench" that mediates the assembly of new proteins. Here, mRNA directs the synthesis of the designated new proteins according to the DNA code in the activated genes (step 7). The newly synthesized protein, either enzymatic or structural, is released from the ribosome (step 8) and produces the target cell's ultimate response to the hormone (step 9). By means of this mechanism, different genes are activated by different lipophilic hormones, resulting in different biological effects.

By means of this mechanism of nuclear receptors, different lipophilic hormones activate different genes, resulting in hormone-specific biological effects. Genomic and evolutionary analysis of nuclear receptors has revealed that they share an extensive homology and so are grouped into a large superfamily divided into six subfamilies. For example, one subfamily places the vertebrate thyroid-hormone receptor in the same class as the vertebrate vitamin D receptor and the arthropod ecdysone receptor. Another subfamily contains the vertebrate steroid receptors; vertebrate genomes have six nuclear steroid receptors: two

for estrogens, and one each for testosterone/androgens, glucocorticoids, mineralocorticoids (such as aldosterone), and progesterone (hormones we discuss later). Recently, researchers have found that the genome of a mollusk, the seaslug *Aplysia* (p. 198), has an estrogen-type receptor. Although this receptor is not activated by steroids, its existence suggests that steroid receptors evolved before chordates arose.

Even though most steroid actions are accomplished by hormonal binding with intracellular receptors that leads to gene activation, recent studies have unveiled another mechanism by which steroid hormones induce effects that occur too rapidly to be mediated by gene transcription. Some ste-

roid hormones, most notably some of the sex hormones, bind with unique steroid receptors in the plasma membrane, in addition to binding with the traditional steroid receptors in the nucleus. This membrane binding leads to *nongenomic steroid receptor actions*, that is, actions accomplished by something other than altering gene activity, such as by inducing changes in ionic flux across the membrane or by altering activity of cellular enzymes.

Onset and Duration of Hormonal Responses Compared to neural responses that are brought about within milliseconds, hormone action is relatively slow and prolonged, taking minutes to hours for the response to take place after the hormone binds to its receptor. The variability in time of onset for hormonal responses depends on the mechanism employed. Hormones that act through a second-messenger system to alter a preexisting enzyme's activity elicit full action within a few minutes. In contrast, hormonal responses that require the synthesis of new protein may take up to several hours before any response can be measured.

Also, in contrast to neural responses that are quickly terminated once the triggering signal ceases, hormonal responses persist for a period of time after the hormone is no longer bound to its receptor. Once an enzyme is activated in response to hydrophilic hormonal input, it no longer depends on the presence of the hormone. Thus, the response lasts until the enzyme is inactivated. As a result, a hormone's effect usually lasts for some time after its withdrawal. Predictably, the responses that depend on protein synthesis last longer than do those stemming from enzyme activation.

Furthermore, as we explain shortly, compared to hydrophilic hormones, lipophilic hormones usually persist longer after secretion before being inactivated.

Hormone actions are greatly amplified at the target cell

The actions of hormones are greatly amplified at the target cell. As we noted earlier, hormones exert their effect at incredibly low concentrations—as low as 1 picogram (10^{-12} gram; 1 millionth of a millionth of a gram) per mL—as opposed to the much higher localized concentration of neurotransmitter at the target cell during neural communication. Interaction of one hormonal molecule with its receptor can result in the formation of many active protein products that ultimately carry out the physiological effect. For example, one peptide hormone results in the production of many cAMP messengers, each in turn activating many latent enzymes (see p. 97). Similarly, one steroid-hormone-activated gene induces formation of many messenger RNA molecules, each of which is used to make numerous new proteins.

Endocrine-disrupting chemicals can mimic the effects of native hormones

As we noted earlier, endocrine-disrupting chemicals (EDCs) are human-made substances that are released into the environment and interfere with the endocrine modulation of neural and behavioral maturation of animals. EDCs range across all continents and oceans, are found in animal populations from the poles to the tropics, and can be passed from generation to generation. The discovery of hormonally me-

diated toxic effects in fish downstream of sewage discharge points led to the realization that wastewater contains EDCs. Even so, some scientists have suggested that environmental EDCs, except in extreme cases of a discrete spill or a point source, rarely occur in high enough concentrations to impact endocrine function. Further, natural endocrine disruption has been happening for millions of years as exemplified by some plants, which evolved these secondary products to serve as plant regulators or as endocrine-disrupting defenses against herbivores, especially insects.

Sexual development of the vertebrate brain is influenced by estrogenic (female) and androgenic (male) hormones. Researchers have found that many EDCs either mimic (as agonists) the actions of estrogens or oppose (as antagonists) their actions (anti-estrogenic); in some situations EDCs may even function as anti-androgens. For example, DDE (dichlorodiphenyldichloroethylene), a breakdown product of the pesticide DDT (dichlorodiphenyltrichloroethane), which was used globally from the 1940s to 1960s to kill mosquitoes and other insect pests, can be found in almost all living tissue on Earth and acts as an anti-androgen in mammals. More recent discoveries have demonstrated that common household products (for example, heavy-duty laundry powders and liquid detergents, personal care products, and household cleaners) contain nonionic surfactants that break down in the environment to form estrogen agonists (which interact with estrogen receptors). EDCs that interfere with sex hormone activity and production have the potential to disturb normal brain sexual development, as has been demonstrated in wildlife studies of birds, fishes, whales, porpoises, alligators, and turtles. These effects have been linked with direct exposure to sewage and industrial effluents and pesticides, and indirectly to accumulation through aquatic food webs. Similarly, EDCs that impair thyroid function are believed to contribute to learning difficulties in animals, in addition to other neurological abnormalities.

The effective plasma concentration of a hormone is normally regulated by changes in its rate of secretion

The primary function of most hormones is the regulation of various homeostatic activities. Because hormones' effects are proportional to their concentrations in the blood, it follows that these concentrations must be subject to control according to homeostatic need (Figure 7-5). The plasma concentration of free, biologically active hormone—and thus the hormone's availability to its receptors—depends on several factors: (1) the hormone's rate of secretion into the blood by the endocrine gland; (2) for a few hormones, rate of metabolic activation; (3) for lipophilic hormones, extent of binding to plasma proteins; and (4) rate of removal from the circulation by metabolic inactivation and excretion in urine. Furthermore, the magnitude of the hormonal response depends on the availability and sensitivity of the target cell's receptors for the hormone. Let's first examine the factors that influence the plasma concentration of the hormone before turning our attention to the target cells' responsiveness to the hormone.

Normally, the effective plasma concentration of a hormone is regulated by appropriate adjustments in the rate of its secretion. Secretion rates of all hormones are subject to

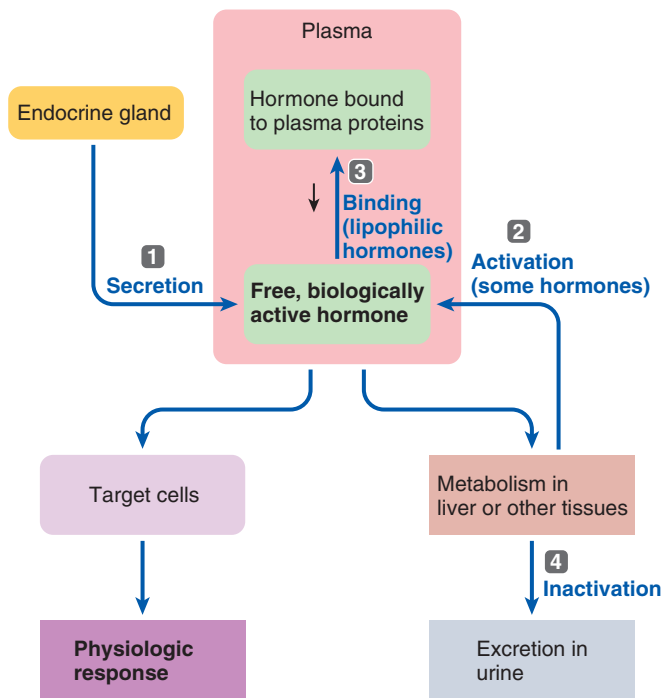

FIGURE 7-5 Factors affecting the plasma concentration of free, biologically active hormone. The plasma concentration of free, biologically active hormone, which can interact with its target cells to produce a physiological response, depends on (1) the hormone's rate of secretion by the endocrine gland, (2) its rate of metabolic activation (for a few hormones), (3) its extent of binding to plasma proteins (for lipophilic hormones), and (4) its rate of metabolic inactivation and excretion.

© Cengage Learning, 2013

control, often by a combination of several complex mechanisms. The regulatory system for each hormone is considered in detail in later sections. For now, we address these general mechanisms, which are common to many different hormones: negative-feedback control, neuroendocrine reflexes, and diurnal (circadian) rhythms.

Negative-Feedback Control Negative feedback is a prominent feature of most biological control systems (see p. 13), including hormonal. Recall that *negative feedback exists when the output of a system counteracts a change in input*, thus maintaining a controlled variable within a narrow range around a set level. Control of hormonal secretion to maintain a hormone's plasma concentration provides some classic physiological examples of negative feedback. For example, when the plasma concentration (in a mammal) of free circulating thyroid hormone falls below a given “set point,” the anterior pituitary secretes thyroid-stimulating hormone (TSH), which stimulates the thyroid to increase its secretion of thyroid hormone. Thyroid hormone in turn inhibits further secretion of TSH by the anterior pituitary. Negative feedback ensures that once thyroid gland secretion has been “turned on” by TSH, it will not continue unabated but instead will be “turned off” when the appropriate level of free circulating thyroid hormone has been achieved. Thus, the effect of a particular hormone's actions can inhibit its own secretion.

Neuroendocrine Reflexes Many endocrine control systems involve **neuroendocrine reflexes**, which include neural as well as hormonal components. The purpose of such reflexes is to produce a sudden increase in hormone secretion (that is, a *reset* mechanism, p. 18, that “turns up the thermostat setting”) in response to a specific stimulus, frequently a stimulus external to the body. In some instances, neural input to the endocrine gland is the only factor regulating secretion of the hormone. For example, secretion of epinephrine by the adrenal medulla is solely controlled by the sympathetic nervous system. Some endocrine control systems, in contrast, include both feedback control, which maintains a constant basal level of the hormone, and neuroendocrine resetting reflexes (which cause sudden bursts in secretion in response to a sudden increased need for the hormone). An example is the increased secretion of cortisol by the adrenal cortex during a stress response (see p. 305).

Diurnal (Circadian) and Other Biological Rhythms Although some form of negative feedback usually regulates hormone secretion rates, this does not imply that hormones are always maintained at a constant level. Instead, the secretion rates of most hormones rhythmically fluctuate up and down as a function of time. The most common endocrine rhythm is the **diurnal** (“day–night”), or **circadian** (“around a day”), **rhythm**, which is characterized by repetitive oscillations in gene expression that correspond with changes in the physiology, metabolism, and behavior in nearly all organisms on Earth, from bacteria to mammals. As we'll see, fluctuations in certain hormone levels are very regular and have a frequency of one cycle every 24 hours. This rhythmicity is caused by endogenous oscillators, called **biological clocks**, similar to the self-paced respiratory neurons in the brainstem that govern the rhythmic motions of breathing, except the time-keeping oscillators cycle on a much longer time scale. Furthermore, unlike the rhythmicity of breathing, endocrine rhythms are locked on, or **entrained**, to external cues, called **zeitgebers** (“time givers”), such as the light–dark cycle; that is, the inherent 24-hour cycles of peak and ebb of hormone secretion are set to “march in step” with cycles of light and dark. Such biological rhythms are a classic example of *anticipatory regulation* (Chapter 1): Once synchronized with a regular environmental cycle such as day–night or summer–winter, clocks allow organisms to prepare for these cyclical changes in advance of their actual occurrence. For example, *cortisol* secretion (p. 286) in a diurnal mammal rises during the late night, reaching its peak secretion in the early morning just before waking time, and then falls throughout the day to its lowest level at dusk (Figure 7-6). This prepares the animal for the stresses associated with waking up and initiating activity such as finding food.

Inherent hormonal rhythmicity and the entrainment of zeitgebers are not accomplished by the endocrine organs themselves but instead result from the central nervous system changing the set point of these organs. Indeed, neural clocks regulate many neuromuscular functions such as feeding and other behaviors, as well as hormonal secretion. In turn, the neurons themselves exhibit clock cycles due to *clock genes*, which are found in all organisms. (We examine these neural and molecular biological mechanisms in detail later; p. 284) Negative-feedback control mechanisms maintain whatever set point is established for that time of day.

FIGURE 7-6 Diurnal rhythm of cortisol secretion.

Source: Adapted from George A. Hedge, Howard D. Colby, & Robert L. Goodman. (1987). *Clinical Endocrine Physiology*. Philadelphia: W. D. Saunders Company, Figure 1-13, p. 28.

Some endocrine cycles operate on time scales other than a circadian rhythm—some much shorter than a day and some much longer. A well-known example of the latter is the monthly menstrual cycle in humans, and a tidal rhythm called **circalunadian** (“about a lunar day”) in many shoreline animals. Another common cycle is the **circannual** (yearly) rhythm in seasonally reproducing organisms and hibernating animals.

The effective plasma concentration of a hormone can be influenced by the hormone’s transport, metabolism, and excretion

Even though the effective plasma concentration of a hormone is normally regulated by appropriate adjustments in the rate of secretion, alterations in the transport, metabolism, or excretion of a hormone can also influence the size of its effective pool, sometimes inappropriately. For example, the vertebrate liver synthesizes plasma proteins, so liver disease may result in abnormal endocrine activity because of a change in the balance between free and bound pools of certain hormones.

Eventually, all hormones are metabolized by enzyme-mediated reactions that modify the hormonal structure in some way. In most cases, this inactivates the hormone. Hormone metabolism is not always a mechanism for removal of used hormones, however. In some cases, a hormone is activated by metabolism; that is, the hormone’s product has greater activity than the original hormone. For example, after the thyroid hormone thyroxine is secreted, it is converted to a more powerful hormone by enzymatic removal of one of the iodine atoms it contains. Usually the rate of such hormone activation is itself under hormonal or metabolic control.

Metabolic Inactivation and Urinary Excretion of Hormones

The liver is the most common site for metabolic hormonal inactivation in vertebrates, but some hormones are also metabolized in the kidneys, blood, or target cells. In contrast to hormone activation, which is typically regulated, hormonal inactivation and excretion are not subject to control. The primary means of eliminating hormones and their metabolites from vertebrate blood is by urinary excretion. When liver and kidney function are normal, measuring urinary

concentrations of hormones and their metabolites provides a useful, noninvasive way to assess endocrine function because the rate of excretion of these products in urine directly reflects their rate of secretion by the endocrine glands. This type of information may provide the only clue that an animal has come into breeding condition and can participate in a captive breeding program. Because the liver and kidney are important in removing hormones from the blood by means of metabolic inactivation and urinary excretion, animals with liver or kidney disease may suffer from excess activity of certain hormones solely as a result of reduced hormone elimination.

The amount of time after a hormone is secreted before it is inactivated and the means by which this is accomplished differ for different classes of hormones. In general, the hydrophilic peptides and catecholamines are easy targets for blood and tissue enzymes, so they remain in the blood only briefly (a few minutes to a few hours) before being enzymatically inactivated. In the case of some peptide hormones, the target cell actually engulfs the bound hormone by endocytosis and degrades it intracellularly. In contrast, binding of lipophilic hormones to plasma proteins renders them less vulnerable to metabolic inactivation and prevents them from escaping into the urine. Therefore, lipophilic hormones are removed from the plasma much more slowly. They may persist in the blood for hours (steroids) or up to a week in humans (thyroid hormone). In general, lipophilic hormones must undergo a series of reactions to reduce their biological activity and enhance their H₂O solubility so that they can be freed of their plasma protein carriers and be eliminated in the urine.

The responsiveness of a target cell to its hormone can be varied by regulating the number of its hormone-specific receptors

A target cell’s response to a hormone is correlated with the number of the cell’s receptors occupied by molecules of that hormone, which in turn depends on the number of receptors present in the target cell and on the plasma concentration of the hormone. Thus, the response of a target cell to a given plasma concentration can be fine-tuned up or down by varying the number of receptors available for hormone binding.

Down-Regulation As an illustration, when the plasma concentration of insulin is chronically elevated, the total number of target cell receptors for insulin is reduced as a direct result of the effect that an elevated level of insulin has on the insulin receptors. This phenomenon, known as **down-regulation**, constitutes an important locally acting negative-feedback mechanism that prevents the target cells from overreacting to the high concentration of insulin; that is, the target cells are desensitized to insulin, helping blunt the effect of insulin hypersecretion. This is a form of **acclimatization**, one of the key regulatory mechanisms we discussed in Chapter 1 (p. 17). Down-regulation of insulin is accomplished by the following mechanism. The binding of insulin to its surface receptors induces endocytosis of the hormone–receptor complex, which is subsequently attacked by intracellular lysosomal enzymes. This internalization serves a twofold purpose: It provides a pathway for degradation of the hormone, and it also plays a role in regulating the number of receptors available for

binding on the target cell's surface. At high plasma-insulin concentrations, the number of surface receptors for insulin is gradually reduced as a result of the accelerated rate of receptor internalization and degradation brought about by increased hormonal binding. The rate of synthesis of new receptors within the endoplasmic reticulum and their insertion in the plasma membrane do not keep pace with their rate of destruction. Over time, this self-induced loss of target cell receptors for insulin reduces the target cell's sensitivity to the elevated hormone concentration.

Permissiveness, Synergism, and Antagonism A given hormone's effects are influenced not only by the concentration of the hormone itself but also by the concentrations of other hormones that interact with it. Because hormones are widely distributed through the blood, target cells may be exposed simultaneously to many different hormones, giving rise to numerous complex hormonal interactions on target cells. Hormones frequently alter the receptors for other kinds of hormones as part of their normal physiological activity. A hormone can influence the activity of another hormone at a given target cell in one of three ways: permissiveness, synergism, and antagonism.

- With **permissiveness**, one hormone must be present in adequate amounts for the full exertion of another hormone's effect. In essence, the first hormone, by enhancing a target cell's responsiveness to another hormone, "permits" this other hormone to exert its full effect. For example, thyroid hormone increases the number of receptors for epinephrine in epinephrine's target cells, increasing the effectiveness of epinephrine. Epinephrine is only marginally effective in the absence of thyroid hormone.
- **Synergism** occurs when the actions of several hormones are complementary and their combined effect is greater than the sum of their separate effects. An example is the synergistic action of follicle-stimulating hormone and testosterone, both of which are required to maintain the normal rate of sperm production. Synergism probably results from each hormone's influence on the number or affinity of receptors for the other hormone.
- **Antagonism** occurs when one hormone causes the loss of another hormone's receptors, reducing the effectiveness of the second hormone. To illustrate, progesterone (a mammalian hormone secreted during pregnancy that decreases contractions of the uterus) inhibits uterine responsiveness to estrogen (another hormone secreted during pregnancy that increases uterine contractions). By causing loss of estrogen receptors on uterine smooth muscle, progesterone prevents estrogen from exerting its excitatory effects during pregnancy and thus keeps the uterus in a quiet (noncontracting) environment suitable for the developing fetus.

Endocrine disorders are attributable to hormonal excess, hormonal deficiency, or decreased responsiveness of the target cells

From the preceding discussion, you can see that abnormalities in a hormone's effective plasma concentration can arise from a variety of factors. Endocrine disorders most commonly result from abnormal plasma concentrations of a

hormone caused by inappropriate rates of secretion—that is, too little hormone secreted (**hyposecretion**) or too much hormone secreted (**hypersecretion**). Occasionally endocrine dysfunction arises because target cell responsiveness to the hormone is abnormally low, even though the plasma concentration of the hormone is normal.

Hyposecretion If an endocrine gland (such as the adrenal gland) is secreting too little of its hormone because of an abnormality within that gland, the condition is referred to as *primary hyposecretion*. If, in contrast, the endocrine gland is normal but is secreting too little hormone because of a deficiency of its tropic hormone, the condition is known as *secondary hyposecretion*. The following are among the many different factors (each listed with an example) that may be responsible for hormone deficiency: (1) *genetic* (inborn absence of an enzyme that catalyzes synthesis of the hormone); (2) *dietary* (lack of iodine, which is necessary for synthesis of thyroid hormone); (3) *chemical or toxic* (certain insecticide residues may destroy the adrenal cortex); (4) *immunologic* (auto-immune antibodies may cause self-destruction of the animal's own thyroid tissue); (5) *other disease processes* (cancer or tuberculosis may coincidentally destroy endocrine glands); (6) *iatrogenic* (physician or veterinarian-induced, such as surgical removal of a cancerous thyroid gland); and (7) *idiopathic* (meaning the cause is not known).

The most common method of treating hormone hyposecretion is to administer a hormone that is the same as (or similar to, such as from another species) the one that is deficient or missing. The sources of hormone preparation for clinical use include (1) endocrine tissues from domestic livestock; (2) placental tissue and urine of pregnant women; (3) laboratory synthesis of hormones; and (4) genetically engineered "hormone factories": bacteria into which genes coding for the production of mammalian hormones have been introduced. The method of choice for a given hormone is determined largely by its structural complexity and degree of species specificity.

Hypersecretion Like hyposecretion, hypersecretion by a particular endocrine gland is designated as primary or secondary depending on whether the defect lies in that gland or is due to excessive stimulation from the outside, respectively. Hypersecretion may be caused by (1) tumors that ignore the normal regulatory input and continuously secrete excess hormone and (2) immunologic factors, such as excessive stimulation of the thyroid gland by an abnormal antibody that mimics the action of TSH, the thyroid tropic hormone. Excessive levels of a particular hormone may also arise from substance abuse, such as the banned practice among athletes of using certain steroids that increase muscle mass by promoting protein synthesis in muscle cells, and the injections of these and other hormones into livestock to enhance production (such as GH, p. 291). Note however that such injections lead to feedback inhibition of natural hormone production (see p. 296).

There are several ways of treating hormonal hypersecretion. If a tumor is the culprit, it may be surgically removed or destroyed with radiation treatment. In some instances, drugs that block hormone synthesis or inhibit hormone secretion can limit hypersecretion. Sometimes giving drugs that inhibit the action of the hormone without actually reducing the excess hormone secretion may treat the condition.

Having completed our discussion of the general principles of endocrinology, we now look at the function of selected nonvertebrate and vertebrate endocrine glands.

check your understanding 7.1

How do hormones produce their effects on a target cell?

What factors determine the plasma concentration of a hormone?

7.2 Nonvertebrate Endocrinology

Considerable diversity is evident in the function of endocrine systems in nonvertebrates, not surprising since the term “nonvertebrate” includes over 30 phyla and is not a true evolutionary grouping. Currently researchers are seeking to determine how homologous these systems are among different animal groups. Earlier we noted evidence that sponges and Cnidaria have signal molecules similar or identical to those of more complex animals, but these would likely act locally (paracrine fashion), slowly by diffusion to distant cells, or through external fluids. True hormone (endocrine) systems arose along with internal body fluids that provided a route for transport, and may have started first with neuroendocrine systems. Nonvertebrate hormones are produced either by neuroendocrine cells or distinct glands in **neural haemal organs** where the axonal endings secrete the hormone into the coelom (body cavity), hemolymph, or blood, which then can bind to specific receptors on peripheral organs. Nonvertebrate hormonal systems that have been documented include the following.

Mollusks Gastropods produce hormones that regulate such functions as egg laying and growth. For example, the **juxtaganglionic organ (JO)** consists of scattered cells in the connective tissue around the cerebral ganglion; the cells release peptides of uncertain function into the hemolymph during egg laying. Also, **bag cells** (two clusters in connective tissue above the abdominal ganglion) produce a peptide called **egg-laying hormone (ELH)**. When injected into the seaslug *Aplysia* (p. 198), ELH elicits ovulation and egg-laying behaviors such as head tamping on the sand to cover eggs.

In addition, the intestines of some bivalves have been found to produce insulin, which may have a carbohydrate-regulating role similar to that in vertebrates. Moreover, steroid (estrogen) receptors have been found in *Aplysia* and an octopus, though they do not respond to vertebrate estrogen, so their functions are uncertain.

Annelids Earthworms and leeches have ganglionic tissues that have been found to contain molecules closely related to vertebrate hormones. These molecules are also in the circulatory fluid. One of these, *annetocin* (related to vertebrate *oxytocin*, p. 286), elicits egg-laying behavior when injected into a leech or earthworm.

Consider the striking changes associated with the metamorphosis of this caterpillar into an imperial moth (*Eacles imperialis*).

Crustaceans Decapods (crabs, shrimp, and so on) have a number of endocrine glands. The best studied are the Y- and X-organs:

- **Y-organs** in the head make **crustecdysone** to promote molting. This hormone is identical to ecdysone in insects, which we discuss shortly
- **Neurosecretory** (p. 91) **X-organs** (in the eyestalks) send their axons into **sinus glands** (also in eyestalks) to release several neurohormones, including (an incomplete list): (1) **chromatophorotropins** that activate **chromatophores** (p. 154) for changing color of the cuticle; (2) **crustacean hyperglycemic hormone** that triggers release of glucose from glycogen in the hepatopancreas (similar to vertebrate *glucagon*, p. 316); and (3) **vitellogenesis-inhibiting hormone**, which inhibits egg development.

Insects The most intensely studied of nonvertebrate endocrine systems is that of insects, which we discuss in detail. Several tissues in insects produce hormones, including (Figure 7-7a):

- The paired **corpora allata**, located behind the brain, with one lying on either side of the esophagus or fused

FIGURE 7-7 Developmental hormones in insects. (a) Hormone-producing tissues of an insect. (b) Ecdysone and juvenile hormone (JH) are two of the hormones involved in larval development and metamorphosis.

© Cengage Learning, 2013

into a single organ (as in higher Diptera), which secrete hormones, including **juvenile hormone (JH)**.

- The prothoracic glands, a pair of diffuse glands that are usually located at the back of the head or in the thorax, and that secrete **ecdysone** into the circulatory system.
- Neurosecretory cells in the brain that produce one or more neurohormones, including **prothoracicotrophic hormone (PTTH)**.
- The paired **corpora cardiaca**, which form a part of the wall of the dorsal longitudinal circulatory vessel (aorta).

The function of insect hormones has been studied with regard to their role in molting, osmoregulation, and reproduction, with molting processes receiving the most study. It is that process that we now examine.

Molting is the process of replacing one exoskeleton with another

To develop from larvae to adult, arthropods must periodically shed their chitin exoskeleton and replace it with a larger one. This cyclical pattern of replacement of the exoskeleton is essential for increasing body size as well as for any changes in body form (such as the acquisition of wings in adults). **Molting** is the process of replacing the exoskeleton with another, whereas the shedding of the old exoskeleton is termed **ecdysis**. Ecdysis is controlled by at least two neuropeptides including **ecdysis-triggering hormone** and **eclosion hormone**. Ecdysis-triggering hormone triggers the molting of the cuticle, while eclosion hormone initiates a sequence of behaviors that must occur in a stereotyped sequence for the insect to successfully molt. These behaviors include:

- Abdominal movements that loosen the connections between the old and new cuticle.
- Waves of peristalsis that move from posterior to anterior up the abdomen, which culminates in the shedding of the old cuticle.

- Tonic abdominal contractions to promote the movement of blood into the thorax and wings, followed by a stereotyped series of wing movements.

Eclosion hormone also regulates the release of **bursicon**, the hormone that orchestrates the final steps of adult ecdysis by increasing the plasticity of wing cuticle (wing expansion) and mediates tanning in the cuticle. Bursicon is released from neurons in the abdominal ganglia into the hemolymph. In most insects, a final molt occurs when the adult characteristics are expressed and the juvenile characteristics are lost. **Ecdysone** and **juvenile hormone (JH)** are two of the regulatory hormones involved in larval development and **metamorphosis**, the change from the juvenile form to the adult stage (Figure 7-7b). Ecdysone, a member of the steroid family of **ecdysteroids**, is secreted by the prothoracic glands or their equivalent homologs, and governs the initiation of the molting process. Ecdysteroid hormones (as with other steroid hormones) bind to a receptor in the nucleus, in this case the **ecdysone receptor (EcR)**, which activates gene transcription. All arthropods use ecdysteroids as a type of growth hormone.

The secretion of ecdysteroids in insects is principally regulated by a tropic neurohormone, **prothoracicotrophic hormone (PTTH)**. PTTH is synthesized by neurosecretory cells in the brain and travels along axons to peripheral neurohemal organs, the corpora cardiaca and corpora allata, where it is released into the circulation. At the time of molt, neural signals trigger the release of PTTH, which then is transported by the hemolymph to the prothoracic glands, where it stimulates the release of ecdysone, the molt-inducing hormone. In most species the prothoracic glands break down after the final molt to the adult stage. Ecdysone is later peripherally converted into another ecdysteroid, **20-OH-ecdysone**, in various tissues, and this form is recognized as the molt-inducer.

The quantity of JH released determines the quality of the molt

JH, secreted from the corpora allata, partners the release of ecdysone and ultimately determines the “quality” of the molt. JH has two broad actions in insects: It has a “priming” or activating action whereby it prepares a tissue for hormonal response by directing the synthesis and assembly of the cell machinery necessary to carry out the responses elicited by the binding of JH to its receptor. It also performs a regulatory role by controlling the rate of functioning of the primed tissue. For example, the fat body of virtually all insects cannot synthesize the protein **vitellogenin** (protein taken up by the developing oocyte as **vitellin**, the principal yolk protein) until it has been primed by exposure to JH. Thus, in addition to controlling metamorphosis, JH regulates many aspects of reproduction as well. The fat body is most highly developed during the larval instars and normally regresses at the end of metamorphosis, except in some adult species of insects that do not actively feed.

The quantity of JH released at each molt determines whether molting will ultimately produce a larva or an adult, because when released, JH ensures that larval characteristics are retained. For example, in insects such as moths and beetles JH is released at progressively decreasing concentrations during each larval stage (or instar) until the final stage, when its release is inhibited and negligible concentrations of JH are detectable. JH release is regulated by the cerebral neuropeptide **allostatin**, which suppresses the release of JH, as well as by **allotropin**, which stimulates the release of JH. During the time of molt the tissues are exposed to a pulse of ecdysteroids in the absence of JH, which enables metamorphosis of the tissues into the adult form. However, if the corpora allata are prematurely removed from an insect, metamorphosis occurs, producing a small adult. Conversely, if JH is administered at each molt the juvenile fails to develop into the adult form.

There is also evidence that JH induces the production and release of pheromones in several species of insects (such as cockroaches, some coleopterans, and lepidopterans) and in the boll weevil. JH enhances the production of sex pheromone in the male fat body. Concentrations of JH are regulated by the proteins **juvenile hormone-binding protein (JHBP)** and **juvenile hormone esterase (JHE)**. JHBP is produced by the fat body and released into the hemolymph, where it binds JH for transport and protection from degrading enzymes, including JHE. Fat bodies make JHE at increasing levels before the final larval molt to degrade JH; at high concentrations, JHE can degrade the JH bound to the transporter JHBP.

With the prevalence of insects in terrestrial ecosystems, their endocrine system is a prominent target of evolutionary adaptation in plants that are eaten by insects. Substances closely related to ecdysone occur in certain varieties of plants and are believed to protect the plants from feeding by insects. Plant substances called **precocenes** block JH production by the corpora allata, triggering a premature metamorphosis in species in which the larval stage (such as caterpillars) and not the adult is the herbivore. Similarly, to protect crops humans have targeted insect endocrine and pheromone systems. EcR, for example, is now an important target in the design of novel, environmentally safe insecticides. Also, the genes for JHBP and JHE have recently been cloned

and are being studied as a mechanism for controlling development of insect pests.

Pheromones are used in mating and colonial interactions

Let's end our examination of insect endocrinology with a brief look at pheromones. Although, strictly speaking, pheromones are neither hormones nor endocrine in origin, they are used in very similar ways, traveling from one body to another and binding to receptors to stimulate specific behaviors. The most widespread use of pheromones in all animals including insects is in mating. This was first discovered in the 1870s by the French naturalist Jean-Henri Fabré. A female great peacock moth that hatched from a cocoon in his laboratory was soon surrounded by dozens of male great peacocks coming in through the windows. He postulated the existence of an attractive odorant, which we now know is the case. Males, using receptors on their antennae, are incredibly sensitive to these female **sex pheromones**, and some species can detect just a single molecule that has traveled a great distance from the female. Pheromone synthesis in insects is regulated by the neurohormone **pheromone biosynthesis activation peptide (PBAN)**, which controls the enzymes involved in pheromone synthesis via G-protein coupled receptors. The release of PBAN is regulated by environmental factors such as day length and host-plant odors.

Pheromone use beyond reproduction has probably diversified more in insects than in any other animal group. Social insects, such as ants, termites, and bees, rely heavily on pheromones to control and coordinate colony functions and development of castes such as workers and soldiers. For example, **alarm pheromones** are released when a colony is attacked; these signal molecules trigger rapid and violent defense behaviors. Many biologists consider insect colonies “superorganisms,” with individual insects acting like cells and organs and with pheromones acting like true hormones.

Describe the process of molting in insects. What factor(s) determine the onset of metamorphosis?

7.3 Vertebrate Endocrinology: Central Endocrine Glands

The central endocrine glands of vertebrates include the **hypothalamus**, the **pituitary gland**, and the **pineal gland**. The hypothalamus, a part of the brain, and the posterior pituitary gland act as a unit to release hormones essential for maintaining water balance and reproduction. The hypothalamus also secretes regulatory hormones that control the hormonal output of the **anterior pituitary gland**, which secretes seven hormones that in turn largely control the hormonal output of several peripheral endocrine glands.

Earlier, we discussed the concept of biological clocks, zeitgebers, and rhythmicity in hormone production. The pineal gland is a part of the brain that secretes a hormone

important in establishing such rhythms, a topic we now discuss in detail.

Biological clocks involve the pineal gland and the suprachiasmatic nuclei

The **pineal gland**, a tiny, pinecone-shaped structure located in the center of the brain, secretes the hormone **melatonin**, an indoleamine hormone derived from the amino acid tryptophan. (Do not confuse melatonin with the skin-darkening pigment, melanin—see p. 284). Melatonin was named after its lightening action on amphibian skin: Adding a pineal extract to water that contained tadpoles blanched their skin.

One of melatonin's most widely accepted roles is helping to keep the vertebrate body's inherent circadian rhythms in synchrony with the light–dark cycle (although studies in the quail and chicken demonstrated that the pineal and its melatonin rhythm are not essential for circadian function). Melatonin is the hormone of darkness: Its secretion increases up to 10-fold during the darkness of night and then falls to low levels during the light of day. Short-day breeders (such as sheep and deer) rely on steadily increasing concentrations of melatonin (Figure 7-8), whereas long-day breeders (such as many birds) rely on the progressively decreasing concentrations of melatonin to trigger reproduction. In fish, reptiles, birds, and amphibians, the pineal is photosensitive and is not directly controlled by nervous input, but rather by sunlight penetrating the skull. Pineal cells in these vertebrates are modified rod cells with reduced outer segments, containing photosensitive pigments structurally related to rhodopsin. As in mammals, there is a diurnal rhythm of melatonin, which is independent of cues from the eye. Some studies also show that melatonin controls color changes in certain ectothermic vertebrates independently of the control pathway of *melanocyte-stimulating hormone* regulation, which we will discuss later.

The master biological clock that serves as the pace-maker for circadian rhythms in mammals is the **suprachiasmatic nucleus (SCN)** (*mediobasal hypothalamus* in birds) a cluster of nerve cell bodies in the hypothalamus above the optic chiasm (the point at which part of the nerve fibers from each eye cross to the opposite half of the brain; see p. 255) (*supra*, “above”; *chiasm*, “cross”). The SCN is strategically located to receive light–dark information from the eyes. The release of glutamate by the neural input to the SCN acts to entrain the individual cells to the SCN to produce a coordinated 24-hour signal that is conveyed to multiple sites in the brain to control rhythmic patterns of body temp, feeding behavior, and so forth.

FIGURE 7-8 Pineal synchronization of reproductive activity in a seasonally breeding animal. In this example, a short-day breeder responds to a declining photoperiod by increasing melatonin secretion. In turn, GnRH pulse frequency is increased, which increases LH pulse frequency and stimulates gonadal development. Low concentrations of gonadal estrogen inhibit GnRH release during anestrous by binding to estrogen receptors on neurons in the periventricular and arcuate nuclei, limiting the release of kisspeptin. During the breeding season, this estrogen negative feedback decreases and kisspeptin stimulates GnRH pulse frequency, increasing follicular development and estrogen secretion and leading to positive feedback of estrogen, triggering an LH surge to cause ovulation.

© Cengage Learning, 2013

In mammals, pineal and melatonin output are under the control of the SCN. Daily changes in light intensity become the major environmental cue used to adjust this master clock. Special photoreceptors in the retina pick up light signals and transmit them directly to the SCN. Intermingled among the visually oriented retinal ganglion cells, about 1 to 2% of the retinal ganglion cells form an entirely independent light-detection system that responds to levels of illumination, like a light meter on a camera, rather than the contrasts, colors, and contours detected by the image-forming visual system. These photoreceptors are distinct from the rods and cones used to perceive, or see, light (see p. 248) and are located in the preganglionic region of the retina. These cells express **melanopsin**, a photoreceptor protein originally isolated in frogs and act to entrain the circadian clock (see *Molecular Biology and Genomics: Clocks*

and *Genes*). The melanopsin-containing, illumination-detecting retinal ganglion cells cue the pineal gland about the absence or presence of light by sending their signals along the **retino-hypothalamic tract** to the SCN. This pathway is distinct from the neural systems that result in vision perception. This is the major way the internal clock is coordinated to a 24-hour day. In rodent models in which the rods and cones of the retina are absent due to genetic modification and the animals are visually blind, they are still able to adjust their circadian system normally to light due to persistent regulation by the melanopsin cells. In many blind people it is the melanopsin cells that allow a relatively normal lifestyle in spite of the lack of normal visual input. However, in a few individuals that totally lack a retina or have no eyes, the circadian system free-runs and these individuals suffer severely due to the lack of synchrony to the natural environment. These subjects can be treated successfully by the administration of melatonin at the normal sleep time to restore normal timing.

Moreover the SCN signals the adrenal gland through the sympathetic nervous system to control the production of adrenal hormones including *cortisol* or *corticosterone*. The consequent adrenal steroid hormone rhythm also plays a role in coordinating the daily biological rhythmicity. These peripheral mechanisms are particularly important in synchronizing the different body organs, which have their own biological rhythms to ensure optimal timing.

All eukaryotic cells, including all those within an animal, express clock genes

The molecular biology of the circadian clock was first elucidated in *Drosophila* and other simple models. These studies determined that clock function is generated by the interplay of a small number of genes called **clock genes**, which have now been found in all eukaryotes examined (as well as some bacteria and archaea). Clock genes interact with each other through both transcription and negative-feedback loops to produce a cycle that lasts approximately a day, that is, a circadian rhythm. Remarkably the clock genes expressed in insects and vertebrates have a major degree of homology (see *Molecular Biology and Genomics: Clocks and Genes*), which allowed the rapid discovery of the clock gene mechanisms in birds and mammals. Initially the expectation was that the clock genes would be expressed solely in the SCN, which was recognized as the central pacemaker for the circadian system. However, it was discovered that clock genes were expressed in virtually all cells in the body, consistent with their early evolution, and which endows all organ systems their own circadian rhythms. Thus, the SCN acts as the conductor, which synchronizes all the multiple organs in the body to have the appropriate timing across the day. For example, the liver produces enzymes in anticipation of mealtimes. If these rhythms are disrupted, such as travel across time zones as occurs when horses are transferred between Europe and Asia for horseracing, these internal rhythms become desynchronized. It has been demonstrated in rodents that it takes about three days for the brain to readjust to an eight-hour phase (time zone) shift. However it takes as long as seven days for the gut and liver to adjust to such a phase change.

The biological clock must be synchronized with environmental cues

On its own, the circadian biological clock generally cycles a bit slower or faster than the 24-hour environmental cycle. In many insects and vertebrates (including humans), this rhythm is slightly longer than 24 hours and so must be adjusted each day by light from the environment to reset the natural daylight cycle to a period of 24 hours. (Blind cave fish and salamanders may exhibit rhythmic behaviors, but they generally do not follow a 24-hour cycle.) If this master clock were not continuously adjusted to keep pace with the world outside, the body's circadian rhythm would lag progressively out of synchrony with the daily cycles of light and dark. The existence of internal clocks was revealed by the discovery that circadian rhythms persist even if the light-dark cycle is artificially reverted to constant light (LL) or constant dark (DD). Under these conditions the rhythm is allowed to **free-run**, and animals may entrain on other zeitgebers, including environmental temperature, or the noises associated with individuals providing food at particular time in the day. Thus, the SCN must be reset daily by external cues so that the body's biological rhythms synchronize with the activity levels driven by the surrounding environment. The SCN works in conjunction with the pineal gland and its hormonal product melatonin to synchronize the various circadian rhythms with the 24-hour day-night cycle.

Biological clocks are ultimately regulated by genes and proteins that must somehow respond to sunlight, but until recently these were almost completely unknown. See *Molecular Biology and Genomics: Clocks and Genes* for these findings.

The pituitary gland descends from the hypothalamus and consists of two or three lobes

The **pituitary gland**, or **hypophysis**, is a small endocrine gland in a bony cavity at the base of the vertebrate brain just below the hypothalamus (Figure 7-9). The pituitary is connected to the hypothalamus by a thin stalk, the **infundibulum**, which contains nerve fibers and small blood vessels.

The pituitary has two anatomically and functionally distinct lobes, the **posterior pituitary** and the **anterior pituitary**. The posterior pituitary, being derived embryonically from an outgrowth of the brain, consists of nervous tissue from the hypothalamus and thus is also termed the **neurohypophysis**. The anterior pituitary, in contrast, consists of glandular epithelial tissue derived embryonically from an outpouching of ectoderm that buds off from the roof of the mouth. Accordingly, the anterior pituitary is also known as the **adenohypophysis** (*adeno*, "glandular"). The anterior pituitary consists of the **pars distalis (PD)** (main body of the pituitary gland) and the **pars tuberalis (PT)**, which forms the stalk of the pituitary gland immediately adjacent to the base of the brain. The posterior pituitary is connected to the hypothalamus by a neural pathway, whereas the anterior pituitary is connected to the hypothalamus by a vascular link.

The Intermediate Lobe and Melanocyte-Stimulating Hormone In lampreys and hagfish (jawless fishes), amphibians, reptiles, and most mammals, the adenohypophysis includes a third, well-defined intermediate lobe (*pars intermedia*). Although absent in birds and cetaceans (whales and dolphins),

Molecular Biology and Genomics: Clocks and Genes

Biological clocks have been known for over a century, but the molecular mechanisms have only been uncovered in the last two decades, with the fullest details uncovered in the fungus *Neurospora*, certain plants, fruit flies, and mice. Numerous clock genes have been discovered and their expression activities tracked. In mice, transcription of clock genes named *BMAL1* and *CLOCK* within the nuclei of SCN neurons start the cycle via synthesis of the corresponding proteins *Bmal1* and *Clock* in the cytosol. *Bmal1* and *Clock* proteins are transported back into the nucleus, where they bind to and activate specific promoter sequences for genes that ultimately increase their own production. They also bind to and activate promoters for genes called *PERIOD* and *CRYPTOCHROME (CRY)*. Thus, there is increasing production of *Bmal1*, *Clock*, *Period*, and *CRY* proteins. However, *Period* and *CRY* slowly but increasingly block the actions of *Bmal1* and *Clock* proteins, thus

reducing the transcription of all four genes. The level of clock proteins gradually dwindles as they degrade. This removes the inhibitory influence of *Period* and *CRY*. No longer being blocked, the *BMAL1* and *CLOCK* genes once again rev up the production of more clock proteins, as the cycle repeats itself. Each cycle takes about a day. The fluctuating levels of clock proteins bring about cyclical changes in neural output from the SCN that in turn lead to cyclic changes in effector organs throughout the day. An example is the diurnal variation in cortisol secretion (see Figure 7-6). Circadian rhythms are thus linked to fluctuations in clock proteins, which use a feedback loop to control their own production at the transcriptional (gene) level. In this way, internal timekeeping is a self-sustaining mechanism built into the genetic makeup of the SCN neurons.

These clock protein cycles allow the clock mechanism to run without any input

from the environment. But at some point, all clocks need to be synchronized with external signals (see text). This appears to be the role of one or more light-sensitive proteins, such as *CRY*. *CRY* belongs to the larger class of *cryptochromes* found first in plants and later in the retinas and SCN of fruit flies, mice, and humans. Cryptochromes in the retina react to blue light and are probably activated at dawn, and appear (based on knockout experiments) to be crucial to setting clocks in *Drosophila*. In mammals, **melanopsin** is thought to have that function. This protein is found in retinas of fishes, frogs, and mammals. It is a type of *opsin*, a family of genes used to make proteins for light absorption in vision (see Figure 6-35, p. 247). Melanopsin's gene, though related to visual opsins, is distinctly different enough to suggest a function other than vision. Knockout mice unable to make melanopsin were found to have 50 to 80% less sensitivity to light in setting their SCN clocks.

an intermediate lobe exists in the human fetus but becomes rudimentary after birth. Compared to the other regions of the pituitary gland and endocrine tissues in general, the intermediate lobe is poorly vascularized. Generally the size of the intermediate lobe is correlated with the ability of the animal to adapt to the coloration of its environment. For example, the lobe is enlarged in the chameleon, a champion of color change in lizards.

The intermediate lobe secretes several **melanocyte-stimulating hormones**, or **MSHs**. MSH is under primarily inhibitory control, as evidenced from experiments where ectopic transplantation of the entire pituitary gland lead to hypertrophy of the intermediate lobe and an increase in MSH secretion. Inhibition of MSH secretion by the hypothalamus is by the catecholamine dopamine. The two forms of melanocyte-stimulating hormone, **α -MSH** and **β -MSH**, are derived from the larger precursor protein *POMC* (p. 271). β -MSH has no known physiological role and may only be a structural component of *POMC*, whereas α -MSH controls skin coloration via the dispersion of storage granules containing the pigment **melanin**. These granules are in **melanocytes** (melanin-containing cells), found in the skin of most vertebrate species.

Melanocytes in the epidermis synthesize the colored substance melanin using the precursor amino acid tyrosine. Melanins that appear brown or black are referred to as **eumelanins**, whereas red or lighter colored melanins are termed **phaeomelanins**. Melanin is stored in melanin granules, or **melanosomes**, where it is released into the skin cells in response to environmental photic cues. By causing variable skin darkening in certain amphibians, reptiles, and

fishes, MSHs play a vital role in the camouflage of these species. In some lower vertebrates the action of α -MSH is opposed by an antagonistic pituitary hormone **melanin-concentrating hormone (MCH)**. Teleost MCH induced blanching of the skin when injected into dark-adapted fishes by stimulating melanosome pigment aggregation.

Some species of mammals and birds also rely on seasonal changes in melanin deposition in the pelage or feathers to minimize detection by predators or prey. MSH and steroid hormones can also differentially affect melanin deposition in the hairs and feathers of mammals and birds, although scientists do not understand the mechanism of melanin pigmentation of feathers. Nonetheless some mammals (such as the hare *Lepus americanus*) and some birds (such as the ptarmigan *Lagopus lagopus*) can change from a brown summer coat to a white winter coat in response to the dramatic changes in photoperiod.

In adult humans, the skin secretes small amounts of MSH. However, MSH is not involved in differences in the amount of melanin deposited in the skin in response to sunlight, nor with the process of skin tanning, although excessive MSH secretion does darken skin. Rather it is the activated form of vitamin D (alone or synergistically with other hormonal factors) that has been suggested to simulate melanogenesis (sun tanning). In animals without a pars intermedia (and so lacking a source of MSH), it is the intrinsic activity of the **melanocortin-1 receptor (MC1R)** that accounts for differences in skin color in humans, pelage (hair, fur, wool covering in a mammal), and feather pigmentation in birds. Another role for α -MSH lies in the appetite-suppressing neurons in the hypothalamus, which secrete this hormone

Dispersion of pigment granules in the melanocytes by β -MSH permits the skin coloration of the California lizard, *Sceloporus*, to approximate that of the background.

control food intake (see p. 725). MSH has also been shown to suppress the immune system, possibly serving in a check-and-balance way to prevent excessive immune responses.

The hypothalamus and posterior pituitary form a neurosecretory system that secretes vasopressin and oxytocin

The release of hormones from both the posterior and the anterior pituitary is directly controlled by the hypothalamus, but the nature of the relationship is entirely different. The

posterior pituitary connects to the hypothalamus by a neural pathway, whereas the anterior pituitary connects to the hypothalamus by a unique vascular link.

Let's look first at the posterior pituitary. The hypothalamus and posterior pituitary form a neuroendocrine system that consists of a population of neurosecretory neurons whose cell bodies lie in two well-defined clusters in the hypothalamus, the **supraoptic** and **paraventricular nuclei**. The axons of these neurons pass down through the thin connecting stalk to terminate on capillaries in the posterior pituitary (Figure 7-10). The posterior pituitary consists of these neuronal terminals plus glial-like supporting cells called **pituicytes**. Functionally as well as anatomically, the posterior pituitary is simply an extension of the hypothalamus. This is similar to the relationship between the X-organ and sinus gland in crustaceans (p. 279).

The posterior pituitary stores and, on appropriate stimulation, releases into the blood two small peptide neurohormones, **vasopressin** and **oxytocin**, which are synthesized by the neuronal cell bodies in the hypothalamus. The form of vasopressin in mammals is **arginine vasopressin (AVP)**. Of note is the ancient origin of these two messengers—both hormones or closely related peptides appear in all animal species, from hydra to worms and snails, to fishes, birds, and mammals. In vertebrates the ancestor is thought to be **arginine vasotocin (AVT)**, a peptide found in hagfishes and lampreys, primitive jawless fishes (agnathans) that originated over 500 million years ago. AVT also found in other vertebrates (see p. 574).

The synthesized hormones are packaged in secretory granules that are transported by axoplasmic flow down the cytoplasm of the axon (see Figure 4-21) to be stored in the neuronal terminals within the posterior pituitary. Each terminal stores either vasopressin or oxytocin but not both. Thus, these hormones can be released independently as needed. On stimulatory input to the hypothalamus, either vasopressin or oxytocin is released into the systemic blood from the posterior pituitary by exocytosis of the appropriate secretory granules. This hormonal release is triggered in response to action potentials that originate in the hypothalamic cell body and sweep down the axon to the neuronal terminal in the posterior pituitary. As in any other neuron, action potentials are generated in these neurosecretory neurons in response to synaptic input to their cell bodies.

The actions of vasopressin and oxytocin are only briefly summarized here, but they are described more thoroughly in later chapters.

Vasopressin In most mammals, vasopressin (also called **antidiuretic hormone, ADH**) has two major effects that correspond to its two names: (1) it enhances retention of H_2O by kidneys (an antidiuretic effect), and (2) it causes contraction of arteriolar smooth muscle (a vasopressor effect).

1 The paraventricular and supraoptic nuclei both contain neurons that produce vasopressin and oxytocin. The hormone, either vasopressin or oxytocin depending on the neuron, is synthesized in the neuronal cell body in the hypothalamus.

2 The hormone travels down the axon to be stored in the neuronal terminals within the posterior pituitary.

3 When the neuron is excited, the stored hormone is released from the terminals into the systemic blood for distribution throughout the body.

FIGURE 7-10 Relationship of the hypothalamus and posterior pituitary.

© Cengage Learning, 2013

Under normal conditions, vasopressin is the primary endocrine factor that regulates urinary H₂O loss and overall H₂O balance. The major control for hypothalamic-induced release of vasopressin from the posterior pituitary is input from hypothalamic *osmoreceptors*, which increase vasopressin secre-

tion in response to a rise in plasma osmolarity (see Chapters 12 and 13). More recently, vasopressin has also been found to play roles in fever, learning, memory, and behavior.

Earlier we noted that the equivalent hormone in lower vertebrates is *arginine vasotocin* (AVT). In addition to its role in osmoregulation, AVT produces vasoconstriction and an increase in blood pressure in most ectotherms. In flounder, during the initial phase of adaptation from fresh water to seawater there is a transitory rise in plasma osmolarity, which increases plasma AVT. During metamorphosis of tadpoles into frogs, the increase in AVT stimulates ACTH-induced steroidogenesis, which raises concentrations of corticosterone (see p. 305). AVT's evolutionary role in smooth muscle contraction is also evidenced in birds, where it governs *oviposition*, the physical process of laying an egg; administering AVT into a laying hen causes contraction of the uterus (shell gland) and expulsion of the egg. AVT also causes uterine contractions that accompany birth in viviparous ("live birth") snakes (*Nerodia*).

Oxytocin Oxytocin in mammals has been described as the "hormone of love" for a variety of social bonding influences; for example, its release in lactating rat mothers provides the urge to nurse their pups. Behaviorally it keeps male prairie voles monogamous and induces trust in people (see Chapter 16 for details on these and other examples). Physiologically, through positive-feedback regulation, it stimulates contraction of the uterine smooth muscle to help expel the fetus during birth and promotes ejection of the milk from the mammary glands (see Chapter 16).

The nonmammalian homologue, **mesotocin** (MT), does not affect the uterus but rather influences the blood flow to some organs (for example, in poultry an increased concentration of MT reduces the blood flow to the lower limbs and comb) in addition to reducing the circulating concentrations of aldosterone.

The anterior pituitary secretes six established hormones, many of which are tropic

Unlike the posterior pituitary, which releases hormones that are synthesized by the hypothalamus, the anterior pituitary itself synthesizes the hormones that it releases into the blood. Different cell populations within the anterior pituitary produce and secrete six established peptide hormones. The action of each of these hormones is discussed in detail in subsequent sections and chapters. For now, we briefly state their primary effects to explain their names (Figure 7-11):

1. The type of anterior pituitary cells known as **somatotrope**s secrete **growth hormone** (GH, **somatotropin**), the primary hormone responsible for regulating overall body growth (*somato* means "body"). GH also exerts important metabolic actions.
2. **Thyrotrope**s secrete **thyroid-stimulating hormone** (TSH, **thyrotropin**), which stimulates secretion of thyroid hormone and growth of the thyroid gland.
3. **Corticotrope**s produce and release **adrenocorticotropic hormone** (ACTH, or **corticotropin**), the hormone that stimulates cortisol secretion by the adrenal cortex and promotes growth of the adrenal cortex. In advanced vertebrates ACTH is derived from the large precursor molecule *POMC* (p. 271) produced within the endoplas-

FIGURE 7-11 Functions of the anterior pituitary hormones. Five different endocrine cell types produce the six anterior pituitary hormones—TSH, ACTH, growth hormone, LH and FSH (produced by the same cell type), and prolactin—which exert a wide range of effects throughout the body.

© Cengage Learning, 2013

mic reticulum of the anterior pituitary's ACTH-secreting cells.

4. **Gonadotropes** secrete two **gonadotropins**, hormones that act on the gonads (reproductive organs, namely the ova-

ries and testes)—follicle-stimulating hormone and luteinizing hormone. **Follicle-stimulating hormone (FSH)** helps regulate gamete (reproductive cells, namely ova and sperm) production in both sexes. In females it stimulates

growth and development of ovarian follicles, within which the ova, or eggs, develop. It also promotes secretion of the sex steroid hormone *estrogen* by the ovaries. In males FSH is required for sperm production.

5. **Luteinizing hormone (LH)**, the other gonadotropin, helps control sex hormone secretion in both sexes, among other important actions in females. In females LH is responsible for ovulation and luteinization (that is, the formation of a hormone-secreting corpus luteum in the ovary following ovulation). LH also regulates ovarian secretion of the female sex hormones, estrogen and progesterone. In males the same hormone stimulates the Leydig (interstitial) cells in the testes to secrete the male sex steroid hormone, *testosterone*.
6. **Lactotropes secrete prolactin**, which is structurally similar to growth hormone and exhibits some overlapping functions. Prolactin was originally determined to be involved in mammalian reproductive functions; for example, in female mammals prolactin stimulates milk production and nurturing of young whereas in males, evidence indicates it may induce production of testicular LH receptors and paternal bonding with offspring. However, throughout the vertebrates, prolactin now known to be involved in a remarkable spectrum of functions beyond reproduction, including osmoregulation, promotion of growth, support of metabolism, water drive, and metamorphosis. No other polypeptide hormone has such a wide repertoire of biological actions, some of which we will cover in this chapter later (p. 296) and Chapter 16. Prolactin's osmoregulatory roles have been primarily demonstrated in freshwater fishes, a topic we explore in Chapter 13. Thus, unlike other pituitary hormones, prolactin was not committed early in evolution to the control of one or few related processes but remained diversified and adaptive in nature. This multiplicity of functions is likely why lactotropes constitute the largest category of the anterior pituitary cell types.

TSH, ACTH, FSH, and LH all act at their target organs by binding with G-protein coupled receptors that activate the cAMP second-messenger system (see p. 97). GH and PRL both exert their effects via a different second-messenger pathway, which we have not previously mentioned—the **JAK/STAT** pathway. Binding of these hormones to their target-cell surface membrane receptors on the ECF side activates the enzyme *Janus kinase (JAK)* attached to the cytosolic side of the receptor. JAK phosphorylates *signal transducers and activators of transcription (STAT)* within the cytosol. Phosphorylated STAT moves to the nucleus and turns on gene transcription, resulting in the synthesis of new proteins that carry out the cellular response.

Hypothalamic releasing and inhibiting hormones that regulate secretion in the anterior pituitary are delivered to it by the hypothalamic–hypophyseal portal system

None of the anterior pituitary hormones are secreted at a constant rate. Even though each of these hormones has a unique control system, there are some common regulatory patterns. The two most important factors that regulate se-

cretion of anterior pituitary hormone are (1) hypothalamic hormones and (2) feedback by target gland hormones.

Because the anterior pituitary secretes hormones that control the secretion of various other hormones, it has long had the undeserved title of “master gland.” It is now known that the release of each of the anterior pituitary hormones is largely controlled by still other hormones produced by the hypothalamus, and that secretion of these regulatory neurohormones in turn is controlled by a variety of neural and hormonal inputs to the hypothalamic neurosecretory cells.

Role of Hypothalamic Releasing and Inhibiting Hormones

The secretion of each anterior pituitary hormone is stimulated or inhibited by hypothalamic **hypophysiotropic** (*hypophysis* means “pituitary”) **hormones**. Depending on their actions, these hormones are called **releasing hormones** or **inhibiting hormones**. Their names and basic functions are:

1. **Thyrotropin-releasing hormone (TRH)**: Stimulates release of TSH (thyrotropin) and prolactin.
2. **Corticotropin-releasing hormone (CRH)**: Stimulates release of ACTH (corticotropin).
3. **Gonadotropin-releasing hormone (GnRH)**: Stimulates release of FSH and LH (gonadotropins).
4. **Growth hormone–releasing hormone (GHRH)**: Stimulates release of growth hormone.
5. **Growth hormone–inhibiting hormone (GHIH)**: Inhibits release of growth hormone and TSH.
6. **Prolactin-releasing hormone (PRH)**: Stimulates release of prolactin.
7. **Prolactin-inhibiting hormone (PIH)**: Inhibits release of prolactin.

Also, in most vertebrates, including birds, amphibians, and fishes, there is evidence of a **gonadotropin-inhibitory hormone (GnIH)**. Most of these are small peptides, although PIH is **dopamine** (the neurotransmitter found in the “pleasure” pathways in the brain).

Note that vertebrate hypophysiotropic hormones in most cases are involved in a three-hormone hierarchical chain of command (Figure 7-12): The hypothalamic hypophysiotropic hormone (hormone 1) controls the output of an anterior pituitary tropic hormone (hormone 2). This tropic hormone in turn regulates secretion of the target endocrine gland's hormone (hormone 3), which exerts the final physiological effect. This three-hormone sequence is called an **endocrine axis**, as in the hypothalamus–pituitary–thyroid axis.

Although scientists originally proposed a neat one-to-one correspondence—one hypophysiotropic hormone for each anterior pituitary hormone—it is now clear that many of the hypothalamic hormones have more than one effect, so their names indicate only the function that was initially attributed to them. Moreover, a single anterior pituitary hormone may be regulated by two or more hypophysiotropic hormones. Several substances elicit release of prolactin in certain species, for example. Note also that some of these hormones exert opposing effects. For example, **growth hormone–releasing hormone (GHRH)** stimulates growth hormone secretion, whereas **growth hormone–inhibiting hormone (GHIH)**, also known as **somatostatin**, inhibits it. The output of the anterior pituitary growth hormone secreting cells (that is, the rate of growth hormone secretion) in response to two such opposing inputs depends on the relative concentrations of these hypothalamic hormones as well as

on the intensity of other regulatory inputs. This is analogous to the output of a nerve cell (that is, the rate of action potential propagation) depending on the relative magnitude of excitatory and inhibitory synaptic inputs (EPSPs and IPSPs) to it (see p. 137).

Role of the Hypothalamic–Hypophyseal Portal System

The hypothalamic regulatory hormones reach the anterior pituitary by means of a unique vascular link. In contrast to the direct neural connection between the hypothalamus and posterior pituitary, the link between the hypothalamus and anterior pituitary is an unusual capillary-to-capillary connection, the **hypothalamic–hypophyseal portal system**. A portal system is a vascular arrangement in which venous blood flows directly from one capillary bed through a connecting vessel to another capillary bed before going back to the heart. The largest and best-known portal system is the *hepatic portal* system (see p. 685). Although much smaller, the hypothalamic–hypophyseal portal system is no less important, because it provides a critical link between the brain and much of the endocrine system. It begins in the base of the hypothalamus with a group of capillaries that recombine into small portal vessels, which pass down through the connecting stalk into the anterior pituitary. Here they branch to form most of the anterior pituitary capillaries, which in turn drain into the venous system (Figure 7-13).

As a result, almost all the blood supply to the anterior pituitary must first pass through the hypothalamus. Because materials can be exchanged between the blood and surrounding tissue only at the capillary level, the hypothalamic–hypophyseal portal system provides a route where releasing and inhibiting hormones can be picked up at the hypothalamus and delivered immediately and directly to the anterior pituitary at relatively high concentrations, completely bypassing the general circulation.

The axons of the neurosecretory neurons that produce the hypothalamic regulatory hormones terminate on the capillaries at the origin of the portal system. These hypothalamic neurons secrete their (neuro) hormones in the same way as the hypothalamic neurons that produce vasopressin and oxytocin, but into the portal vessels rather than into the general circulation.

Control of Hypothalamic Releasing and Inhibiting Hormones

What regulates the secretion of these hypophysiotropic hormones? Like other neurons, the neurons secreting these regulatory hormones receive abundant input of information (both neural and hormonal and both excitatory and inhibi-

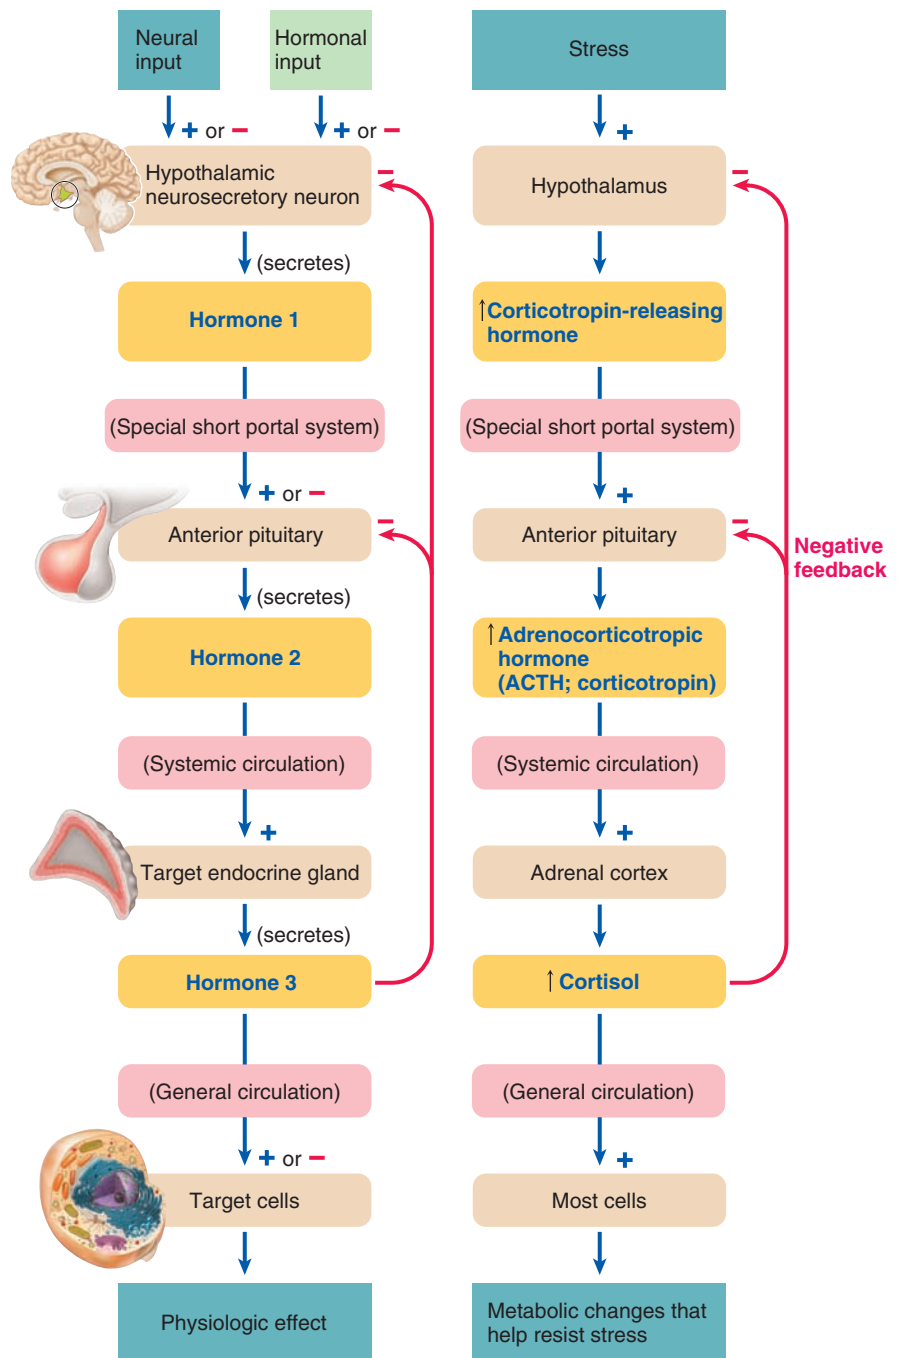

FIGURE 7-12 Hierarchic chain of command in endocrine control.

tory) that they must integrate. Studies are still in progress to unravel the complex neural input from many diverse areas of the brain to the hypophysiotropic secretory neurons. Some of these inputs carry information about a variety of environmental conditions. One example is the marked increase in the secretion of corticotropin-releasing hormone (CRH) in response to stressful situations (Figure 7-12).

FIGURE 7-13 Vascular link between the hypothalamus and anterior pituitary.

© Cengage Learning, 2013

Numerous neural connections also exist between the hypothalamus and the portions of the brain concerned with emotions (such as the *amygdala*—see p. 187). Thus, secretion of hypophysiotropic hormones can be greatly influenced by emotions. The reproductive irregularities sometimes experienced by animals maintained under stressful conditions are a common manifestation of this relationship.

In addition to being regulated by different regions of the brain, the hypophysiotropic neurons are also controlled by various chemical inputs that reach the hypothalamus through the blood. Unlike other regions of the brain, portions of the hypothalamus are not guarded by the blood-brain barrier, so the hypothalamus can easily monitor chemical changes in the blood. The most common blood-borne factors that influence hypothalamic neurosecretion are the negative-feedback effects of either anterior pituitary or target gland hormones, to which we now turn our attention.

Target gland hormones inhibit hypothalamic and anterior pituitary hormone secretion via negative feedback

In most cases, hypophysiotropic hormones initiate a three-hormone sequence: (1) hypophysiotropic hormone, (2) anterior pituitary tropic hormone, and (3) peripheral target-endocrine gland hormone (Figure 7-12). Typically, in addition to producing its physiologic effects, the target gland hormone also acts to suppress secretion of the tropic hormone that is driving it. This negative feedback is accomplished by the target gland hormone acting either directly on the pituitary itself or on the release of hypothalamic hor-

mones, which in turn regulate anterior pituitary function. As an example, consider the CRH–ACTH–cortisol system. Hypothalamic CRH stimulates the anterior pituitary to secrete ACTH (corticotropin), which in turn stimulates the adrenal cortex to secrete cortisol. The final hormone in the system, cortisol, inhibits the hypothalamus to reduce CRH secretion and also acts directly on the corticotropes in the anterior pituitary to reduce synthesis of pro-opiomelanocortin (POMC) and ACTH secretion. Through this double-barreled approach, cortisol exerts negative-feedback control to stabilize its own plasma concentration. If plasma cortisol levels start to rise above a prescribed set level, cortisol suppresses its own further secretion by these inhibitory actions. If plasma cortisol levels fall below the desired set point, cortisol's inhibitory actions are reduced, so cortisol secretion (CRH–ACTH) increases accordingly. The other target-gland hormones act by similar negative-feedback loops to maintain their plasma levels relatively constant at a set point. For example, feedback of testosterone to the hypothalamus maintains levels of LH, FSH, and sex steroids via GnRH production. Male mammals injected with testosterone-like steroids can become sterile because of this feedback, which causes FSH levels to decline. Birth control pills with female sex steroids work similarly.

The one exception to the negative-feedback relationship just described is the preovulatory positive-feedback effect of estrogen on LH secretion in female mammals. This causes an extremely dramatic rise in LH secretion that triggers ovulation. This relationship is discussed further in Chapter 16.

Diurnal rhythms are superimposed on this type of stabilizing negative-feedback regulation; that is, the set point changes as a function of the time of day. Furthermore, other controlling inputs may break through the negative-feedback

control to alter hormone secretion (that is, change the set point level) at times of special need. For example, stress raises the set point for cortisol secretion.

In addition, other hormones outside a particular sequence may also exert important influences, either stimulatory or inhibitory, on the secretion of hypothalamic or anterior pituitary hormones within a given sequence. For example, even though estrogen is not in the direct chain of command for prolactin secretion, this sex steroid notably enhances prolactin secretion by the anterior pituitary. This is but one example of the common phenomenon in the endocrine system that one seemingly unrelated hormone can have pronounced effects on the secretion or actions of another hormone.

7.4 Endocrine Control of Growth and Development in Vertebrates

Next we turn to growth and postnatal development, body-wide processes that are coordinated by central glands, and sometimes involve peripheral ones. Both are examples of a regulated change (p. 17) as opposed to a homeostatic process. Development involves *differentiation* of cells into specific functions, whereas growth requires net synthesis of proteins and includes lengthening of the long bones (the bones of the extremities) as well as increases in the size and number of cells in the soft tissues throughout the body. Weight gain alone is not synonymous with growth as it is meant here, because weight gain may occur as a result of retention of excess H₂O or fat without true structural growth of tissues. If the pituitary of a young vertebrate animal is surgically removed, the animal ceases growth; only by the administration of extracts of the pituitary gland can this defect be partially remedied.

Growth depends on growth hormone but is influenced by other factors as well

Although, as the name implies, **growth hormone (GH)** is absolutely essential for growth, it alone is not wholly responsible for determining the rate and final magnitude of growth in a given animal. The following factors also affect an animal's growth potential:

- *An adequate diet*, including sufficient total protein and ample essential amino acids to accomplish the protein

synthesis necessary for growth. Malnourished animals never achieve their full growth potential. The growth-stunting effects of inadequate nutrition are most profound when they occur in infancy. In severe cases, the animal may be locked into irreversible stunting of body growth and neural development. For example, about 70% of the total growth of the human brain occurs in the first two years of life. In contrast, mammals cannot exceed a *genetically determined maximum* by eating more than an adequate diet. The excess food intake produces obesity instead of growth in stature (this is not true of fish, as you will see).

- *Freedom from chronic disease and stressful environmental conditions.* Stunting of growth under adverse circumstances is due in large part to the prolonged stress-induced secretion of glucocorticoid (e.g., cortisol) secretion from the adrenal cortex. Glucocorticoids exert several potent antigrowth effects, such as promoting protein breakdown, inhibiting growth in the long bones in land vertebrates, and blocking the secretion of GH. This applies to aquatic vertebrates also; fish grown in modern aquaculture facilities do not maximize their growth potential, because of the metabolic costs associated with crowding. Even though sickly or stressed animals do not grow well, if the condition is rectified before adult size is achieved, they can rapidly catch up to their normal growth curve through a remarkable spurt in growth.
- *Normal concentrations of growth-influencing hormones.* In growing animals, numerous genes code for particular proteins and protein regulators of growth. In addition to GH, peripheral hormones, including thyroid hormone, insulin, and the sex hormones, play secondary roles in promoting growth.

Rapid-Growth Periods The rate of growth is not continuous in animals, nor are the factors responsible for promoting growth the same throughout the growth period. In mammals, fetal growth is promoted largely by certain hormones from the placenta (see p. 804), with the size at birth being determined principally by genetic and environmental factors. GH and other nonplacental hormonal factors begin to play an important role in regulating growth after birth. Genetic and nutritional factors also strongly affect growth during this period. In addition, day length affects growth in juvenile animals because day length influences energy intake and energy expenditure. For example, exposure of an animal to short day lengths, as occurs seasonally in northern and southern latitudes, results in long nocturnal periods of food deprivation. During the comparatively short light period, large amounts of food are consumed, which makes available to the tissues increased concentrations of amino acids. In a growing animal, these dietary amino acids are particularly important for protein synthesis (repair, growth, and maintenance) as well as storage for use in subsequent periods of food deprivation. Normally, when the supply of amino acids exceeds the protein synthesis capacity of the animal, the excess amino acids are oxidized and thus lost to the animal. However, during periods of food unavailability such as overnight fasting, protein synthesis rates drop significantly, which may severely limit growth rates.

Unlike birds and mammals, which reach a maximum body size and then cease growing, most cultured fish species

continue to grow if food supplies remain available. However, species such as trout show periodic growth spurts, which depend on season and stage of development. For example, growth is reduced during the winter months as well as during the reproductive period. This is due in part to the lowered energy requirements of fishes because they are ectotherms (Chapter 15). Superimposed on the seasonal variations in growth rate in many fishes is a 14-day semilunar cycle of growth rate, which correlates with a rhythm in food consumption. Slow growth rates are associated with either the full or new moon, which are associated with reduced food requirements.

In contrast, most mammals display two periods of rapid growth—a postnatal growth spurt during their first years of life and a pubertal growth spurt during adolescence. Much of the growth observed in young animals is due to the increase in body protein, with skeletal muscle showing the greatest percentage change in body composition. Growth is achieved when protein synthesis rates are higher than protein breakdown rates. The productive efficiency of growing farm animals is determined by the proportion of nutrients partitioned to fat relative to muscle, and by the rate at which growth occurs.

Before puberty there is little sexual difference in height or weight in most mammals. During puberty, a marked acceleration in linear growth takes place because of the lengthening of the long bones, with males outgrowing females in most species (with some notable exceptions such as spotted hyenas and blue whales). The mechanisms responsible for the pubertal growth spurt are not clearly understood. Apparently both genetic and hormonal factors are involved. During rapid mammalian growth in puberty, there is a marked increase in the magnitude and frequency of GH release, which induces **insulin-like growth factor (IGF-I)** expression in the liver and other tissues, including the skeleton. In turn, systemic and local IGF-I contributes to the acceleration of growth during this time. Furthermore, **androgens** (“male” sex hormones), whose secretion increases dramatically at puberty, also contribute to the pubertal growth spurt by promoting protein synthesis and bone growth. The potent androgen from the male testes, testosterone, is of greatest importance in promoting a sharp increase in body size in adolescent males in most species, as well as development of male secondary sexual characteristics. In contrast, the less potent adrenal androgens from the adrenal gland, which also show a sizable increase in secretion during adolescence, are most likely important in the female pubertal growth spurt. Although estrogen secretion by the ovaries also begins during puberty, inducing development of female secondary sex characteristics, it is unclear what role this “female” sex hormone may play in the pubertal growth spurt in females. There is no doubt that testosterone and estrogen both ultimately act on bone to halt its further growth so that full adult height is attained by the end of adolescence.

Growth hormone exerts metabolic effects not related to growth

In addition to promoting growth, GH has important metabolic effects and enhances the immune system. In fishes GH has partially retained ancestral osmoregulatory features independent of its growth-promoting functions. We briefly describe GH's metabolic actions before turning our attention to its growth-promoting actions.

Metabolic Actions To exert its metabolic effects, GH binds directly with receptors on its target organs, namely adipose tissue, skeletal muscles, and liver. GH increases fatty acid levels in the blood by enhancing the breakdown of triglyceride fat stored in adipose tissue, and it increases blood glucose levels by decreasing glucose uptake by muscles and increasing glucose output by the liver. Muscles use the mobilized fatty acids instead of glucose as a metabolic fuel. Thus, the overall metabolic effect of GH is to mobilize fat stores as a major energy source while conserving glucose for glucose-dependent tissues such as the brain. The brain can use only glucose as its metabolic fuel, yet nervous tissue cannot store much glycogen (stored glucose polymer). This metabolic pattern is suitable for maintaining the body during prolonged fasting or other situations when the body's energy needs exceed available glucose stores. GH also stimulates amino acid uptake and protein synthesis, but, in most tissues, it does so *indirectly* to accomplish these growth-promoting actions. In some cases, however, it does so directly, such as protein synthesis in the liver, diaphragm, and heart. Before examining the means by which GH indirectly promotes growth, let's summarize its metabolic effects: It increases blood fatty acids, increases blood glucose and spares glucose for the brain, and stimulates protein synthesis (decreasing blood amino acids in the process).

Indirect effects of growth hormone are exerted through insulin-like growth factors

GH's indirect growth-promoting actions are mediated by IGFs (as we noted earlier), which act on the target cells to cause growth of both soft tissues and bones. IGFs are produced in many tissues and have endocrine, paracrine, and autocrine actions. Originally called **somatomedins**, these peptide mediators are now preferentially called insulin-like growth factors because they are structurally and functionally similar to insulin. Like insulin, IGFs exert their effects largely by binding with receptor-enzymes that activate designated effector proteins within the target cell by phosphorylating the tyrosines in the protein (the tyrosine kinase pathway; see p. 96). There are two IGFs—IGF-I and IGF-II. Fish are the first vertebrate group that has a complete system of hormones and receptors for the insulin, IGF-I and IGF-II molecules.

IGF-I Synthesis of IGF-I in mammals is stimulated by GH and mediates most of this hormone's growth-promoting actions. The major source of circulating IGF-I is the liver, which (acting as a peripheral endocrine gland) releases this peptide product into the blood in response to GH stimulation. However, IGF-I is produced in many if not most tissues, although it is not released into the blood from these other sites. Scientists have proposed that IGF-I produced locally in target tissues may act through paracrine means (see p. 91) for at least some of the growth-hormone-induced effects. Local production of IGF-I in target tissues may possibly be more important than delivery of blood-borne IGF-I during this time.

Production of IGF-I is controlled by a number of factors other than GH in humans, including nutritional status, age, and tissue-specific factors as follows:

- IGF-I production depends on adequate nutrition. Inadequate food intake results in reduced IGF-I production,

apparently brought about by decreased sensitivity to GH of the tissues that produce IGF-I. As a result, changes in circulating IGF-I levels do not always coincide with changes in GH secretion. For example, fasting decreases IGF-I levels even though it increases GH secretion.

- Age-related factors also influence IGF-I production. A dramatic increase in circulating IGF-I levels accompanies the moderate increase in GH at puberty, which may, of course, be an important factor in the pubertal growth spurt.
- Finally, various tissue-specific stimulatory factors can increase IGF-I production in particular tissues. To illustrate, the gonadotropins and sex hormones stimulate IGF-I production within reproductive organs such as the testes in males and the ovaries and uterus in females.

Thus, control of IGF-I production is complex and subject to a variety of systemic and local factors.

IGF-II In contrast to IGF-I, IGF-II production does not depend on GH. IGF-II is known to be important during fetal development. Unlike IGF-I, IGF-II does not increase during the pubertal growth spurt. IGF-II continues to be produced during adulthood and may be involved in muscle growth. Recently, a study found that a simple mutation that increased IGF-II gene activity in pig muscle resulted in a 3 to 4% growth in meat (muscle) mass.

From the preceding discussion of the factors involved in controlling growth and development, you can see that many gaps still exist in the state of knowledge in this important area.

Growth hormone/IGF-I promote growth of soft tissues by stimulating hyperplasia and hypertrophy

GH stimulates growth of both soft tissues and the skeleton. GH (acting through IGF-I) is thus *trophic* (p. 272), promoting growth of soft tissues by (1) increasing the number of cells (**hyperplasia**) and (2) increasing the size of cells (**hypertrophy**). GH increases the number of cells by stimulating cell division and by preventing apoptosis (programmed cell death). GH increases the size of cells by favoring synthesis of proteins, the main structural component of cells. GH stimulates almost all aspects of protein synthesis while it simultaneously inhibits protein degradation. It promotes the uptake of amino acids (the raw materials for protein synthesis) by cells, decreasing blood amino acid levels in the process. Furthermore, it stimulates the cell machinery responsible for accomplishing protein synthesis according to the cell's genetic code. It increases DNA and RNA synthesis and increases incorporation of amino acids into the new proteins at the ribosomal level.

Growth-Promoting Actions on Bones Growth of the long bones, resulting in increased height, is the most dramatic effect of GH. Bone is a living tissue. Being a form of connective tissue, it consists of cells and an extracellular organic matrix known as **osteoid** that is produced by the cells. The bone cells that produce the organic matrix are known as **osteoblasts** ("bone-formers"). Osteoid is composed of col-

lagen fibers (see p. 65) in a mucopolysaccharide-rich semi-solid gel. This matrix has a rubbery consistency and is responsible for the tensile strength of bone (the resilience of bone to breakage when tension is applied). Bone is hardened by impregnation with **hydroxyapatite crystals**, which consist primarily of precipitated $\text{Ca}_3(\text{PO}_4)_2$ (calcium phosphate) salts. These inorganic crystals provide the bone with compressional strength (the ability of bone to hold its shape when squeezed or compressed). Bones have structural strength approaching that of reinforced concrete, yet they are not brittle and are much lighter in weight, as a result of the structural blending of an organic scaffolding hardened by inorganic crystals. **Cartilage** is similar to bone, except that living cartilage is not calcified.

A long bone basically consists of a fairly uniform cylindrical shaft, the **diaphysis**, with a flared articulating knob at either end, an **epiphysis**. In a growing bone, the diaphysis is separated at each end from the epiphysis by a layer of cartilage known as the **epiphyseal plate** (Figure 7-14a). The central cavity of the bone is filled with bone marrow, which is the site of blood cell production (see p. 392).

Growth in *thickness* of bone is achieved by the addition of new bone on top of the already existing bone on the outer surface. This growth occurs through activity of **osteoblasts** within the **periosteum**, a connective tissue sheath that covers the outer bone surface. As new bone is being deposited by osteoblast activity on the external surface, other cells within the bone, the **osteoclasts** ("bone breakers"), dissolve the bony tissue on the inner surface adjacent to the marrow cavity (see p. 325 for more on these cells). In this way, the marrow cavity is enlarged to keep pace with the increase in the circumference of the bone shaft.

Growth in *length* of long bones is accomplished by a different mechanism from growth in thickness. Bones grow in length as a result of proliferation of the cartilage cells, or **chondrocytes**, in the epiphyseal plates (Figure 7-14b). During growth, cartilage cells on the outer edge of the plate next to the epiphysis divide and multiply, temporarily widening the epiphyseal plate. As new chondrocytes are formed on the epiphyseal border, the older cartilage cells toward the diaphyseal border are enlarging. This combination of proliferation of new cartilage cells and hypertrophy of maturing chondrocytes temporarily widens the epiphyseal plate. This thickening of the intervening cartilaginous plate pushes the bony epiphysis farther away from the diaphysis. Soon the matrix surrounding the oldest hypertrophied cartilage becomes calcified. Because cartilage lacks its own capillary network, the survival of cartilage cells depends on diffusion of nutrients and O_2 through the matrix, a process prevented by the deposition of calcium salts. As a result, the old nutrient-deprived cartilage cells on the diaphyseal border die. As osteoclasts clear away dead chondrocytes and the calcified matrix that imprisoned them, the area is invaded by osteoblasts, which swarm upward from the diaphysis, trailing their capillary supply with them. These new tenants lay down bone around the persisting remnants of disintegrating cartilage until bone entirely replaces the inner region of cartilage on the diaphyseal side of the plate. When this **ossification** ("bone formation") is complete, the bone on the diaphyseal side has lengthened and the epiphyseal plate has returned to its original thickness. The cartilage that bone has replaced on the diaphyseal end of the plate is as thick as the new cartilage on the epiphyseal end of the plate. Thus, bone

growth is made possible by the growth and death of cartilage, which acts like a “spacer” to push the epiphysis farther out while it provides a framework for future bone formation on the end of the diaphysis.

GH promotes growth of bone in both thickness and length. It stimulates the proliferation of epiphyseal cartilage, thereby making space for more bone formation, and also stimulates osteoblast activity. GH can promote lengthening of long bones as long as the epiphyseal plate remains cartilaginous, or is “open.” At the end of adolescence, under the influence of the sex hormones, these plates completely ossify, or “close,” so that the bones can grow no further in length despite the presence of GH. Thus, after the plates are closed, the individual animal does not grow any taller.

Growth hormone secretion is regulated by two hypophysiotropic hormones and influenced by a variety of other factors

The control of GH secretion is complex, with two hypothalamic hypophysiotropic hormones playing a key role.

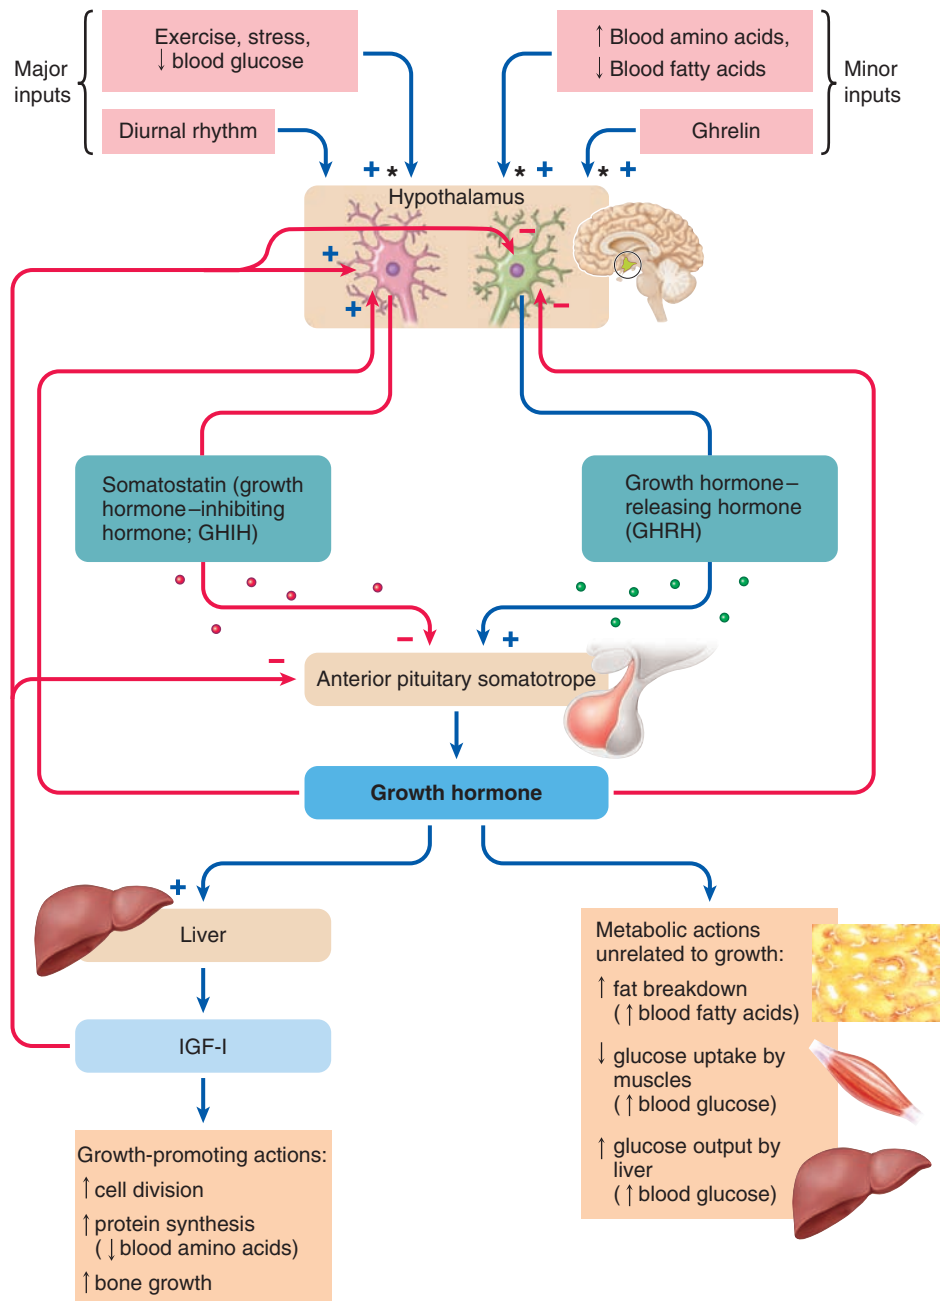

Growth Hormone-Releasing Hormone and Growth Hormone-Inhibiting Hormone Two antagonistic regulatory hormones from the hypothalamus are involved in controlling GH secretion: growth hormone-releasing hormone (GHRH), which is stimulatory, and growth hormone-inhibiting hormone (GHIH or somatostatin), which is inhibitory (Figure 7-15). Both GHRH and somatostatin act on the anterior

pituitary somatotropes by binding with G-protein coupled receptors linked to the cAMP second-messenger pathway, with GHRH increasing cAMP and somatostatin decreasing cAMP.

As with the other hypothalamus–anterior pituitary axes, negative-feedback loops participate in regulating GH secretion. Complicating the feedback loops for the hypothalamus–pituitary–liver axis is the fact that GH secretion is directly regulated by both stimulatory and inhibitory factors. Therefore negative-feedback loops involve both inhibition of stimulatory factors and stimulation of inhibitory factors. GH stimulates IGF-I secretion by the liver, and IGF-I in turn is the primary inhibitor of GH secretion by the anterior pituitary. IGF-I inhibits the somatotropes in the pituitary directly and further decreases GH secretion by inhibiting GHRH-secreting cells and stimulating the somatostatin-secreting cells in the hypothalamus, thus decreasing hypothalamic stimulation of the somatotropes. Furthermore, GH itself inhibits hypothalamic GHRH secretion and stimulates somatostatin release.

Other Factors That Influence GH Secretion A number of factors influence GH secretion by acting on the hypothalamus. GH secretion displays a well-characterized circadian rhythm. In a diurnal mammal, through most of the day GH levels tend to be low and fairly constant. About one hour after the onset of deep sleep, however, GH secretion markedly increases, then rapidly drops over the next several hours.

Superimposed on this circadian fluctuation in GH secretion are further bursts in secretion, in response to exercise, stress, and hypoglycemia (low blood glucose), the major stimuli for increased secretion. The benefit of increased GH secretion during these situations when energy demands outstrip the body's glucose reserves is presumably to conserve glucose for the brain and to provide fatty acids as an alternative energy source for muscle. Because GH uses up fat stores and promotes synthesis of body proteins, it encourages a change in body composition away from adipose deposition toward increased muscle protein. Accordingly, the increased GH secretion that accompanies exercise may at least in part mediate exercise's effects in reducing percentage of body fat while increasing lean body mass.

*These factors all increase growth hormone secretion, but it is unclear whether they do so by stimulating GHRH or inhibiting GHIH somatostatin, or both.

FIGURE 7-15 Control of growth hormone secretion.

© Cengage Learning, 2013

A rise in blood amino acids after a high-protein meal also enhances GH secretion. In turn, GH promotes use of these amino acids for protein synthesis. GH release is also stimulated by a decline in level of blood fatty acids. Because of the fat-mobilizing actions of GH, such regulation helps maintain fairly constant blood fatty-acid levels. Finally, *ghrelin*, a potent appetite stimulator released from the stomach, also stimulates GH secretion (see p. 712). This “hunger hormone” may play a role in coordinating growth with nutrient acquisition.

Growth Hormone Administration GH is readily available for administering to humans and to domestic and laboratory animals. In humans, it is used to treat dwarfism (and abused by some athletes). Administering GH to swine dramatically increases protein deposition and muscle mass in addition to reducing adipose tissue growth. However, deposition of greater lean tissue requires an increased amount of amino acids in the diet of treated animals. Uptake of glucose into target tissues is also reduced, which results in increased concentrations of both plasma glucose and insulin. In swine, concentrations of GH peak between four and seven hours after subcutaneous injection and are associated with increased plasma IGF-I concentrations as well. However, in poultry, unless GH is administered in pulses, there is no effect of exogenously administered GH on growth.

Administering GH to dairy cows results in an exquisite coordination of metabolism to meet the nutrient needs associated with increased synthesis of milk components (Table 7-2). Glucose production and oxidation are modified to supply the increased glucose needs of the mammary glands with such precision that plasma glucose concentrations remain unaltered. When feed intake does not meet the energy needs required for milk production, treated animals must capitalize on alternate energy sources such as fatty acids.

Prolactin has a wide range of growth-related effects, including lactogenesis

Prolactin (p. 288) is another central hormone involved in growth and development, for example, mammary gland development and lactation (milk production) to aid growth of newborn mammals. The first suggestion that a hormone of the anterior pituitary might affect lactation in mammals arose from the experiments of Stricker and Grueter in 1928, who found that lactation could be elicited in the pseudo-pregnant rabbit, before and after spaying, by injections of an anterior pituitary extract. Prolactin was eventually isolated and found to be essential for initiating and maintaining lactation (only in mammals, whose very name is based on this). **Lactogenesis**, the initiation of lactation, involves mammary cell differentiation and increased activity of the enzymes responsible for the production of milk components (see Chapter 16).

As we noted earlier (p. 288), prolactin has remarkably diverse roles. In addition to influencing parental behavior, some roles bear no relationship to reproduction. Recent studies suggest that prolactin in mammals may enhance the immune system and support the development of new blood vessels at the tissue level in both sexes, another growth function. But what about other vertebrates that lack milk? Lactogenic (“milk generating”) effects have been found (by administering prolactin to laboratory mammals) in the pituitary extracts of mammals, fish, amphibians, reptiles, and birds, showing that all vertebrates have this hormone. Obviously, it is not involved in lactogenesis in nonmammals! For example, Riddle and coworkers in 1931 found that administering pituitary extract to pigeons resulted in development of the crop sac (see p. 668). Subsequent work demonstrated that this response in birds is caused by the same hormone that induces lactation in mammals. Prolactin in birds is also important for brood patch formation (see the accompanying box, *A Closer Look at Adaptation: Brood Patch Development: Some Have It, Others Don't!*), as well as migratory

TABLE 7-2 Effect of Bovine Somatotropin Supplement of Lactating Cows on Specific Tissues and Physiological Processes

Tissue	Process Affected during First Few Days and Weeks of Supplement	
Mammary	↑	Synthesis of milk with normal composition
	↑	Uptake of all nutrients used for milk synthesis
	↑	Activity per secretory cell
	↓	Loss of secretory cells (i.e., enhanced persistence)
	↑	Blood flow consistent with increase in milk yield
Liver	↑	Basal rates of gluconeogenesis
	↓	Ability of insulin to inhibit gluconeogenesis
	φ	Glucagon effects on gluconeogenesis and/or glycogenolysis
Adipose	↓	Basal lipogenesis if in positive energy balance
	↑	Basal lipolysis if in negative energy balance
	↓	Ability of insulin to stimulate lipogenesis
	↑	Ability of insulin to inhibit lipolysis
	↑	Ability of catecholamines to stimulate lipolysis
Muscle	↓	Uptake of glucose
Pancreas	φ	Basal or glucose-stimulated secretion of insulin
	φ	Basal or insulin/glucose-stimulated secretion of glucagon
Kidney	↑	Production of 1,25 vitamin D ₃
Intestine	↑	Absorption of Ca, P, and other minerals required for milk
	↑	Ability of 1,25 vitamin D ₃ to stimulate calcium-binding protein
	↑	Calcium-binding protein
Whole Body	↓	Oxidation of glucose
	↑	Fatty-acid oxidation if in negative energy balance
	φ	Insulin and glucagon clearance rates
	φ	Energy expenditure for maintenance
	↑	Energy expenditure consistent with increase in milk yield (i.e., heat per unit of milk not changed)
	↑	Cardiac output consistent with increases in milk yield
	↑	Productive efficiency (milk per unit of energy intake)

Note: Changes (↑ = increased, ↓ = decreased, φ = no change).

behavior in birds and mammals. Prolactin's effects are explored in more detail in Chapter 16.

Further evidence of the complex role of prolactin is suggested by the finding that the gene-encoding prolactin receptor is widely expressed in avian peripheral tissues, including kidneys, skin, brood patch, gut, gonads, adrenal glands, liver, adipose tissue, and spleen, whereas in the CNS the

A Closer Look at Adaptation

Brood Patch Development: Some Have It, Others Don't!

The vast majority of birds incubate their eggs by transfer of heat between parts of their body, usually but not always their ventral surface, and the clutch of eggs. That region of the incubating bird in contact with the egg is commonly termed the incubation or **brood patch**. Hormonal regulation of this patch of skin differs between sexes as well as species of birds.

Although the evolution of this structure is open to conjecture, one possibility is that the appearance of a brood patch was a definitive step in the evolution of birds from reptiles, and it has been thus suggested to share a common ancestry with the mammalian mammary gland. The nature, formation, and structure of this patch varies enormously between species, reflecting the diverse mechanisms and methods adopted by different species in the incubation of eggs. In some birds such as the domestic pigeon and ring dove, there is a form of pocket or apterium on the ventral surface of both sexes, which is devoid of feathers throughout adult life. In other species, patch formation occurs periodically and is closely related to the period of egg laying and incubation. Furthermore, although both sexes may have the potential to develop a brood patch, it is a general observation that the patch only develops in the sex actually involved in incubation. There is also a relationship between the gender that incubates, and the form of steroid that is most effective, in combination with prolactin, to produce a full brood patch. In those species in which the female alone incu-

The brood patch of a female bluebird (*Sialia sialis*). Its function is to transfer heat to the developing chicks. Brood patch development is hormonally controlled, primarily by prolactin secretion from the adenohypophysis. In some species, only the female develops a brood patch, while in others, both the male and female develop patches.

bates, it is estrogen, whereas in those species in which the male incubates, it is androgen. Consistent with this, species that might be considered as intermediate, such as the California quail and laughing gull, are sensitive, in terms of brood patch development, to both estrogen plus prolactin and androgen plus prolactin.

In most species, brood patch development involves a number of morphological changes to the ventral body area: defeathering (mainly down feathers); a significant increase in the folding of the skin, together with an infiltration of leukocytes (edema formation); a thickening of the cornified

layer of the ventral skin surface (epidermal hyperplasia); and an increase in both size and number of local blood vessels (vascularization). The structure is surprisingly sophisticated in that the musculature of arterioles supplying blood to the patch also increases and thus can shut down blood flow to this region when the parent is off the nest. In some species, such as the house sparrow (*Passer domesticus*), there is also an increase in the amount of underlying defatted tissue.

Taken together, these dramatic changes are superbly evolved to facilitate a closer contact and more effective heat transfer between the parenting bird and the surface of the eggs, while minimizing any possible damage caused to the skin by the sustained period of contact time. The function of the brood patch during the incubatory period of the breeding cycle is complex and multifactorial. Much still remains to be understood, and one early suggestion for a possible purpose of the patch, that the bird finds relief from the peripheral irritation of the developing brood patch by sitting on eggs, remains plausible.

Not all birds have such patches. For example, the northern gannet (see chapter opening picture) does not develop one and instead incubates its egg by increasing blood flow (and heat exchange) through the webbing in its feet. Because these birds dive into the cold waters of the Atlantic Ocean, this adaptation reduces potential heat loss to the environment.

gene is highly expressed in the anterior pituitary gland and in the hypothalamus.

In the previous sections, we discussed the major central endocrine glands of vertebrates, and noting the peripheral endocrine role of the liver. We now turn our attention to other peripheral glands.

7.5 Thyroid Gland

The **thyroid gland** is a major regulator of metabolism and other metabolic and developmental processes. Thyroid hormones are produced by endocrine cells arranged in a very characteristic anatomical structure called a *thyroid follicle*. In mammals the thyroid gland consists of two lobes of thyroid follicles joined in the middle by a narrow portion of the gland, giving it a bowtie shape (Figure 7-16a). The gland is even located in the appropriate place for a bow tie in a human, lying over the trachea just below the larynx. In contrast, the thyroid gland of most nonmammalian vertebrates consists of discrete clusters of thyroid follicles, sometimes central, sometimes paired, lying at varying distances lateral to the esophagus; in agnathans and most teleosts the thyroid

FIGURE 7-16 Anatomy of the thyroid gland. (a) Gross anatomy of the thyroid gland, anterior view. The thyroid gland lies over the trachea just below the larynx and consists of two lobes connected by a thin strip called the *isthmus*. (b) Light-microscope appearance of the thyroid gland. The thyroid gland consists primarily of colloid-filled spheres enclosed by a single layer of follicular cells.

consists of diffuse clusters of follicles distributed throughout the ventral region of the head. In spite of the varied gross morphology of the thyroid gland, the follicular structure is highly conserved and essential for the unique method of extracellular hormone synthesis utilized by this gland.

The major thyroid hormone secretory cells are organized into colloid-filled follicles

The major thyroid secretory cells, known as **follicular cells**, are arranged into fluid-filled spheres, each of which forms a functional unit called a **follicle**. On a microscopic section (Figure 7-16b), the follicles appear as rings of follicular cells enclosing an inner lumen filled with **colloid**, a substance that serves as an extracellular storage site for thyroid hormones.

The chief constituent of the colloid is a large, complex glycoprotein known as **thyroglobulin (Tg)**, within which are incorporated the thyroid hormones in their various stages of synthesis. Extracellular hormone storage is unique to the thyroid gland and probably exists because the thyroid evolved from an exocrine-secreting digestive organ called the endostyle. As we'll see, the colloid indirectly stores the scarce trace element iodine, which is an essential component of the thyroid gland, and prevents diffusion of the steroid-like thyroid hormone out of the colloid.

Thyroid hormone is synthesized and stored on the thyroglobulin molecule

The follicular cells of vertebrates produce two iodine-containing hormones derived from the amino acid tyrosine: **tetraiodothyronine (T₄, or thyroxine)** and **tri-iodothyronine (T₃)**. The prefixes *tetra* and *tri* and the subscripts 4 and 3 denote the number of iodine atoms incorporated into each of these hormones. These two hormones, together referred to as **thyroid hormone**, are important regulators of development and overall basal metabolic rate. The basic ingredients for thyroid hormone synthesis are tyrosine and iodine, both of which must be taken up from the blood by the follicular cells. Tyrosine, an amino acid, is synthesized in sufficient amounts by the body, so it is not an essential dietary requirement. By contrast, the iodine needed for thyroid hormone synthesis must be obtained from dietary intake. Dietary iodine (I) is reduced to iodide (I⁻) prior to absorption by the small intestine. The synthesis, storage, and secretion of thyroid hormone involve the following steps:

1. All steps of thyroid hormone synthesis take place on the thyroglobulin molecules within the colloid. Thyroglobulin itself is produced by the endoplasmic reticulum/Golgi complex of the thyroid follicular cells. The amino acid tyrosine becomes incorporated in the much larger thyroglobulin molecules as the latter are being produced. Once produced, tyrosine-containing thyroglobulin is exported from the follicular cells into the colloid by exocytosis (step 1 in Figure 7-17).
2. The thyroid captures I⁻ from the blood and transfers it into the colloid by means of an *iodide pump*, energy-requiring transport proteins located in the outer membranes of the follicular cells (step 2). The iodide pump is a symporter driven by the Na⁺ concentration gradient established by the Na⁺/K⁺ pump at the basolateral membrane (the outer membrane of the follicular cell in contact with the interstitial fluid). The iodide pump transports Na⁺ into the follicular cell down its concentration gradient and I⁻ into the cell against its concentration gradient. Almost all the I⁻ in the body is transported against its concentration gradient to become trapped in the thyroid for the purpose of thyroid hormone synthesis. Iodine serves no other known purpose in the vertebrate body.
3. Within the membrane–colloid interface, iodide is oxidized to “active” iodide by a membrane-bound enzyme, **thyroperoxidase (TPO)**, located at the luminal membrane, the membrane of the follicular cell in contact with the colloid (step 3). This active iodide exits through a channel in the luminal membrane to enter the colloid (step 4). Attachment of one iodine to tyrosine yields

1 Tyrosine-containing Tg produced within the thyroid follicular cells by the endoplasmic reticulum/Golgi complex is transported by exocytosis into the colloid.

2 Iodide is carried by secondary active transport from the blood into the colloid by symporters in the basolateral membrane of the follicular cells.

3 In the follicular cell, the iodide is oxidized to active form by TPO at the luminal membrane.

4 The active iodide exits the cell through a luminal channel to enter the colloid.

5a Catalyzed by TPO, attachment of one iodide to tyrosine within the Tg molecule yields MIT.

5b Attachment of two iodides to tyrosine yields DIT.

6a Coupling of one MIT and one DIT yields T₃.

6b Coupling of two DITs yields T₄.

7 On appropriate stimulation, the thyroid follicular cells engulf a portion of Tg-containing colloid by phagocytosis.

8 Lysosomes attack the engulfed vesicle and split the iodinated products from Tg.

9a T₃ and T₄ diffuse into the blood (secretion).

9b MIT and DIT are deiodinated, and the freed iodide is recycled for synthesizing more hormone.

FIGURE 7-17 Synthesis, storage, and secretion of thyroid hormone. Note that the organelles are not drawn to scale. The endoplasmic reticulum/Golgi complex are proportionally too small.

© Cengage Learning, 2013

- monoiodotyrosine (MIT) (step 5a). Attachment of two iodines to tyrosine yields di-iodotyrosine (DIT) (step 5b).
- Next, a coupling process occurs between the iodinated tyrosine molecules to form the thyroid hormones. Coupling of two DITs (each bearing two iodine atoms) yields tetraiodothyronine (T₄ or thyroxine), the four-iodine form of thyroid hormone (step 6b). Coupling of one MIT (with one iodine) and one DIT (with two iodines) yields tri-iodothyronine or T₃ (with three iodines) (step 6a). Coupling does not occur between two MIT molecules. All these products remain attached to thyro-

globulin by peptide bonds. Thyroid hormones remain stored in this form in the colloid until they are split off and secreted. Sufficient thyroid hormone is normally stored to supply the body's needs for several months.

Because these reactions occur within the thyroglobulin molecule, all the products remain attached to this large protein. Immobilized in this fashion they, contrary to their steroid-hormone-like behavior, cannot freely diffuse into the circulation after synthesis. Thyroid hormones remain stored in this form in the colloid until they are split off and

Molecular Biology and Genomics

Crosstalk between the Pituitary and Hypothalamus

The anterior pituitary consists of the pars distalis (PD) (main body of the pituitary gland) and the pars tuberalis (PT), which forms the stalk of the pituitary gland immediately adjacent to the base of the brain. As we have seen, the PD receives signals from the hypothalamus via the portal system to regulate the multiple cell types in this tissue. The PT forms a specialized tissue that expresses melatonin receptors and thus responds to the daily light–dark cycle that regulates seasonal changes in pituitary function. In turn, *retrograde signaling* from the PT directs the hypothalamus to govern neuroendocrine control of reproduction, food intake, and other seasonal characteristics. PT thyrotrophs do not express TRH receptors and are not under inhibitory control by the thyroid gland, and also do not produce the transcription factor *PIT1* that drives normal PD cell differentiation. PIT1 in

PD cells also regulates the genes for TSH and prolactin.

The primary cell type in the PT is a thyrotroph-like cell that is distinct from the thyrotrophs in the PD that secretes TSH to regulate the thyroid glands. In birds and mammals, the PT secretes TSH only locally, which then diffuses into the basal hypothalamus and binds to TSH receptors on the *tanycytes* (specialized cells in the ependymal layer) that line the third ventricle. In this fashion, these nonneural tanycytes can be induced to express the outer-ring (type 2) *deiodinase*, the enzyme that catalyzes the conversion of thyroxine to its biologically active form T_3 . This results in a local increase in T_3 concentration in the medial basal hypothalamus (MBH), which activates a major cascade of new secretory responses that drive reproduction and other centrally related functions, which have long

been recognized to be thyroid-hormone dependent. In seasonally breeding animals, the experimental introduction of TSH locally into the ventricle of the brain in animals exposed to winter photoperiod induces all the biological responses normally associated with summer photoperiod. Thus, it is the PT that initiates the response to spring photoperiods, relays the information to the brain, and activates the associated biology. In addition, it is believed that these local changes in thyroid hormone are required for neurogenesis within the tissue and this provides the basis for the long-term transformation in the cell biology of the brain. Thus, over a period of weeks and months, the animal transforms its physiology from winter to summer, readjusting a functional set point for homeostasis.

secreted. As a result of this unique extracellular synthetic process, researchers estimate that sufficient thyroid hormone to supply a mammal's needs for several months is normally stored in the colloid. Should a predator consume the thyroid gland of its prey, it would receive a physiologically significant dose upon consumption.

To secrete thyroid hormone, the follicular cells phagocytize thyroglobulin-laden colloid

The release of the thyroid hormones into the systemic circulation is a rather complex process, for two reasons. First, before their release T_4 and T_3 are still bound within the thyroglobulin molecule. Second, these hormones are stored in the follicular lumen, so they must be transported completely across the follicular cells to reach capillaries that course through the interstitial spaces between the follicles.

The process of thyroid hormone secretion essentially involves the follicular cells “biting off” a piece of colloid, breaking the thyroglobulin molecule down into its component parts, and “spitting out” the freed T_4 and T_3 into the blood. On appropriate stimulation for thyroid hormone secretion, the follicular cells internalize a portion of the thyroglobulin–hormone complex by phagocytizing a piece of colloid (step 7 of Figure 7-17). Within the cells, the membrane-enclosed droplets of colloid coalesce with lysosomes, whose enzymes split off the biologically active thyroid hormones, T_4 and T_3 , as well as the inactive iodotyrosines, MIT and DIT (step 8). The thyroid hormones, being lipophilic, pass through the outer membranes of the follicular cells and into the blood (step 9a).

The MIT and DIT have no known endocrine function. The follicular cells contain an enzyme that swiftly removes the iodine from MIT and DIT, allowing the freed iodine to be recycled for synthesis of more hormone (step 9b). Some intact thyroglobulin is also released into the general circulation, although this protein has no known physiological function.

For the most part, both T_4 and T_3 are transported bound to specific plasma proteins

Once released into the blood, the highly lipophilic thyroid hormone molecules very quickly bind with several plasma proteins. Less than 1% of the T_3 and less than 0.1% of the T_4 remain in the **unbound (free) form**. This is remarkable, considering that only the free portion of the total thyroid hormone pool has access to the target cell receptors and thus can exert a biological effect.

Three different plasma proteins synthesized within the liver are important in thyroid hormone binding: In mammals (excluding cats), **thyroxine-binding globulin (TBG)** selectively binds all thyroid hormones even though its name specifies only “thyroxine” (T_4); binding proteins in other species include **albumin**, which nonselectively binds many lipophilic hormones, including T_4 and T_3 ; and **transthyretin (TTR)**, which binds the remaining T_4 . TTR appears to be produced in the liver of amphibians and fish during transient periods of hyperthyroidism and more constantly in endotherms. TTR appears to be selectively secreted into the CSF by the choroid plexus of animals with a neocortex, supporting a role for this hormone in CNS development and function. The turnover of T_4 is comparatively slow in species that utilize TBG as a binding protein.

Most of the secreted T_4 is converted into T_3 outside the thyroid

In general, the proportion of T_4 and T_3 present in the thyroid gland of vertebrates is variable, although most thyroids secrete primarily T_4 , most likely because more DIT is made than MIT. Regardless, in the peripheral tissues (e.g., liver and kidney), most of the secreted T_4 is converted into T_3 , or *activated*, by an outer-ring deiodinase enzyme (Type II) that strips off one of its iodines. T_3 is the major biologically active form of thyroid hormone at the cellular level. T_4 can also be *inactivated* by inner-ring deiodinase (Type I) and converted into the metabolically inactive **reverse tri-iodothyronine**, or rT_3 . Peripherally produced T_3 can bind to receptors with 10 times the affinity of T_4 , giving peripheral cells the ability to activate their own hormone stimulation (or inactivate it by conversion to rT_3). It is now becoming apparent that regulation of these deiodinase enzymes is a major determinant of thyroid hormone stimulation of targets. For example, the stimulation of neuron growth during development of the brain is dependent on the deiodination of T_4 by astrocytes. Cells in the chick embryo produce only rT_3 until the time of piping (the bill piercing the air sack), whereon the enzymatic machinery begins to synthesize the metabolically active T_3 . These inactivation pathways are also important in preserving energy stores during periods of limited food availability and are associated with reduced activity of the enzymatic machinery that generates T_3 .

Thyroid hormone is the primary determinant of overall metabolic rate and exerts other effects as well

Thyroid hormone does not have any discrete target organs. It affects virtually every tissue in the body. Like all lipophilic hormones, thyroid hormone crosses the plasma membrane and binds with an intracellular receptor, in this case a nuclear receptor bound to the **thyroid-response element** of DNA. This binding alters the transcription of specific mRNAs and thus synthesis of specific new proteins, typically enzymes that carry out the cellular response.

Compared to other hormones, the action of thyroid hormone is “sluggish.” The response to an increase in thyroid hormone is detectable only after a delay of several hours, and the maximal response is not evident for several days. The duration of the response is also quite long, partially because thyroid hormone is not rapidly degraded but also because the response to an increase in secretion continues to be expressed for days or even weeks after the plasma thyroid hormone concentrations have declined.

The effects of T_3 and T_4 can be grouped into several overlapping categories.

Effect on Metabolic Rate and Heat Production The evolution from ectothermy to endothermy necessitated development of a mechanism to regulate metabolic heat production. The solution provided by thyroid hormones is to increase a bird’s or mammal’s overall basal metabolic rate (BMR), or “idling speed” (see p. 320). This occurs by regulating mitochondrial function as well as certain mitochondrial proteins. For example, the number of active Na^+/K^+ ATPase pump units in the membrane is closely regulated in endotherms.

The transport of Na^+ relies on the hydrolysis of ATP, which yields heat as a by-product. Considering that as much as 20 to 40% of the total cell energy supply is required to maintain the pump activity, a considerable amount of heat is liberated in the process. Thyroid hormone is thus the most important regulator of the rate of O_2 consumption and energy expenditure under resting conditions. Inhibition of the Na^+/K^+ ATPase pump activity by ouabain (p. 87) markedly reduces the effect of thyroid hormone on heat production and oxygen consumption. Whereas thyroid hormones are generally elevated in endotherms, they are selectively elevated in ectotherms during periods of metabolically demanding activity (e.g., mating, migration, active feeding), although much less is known about their regulation in ectotherms.

Effect on Intermediary Metabolism In addition to increasing the general metabolic rate, thyroid hormone modulates the rates of many specific reactions involved in fuel metabolism. The effects of thyroid hormone on the metabolic fuels are multifaceted; not only can it influence both the synthesis and degradation of carbohydrate, fat, and protein, but small or large amounts of the hormone may induce opposite effects. For example, conversion of glucose to glycogen, the storage form of glucose, is facilitated by small amounts of thyroid hormone, but the reverse—breakdown of glycogen into glucose—occurs with large amounts of the hormone. Similarly, adequate amounts of thyroid hormone are essential for the protein synthesis needed for normal bodily growth, yet protein degradation effects predominate at high doses. In general, at abnormally high plasma levels of thyroid hormone, as in thyroid hypersecretion, the overall effect is to favor consumption rather than storage of fuel, as shown by depleting liver glycogen stores, depleting fat stores, and muscle wasting from protein degradation.

In many birds and mammals thyroid hormone levels vary on daily and/or seasonal bases. For example, in birds, daily changes in circulating levels of thyroid hormone are driven in part by food intake, T_3 increasing during the day associated with a reciprocal decline in T_4 . In the American black bear, serum levels of T_3 and T_4 decrease during winter sleep (often loosely called *hibernation*; see p. 751) in association with reduced metabolism. An increase in thyroid hormone is also associated with the molt process in mammals and birds as well as the formation of new feathers and growth of horns or hair. For other seasonal changes, see the box *Molecular Biology and Genomics: Crosstalk between the Pituitary and Hypothalamus*.

Sympathomimetic Effect Any action similar to one produced by the sympathetic nervous system is known as a **sympathomimetic** (“sympathetic-mimicking”) effect. Thyroid hormone increases target cell responsiveness to catecholamines (epinephrine and norepinephrine), the chemical messengers used by the sympathetic nervous system and its hormonal reinforcements from the adrenal medulla. Thyroid hormone presumably accomplishes this permissive action by causing a proliferation of specific catecholamine target-cell receptors (see p. 309). Because of this action, many of the effects observed when thyroid hormone secretion is elevated are similar to those that accompany activation of the sympathetic nervous system (a sympathomimetic effect).

FIGURE 7-18 **Thyroid hormones and amphibian metamorphosis.** (a) A grass frog. The frog spends the first weeks of its life as an aquatic herbivore—a tadpole—in which the thyroid gland and other organs gradually mature. During this period, its skeletal muscles and other tissues are relatively insensitive to thyroxine, which is being synthesized in the thyroid, although little is released. At about 21 days (b), a spurt in thyroxine secretion begins to trigger major remodeling of the amphibian body. These developmental changes only occur if growth hormone also is present. The entire process may be triggered by changing environmental conditions. As metamorphosis gets under way, shifts in gene expression in cells of various tissues lead to major changes in body structures and physiological functions. Among other alterations, the tail regresses, digested away by newly synthesized lysosomal enzymes, and limbs grow. Lungs develop and gills degenerate, and the digestive tract becomes more suited to processing animal foods such as insects. The kidneys shift from excreting nitrogenous wastes as ammonia—an adaptation typical of aquatic animals—to eliminating urea.

Effect on the Cardiovascular System Through its effect of increasing the heart's responsiveness to circulating catecholamines, thyroid hormone increases heart rate and force of contraction, thus increasing cardiac output. In addition, in response to the heat load generated by the calorogenic effect of thyroid hormone, peripheral vasodilation occurs to carry the extra heat to the body surface for elimination to the environment.

Effect on Growth and the Nervous System Thyroid hormone is essential for normal growth. Thyroid hormones act *permissively* (indirectly) in concert with other hormones in

stimulating the growth process. Thyroid hormone is required for GH secretion in mammals and also promotes the effects of GH (or IGFs) on the synthesis of new structural proteins and on skeletal growth. Thyroid-deficient animals have stunted growth that is reversible with thyroid replacement therapy. Unlike excess GH, however, excess thyroid hormone does not result in excessive growth.

Thyroid hormone plays a crucial role in normal development of the nervous system, especially the CNS, an effect impeded in animals with thyroid deficiency from birth (or hatch). Thyroid hormone is also essential for normal CNS activity in adult animals. Furthermore, the conduction ve-

locity of peripheral nerves varies directly with the availability of thyroid hormone.

Developmental Effects of Thyroid Hormone Thyroid hormone also controls *metamorphosis* in amphibians (Figure 7-18). **Metamorphosis** is associated with radical developmental changes in body structure that permit transition of an amphibian from an aquatic to a terrestrial habitat. The enzyme *hyaluronidase* is normally induced when tissues mature and thus serves as a signal for differentiation. Concentrations of hyaluronic acid are elevated in proliferating tissue and decline as the cells become increasingly differentiated (specialized). Researchers have recognized that at the time of tadpole differentiation, generation of T_3 increases, paralleled by a decrease in hyaluronic acid. Administering thyroid hormone to a tadpole also accelerates metamorphosis of the juvenile stage into the adult stage. Conversely, if the thyroid gland is prematurely removed from a tadpole, metamorphosis does not occur and the animals eventually develop into giant juveniles.

In at least one species of fish, an increase in thyroid hormone is associated with metamorphosis. In flounder, migration of the eye from one side of the head to the other is triggered by increased thyroid hormone secretion.

Thyroid hormone is regulated by the hypothalamus–pituitary–thyroid axis

Thyroid-stimulating hormone (TSH), the thyroid tropic hormone from the anterior pituitary, is the most important physiological regulator of thyroid hormone secretion (Figure 7-19). TSH stimulates almost every step of thyroid hormone synthesis and release.

In addition to enhancing thyroid hormone secretion, TSH maintains structural integrity of the thyroid gland. In the absence of TSH, the thyroid atrophies (decreases in size) and secretes its hormones at a very low rate. Conversely, it undergoes hypertrophy (increase in the size of each follicular cell) and hyperplasia (increase in number of follicular cells) in response to excess TSH stimulation, which results in thyroid enlargement or **goiter**.

In mammals, hypothalamic **thyrotropin-releasing hormone (TRH)**, in tropic fashion, “turns on” TSH secretion by the anterior pituitary, whereas thyroid hormone, in negative-feedback fashion, “turns off” TSH secretion by inhibiting the anterior pituitary and hypothalamus. TRH functions via the $IP_3/DAG/Ca^{2+}$ second-messenger pathway. Like other negative-feedback loops, the one between thyroid hormone and TSH tends to maintain a stable thyroid hormone output. However, in some nonmammalian vertebrates CRH has been found to be more important in the regulation of TSH secretion. Various types of stress inhibit TSH and thyroid hormone secretion, presumably through neural influences on the hypothalamus, although the adaptive importance of this inhibition is unclear.

Unlike most other hormonal systems, hormones in the thyroid axis in an adult mammal normally do not undergo sudden, wide swings in secretion. The relatively steady rate of thyroid hormone secretion is in keeping with the sluggish, long-lasting responses that this hormone induces; there would be no adaptive value in suddenly increasing or decreasing plasma thyroid-hormone levels. Seasonal changes in TRH are known to occur in some mammals; however, the

FIGURE 7-19 Regulation of thyroid hormone secretion.

© Cengage Learning, 2013

only known consistent factor that increases TRH secretion in mammals (and, accordingly, TSH and thyroid hormone secretion) is exposure to cold. This mechanism is highly adaptive in newborn mammals. The dramatic increase in heat-producing thyroid hormone secretion is thought to help maintain body temperature in the abrupt drop in surrounding temperature at birth, as the infant passes from the mother's warm body to the cooler environmental air. A similar TSH response to cold exposure does not occur in adult mammals. Some evidence suggests that on a longer-term basis during acclimatization to a cold environment, the concentration of hormones in this axis does increase as a means to increase the BMR and heat production.

Abnormalities of thyroid function include both hypothyroidism and hyperthyroidism

Normal thyroid function is called **euthyroidism**. Abnormalities of thyroid function are among the most common of all endocrine disorders in humans and domestic (and some wild) birds and mammals. Disorders fall into two major categories—*hypothyroidism* and *hyperthyroidism*—reflecting deficient and excess thyroid-hormone secretion, respectively.

A number of specific causes can give rise to each of these conditions. Whatever the cause, the consequences of too little or too much thyroid hormone secretion are largely predictable, given a knowledge of the functions of thyroid hormone.

Hypothyroidism Low thyroid activity, or **hypothyroidism**, can result (1) from primary failure of the thyroid gland itself; (2) secondary to a deficiency of TRH, TSH, or both; or (3) from an inadequate dietary supply of iodine. The symptoms of hypothyroidism largely stem from reduced overall metabolic activity. Among other things, a mammal with hypothyroidism has a reduced basal metabolic rate; displays poor tolerance of cold (lack of the calorogenic effect); has a tendency to gain excessive weight (not burning fuels at a normal rate); is easily fatigued (lower energy production); has a slow, weak pulse (caused by reduced rate and strength of cardiac contraction and lowered cardiac output); and exhibits slow reflexes and slow mentation (because of the effect on the nervous system), characterized by diminished alertness, and poor memory.

In most endotherms, hypothyroidism diminishes quality of fur or feathers. For example, without adequate thyroid hormone concentrations, the seasonal growth in their pelage fails to occur, whereas in birds plumage fails to develop.

Hyperthyroidism As you would expect, the hyperthyroid mammal has an elevated basal metabolic rate. The resulting increase in heat production leads to excessive perspiration or panting and poor tolerance of heat. Despite the increased appetite and food intake in response to the increased metabolic demands, body weight typically falls because the body is burning fuel abnormally fast. Net degradation of endogenous carbohydrate, fat, and protein stores occurs. The loss of skeletal muscle protein results in weakness. Various cardiovascular abnormalities are associated with hyperthyroidism, caused both by the direct effects of thyroid hormone and by its interactions with catecholamines. Heart rate and strength of contraction may rise to dangerous levels. In severe cases, the heart may fail to meet the body's metabolic demands in spite of increased cardiac output. Nervous system involvement is manifested by excessive mental alertness to the point where the animal is irritable, tense, and anxious.

Three general methods of treatment are available for suppressing excess thyroid-hormone secretion: surgical removal of a portion of the oversecreting thyroid gland; administration of radioactive iodine, which, after being concentrated in the thyroid gland by the iodine pump, selectively destroys thyroid glandular tissue; and antithyroid drugs that specifically interfere with thyroid hormone synthesis and generation of T_3 .

7.6 Adrenal Glands

The **adrenal gland** (*adrenal*, “next to the kidney”) (Figure 7-20a) of higher vertebrates consists of two distinct cell types: **chromaffin** (*chroma*, “color”; *affinis*, “affinity”) cells, which are derived from the neural crest, and **steroidogenic cells**, which are of mesodermal origin.

In most vertebrates, the adrenal gland consists of a steroid-secreting cortex intermingled with chromaffin tissue

The term *chromaffin* arises from the observation that the tissue stains the color brown when reacted with oxidizing agents such as chromate. In mammals there are two adrenal glands, one embedded above each kidney in a capsule of fat. The shape of the adrenal varies considerably and in some species actually fuses with the kidney. In most mammals the adrenal gland consists of an outer, steroid-secreting **adrenal cortex** and an inner, catecholamine-secreting **adrenal medulla**. For this reason the chromaffin tissue is referred to as the adrenal medulla. However, in most nonmammalian species the chromaffin tissue is not associated with any surrounding cortex and in many instances, rather than forming distinct zones, the two tissue types are intermingled in the adrenal gland. In elasmobranchs, **interrenal tissue**, which is homologous with the adrenal cortex of higher vertebrates, is organized into glands situated between the posterior regions of the kidneys.

The steroid-secreting adrenal cortex and catecholamine-secreting medulla produce hormones belonging to different chemical categories, whose functions, mechanisms of action, and regulation are entirely different.

The adrenal cortex secretes mineralocorticoids, glucocorticoids, and sex hormones

About 80% of the adrenal gland of most mammals is composed of the cortex, which consists of three different layers or zones: the **zona glomerulosa**, the outermost layer; the **zona fasciculata**, the middle and largest portion; and the **zona reticularis**, the innermost zone (Figure 7-20b). The adrenal cortex produces a number of different adrenocortical hormones, all of which are steroids derived from the common precursor molecule, cholesterol. All steroidogenic (“steroid-producing”) cells are filled with lipid droplets (**liposomes**) containing cholesterol. Cholesterol is first converted to *pregnenolone*, then modified by stepwise enzymatic reactions to produce active steroid hormones (Figure 7-3). Each steroidogenic tissue has a complement of enzymes to produce one or several but not all steroid hormones. Slight variations in structure confer different functional capabilities on the various adrenocortical hormones. On the basis of their primary actions, the adrenal steroids can be divided into three categories:

1. **Mineralocorticoids**, mainly *aldosterone*, which influence mineral (electrolyte) balance, specifically Na^+ and K^+ balance (produced exclusively in the zona glomerulosa). The actions and regulation of the primary adrenocortical mineralocorticoid, **aldosterone**, are described thoroughly elsewhere (Chapter 12).
2. **Glucocorticoids**, primarily *cortisol* and *corticosterone*, which play a major role in glucose metabolism as well

FIGURE 7-20 Anatomy of the adrenal glands.

© Cengage Learning, 2013

as in protein and lipid metabolism (synthesized in the two inner layers, with the zona fasciculata being the major source of this glucocorticoid).

3. **Sex steroids** identical or similar to those produced by the gonads (testes in males, ovaries in females). The most abundant and physiologically important of the adrenocortical sex hormones is *dehydroepiandrosterone (DHEA)*, a “male” sex hormone (produced by the two inner zones).

The production of adrenocortical and other steroid hormones requires a series of steps in which the cholesterol molecule undergoes various enzymatic modifications (see p. 272). The enzymes that carry out the synthesis of the major steroids are highly conserved among vertebrates and homologous to those characterized in mammals. The different functional types of adrenal steroids are produced in anatomically distinct portions of the adrenal cortex, as noted in the preceding list.

Being lipophilic, the adrenocortical hormones are all carried in the blood extensively bound to plasma proteins. About 60% of circulating aldosterone is protein bound, primarily to nonspecific albumin, whereas approximately 90% of the glucocorticoids are bound, mostly to a plasma protein specific for it called **corticosteroid-binding globulin**

(**transcortin**). Likewise, 98% of dehydroepiandrosterone is bound, in this case, exclusively to albumin.

Each of the adrenocortical steroid hormones binds with a receptor specific for it within the cytoplasm of the hormone’s target cells: Mineralocorticoids bind to the **mineralocorticoid receptor (MR)**, glucocorticoids to the **glucocorticoid receptor (GR)**, and dehydroepiandrosterone to the **androgen receptor (AR)**. As is true of all steroid hormones, each hormone-receptor complex moves to the nucleus and binds with a complementary hormone-response element in DNA, namely the *mineralocorticoid response element*, *glucocorticoid response element*, and *androgen response element*. This binding initiates specific gene transcription leading to synthesis of new proteins that carry out the effects of the hormone.

Glucocorticoids exert metabolic effects and have an important role in adaptation to stress

Cortisol and **corticosterone** play an important role in carbohydrate, protein, and fat metabolism; execute significant permissive actions for other hormonal activities; and help animals cope with stress.

Metabolic Effects The overall effect of glucocorticoids' metabolic actions is to *increase the concentration of blood glucose* at the expense of protein and fat stores. Specifically, cortisol performs the following functions:

- It stimulates hepatic **gluconeogenesis**, the conversion of noncarbohydrate sources (namely, amino acids) into carbohydrate within the liver (*gluco* means “glucose”; *neo* means “new”; *genesis* means “production”). Between meals or during periods of fasting, when no new nutrients are being absorbed into the blood for use and storage, the glycogen (stored glucose) in the liver tends to become depleted as it is broken down to release glucose into the blood. Gluconeogenesis is an important factor in replenishing hepatic glycogen stores and thus in maintaining normal blood-glucose levels between meals. This is essential because the vertebrate brain can use only glucose as its metabolic fuel, yet nervous tissue cannot store glycogen to any extent. The concentration of glucose in the blood must therefore be maintained at an appropriate level to adequately supply the glucose-dependent brain with nutrients.
- It *inhibits glucose uptake* and use by many tissues, but not the brain, thus sparing glucose for use by the brain, which absolutely requires it as a metabolic fuel. This action contributes to the increase in blood glucose concentration brought about by gluconeogenesis.
- It *stimulates protein degradation* in many tissues, especially muscle. By breaking down a portion of muscle proteins into their constituent amino acids, cortisol increases the blood amino acid concentration. These mobilized amino acids are available for use in gluconeogenesis or wherever else they are needed, such as for repair of damaged tissue or synthesis of new cellular structures. For example, an anuran amphibian's cortisol is markedly elevated during metamorphosis of tadpole into frog (metamorphic climax). This is associated with increased mRNA levels of *POMC* (see p. 271) during this developmental stage.
- It *facilitates lipolysis* (*lysis*, “breakdown”), the breakdown of lipid (fat) stores in adipose tissue, releasing free fatty acids into the blood. The mobilized fatty acids are available as an alternative metabolic fuel for tissues that can use this energy source in lieu of glucose, conserving glucose for the brain.
- It stimulates *acclimatization to seawater* in euryhaline fishes (see pp. 626–627).

Permissive Actions Glucocorticoids are extremely important for their permissiveness (see p. 278). For example, in mammals glucocorticoids must be present in adequate amounts to permit the catecholamines to induce vasoconstriction. An animal lacking cortisol, if untreated, may go into circulatory shock in a stressful situation that demands immediate widespread vasoconstriction.

Effects on the Brain Glucocorticoids also affect neural functions such as memory. For example, elevated concentrations of plasma cortisol in Pacific salmon during home-stream migration aids in recalling the imprinted memory of the home-stream chemical aroma. Mammalian memory centers (such as the hippocampus) have cortisol receptors of uncertain function. In contrast to salmon, prolonged elevation in

cortisol from stress is associated with memory loss in humans and laboratory mammals, but this is considered an abnormal situation.

Role in Adaptation to Long-Term Stress Glucocorticoids play a key role in adaptation to stress, particularly *long-term* stress (you will learn in the section on adrenal medulla hormones about *short-term* stress responses). **Stress** is the generalized, nonspecific response to any factor that overwhelms, or threatens to overwhelm, the body's compensatory abilities to maintain homeostasis. Contrary to popular usage, the agent inducing the response is correctly called a *stressor*, whereas *stress* refers to the state induced by the stressor. Stressors include those that are *physical* (trauma, intense heat or cold); *chemical* (reduced O₂ supply, acid–base imbalance, nutritional deficit); *physiological* (hemorrhagic shock, pain); *psychological* or *emotional* (anxiety, fear such as that generated from an approaching thunderstorm); and *social* (conflict, isolation from a group). The following types of noxious stimuli illustrate the range of factors that can induce a stress response in fish: poor water quality, handling, and confinement.

Dramatic increases in glucocorticoid secretion, mediated by the central nervous system, occur in response to all kinds of stressful situations. For this reason, measurement of cortisol/corticosterone in an animal's blood is one of the best indicators of stress. For example, cortisol levels skyrocket in infant chimps separated from their mothers, and conversely, cortisol levels decline below average when their mothers are grooming these chimps. Similarly, a horse that is separated from its herd exhibits increased cortisol and other stress symptoms, showing the importance of social contact in this herd animal. The magnitude of the increase in plasma glucocorticoid concentration is generally proportional to the intensity of the stressful stimulation; a greater increase in glucocorticoid concentrations is evoked in response to severe stress than to mild stress.

Although the precise role of glucocorticoids in adapting to stress is not known, a speculative but plausible explanation might be as follows. An animal wounded or faced with a life-threatening situation must forgo eating. A glucocorticoid-induced enhancement of breakdown of carbohydrate stores (which increases the availability of blood glucose) would help protect the brain from malnutrition during the imposed fasting period. Also, the amino acids liberated by protein degradation would provide a readily available supply of building blocks for tissue repair should physical injury occur. Thus, an increased pool of glucose, amino acids, and fatty acids is available for use as needed.

Anti-Inflammatory and Immunosuppressive Effects When stress is accompanied by tissue injury, inflammatory and immune responses accompany the stress response. Cortisol exerts *anti-inflammatory* and *immunosuppressive* effects to help hold these immune system responses in check and balance. An exaggerated inflammatory response has the potential of causing harm. Cortisol interferes with almost every step of inflammation. For example, among other anti-inflammatory actions, cortisol partially blocks production of inflammatory chemical mediators, such as prostaglandins and leukotrienes (see p. 470); it suppresses migration of neutrophils to the injured site and interferes with their phagocytic activity (see Figure 10-7, p. 468); and it inhibits proliferation of fibroblasts in wound repair (see p. 469). Cortisol also inhibits immune

responses by interfering with antibody production by lymphocytes. Blurring the line between endocrine and immune control, lymphocytes have been shown to secrete ACTH, and some of the cytokines (such as IL-1, IL-2, and IL-6; see p. 460) released from immune cells can stimulate the hypothalamus–pituitary–adrenal axis. In feedback fashion, cortisol in turn has a profound dampening (turning-down) impact on the immune system. These interactions between the immune system and cortisol secretion help maintain immune homeostasis, an area only beginning to be explored.

Administering large amounts of glucocorticoid inhibits almost every step of the inflammatory response, making these steroids effective drugs in treating conditions in which the inflammatory response itself has become destructive. Glucocorticoids used in this manner do not affect the underlying disease process; they merely suppress the body's response to the disease. Because glucocorticoids also exert multiple inhibitory effects on the overall immune process, such as “knocking out of commission” the white blood cells responsible for antibody production as well as those that directly destroy foreign cells, these agents have also proved useful in managing various allergic disorders and in preventing organ transplant rejections.

When glucocorticoids are administered at pharmacological levels (that is, at higher-than-physiologic concentrations), not only are their anti-inflammatory and immunosuppressive effects increased but their metabolic effects are also magnified. Therefore, synthetic glucocorticoids have been developed that maximize the anti-inflammatory and immunosuppressive effects of these steroids while minimizing the metabolic effects.

Glucocorticoid secretion is directly regulated by the hypothalamic–pituitary–adrenal axis

Glucocorticoid secretion by the adrenal cortex is regulated by a negative-feedback system involving the hypothalamus and anterior pituitary (Figure 7-21). ACTH from the anterior pituitary corticotropes, acting through the cAMP pathway, stimulates the adrenal cortex to secrete cortisol. Hormonal steroid output by the adrenal cortex is seen within two minutes of exposure to ACTH, with the rate-limiting step in the biosynthesis of glucocorticoid being the conversion of cholesterol into pregnenolone (see Figure 7-3). Being tropic to the zona fasciculata and zona reticularis, ACTH stimulates both the growth and the secretory output of these two inner layers of the cortex, which shrink considerably in the absence of adequate amounts of ACTH.

The ACTH-producing cells in turn secrete only at the command of CRH from the hypothalamus. CRH stimulates the corticotropes via the cAMP pathway. The feedback control loop is completed by glucocorticoid's inhibitory actions on CRH and ACTH secretion by the hypothalamus and anterior pituitary, respectively. Superimposed on the basic negative-feedback control system are two additional factors that influence plasma glucocorticoid concentrations by changing the set points: These are *stress* and *circadian rhythms*, both of which act on the hypothalamus to vary the secretion rate of CRH.

Influence of Circadian Rhythm on Cortisol Secretion Recall that there is a characteristic circadian rhythm in plasma cortisol concentration, with the highest level occurring in

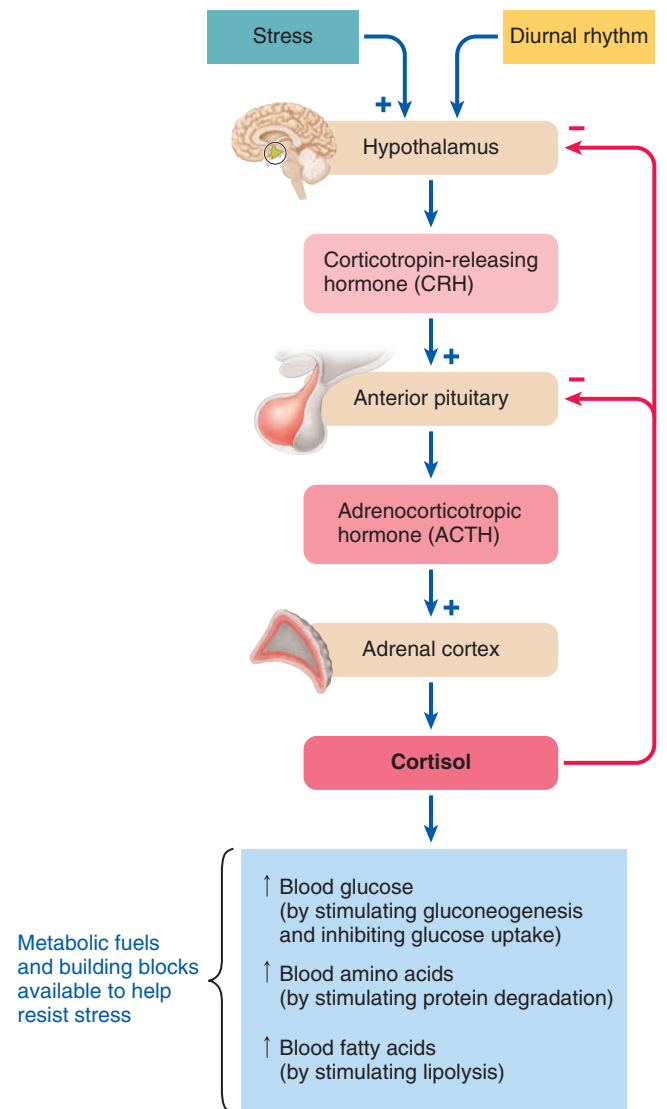

FIGURE 7-21 Control of cortisol secretion.

© Cengage Learning, 2013

diurnal animals in the morning and the lowest level at night (see Figure 7-6). This rhythm, which is governed by the SCN (the master biological clock we described earlier), is related primarily to the sleep–wake cycle. The peak and low levels are thus reversed in animals that are nocturnal.

The adrenal cortex secretes both male and female sex hormones in both sexes

In both sexes, the adrenal cortex produces both *androgens*, or “male” sex hormones, and *estrogens*, or “female” sex hormones. Under normal circumstances in mammals, the adrenal androgens and estrogens are not sufficiently abundant or powerful to induce masculinizing or feminizing effects, respectively. The only adrenal sex hormone that has any biological importance is the androgen **dehydroepiandrosterone (DHEA)**. Adrenal DHEA is overpowered by testicular testosterone in males but is of physiological significance in female humans, who otherwise lack androgens. This adrenal androgen is responsible for androgen-dependent processes in the female such as growth of pubic and axillary (armpit) hair,

enhancement of the pubertal growth spurt, and development and maintenance of the female sex drive. Because the enzymes required for producing estrogens are found in very low concentrations in the adrenocortical cells, estrogens are normally produced in very small quantities from this source.

The adrenal cortex may secrete too much or too little of any of its hormones

There are a number of different disorders of adrenocortical function. Excessive cortisol secretion (**Cushing's syndrome**), which occurs in many older dogs, is most commonly caused by overstimulation of the adrenal cortex by excessive amounts of CRH and/or ACTH. A rarer cause is an adrenal tumor that uncontrollably secretes cortisol independent of ACTH. Regardless of the cause, the prominent characteristics of this syndrome are related to the exaggerated effects of glucocorticoid, with the main symptoms being reflections of excessive gluconeogenesis. When too many amino acids are converted into glucose, the body suffers from combined glucose excess (high blood glucose) and protein shortage. Because the resultant hyperglycemia, glucosuria (glucose in the urine), and thirst mimic diabetes mellitus, the condition is sometimes referred to as *adrenal diabetes*. For reasons that are unclear, some of the extra glucose is deposited as body fat in locations characteristic for this disease, typically in the abdomen in dogs.

In **primary adrenocortical insufficiency**, also known as **Addison's disease**, all layers of the adrenal cortex are under-secreting. Certain dog breeds are prone to this condition, which is most commonly caused by autoimmune destruction of the cortex by erroneous production of adrenal cortex-attacking antibodies, in which case both aldosterone and cortisol are deficient. The symptoms associated with aldosterone deficiency in Addison's disease are the most threatening. If severe enough, the condition is fatal because aldosterone is essential for life. Symptoms of cortisol deficiency are as would be expected: poor response to stress, hypoglycemia caused by reduced gluconeogenic activity, and lack of permissive action for many metabolic activities.

Having completed discussion of the adrenal cortex, we now shift attention to the adrenal medulla.

The catecholamine-secreting adrenal medulla is a modified sympathetic ganglion

The adrenal medulla is actually a modified part of the sympathetic nervous system. A sympathetic pathway consists of two neurons in sequence—a *preganglionic neuron* originating in the CNS, whose axonal fiber terminates on a second peripherally located *postganglionic neuron*, which in turn terminates on the effector organ (see Figure 5-8, p. 162). The neurotransmitter released by sympathetic postganglionic fibers is norepinephrine (NE), which interacts locally with the innervated organ by binding with specific target receptors known as *adrenergic receptors*.

The adrenal medulla consists of modified postganglionic sympathetic neurons called **chromaffin cells**. Unlike ordinary postganglionic sympathetic neurons, chromaffin cells do not have axonal fibers that terminate on effector organs. Instead, on stimulation by the preganglionic fiber the chromaffin cells release their chemical transmitter di-

rectly into the circulation (see Figure 5-9, p. 163) as a neurohormone. Like sympathetic fibers, the adrenal medulla does release NE, but in mammals its most abundant secretory output is the similar chemical messenger **epinephrine**. Both epinephrine and NE belong to the chemical class of *catecholamines*, which are derived from the amino acid tyrosine (see Table 7-1). Epinephrine is similar in structure to NE except that it has a methyl group added to it. In species where the chromaffin tissue is separated from the steroidogenic tissue, such as the dogfish shark, NE is the only catecholamine produced. However, in frogs, where chromaffin tissue is loosely intermingled with steroidogenic tissue, NE is reduced to about 55 to 70% of the total catecholamine content.

Storage of Catecholamines in Chromaffin Granules Catecholamine synthesis in vertebrates is accomplished almost entirely within the cytosol of the adrenomedullary secretory cells, with only one step taking place within the hormonal storage granules. Whereas epinephrine is produced exclusively by the adrenal medulla, the bulk of NE is produced by sympathetic postganglionic fibers. Once produced, epinephrine and NE are stored in **chromaffin granules**, which are similar to the transmitter storage vesicles in sympathetic nerve endings. Catecholamines are ultimately secreted into the circulation by exocytosis of chromaffin granules; their release is analogous to the release mechanism for secretory vesicles that contain stored peptide hormones or the release of NE at sympathetic postganglionic terminals. Once in the circulation catecholamines are rapidly degraded resulting in a fast turnover: they are specialized for short-term actions associated with the stress response.

Sympathetic stimulation of the adrenal medulla is solely responsible for epinephrine release

Catecholamine secretion by the adrenal medulla is controlled entirely by sympathetic input to the gland. When the sympathetic system is activated under conditions of fear or stress, it simultaneously triggers a surge of adrenomedullary catecholamine release, flooding the circulation with up to 300 times the normal concentration of epinephrine. Although a number of different factors influence adrenal catecholamine secretion, they all act by increasing preganglionic sympathetic impulses to the adrenal medulla. Among the major factors that stimulate increased adrenomedullary output are a variety of stressful conditions such as physical or environmental disturbances, hemorrhage, illness, exercise, hypoxia (low arterial O₂), cold exposure, and hypoglycemia.

Epinephrine reinforces the sympathetic nervous system in "fight-or-flight" short-term stress, and exerts additional metabolic effects

Catecholamine hormones are not essential for life, but virtually all organs in the body are affected by them. They play important roles in stress responses, regulation of arterial blood pressure, and control of fuel metabolism. Together, the sympathetic nervous system and adrenomedullary epinephrine mobilize the body's resources to support peak physical exertion in the face of impending danger ("short-

term” stress). The sympathetic and epinephrine actions constitute a “fight-or-flight” response that prepares the animal to deal with a range of physical and environmental disturbances. An arthropod and molluscan equivalent of NE is **octopamine** (first discovered in octopus), a biogenic amine derived from the amino acid tyrosine. In many of these animals, octopamine is a neurotransmitter, neuromodulator, and neurohormone. In response to stressful situations in insects, such as handling or during the early stage of flight, octopamine mobilizes stores from the fat body for release into the hemolymph.

The following sections discuss epinephrine’s major effects, which it accomplishes in collaboration with NE or performs alone to complement direct sympathetic response.

Effects on Organ Systems Together, the sympathetic nervous system and adrenomedullary epinephrine mobilize the body’s resources that are ideally suited for fight-or-flight responses (see p. 159). Specifically, the sympathetic system and epinephrine increase the rate and strength of cardiac contraction, increasing cardiac output, and their generalized vasoconstrictor effects increase total peripheral resistance. These effects cause an increase in arterial blood pressure, thus ensuring an appropriate driving pressure to force blood to the organs that are most vital for meeting the emergency. Meanwhile, vasodilation of coronary and skeletal-muscle blood vessels induced by epinephrine and local metabolic factors shifts blood to the heart and skeletal muscles from other vasoconstricted regions of the body. In fishes, the physiological effects of catecholamines are also used to maintain levels of energy and oxygen supply under conditions such as hypoxia. However, in teleosts, adrenergic control of the heart is mainly neuronal, and it is only under severe stress that circulating levels of epinephrine increase sufficiently to affect cardiac function. Catecholamines also increase oxygen delivery to the tissues, change gill diffusion capacity, increase erythrocyte release from the spleen, increase the blood oxygen capacity by elevating intracellular pH, and increase blood flow and ventilation rate.

Epinephrine (but not NE) dilates the respiratory airways to reduce the resistance encountered in moving air in and out of the lungs. Epinephrine also reduces digestive activity and inhibits bladder emptying, both activities that can be “put on hold” during a fight-or-flight situation.

Metabolic Effects Epinephrine exerts some important metabolic effects, even at blood hormone concentrations lower than required for eliciting the cardiovascular responses. In general, epinephrine prompts mobilization of stored carbohydrate and fat to provide immediately available energy to fuel muscular work. Specifically, epinephrine increases the blood glucose level by several different mechanisms. First, it stimulates both hepatic (liver) gluconeogenesis and **glycogenolysis**, the latter being the breakdown of stored glycogen into glucose, which is released into the blood. Epinephrine also stimulates glycogenolysis in skeletal muscles. Because of the difference in enzyme content between liver and muscle, however, muscle glycogen is not converted to glucose for the blood. Instead, muscle glycogen is broken down via glycolysis into lactate, providing a burst of ATP for muscles in the emergency situation. In addition to raising blood glucose levels, epinephrine also raises the blood fatty-acids level by promoting lipolysis.

Epinephrine’s metabolic effects are appropriate for transient fight-or-flight situations. The elevated levels of glucose and fatty acids provide additional fuel to power the muscular movement required by the situation and also ensure adequate nourishment for the brain during the crisis when no new nutrients are being consumed. Muscles can use fatty acids for energy production, but the brain cannot.

Because of its other widespread actions, epinephrine also increases overall metabolic rate. Under the influence of epinephrine, many tissues metabolize faster. For example, the work of the heart and respiratory muscles is increased, and the pace of liver metabolism is stepped up. Thus, epinephrine as well as thyroid hormone can increase metabolic rate.

Other Effects Epinephrine affects the central nervous system to promote a state of arousal and increased CNS alertness, also useful to fight-or-flight situations.

Both epinephrine and NE cause sweating in mammals that have sweat glands, which helps the body rid itself of extra heat generated by increased muscular activity. Also, epinephrine acts on smooth muscles within the eyes to dilate the pupil and flatten the lens. These actions adjust the eyes for more encompassing vision so that the whole threatening scene can be quickly viewed.

Epinephrine and norepinephrine vary in their affinities for the different adrenergic receptor types

Epinephrine and NE have differing affinities for four distinctive receptor types: α_1 , α_2 , β_1 , and β_2 adrenergic receptors (see p. 165). NE binds predominantly with α and β_1 receptors located near postganglionic sympathetic-fiber terminals. Hormonal epinephrine, which can reach all α and β_1 receptors via its circulatory distribution, interacts with these same receptors. NE has a slightly greater affinity than epinephrine for the α receptors, and the two hormones have approximately the same potency at the β_1 receptors. Thus, epinephrine and NE exert similar effects in many tissues, with epinephrine generally reinforcing sympathetic nervous activity. In addition, epinephrine activates β_2 receptors, over which the sympathetic nervous system exerts little influence. Many of the essentially epinephrine-exclusive β_2 receptors are located at tissues not even supplied by the sympathetic nervous system but reached by epinephrine through the blood. Examples include skeletal muscle and its blood vessels and bronchiolar smooth muscle, with the effects we just discussed.

Sometimes epinephrine, through its exclusive β_2 -receptor activation, brings about a different action from that elicited by NE and epinephrine action through their mutual activation of other adrenergic receptors. For example, NE and epinephrine bring about a generalized vasoconstrictor effect mediated by α_1 -receptor stimulation. By contrast, epinephrine promotes vasodilation of the blood vessels that supply skeletal muscles and the heart through β_2 -receptor activation.

Realize, however, that epinephrine functions only at the bidding of the sympathetic nervous system, which is solely responsible for stimulating its secretion from the adrenal medulla. Epinephrine secretion always accompanies a generalized sympathetic nervous system discharge, so sympathetic

activity indirectly controls actions of epinephrine. By having the more versatile circulating epinephrine at its call, the sympathetic nervous system has a means of reinforcing its own neurotransmitter effects plus a way of executing additional actions on tissues that it does not directly innervate.

The stress response is a generalized, nonspecific pattern of neural and hormonal reactions to any situation that threatens homeostasis

Because both components of the adrenal gland play an extensive role in responding to stress, this is an appropriate place to pull together the various major factors involved in the stress response. Recall that a variety of noxious physical, chemical, physiological, and psychosocial stimuli that threaten to overwhelm the body’s compensatory ability to maintain homeostasis all can elicit a stress response. Different stressors may produce some specific responses characteristic of that stressor; for example, in some mammals the specific response to cold exposure is shivering and skin vasoconstriction, whereas the specific response to bacterial invasion includes increased phagocytic activity and antibody production. In addition to their specific response, however, all stressors also produce a similar nonspecific, generalized response regardless of the type of stressor.

In the 1930s, Hans Selye was the first to recognize this commonality of responses to noxious stimuli in what he called the **general adaptation syndrome**. When a stressor is recognized, both nervous and hormonal responses are called into play to bring about defensive measures to cope with the emergency. Across the entire vertebrate lineage, the result is a state of intense readiness and mobilization of biochemical resources.

To appreciate the value of the multifaceted stress response, imagine a gazelle that has just seen a lion lurking in the grass. The major neural response to such a stressful stimulus is generalized activation of the sympathetic nervous system. The resultant increase in cardiac output and ventilation as well as diversion of blood from vasoconstricted regions of suppressed activity, such as the digestive tract and kidneys, to the more active vasodilated skeletal muscles and heart prepare the body for a fight-or-flight response. Simultaneously, the sympathetic system calls forth hormonal reinforcements in the form of a massive outpouring of epinephrine from the adrenal medulla. Epinephrine strengthens sympathetic responses and reaches places not innervated by the sympathetic system to perform additional functions, such as mobilizing carbohydrate and fat stores.

Besides epinephrine, a number of other hormones are involved in the overall stress response (Table 7-3). As you have seen, the other predominant hormonal response is activation of the CRH–ACTH–glucocorticoid system, usually for longer-term stress. In our gazelle, this system would dominate if it escapes the lion but receives a serious wound (such as a bite in its leg). Note that a major difference between epinephrine and cortisol is that the former does not promote muscle protein breakdown, whereas the latter does. It would be maladaptive to cannibalize muscles during short-term fight-or-flight, but during long-term trauma it is useful to mobilize amino acids for tissue repair in the event of an injury.

In addition to the effects of cortisol in the hypothalamus–pituitary–adrenal cortex axis, there is much evidence that

TABLE 7-3 Major Hormonal Changes during the Stress Response

Hormone	Change	Purpose Served
Epinephrine	↑ ↑	Reinforces the sympathetic nervous system to prepare the body for “fight-or-flight” Mobilizes carbohydrate and fat energy stores; increases blood glucose and blood fatty acids
CRH–ACTH–Cortisol	↑ ↑	Mobilizes energy stores and metabolic building blocks for use as needed; increases blood glucose, blood amino acids, and blood fatty acids ACTH facilitates learning and behavior
Glucagon	↑	Act in concert to increase blood glucose and blood fatty acids
Insulin	↓	
Renin–Angiotensin–Aldosterone; Vasopressin	↑	Conserve salt and H ₂ O to expand the plasma volume; help sustain blood pressure when acute loss of plasma volume occurs Angiotensin II and vasopressin cause arteriolar vasoconstriction to increase blood pressure Vasopressin facilitates learning

© Cengage Learning, 2013

ACTH may play a role in resisting stress. ACTH suppresses release of GH, TSH, and gonadotropins, suppressing growth, metabolism, and reproduction, respectively. This helps divert energy toward stress needs. ACTH is one of several peptides that facilitate learning and behavior. Thus, it is possible that an increase in ACTH during psychosocial stress might help the body cope more readily with similar stressors in the future by facilitating the learning of appropriate behavioral responses. Furthermore, ACTH is not released alone from its anterior pituitary storage vesicles. Pruning of the large POMC precursor molecule yields not only ACTH but also morphine-like **β-endorphin** and similar compounds. These compounds are cosecreted with ACTH on stimulation by CRH during stress. As a potent endogenous opiate, β-endorphin may exert a role in mediating **analgesia** (reduced pain perception) should physical injury be inflicted during stress (see p. 261), allowing an animal to ignore pain.

The multifaceted stress response is coordinated by the hypothalamus

All the individual responses to stress just described are either directly or indirectly influenced by the hypothalamus (Figure 7-22). The hypothalamus receives input concerning physical and emotional stressors from many areas of the brain and from many receptors throughout the body. In response, the

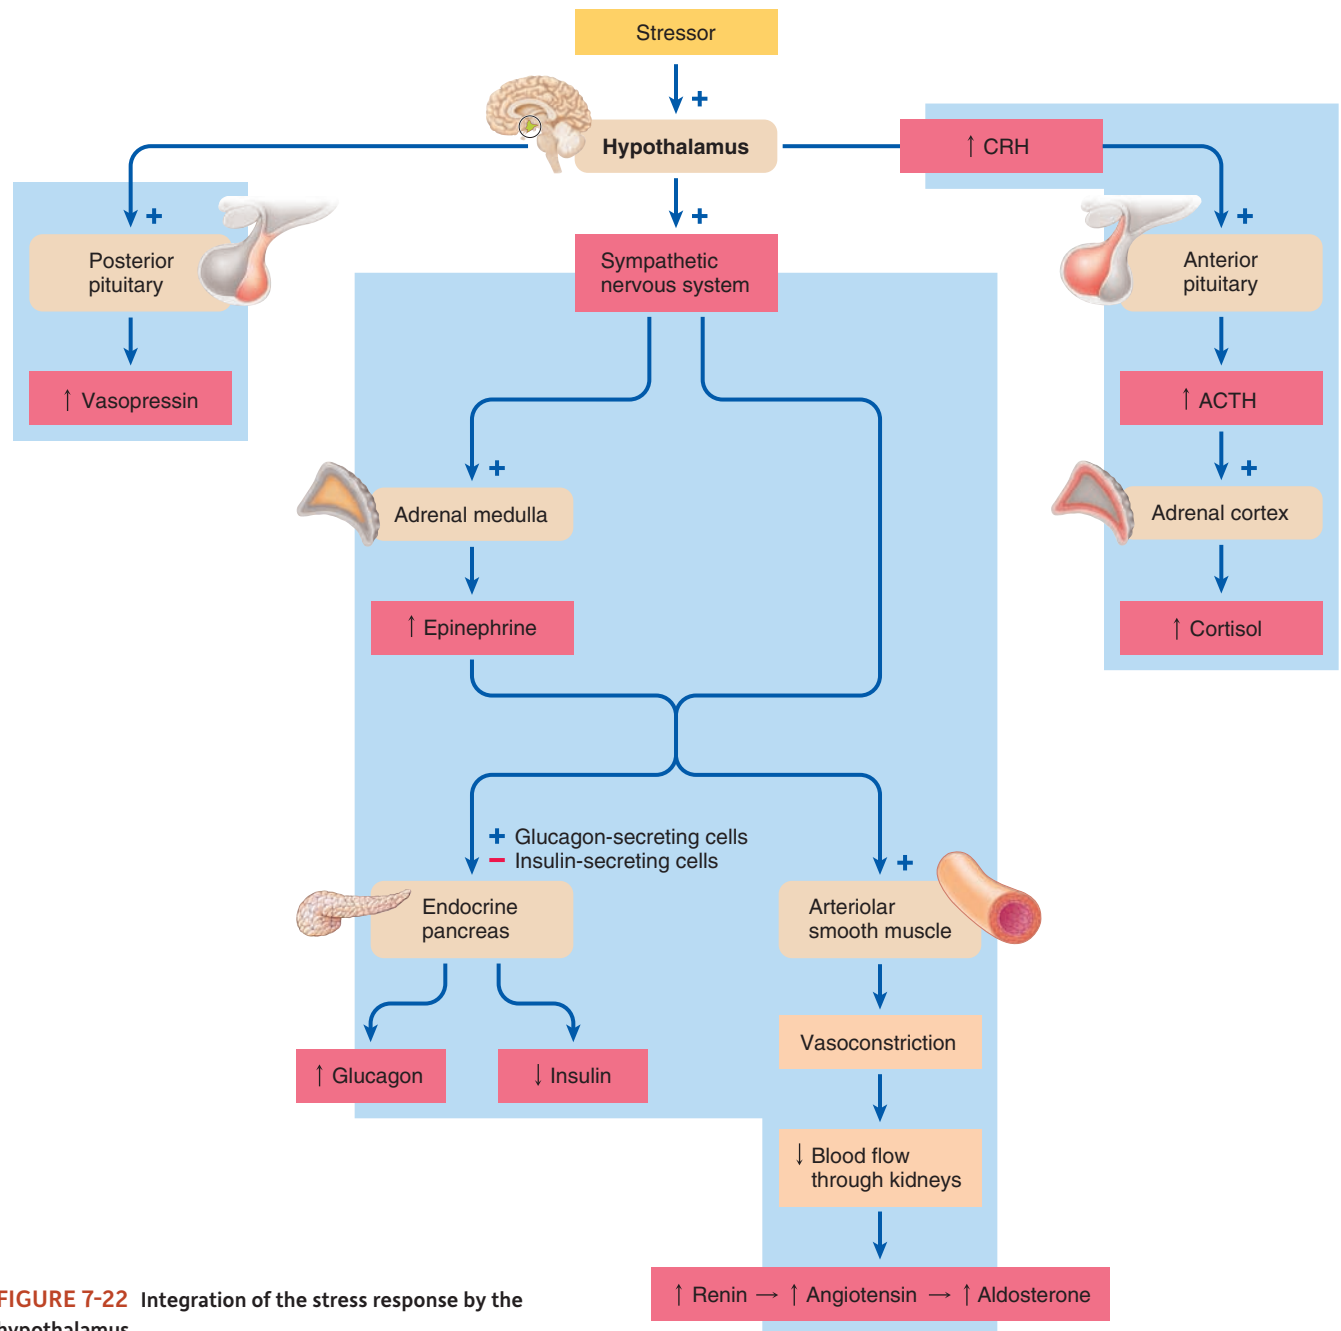

FIGURE 7-22 Integration of the stress response by the hypothalamus.

© Cengage Learning, 2013

hypothalamus directly activates the sympathetic nervous system, secretes CRH to stimulate ACTH and cortisol release, and triggers the release of vasopressin. Sympathetic stimulation in turn brings about the secretion of epinephrine, with which it has a conjoint effect on the pancreatic secretion of insulin and glucagon. Furthermore, vasoconstriction of the renal afferent arterioles by the catecholamines indirectly triggers the secretion of renin by reducing the flow of oxygenated blood through the kidneys. Renin in turn sets in motion the renin–angiotensin–aldosterone mechanism. In this way, the hypothalamus integrates the responses of both the sympathetic nervous system and the endocrine system during stress.

Activation of the stress response by chronic psychosocial stressors may be harmful

Acceleration of cardiovascular and respiratory activity, retention of salt and H_2O , and mobilization of metabolic fuels and building blocks can be of benefit in response to a physical stressor. Many stressors in an animal's life are psychosocial in nature, yet they induce these same magnified responses. Although the mobilization of body resources is appropriate in the face of real or threatened physical injury, it is often inappropriate in response to nonphysical stress. If no extra energy is demanded, no tissue damaged, and no blood lost, body stores are being broken down and fluid retained needlessly.

Other responses can also be harmful. In the acute phase of the stress response, useful behaviors necessary for dealing with an imminent threat (avoidance, escape) emerge, while feeding and reproductive behaviors are temporarily suspended. Such suspension is useful in the short term, but can be harmful in extreme stress. In every animal in which it has been investigated, severe psychological or physical stress reduces appetite and food intake often to dangerous levels. Chronic stress, such as social subordination, may completely shut down reproductive behavior in many vertebrates, where diminished sex-hormone concentrations correlate with elevated levels of POMC, ACTH, and corticosterone. Perhaps most importantly, prolonged glucocorticoid elevation also suppresses the immune system (p. 470).

Overall, chronic stress responses are often to the detriment of the stressed animal, which will have a much greater susceptibility to diseases. You may be aware that overly stressed humans are more prone to diseases; so are zoo animals in poorly designed enclosures, as are social animals in the wild in certain situations. For example, a male baboon entering a troop for the first time must become highly aggressive to be accepted in the social hierarchy. During prolonged aggressive states, cortisol levels rise in this baboon, but his actions also elevate cortisol levels in the rest of the troop. As a result, the number of white blood cells in all the males declines.

The suppression of immunity in these social stresses suggests that this phenomenon is not an adaptation but is rather an inappropriate activation of a system that evolved for more ancient, nonsocial stresses. Considerable work remains to be done to evaluate the contributions that stressors make toward disease in these situations.

Epigenetics Inadequate nutrition and other stresses affecting a pregnant mammal have long been recognized to harm the development of the offspring. More recently it has been recognized that chronic stress during pregnancy can also affect gene expression in the offspring for a number of subsequent generations. This is a type of **epigenetics**—heritable changes in genes that are not due to changes in the underlying DNA code itself. The most common way this occurs is by **methylation** of cytosine (C base of DNA). Methylation occurs in many genes during an organism's life as a regulatory mechanism, but the added methyl groups were long thought to be stripped off in developing gametes so that “original” genes are passed on to the next generation. However, we now know that some gamete genes can be methylated in different ways according to parental sex and environmental effects, a process called **genetic imprinting**. Such methylation patterns may be passed on to more than one generation. In terms of stress, several studies appear to show such effects. For example, studies in the 1980s on birth and death records of humans in an isolated Swedish town show that a severe famine may genetically affect the longevity of grandchildren. More recently, Isabelle Mansuy and colleagues reported that male mice stressed by lack of maternal care not only developed anxiety behaviors but also passed this behavior on to their offspring, which were not stressed.

What is the role of the catecholamines in the stress response?

7.7 Endocrine Control of Fuel Metabolism in Vertebrates

Next let's turn to the metabolic patterns that occur in the absence of stress, including the hormonal factors that govern this normal metabolism.

Fuel metabolism includes anabolism, catabolism, and interconversions among energy-rich organic molecules

The term **metabolism** refers to all chemical reactions that occur within body cells. Those reactions involving degradation, synthesis, and transformation of the three classes of energy-rich organic molecules—protein, carbohydrate, and fat—are collectively known as **intermediary metabolism** or **fuel metabolism** (Table 7-4).

During digestion, large nutrient molecules (**macromolecules**) are broken down into their smaller, absorbable subunits as follows: Proteins are converted into amino acids, complex carbohydrates into monosaccharides (mainly glucose), and triglycerides (dietary fats) into monoglycerides and free fatty acids. These absorbable units are transferred from the digestive tract lumen into the blood directly or by way of lymph (Chapter 14).

Anabolism and Catabolism These organic molecules are constantly exchanged between the blood and the cells of the body (Figure 7-23). The chemical reactions in which the organic molecules participate within the cells are categorized into two metabolic processes: anabolism and catabolism. **Anabolism** is the buildup or synthesis of larger organic macromolecules from the small organic molecular subunits. Anabolic reactions generally require the input of energy in the form of ATP. These reactions result in either (1) the manufacture of materials needed by the cell, such as cellular structural proteins or secretory products, or (2) storage of excess ingested nutrients not immediately needed for energy production or needed as cellular building blocks. Storage is in the form of glycogen (the storage form of glucose) or fat reservoirs. **Catabolism** is the breakdown, or degradation, of large, energy-rich organic molecules within cells. Catabolism encompasses two levels of breakdown: (1) *hydrolysis* (see p. 656) of large, cellular, organic macromolecules into their smaller subunits intracellularly as in release of glucose from glycogen stores (also occurring extracellularly in the digestive tract), and (2) oxidation of smaller subunits, such as glucose, to release energy for ATP production (see Chapter 2).

As an alternative to energy production, the smaller, multipotential organic subunits derived from intracellular hydrolysis may be released into the blood. These mobilized glucose, fatty acid, and amino acid molecules can then be used as needed for ATP production or cellular synthesis elsewhere in the body.

In an adult, the rates of anabolism and catabolism are generally in balance, so an adult body remains in a dynamic steady state and appears unchanged even though the organic molecules that determine its structure and function are continuously being turned over. During growth, anabolism exceeds intracellular catabolism.

TABLE 7-4 Summary of Reactions in Fuel Metabolism

Metabolic Process	Reaction	Consequence
Glycogenesis	Glucose \rightarrow glycogen	\downarrow Blood glucose
Glycogenolysis	Glycogen \rightarrow glucose	\uparrow Blood glucose
Gluconeogenesis	Amino acids \rightarrow glucose	\uparrow Blood glucose
Protein Synthesis	Amino acids \rightarrow protein	\downarrow Blood amino acids
Protein Degradation	Protein \rightarrow amino acids	\uparrow Blood amino acids
Fat Synthesis (Lipogenesis or Triglyceride Synthesis)	Fatty acids and glycerol \rightarrow triglycerides	\downarrow Blood fatty acids
Fat Breakdown (Lypolysis or Triglyceride Degradation)	Triglycerides \rightarrow fatty acids and glycerol	\uparrow Blood fatty acids

Interconversions among Organic Molecules In addition to being able to resynthesize catabolized organic molecules back into the same type of molecules, many cells of the body, especially liver cells, can convert most types of small organic molecules into other types—as in, for example, the transformation of amino acids into glucose or fatty acids. Because of these interconversions, adequate nourishment can be provided by a wide range of molecules present in different types of foods. There are limits, however. **Essential nutrients**, such as the essential amino acids and vitamins, cannot be formed in the body by conversion from another type of organic molecule.

The major fate of both ingested carbohydrates and fats is catabolism to yield energy. Amino acids are predominantly used for protein synthesis but can be used to supply energy after being converted to carbohydrate or fat. Thus, all three categories of foodstuff can be used as fuel, and excesses of any foodstuff can be deposited as stored fuel.

At a superficial level, fuel metabolism appears relatively simple: The amount of nutrients in the diet must be sufficient to meet the body's needs for energy production and cellular synthesis. This simple relationship is complicated, however, by two important considerations: (1) Nutrients taken in at meals must be stored and then released between meals, and (2) the brain must be continually supplied with glucose. Let's examine the implications of each of these considerations.

Because food intake is intermittent, nutrients must be stored for use between meals, primarily as adipose tissue

Dietary fuel intake is generally intermittent, not continuous; even an animal that grazes on grass for many hours must walk, rest, and sleep. As a result, excess energy must be absorbed during meals and stored for use during fasting periods between meals, when dietary sources of metabolic fuel are not available (Table 7-5). Despite discontinuous energy intake, the body cells' demand for energy is ever-present and fluctuating. That is, energy must constantly be available for

cells to use on an as-needed basis no matter what the status of food intake is. The goal of these storage processes is *energy homeostasis*: maintaining an adequate supply of energy for both short- and long-term needs (see also Chapter 15). Energy storage takes three forms:

- *Excess circulating glucose* is stored in the liver, glial cells, and muscle of vertebrates and in the fat body in insects as *glycogen* (p. 26). For many species, researchers ignore the importance of glycogen storage because its contribution to energy metabolism is trifling compared to the energy value of lipid deposits or bulk increases in body protein. For example, the crucian carp (*Carassius carassius*) has the highest glycogen accumulation of any vertebrate (approximately 20% of liver mass), yet its contribution to body weight and caloric content is minimal. Carbohydrate reserves in the liver and muscle are useful as a limited short-term energy reserve because they are easy to mobilize. Once the liver and muscle glycogen stores are “filled up,” additional glucose is transformed into fatty acids and glycerol, which are used to synthesize *triglycerides* (glycerol with three fatty acids attached; p. 26), primarily in adipose tissue (fat) and to a lesser extent in muscle. *Excess circulating fatty acids* derived from dietary intake also become incorporated into triglycerides.
- *Excess circulating amino acids* are used first for protein synthesis, but those not needed for this are not stored as extra protein but are converted to glucose and fatty acids, which ultimately end up being stored as triglycerides.

Thus, the major site of energy storage for excess nutrients of all three classes is adipose tissue. The reasons for this are straightforward. Lipids require much less space and mass than glycogen to store the same energy content, for two reasons. First, lipids (being hydrophobic) form droplets with no water content, whereas glycogen (being hydrophilic) attracts a large number of water molecules, taking up space and weight with no usable energy. Second, lipids are dominated by high-energy C–H bonds, which can be used to make NADH (see p. 48), whereas glycogen has a large number of C–O bonds that are already oxidized.

Sufficient triglyceride is stored to provide energy for prolonged periods of fasting (such as the emperor penguin, which voluntarily fasts throughout the Antarctic winter); the fatty acids released from triglyceride catabolism serve as the primary source of energy for most tissues. The catabolism of stored triglycerides frees glycerol as well as fatty acids, but quantitatively speaking, the fatty acids are far more important. Catabolism of stored fat yields 90% fatty acids and 10% glycerol by weight. Glycerol can be converted to glucose by the liver and contributes in a small way to maintaining blood glucose during periods of prolonged food withdrawal.

As a third energy reservoir, a substantial amount of energy is stored as *structural protein*, primarily in muscle, the most abundant protein mass in the body. For example, once the triglyceride reserve is exhausted in the wintering emperor penguins and they are forced to catabolize proteins, it is time to begin the long march to the sea in order to replenish body reserves. In most animals protein is not the first choice to tap as an energy source, because it serves other essential functions; in contrast, the glycogen and triglyceride reservoirs serve primarily as energy depots.

Glucose is homeostatically regulated to supply the brain and to prevent damaging processes at high concentrations

The second factor complicating fuel metabolism (in addition to intermittent intake) is that the vertebrate brain normally depends on the delivery of adequate blood glucose as its sole source of energy. Consequently, it is essential that the blood glucose concentration be maintained above a critical level, that is, that hypoglycemia be prevented. The blood glucose concentration of humans is typically 100 mg glucose/100 mL plasma and is normally maintained within the narrow limits of 70 to 110 mg/100 mL in a process of *glucose homeostasis* (you will see later how this is regulated with insulin and glucagon). Blood glucose is typically lower in large mammals and two- to sixfold higher in birds, but all have some general set-point regulation. Liver glycogen is an important reservoir for maintaining blood glucose levels during a short fast, and is the primary reservoir in daily life. However, liver glycogen is depleted relatively rapidly, so during a longer fast than that between daily meals, other mechanisms must ensure that the energy requirements of the glucose-dependent brain are met. First, when new dietary glucose is not entering the blood, tissues not obligated to use glucose shift their metabolic gears to burn fatty acids instead, thus sparing glucose for the brain. Fatty acids are made available by catabolism of triglyceride stores as an alternative energy source for non-glucose-dependent tissues. Second, amino acids can be converted to glucose by gluconeogenesis, whereas fatty acids cannot. Thus, once glycogen stores are depleted despite glucose sparing, new glucose supplies for the brain are provided by catabolism of body proteins and conversion of the freed amino acids into glucose. How then can a crucian carp survive the months of anoxia in frozen ponds? In order to master this feat, glycogen content in the crucian carp's brain increases 15-fold as a reservoir for the neural tissue, concomitant with a 10-fold decline in the activity of the Na^+/K^+ ATPase pump units.

TABLE 7-6 Comparison of Absorptive and Postabsorptive States

Metabolic Fuel	Absorptive State	Postabsorptive State
Carbohydrate	Glucose providing major energy source Glycogen synthesis and storage Excess converted to and stored as tri-glyceride fat	Glycogen degradation and depletion Glucose sparing to conserve glucose for the brain Production of new glucose through gluconeogenesis
Fat	Triglyceride synthesis and storage	Triglyceride catabolism Fatty acids providing the major energy source for non-glucose-dependent tissues
Protein	Protein synthesis Excess converted to and stored as tri-glyceride fat	Protein catabolism Amino acids used for gluconeogenesis

© Cengage Learning, 2013

An alternative fuel for the brain that is derived from fats are ketones, normally generated during starvation. We investigate ketones shortly.

A third complication of fuel metabolism is the potential damage of excessively high blood glucose (**hyperglycemia**). At levels significantly higher than an animal's set point, three harmful processes occur: (1) the osmotic effect of the glucose leads to cell dehydration; (2) glucose can spontaneously react—in a process called **glycation**—with proteins such as hemoglobin and collagen, forming a covalent bond that alters the structure and function of the proteins (see p. 564); and (3) some tissues such as lens convert excess glucose into *sorbitol*, which can cause cataracts. These effects are relatively slow, so that temporary rises in blood glucose are not necessarily dangerous (if not too extreme). Thus, glucose homeostasis is not as precise as other regulation such as mammalian body-temperature homeostasis. In summary, glucose homeostasis works to prevent short-term hypoglycemia and long-term hyperglycemia.

Metabolic fuels are stored during the absorptive state and are mobilized during the postabsorptive state

From the preceding discussion, you can see that the disposition of organic molecules depends on the body's metabolic state. Two functional metabolic states are related to eating and fasting cycles—the absorptive state and the postabsorptive state, respectively (Table 7-6).

Absorptive State After a meal, ingested nutrients are being absorbed and entering the blood during the **absorptive**, or **fed**, state. During this time, glucose is plentiful (assuming the

meal includes carbohydrates) and serves as the major energy source. Very little of the absorbed fat and amino acids is used for energy during the absorptive state because most cells are programmed to use glucose first, when available. Extra nutrients not immediately used for energy or structural repairs are channeled into storage as glycogen or triglycerides.

Postabsorptive State In humans the average meal is completely absorbed in about four hours. Therefore, on a typical three-meals-a-day diet, no nutrients are being absorbed from the digestive tract during late morning and late afternoon and throughout the night. These times constitute the **postabsorptive**, or **fasting**, state. There are few daily fasting periods in nonruminant herbivores, which may graze most of the day, while there are many in carnivores (such as cheetahs), which may gorge on only a few large prey animals per month.

During the fasting state, endogenous energy stores are mobilized to provide energy, whereas gluconeogenesis and glucose sparing are used to maintain the blood glucose at an adequate level to nourish the brain. The synthesis of protein and fat is curtailed. Instead, stores of these organic molecules are catabolized for glucose formation and energy production, respectively. Carbohydrate synthesis does occur through gluconeogenesis, but the use of glucose for energy is greatly reduced.

Note that blood concentration of nutrients does not fluctuate markedly between absorptive and postabsorptive states. During the absorptive state, the glut of absorbed nutrients is swiftly removed from the blood and placed into storage; during the postabsorptive state, these stores are catabolized to maintain blood concentrations at levels necessary to sustain tissue energy demands.

Roles of Key Tissues in Metabolic States During these alternating metabolic states, various tissues play different roles as summarized here:

- The *liver* plays the primary role in maintaining normal blood-glucose levels. It stores glycogen when excess glucose is available, releases glucose into the blood when needed, and is the principal site for metabolic interconversions such as gluconeogenesis.
- *Adipose* tissue serves as the primary energy-storage site and is important in regulating fatty acid levels in the blood.
- *Muscle* is the primary site of amino acid storage and is the major energy user. It also stores glycogen.
- The *brain* normally needs glucose as its main energy source, yet in most species only minor glycogen storage occurs in glial cells,

Lesser energy sources are tapped as needed

Several other organic intermediates play a lesser role as energy sources—namely, glycerol, lactate, and ketones (or ketone bodies):

- As mentioned earlier, *glycerol* derived from triglyceride hydrolysis (it is the backbone to which the fatty acid chains are attached) can be converted to glucose by the liver.
- Similarly, *lactate*, which is produced by the incomplete catabolism of glucose via glycolysis in muscle (see p. 55), can also be converted to glucose in the liver.

- **Ketone bodies** (namely acetone, acetoacetic acid, and β -hydroxybutyric acid) are a group of compounds produced by the liver during glucose sparing. Unlike other tissues, when the liver uses fatty acids as an energy source, it oxidizes them only to acetyl coenzyme A (acetyl CoA), which it cannot process through the citric acid cycle for further energy extraction. Thus, the liver does not degrade fatty acids all the way to CO_2 and H_2O for maximum energy release. Instead, it partially extracts the available energy and converts the remaining energy-bearing acetyl CoA molecules into ketone bodies, which it releases into the blood. Ketone bodies serve as an alternative energy source for tissues capable of oxidizing them further by means of the citric acid cycle.

During long-term starvation, the vertebrate brain starts using ketones instead of glucose as a major energy source because glucose homeostasis cannot be maintained. Because death from starvation is usually due to protein wasting rather than to hypoglycemia, prolonged survival without any caloric intake requires that gluconeogenesis be kept to a minimum as long as the needs of the brain are not compromised. A sizable portion of cell protein can be catabolized without serious cell malfunction, but a point is finally reached at which a cannibalized cell can no longer function adequately. To ward off the fatal point of failure so long as possible during prolonged starvation, the brain starts using ketones as a major energy source, correspondingly decreasing its use of glucose. The brain's use of ketones from the liver limits the necessity of mobilizing body proteins for glucose production to nourish the brain.

Locusts and cockroaches also rely on ketone bodies during periods of starvation. The activities of ketone-body-oxidizing enzymes are also elevated in brain tissue of insects that make extensive use of fatty acids during flight and of insects that do not feed as adults.

The pancreatic hormones, insulin and glucagon, are most important in regulating fuel metabolism

How does the body “know” when to shift its metabolic gears from one of net anabolism and nutrient storage to one of net catabolism and glucose sparing? The flow of organic nutrients along metabolic pathways is influenced by a variety of hormones, including *insulin*, *glucagon*, *epinephrine*, *glucocorticoids* (cortisol or corticosterone), and *GH*. Under most circumstances, the pancreatic hormones, insulin and glucagon, are the dominant hormonal regulators responsible for glucose homeostasis; that is, they shift the metabolic pathways back and forth from net anabolism to net catabolism and glucose sparing, depending on whether the body is feasting or fasting, respectively.

The vertebrate **pancreas** is an organ composed of both exocrine and endocrine tissues. The exocrine portion of the pancreas secretes a watery alkaline solution and digestive enzymes through the pancreatic duct into the digestive tract lumen (Chapter 14). Scattered throughout the pancreas between the exocrine cells are clusters, or “islands,” of endocrine cells known as the **islets of Langerhans** (see Figure 14-15, p. 683). These cells are the integrators of endocrine regulatory responses controlled by the pancreas. The most abundant pancreatic-endocrine cell type in mammals is the **β (beta) cell**, the site of *insulin* synthesis and secretion. The

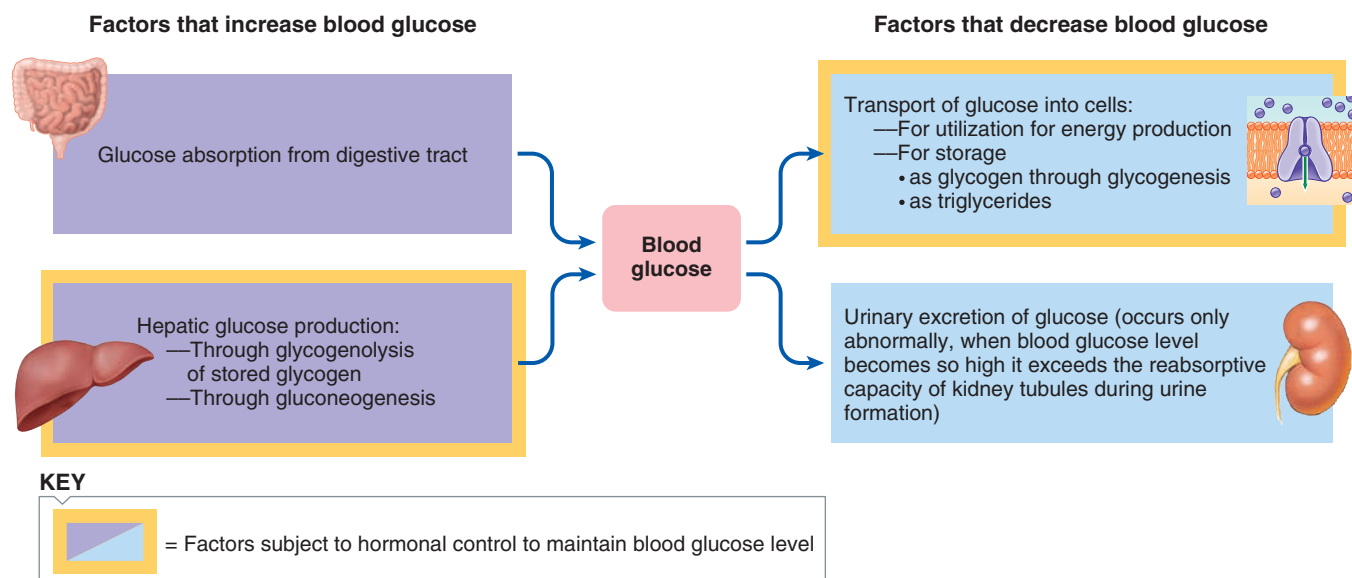

FIGURE 7-24 Factors affecting blood glucose concentration.

© Cengage Learning, 2013

β cells are concentrated centrally in the islets, with the other cells clustered around the periphery. Insulin has been isolated from representative species in all classes of vertebrates including the agnathans. Next most important are the α (alpha) cells, which produce *glucagon*. The **D (delta) cells** are the pancreatic site of *somatostatin* synthesis, whereas the least common islet cells, the **F cells**, secrete *pancreatic polypeptide*, which plays a possible role in reducing appetite and food intake, is poorly understood, and will not be discussed any further.

Somatostatins *Somatostatin* is released from the pancreatic D cells in direct response to an increase in blood glucose and blood amino acids during absorption of a meal. By exerting inhibitory effects on digestion of nutrients and nutrient absorption, pancreatic somatostatin acts as a hormone in negative-feedback fashion to prevent excessive plasma levels of nutrients. Pancreatic somatostatin also acts in a paracrine fashion, decreasing the secretion of insulin, glucagon, and somatostatin itself, but the physiologic importance of such paracrine function has not been determined.

Somatostatin is also produced by cells lining the digestive tract, where it acts locally as a paracrine to inhibit most digestive processes. Furthermore, somatostatin (alias GHIH) is produced by the hypothalamus, where it inhibits the secretion of growth hormone and TSH.

We next consider insulin and then glucagon, followed by a discussion of how both function as an endocrine unit to shift metabolic gears between the absorptive and postabsorptive states.

Insulin lowers blood levels of glucose, amino acids, and fatty acids, and promotes their storage

In vertebrates **insulin** has important effects on carbohydrate, fat, and protein metabolism. It lowers blood levels of glucose, fatty acids, and amino acids and promotes their stor-

age. As these nutrient molecules enter the blood during the absorptive state, insulin promotes their cellular uptake and conversion into glycogen, triglycerides, and protein, respectively. Insulin exerts its many effects either by altering transport of specific bloodborne nutrients into cells or by altering the activity of the enzymes involved in specific metabolic pathways. To accomplish its effects, in some instances insulin increases the activity of an enzyme, for example *glycogen synthase*, the key regulated enzyme that synthesizes glycogen from glucose molecules, a process known as **glycogenesis**. In other cases, however, insulin decreases the activity of an enzyme, for example, by inhibiting *hormone-sensitive lipase*, the enzyme that catalyzes the breakdown of stored triglycerides back to free fatty acids and glycerol.

Vertebrate insulin belongs to a superfamily consisting of a number of peptide hormones including **insulin-like peptides (ILPs)** in some nonvertebrates (mollusks, nematodes, insects). Nonvertebrate versions also consist of two peptide chains cross-linked by highly conserved insulin-type disulfide bonds. Some insect ILPs are neuroendocrine hormones as exemplified by locust insulin-related peptide (LIRP), which was isolated from the neurohemal lobes in the corpora cardiaca (p. 280). Functionally, these nonvertebrate insulin-like peptides act as growth factors and developmental regulators, much like vertebrate IGF. For example, in fruit flies and *C. elegans* (nematode) mutations in the insulin-like receptor genes result in defects in growth and development.

Actions on Carbohydrates The maintenance of blood glucose homeostasis is a particularly important function of the pancreas. Circulating glucose concentrations are determined by the balance among the following processes (Figure 7-24): glucose absorption from the digestive tract; transport of glucose into cells; cellular (primarily hepatic) glucose production; and (abnormally) urinary excretion of glucose. Somatostatins regulate digestive absorption, while insulin and glucagon act on cellular transport and hepatic production.

Insulin exerts four effects to lower bloodglucose levels and promote carbohydrate storage:

1. *Facilitation of glucose transport* into most cells.
2. *Stimulation of glycogenesis*, the production of glycogen from glucose, in both skeletal muscle and the liver.
3. *Inhibition of glycogenolysis*, by inhibiting breakdown of glycogen into glucose. By inhibiting degradation of glycogen, insulin likewise favors carbohydrate storage and decreases glucose output by the liver.
4. *Inhibition of gluconeogenesis* in the liver. By inhibiting gluconeogenesis, the conversion of amino acids into glucose in the liver, hepatic glucose output is reduced. Insulin does so by decreasing the amount of amino acids in the blood that are available to the liver for gluconeogenesis, and by inhibiting the hepatic enzymes required for converting amino acids into glucose.

Thus, insulin decreases concentration of blood glucose by promoting the cells' uptake of glucose from the blood for use and storage, while simultaneously blocking the two mechanisms by which the liver releases glucose into the blood (glycogenolysis and gluconeogenesis). Note that the cells stimulated by glucose are the effectors in a negative-feedback sense, because they make the actual corrective changes, whereas insulin is a signal molecule (akin to the electrical signals running from a thermostat to an air conditioner). Insulin is the *only* hormone capable of lowering glucose concentrations in the blood.

These functions have been primarily explored in depth in mammals, but in nonmammalian vertebrates experiments suggest that insulin has similar roles. For example, removing islet cells from either the teleost *Gillichthys mirabilis* (mud-sucker) or the southern lamprey *Geotria australis* dramatically increases blood glucose concentrations. In general, the hypoglycemic action of insulin in ectotherms develops more slowly compared to endotherms and can require days instead of hours to achieve a full effect.

Glucose Transporter Recruitment Glucose transport between the blood and cells is accomplished by means of plasma membrane carriers known as **glucose transporters (GLUT)**. Fourteen forms of glucose transporters have been identified, named in the order they were discovered—GLUT-1, GLUT-2, and so on. The amino acid structure of each GLUT isoform is nearly identical when the structure is compared with different species, which suggests that all glucose transporters originated from a common ancestor. For example, GLUT-1 is over 95% identical between different mammalian species. These glucose transporters all accomplish passive facilitated diffusion of glucose across the plasma membrane. Once GLUT transports glucose into a cell, an enzyme within the cell immediately phosphorylates glucose to **glucose-6-phosphate**, which has no means out of the cell, unlike “plain” glucose, which could exit through the bidirectional glucose transporter. Therefore, glucose is trapped inside the cell. Furthermore, the phosphorylation of glucose as it enters the cell keeps the intracellular concentration of plain glucose low so that a gradient favoring the facilitated diffusion of glucose into the cell is maintained.

Each member of the GLUT family performs slightly different functions. For example, *GLUT-1* transports glucose across the blood-brain barrier, *GLUT-2* transfers into glucose from kidney (Chapter 12) and intestinal cells (Chapter 14) into the blood, and *GLUT-3* is the main transporter of glucose into neurons. The glucose transporter responsible

for the majority of glucose uptake by most cells of the body is *GLUT-4*, which is the only type of glucose transporter that responds to insulin. Glucose molecules cannot readily penetrate most cell membranes in the absence of insulin, making most tissues highly dependent on insulin for uptake of glucose from the blood and for its subsequent use. *GLUT-4* is especially abundant in the tissues that account for much of glucose uptake from the blood during the absorptive state, namely, skeletal muscle and adipose tissue cells. Unlike the other types of GLUT molecules, which are always present in the plasma membranes at the sites where they perform their functions, *GLUT-4* in the absence of insulin is excluded from the plasma membrane. Insulin promotes glucose uptake by **transporter recruitment**. Insulin-dependent cells maintain a pool of intracellular vesicles containing *GLUT-4*. When insulin binds with its receptor (a receptor that acts as a tyrosine kinase enzyme; see p. 95) on the surface membrane of the target cell, the subsequent signaling pathway induces these vesicles to move to the plasma membrane and fuse with it, thus inserting *GLUT-4* molecules into the plasma membrane. In this way, increased insulin secretion promotes a rapid 10- to 30-fold increase in glucose uptake by insulin-dependent cells. When insulin secretion decreases, these glucose transporters are retrieved from the membrane by endocytosis and returned to the intracellular pool.

Several tissues do not depend on insulin for their glucose uptake—namely, the brain, working muscles, and liver. The brain, which requires a constant supply of glucose for its minute-to-minute energy needs, is freely permeable to glucose at all times by means of *GLUT-1* and *GLUT-3* transporters. Skeletal muscle cells do not depend on insulin for their glucose uptake during exercise, even though they are dependent at rest. Muscle contraction triggers the insertion of *GLUT-4* into the plasma membranes of exercising muscle cells in the absence of insulin. The liver also does not depend on insulin for glucose uptake, because it does not use *GLUT-4*. However, insulin does enhance the metabolism of glucose by the liver by stimulating the first step in glucose metabolism, the phosphorylation of glucose to form glucose-6-phosphate.

Insulin also exerts important actions on fat and protein.

Actions on Fat Insulin exerts multiple effects to lower blood fatty acids and promote triglyceride storage:

1. *Increase in the transport of glucose into adipose tissue cells* by means of *GLUT-4* recruitment. Glucose serves as a precursor for the formation of fatty acids and glycerol, which are the raw materials for triglyceride synthesis.
2. *Activation of enzymes* that catalyze the production of *fatty acids* from glucose derivatives.
3. *Promotion of the uptake of fatty acids* from the blood into adipose tissue cells.
4. *Inhibition of lipolysis* (fat breakdown), by inhibiting *hormone-sensitive lipase*, the enzyme that catalyzes the breakdown of stored triglycerides back to free fatty acids and glycerol, thus reducing release of fatty acids from adipose tissue into the blood. In birds, insulin is not antilipolytic.

Collectively, these actions favor removal of glucose and fatty acids from the blood and promote their storage as triglycerides. Adipose tissue here serves as an effector.

Actions on Protein Insulin lowers blood amino acid levels and enhances protein synthesis through several effects:

1. *Promotion of the active transport of amino acids* from the blood into muscles and other tissues. This effect lowers the circulating amino acid level and provides the building blocks for protein synthesis within the cells.
2. *Enhancing the rate of amino acid incorporation into protein* by stimulating the cells' protein-synthesizing machinery.
3. *Inhibition of protein degradation.*

The collective result of these actions is a protein anabolic effect. For this reason, insulin is essential for normal growth.

Summary of Insulin's Actions In short, insulin stimulates biosynthetic pathways that increase glucose use, carbohydrate and fat storage, and protein synthesis. In so doing, this hormone lowers the blood glucose, fatty acid, and amino acid levels. This metabolic pattern is characteristic of the absorptive state. Indeed, insulin secretion rises during this state and is responsible for shifting metabolic pathways to net anabolism. Consider as well that the number of insulin receptors on a target cell reflects the carbohydrate content of the natural diet and the differential involvement of insulin in the regulation of protein or carbohydrate metabolism in different species. For example, in salmonids, a carnivorous group of fish whose diet consists mainly of protein, the number of insulin receptors is lower compared to either herbivorous (such as the African fish tilapia) or omnivorous (such as carp) species. In general, the number of insulin receptors in ectothermic vertebrates is higher than that of IGF-I receptors, whereas in endotherms the opposite holds true. The increase in ratio between insulin and IGF-I receptors during vertebrate evolution is probably related to the higher physiological response of skeletal muscles to insulin in birds and mammals.

When insulin secretion is low, the opposite effects occur. The rate of glucose entry into cells is reduced and net catabolism rather than net synthesis of glycogen, triglycerides, and protein occurs. This pattern is reminiscent of the postabsorptive state; indeed, insulin secretion falls during the postabsorptive state. However, the other major pancreatic hormone, glucagon, also plays an important role in shifting from absorptive to postabsorptive metabolic patterns, as we describe shortly.

The primary stimulus for increased insulin secretion is an increase in blood glucose concentration

The primary control of insulin secretion is a direct negative-feedback system between the pancreatic β cells and the concentration of glucose in the blood flowing to them. An elevated blood-glucose level, such as during absorption of a meal, directly stimulates synthesis and release of insulin by the β cells. The increased insulin in turn reduces blood glu-

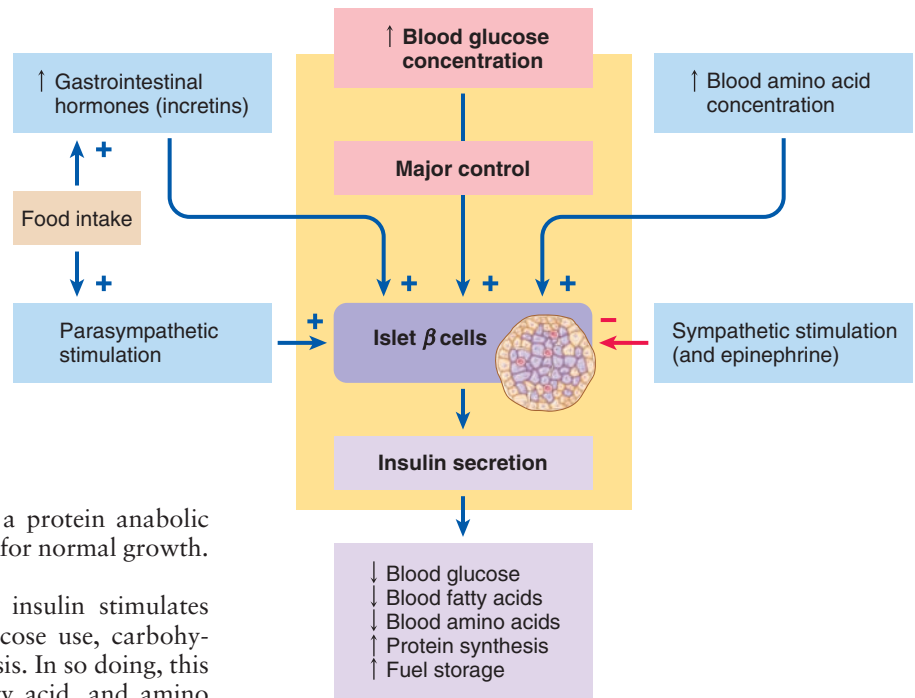

FIGURE 7-25 Factors controlling insulin secretion.

© Cengage Learning, 2013

cose to normal while it promotes use and storage of this nutrient. Conversely, a fall in blood glucose below normal, such as during fasting, directly inhibits insulin secretion. Lowering the rate of insulin secretion shifts metabolism from the absorptive to the postabsorptive pattern. Thus, this simple negative-feedback system can maintain a relatively constant supply of glucose to the tissues without requiring the participation of nerves or other hormones.

In addition to plasma glucose concentration, other inputs are involved in regulating insulin secretion, as follows (Figure 7-25):

- An elevated blood amino acid level, such as after eating a high-protein meal, directly stimulates β cells to increase insulin secretion. In negative-feedback fashion, the increased insulin enhances entry of these amino acids into the cells, lowering blood amino acid level while promoting protein synthesis.
- The major gastrointestinal hormones secreted by the digestive tract in response to food, especially *glucose-dependent insulinotropic peptide (GIP)* (see p. 711) and a similar candidate hormone *glucagon-like peptide (GLP)*, stimulate pancreatic insulin secretion in addition to having direct regulatory effects on the digestive system. Through this control, insulin secretion is increased in feedforward or anticipatory fashion (p. 16) even before nutrient absorption increases the concentration of glucose and amino acids in the blood. Hormones released from the digestive tract that “notify” the β pancreatic cell of the impending rise in blood nutrients (primarily blood glucose) are termed **incretins**. Incretins increase insulin secretion by increasing cAMP, which enhances Ca^{2+} -induced release of insulin.
- The autonomic nervous system also directly influences insulin secretion. The islets are richly innervated by both

parasympathetic (vagal) and sympathetic nerve fibers. The increase in parasympathetic activity that occurs in response to food in the digestive tract stimulates insulin release. This, too, is a feedforward response in anticipation of nutrient absorption. In contrast, sympathetic stimulation and the concurrent increase in epinephrine both inhibit insulin secretion. The reduction in insulin allows the blood glucose concentration to increase, an appropriate response to the circumstances under which generalized sympathetic activation occurs—namely, stress (fight-or-flight) and exercise. In both these situations, extra fuel is needed for increased muscle activity.

Glucagon in general opposes the actions of insulin

Even though insulin plays a central role in controlling the metabolic adjustments between the absorptive and post-absorptive states, the secretory product of vertebrate pancreatic-islet α cells, **glucagon**, is also very important. Many physiologists view the insulin-secreting β cells and the glucagon-secreting α cells as a coupled antagonistic endocrine system whose combined secretory output is a major factor in regulating fuel metabolism.

Glucagon affects many of the same metabolic processes that are influenced by insulin, but in most cases glucagon's actions are opposite to those of insulin. The major site of action of glucagon is the liver (serving as an effector), where it exerts a variety of effects on carbohydrate, fat, and protein metabolism.

Actions on Carbohydrate The overall effects of glucagon on carbohydrate metabolism are to increase hepatic glucose production and release, and thus raise blood glucose levels. Glucagon exerts its hyperglycemic effects by decreasing glycogen synthesis, promoting glycogenolysis, and stimulating gluconeogenesis.

Actions on Fat Glucagon also antagonizes the actions of insulin with regard to fat metabolism by promoting fat breakdown and inhibiting triglyceride synthesis. Glucagon enhances hepatic ketone production (**ketogenesis**) by promoting conversion of fatty acids to ketone bodies. Thus, blood levels of fatty acids and ketones rise under glucagon's influence.

Actions on Protein Glucagon inhibits hepatic protein synthesis and promotes degradation of hepatic protein. Stimulation of gluconeogenesis further contributes to glucagon's catabolic effect on hepatic protein metabolism. Glucagon promotes protein catabolism in the liver, but it does not have any significant effect on blood amino acid levels because it does not affect muscle protein, the major protein store in the body.

Glucagon secretion is increased during the postabsorptive state

Considering the catabolic effects of glucagon on energy stores, you would be correct in assuming that glucagon secretion is increased during the postabsorptive state and decreased during the absorptive state, just the opposite of insulin secretion. In fact, insulin is sometimes called a

“hormone of feasting” and glucagon a “hormone of fasting.” Insulin tends to put nutrients in storage when their blood levels are high, such as following a meal, whereas glucagon promotes catabolism of nutrient stores between meals to keep up the blood nutrient levels, especially blood glucose. The levels of glucagon vary not only within an individual but also among species; for example, the average concentration of glucagon in birds is approximately twice as great as in mammals, presumably because of the higher energy requirements of avian tissues.

As in insulin secretion, the major factor regulating glucagon secretion is a direct effect of the blood glucose concentration on the endocrine pancreas. In this case, the pancreatic α cells increase glucagon secretion in response to a fall in blood glucose. The hyperglycemic actions of this hormone tend to restore the blood glucose concentration to normal. Conversely, an increase in blood glucose concentration, such as after a meal, inhibits glucagon secretion, which likewise tends to restore the blood glucose concentration to normal.

Insulin and glucagon work as a team to maintain blood glucose and fatty acid levels

Thus, there is a direct negative-feedback relationship between blood glucose concentration and the α cells' rate of secretion, but it is in the opposite direction of the effect of blood glucose on the β cells (Figure 7-26). Because glucagon raises blood glucose and insulin decreases blood glucose, the changes in secretion of these pancreatic hormones in response to deviations in blood glucose work together homeostatically to restore blood glucose levels to normal.

Similarly, a fall in blood fatty-acid concentration directly stimulates glucagon output and inhibits insulin output by the pancreas, both of which are negative-feedback control mechanisms to restore the blood fatty-acid level to normal.

The effect of blood amino acid concentration on the secretion of these two hormones is a different story. A rise in blood amino acid concentration stimulates *both* glucagon and insulin secretion (Figure 7-27). Why this seeming paradox, because glucagon does not affect blood amino acid concentration? Because little carbohydrate is available for absorption following consumption of a high-protein meal, the amino-acid-induced increase in insulin secretion would drive too much glucose into the cells, causing a sudden, inappropriate drop in the blood glucose level. The hyperglycemic effects of glucagon counteract the hypoglycemic actions of insulin, with the net result maintenance of normal blood-glucose levels (and prevention of hypoglycemic starvation of the brain) during absorption of a meal that is high in protein but low in carbohydrates.

Epinephrine, cortisol, growth hormone, and thyroid hormone also exert direct metabolic effects

The pancreatic hormones are the most important regulators of normal fuel metabolism. However, several other hormones exert direct metabolic effects, even though control of their secretion is keyed to factors other than transitions in metabolism between feasting and fasting states (Table 7-7).

FIGURE 7-26 Complementary interactions of glucagon and insulin.

© Cengage Learning, 2013

FIGURE 7-27 Counteracting actions of glucagon and insulin on blood glucose during absorption of a high-protein meal.

© Cengage Learning, 2013

As we discussed earlier, the stress hormones, epinephrine and cortisol, both increase blood levels of glucose and fatty acids through a variety of metabolic effects, primarily in stress situations. In addition, cortisol mobilizes amino acids by promoting protein catabolism in long-term stress, including long-term starvation, in which the hormone appears to be important to maintaining blood glucose concentrations.

GH (acting through IGF-I) has protein anabolic effects in muscle. In fact, this is one of its growth-promoting features. Although GH can elevate the blood levels of glucose and fatty acids, it is normally of little importance to the overall regulation of fuel metabolism. Deep sleep, stress, exercise, and severe hypoglycemia stimulate GH secretion, possibly to provide fatty acids as an energy source and spare

TABLE 7-7 Summary of Hormonal Control of Fuel Metabolism

Hormone	MAJOR METABOLIC EFFECTS				CONTROL OF SECRETION	
	Effect on Blood Glucose	Effect on Blood Fatty Acids	Effect on Blood Amino Acids	Effect on Muscle Protein	Major Stimuli for Secretion	Primary Role in Metabolism

glucose for the brain under these circumstances. GH helps maintain blood glucose concentrations during short-term fasts as it opposes the catabolic effects of glucocorticoids on proteins.

Thyroid hormone regulation of basal metabolism is important for fuel homeostasis. The reduction in metabolic rate associated with fasting is associated with a decrease in the concentrations of T_3 while refeeding results in T_3 neogenesis. In ectotherms (and birds as well), increases in thyroid hormone may serve to impact intermediary metabolism by matching utilization of nutrients to nutrient intake.

Note that, with the exception of the anabolic effects of GH on protein metabolism, all the metabolic actions of these other hormones are opposite to those of insulin. Insulin alone can reduce blood glucose and blood fatty-acid levels, whereas glucagon, epinephrine, cortisol, and GH all increase blood levels of these nutrients. Because of this, these other hormones are considered **insulin antagonists**. Thus, the main reason diabetes mellitus (discussed next) has such

devastating metabolic consequences is that no other control mechanism is available to pick up the slack to promote anabolism when insulin activity is insufficient, so the catabolic reactions promoted by other hormones are allowed to proceed unchecked. The only exception is protein anabolism stimulated by GH.

The symptoms of diabetes mellitus are characteristic of an exaggerated postabsorptive state

A common and major form of failed glucose homeostasis is **diabetes mellitus** (*mellitus* means “sweet”). The acute symptoms of diabetes mellitus are attributable to inadequate insulin action coupled with glucagon excess. Because insulin is the only hormone capable of lowering blood glucose levels, one of the most prominent features of diabetes mellitus is elevated blood glucose levels, or *hyperglycemia*. Diabetes

literally means “siphon” or “running through,” a reference to the large urine volume accompanying the condition, caused by osmotic “attraction” from high glucose levels in the urine. Prolonged high-glucose concentrations have other long-term effects, including blindness from lens cataracts (although inappropriate voiding of the bladder is the first symptom a pet owner notices) (see the box, *Avian Longevity: Unraveling the Mystery*, p. 564).

There are two distinct types of diabetes mellitus. **Type I (insulin-dependent) diabetes mellitus** is characterized by a total or near-total lack of insulin secretion by pancreatic β cells, and occurs in many mammalian species. For example, in dogs the incidence of Type I diabetes is greater in smaller breeds, with about 1 in 400 domestic dogs and cats developing diabetes in their lifetime. Type I diabetes requires exogenous insulin for survival. It arises from an autoimmune reaction involving the erroneous, selective destruction of the pancreatic β cells by inappropriately activated T lymphocytes. The precise cause of this self-destructive immune attack remains unclear.

In humans with **Type II (non-insulin-dependent or maturity-onset) diabetes mellitus**, insulin secretion may be normal or even increased, but insulin’s target cells are less sensitive than normal to the hormone. Various genetic and lifestyle factors, most notably obesity, are important in the development of Type II diabetes, although the exact cellular mechanisms underlying the condition have not been completely unraveled. It is thought that reduced sensitivity arises from down-regulation (see p. 277) of insulin receptors in association with obesity. In response to chronic *hyperinsulinemia* (elevated blood insulin, which may result from a diet high in rapidly digesting carbohydrates), the number of insulin receptors gradually decreases over time.

How do insulin and glucagon regulate fuel metabolism?

What hormone(s) predominate in the fed state versus the fasting state? What is their role?

7.8 Endocrine Control of Calcium Metabolism in Vertebrates

Besides regulating the concentration of organic nutrient molecules in the blood by manipulation of anabolic and catabolic pathways, the endocrine system also regulates the plasma concentration of a number of inorganic electrolytes. For example, aldosterone controls Na^+ and K^+ concentrations in the ECF (Chapters 12 and 13). Three other hormones—*parathyroid hormone*, *calcitonin*, and *vitamin D*—control calcium (Ca^{2+}) and phosphate (PO_4^{3-}) metabolism after their ingestion from the diet and/or uptake from the gill. These hormonal agents concern themselves with regulating plasma Ca^{2+} , and in the process, plasma PO_4^{3-} is also maintained. Plasma Ca^{2+} concentration is one of the most tightly controlled variables in vertebrates. The need for the precise regulation of plasma Ca^{2+} stems from its critical influence on so many general physiological processes as well as from the

additional demands imposed by puberty, lactation, or oviposition (egg laying).

Calcium metabolism in water breathers is different from that in terrestrial vertebrates because, in addition to dietary Ca^{2+} , the ion is also available from the aqueous environment. For example, in seawater the concentration of Ca^{2+} is approximately 10 mmol/L (considerably greater than in cells), whereas in freshwater the concentration of Ca^{2+} varies from 0.1 to 4 mmol/L (comparable to intracellular concentrations). Fish can transport Ca^{2+} from either environment and maintain a positive calcium balance unless environmental concentrations of Ca^{2+} are extremely low, or environmental pollutants inhibit the functioning of the transporter.

Plasma calcium must be closely regulated to prevent changes in neuromuscular excitability

In mammals, about 99% of the Ca^{2+} in the body is in crystalline form within the skeleton and teeth. Of the remaining 1%, about 0.9% is found intracellularly within the soft tissues; less than 0.1% is present in the ECF. Approximately half of the plasma Ca^{2+} is either bound to plasma proteins and therefore restricted to the plasma or is complexed with PO_4^{3-} and not free to participate in chemical reactions. The other half of the plasma Ca^{2+} is freely diffusible and can readily pass into the interstitial fluid and interact with the cells. The free Ca^{2+} in the plasma and interstitial fluid is considered a single pool. Only this free Ca^{2+} is biologically active and subject to regulation; it constitutes less than one thousandth of the total Ca^{2+} in the body.

This small, freely diffusible fraction of ECF Ca^{2+} plays a vital role in a number of essential activities, including the following:

1. **Neuromuscular excitability.** Even minor variations in the concentration of free ECF Ca^{2+} can profoundly and immediately affect the sensitivity of excitable tissues. A fall in free Ca^{2+} results in overexcitability of nerves and muscles; conversely, a rise in free Ca^{2+} depresses neuromuscular excitability. These effects result from the influence of Ca^{2+} on membrane permeability to Na^+ . A decrease in free Ca^{2+} increases Na^+ permeability, with the resultant influx of Na^+ moving the resting potential closer to threshold. Consequently, in the presence of **hypocalcemia** (low blood Ca^{2+}) excitable tissues may be brought to threshold by normally ineffective physiological stimuli so that skeletal muscles discharge and contract (go into spasm) “spontaneously” (in the absence of normal stimulation). If severe enough, spastic contraction of the respiratory muscles results in death by asphyxiation. Hypercalcemia (elevated blood Ca^{2+}), in contrast, is also life threatening because it causes cardiac arrhythmias accompanied by generalized depression of neuromuscular excitability.
2. **Excitation–contraction coupling in cardiac and smooth muscle.** Ca^{2+} is the primary trigger of the contractile mechanism in muscles and arises from the ECF in cardiac and smooth muscle (Chapter 8). Note that a *rise in cytosolic Ca^{2+}* within a muscle cell causes contraction, whereas an *increase in free ECF Ca^{2+}* decreases neuromuscular excitability and reduces the likelihood of contraction occurring. Unless this point is kept in mind, it would be difficult to understand why low plasma Ca^{2+}

levels induce muscle hyperactivity when Ca^{2+} is necessary to switch on the contractile apparatus. We are talking about two different Ca^{2+} pools, which exert different effects.

3. **Stimulus–secretion coupling.** The entry of Ca^{2+} into secretory cells, which results from increased permeability to Ca^{2+} in response to appropriate stimulation, triggers the release of the secretory product by exocytosis. This process is important for the secretion of neurotransmitters by nerve cells (p. 131) and for peptide and catecholamine hormone secretion by endocrine cells.
4. **Maintenance of tight junctions between cells.** Calcium forms part of the intercellular cement that holds particular cells tightly together (p. 66).
5. **Clotting of blood.** Calcium serves as a cofactor in several steps of the cascade of reactions that lead to clot formation (p. 397).

In addition to these functions of free Ca^{2+} , intracellular Ca^{2+} serves as a second messenger in many cells and is involved in cell motility and cilia action. Here, calcium levels cannot be allowed to rise too greatly, because elevated Ca^{2+} precipitates readily with PO_4^{3-} as calcium phosphate (free PO_4^{3-} is a major anion in cells, necessary for ATP production, among other uses). Calcium phosphate is essential for bone and teeth formation but is harmful inside a cell.

Because of the profound effects of deviations in free Ca^{2+} , especially on neuromuscular excitability, the plasma concentration of this electrolyte is regulated with extraordinary precision in vertebrates. Let's see how.

Control of Ca^{2+} metabolism includes regulation of both calcium homeostasis and Ca^{2+} balance

Maintaining the proper plasma concentration of free Ca^{2+} differs from regulation of Na^+ and K^+ in two important regards. Na^+ and K^+ homeostasis is maintained primarily by regulating the urinary excretion of these electrolytes so that controlled output matches uncontrolled input (Chapters 12 and 13). In the case of Ca^{2+} , in contrast, not all the ingested Ca^{2+} is absorbed from the digestive tract; instead, the extent of absorption is hormonally controlled and is dependent on the Ca^{2+} status of the body. In addition, bone serves as a large Ca^{2+} reservoir that can be drawn on to maintain the free plasma Ca^{2+} concentration within the narrow limits compatible with life should dietary intake become too low. Exchange of Ca^{2+} between the ECF and bone is also subject to control. Similar in-house stores are not available for Na^+ and K^+ .

Regulation of Ca^{2+} metabolism depends on hormonal control of exchanges between the ECF and three other compartments serving as effectors: bone, kidneys, and intestine. Accordingly, control of Ca^{2+} metabolism encompasses two aspects:

1. Regulation of **calcium homeostasis** involves the immediate adjustments required to maintain a *constant free plasma Ca^{2+}* concentration on a minute-to-minute basis. This is largely accomplished by rapid exchanges between the bone and ECF and to a lesser extent by modifications in urinary excretion of Ca^{2+} .
2. Regulation of **calcium balance** involves the more slowly responding adjustments required to maintain a *constant total amount of Ca^{2+} in the body*. Control of Ca^{2+} balance ensures that Ca^{2+} intake is equivalent to Ca^{2+} ex-

cretion over the long term (weeks to months). Calcium balance is maintained by adjusting the extent of intestinal Ca^{2+} absorption and urinary Ca^{2+} excretion.

Parathyroid hormone (PTH), the principal regulator of Ca^{2+} metabolism, acts directly or indirectly on all three effector sites. It is the primary hormone responsible for maintaining Ca^{2+} homeostasis and is essential for maintaining Ca^{2+} balance, although vitamin D also contributes in important ways to Ca^{2+} balance. The third Ca^{2+} -influencing hormone, calcitonin, is not essential for routine maintenance of Ca^{2+} homeostasis in birds and mammals, though has roles in other vertebrates. We examine the specific effects of each of these hormonal systems in more detail.

Parathyroid hormone raises free plasma calcium levels by its effects on bone, kidneys, and intestine

Parathyroid hormone (PTH), the predominant hypercalcemic hormone in some amphibians, and reptiles, birds, and mammals, is a peptide hormone secreted by the **parathyroid glands**, four small glands located on the back surface of the mammalian thyroid gland, one in each corner. In birds the number of parathyroids varies between two and four and lie caudal to the thyroid. Like aldosterone, PTH is *essential for life*. The overall effect of PTH is to increase the Ca^{2+} concentration of plasma (and, accordingly, of the entire ECF), thereby preventing hypocalcemia. In the complete absence of PTH, death ensues within a few days, usually because of asphyxiation caused by hypocalcemic spasm of respiratory muscles. By its combined actions on bone, kidneys, and intestine (effectors), PTH raises the plasma Ca^{2+} level when it starts to fall so that hypocalcemia and its effects are normally avoided. This hormone also acts to lower plasma PO_4^{3-} concentration. We consider each of these mechanisms next, beginning with an overview of bone remodeling.

Bone continuously undergoes remodeling

Recall that 99% of the body's Ca^{2+} is found in the skeleton as **hydroxyapatite**, $\text{Ca}_3(\text{PO}_4)_2$ (p. 293). Bone has numerous functions:

- Support
- Protection of vital internal organs
- Assistance in body movement by giving attachment to muscles and providing leverage
- Manufacture of blood cells (bone marrow)
- Storage depot for Ca^{2+} and PO_4^{3-} , which can be exchanged with the plasma to maintain plasma concentrations of these electrolytes

Normally, $\text{Ca}_3(\text{PO}_4)_2$ salts are in solution in the ECF, but the conditions within the bone are suitable for these salts to precipitate (crystallize) around the collagen fibers in the matrix. By mobilizing some of these Ca^{2+} stores in the bone, PTH raises the plasma Ca^{2+} concentration when it starts to fall. Egg-laying birds (and dinosaurs as well) have a highly labile reservoir of Ca^{2+} in the form of **medullary bone**, which develops within the long bones in response to an increase in gonadal steroids at puberty. Medullary bone is the most exquisitely estrogen-sensitive form of vertebrate bone. The amount of Ca^{2+} contained in each egg amounts to about

10% of the total body stores of Ca^{2+} , and mobilized medullary bone accounts for approximately 30 to 40% of eggshell calcium.

Bone Remodeling Despite the apparent inanimate nature of bone, bone constituents are continually being turned over. **Bone deposition** and **bone resorption** normally go on concurrently, so bone is constantly being remodeled, much as people remodel buildings by tearing down walls and replacing them. Bone remodeling serves two purposes: (1) It keeps the skeleton appropriately “engineered” for maximum effectiveness in its mechanical uses, and (2) it helps maintain the plasma Ca^{2+} level. Let’s examine in more detail the underlying mechanisms and controlling factors for each of these purposes.

Recall that two key types of bone cells are important for bone growth, maintenance, and repair. The *osteoblasts* secrete the extracellular organic matrix within which the $\text{Ca}_3(\text{PO}_4)_2$ crystals precipitate. The *osteoclasts* resorb bone in their vicinity. (A third type, *osteocytes*, are “retired” osteoblasts imprisoned within the bony wall they have deposited around themselves.) The large, multinucleated osteoclasts attach to the organic matrix and form a “ruffled membrane” that increases its surface area in contact with the bone. Thus attached, the osteoclast actively secretes hydrochloric acid that dissolves the $\text{Ca}_3(\text{PO}_4)_2$ crystals and enzymes that break down the organic matrix. After it has created a cavity, the osteoclast moves on to an adjacent site to burrow another hole or dies by apoptosis (cell suicide), depending on the regulatory signals it receives. Osteoblasts move into the cavity and secrete osteoid to fill in the hole. Subsequent mineralization of this organic matrix results in new bone to replace the bone dissolved by the osteoclast. Thus, a constant cellular tug-of-war goes on in bone, with bone-forming osteoblasts countering the efforts of the bone-destroying osteoclasts. These construction and demolition crews, working side by side, continuously remodel bone. Throughout most of adult life, the rates of bone formation and bone resorption are about equal, so total bone mass remains fairly constant during this period.

Osteoblasts and osteoclasts both trace their origins to the bone marrow. Osteoblasts are derived from *stromal cells*, a type of connective tissue cell in the bone marrow, whereas osteoclasts differentiate from *macrophages*, a type of white blood cell (p. 465). In a unique communication system, osteoblasts and their immature precursors produce two chemical signals that govern osteoclast development and activity in opposite ways—*RANK ligand* and *osteoprotegerin*—as follows (Figure 7-28):

- **RANK ligand (RANKL)** revs up osteoclast action. (A **ligand** is a small molecule that binds with a larger protein molecule, such as an extracellular chemical messenger binding with a plasma membrane receptor.) As its name implies, RANK ligand binds to **RANK** (for *receptor activator of NF- κ B*), a protein receptor on the membrane surface of nearby macrophages. This binding induces the macrophages to differentiate into osteoclasts and helps them live longer by suppressing apoptosis. As a result, bone resorption is stepped up and bone mass decreases.
- Alternatively, neighboring osteoblasts can secrete **osteoprotegerin (OPG)**, which by contrast suppresses osteoclast activity. OPG secreted into the matrix serves as a

FIGURE 7-28 Role of osteoblasts in governing osteoclast development and activity.

© Cengage Learning, 2013

freestanding decoy receptor that binds with RANKL. By taking RANKL out of action so that it cannot bind with its intended RANK receptors, OPG prevents RANKL from revving up osteoclasts’ bone-resorbing activity. As a result, the matrix-making osteoblasts are able to outpace the matrix-removing osteoclasts, so bone mass increases.

The balance between RANKL and OPG thus is an important determinant of bone density. If osteoblasts produce more RANKL, the more osteoclast action, the lower the bone mass. If osteoblasts produce more OPG, the less osteoclast action, the greater the bone mass. Importantly, scientists are currently unraveling the influence of various factors on this balance. For example, the female sex hormone estrogen stimulates activity of the OPG-producing gene in osteoblasts and also promotes apoptosis of osteoclasts, both mechanisms by which estrogen preserves bone mass. It has this role in males as well as females.

PTH raises plasma Ca^{2+} by withdrawing Ca^{2+} from the bone

In addition to the factors geared toward controlling the mechanical effectiveness of bone, throughout life PTH uses bone as a “bank” from which it withdraws Ca^{2+} as needed to maintain plasma Ca^{2+} level. Parathyroid hormone has two major effects on bone that raise plasma Ca^{2+} concentration. First, it induces a fast Ca^{2+} efflux into the plasma from the small *labile pool* of Ca^{2+} in the bone fluid. Second, by stimulating bone dissolution, it promotes a slow transfer into the plasma of both Ca^{2+} and PO_4^{3-} from the *stable pool* of bone minerals in bone itself. As a result, ongoing bone remodeling is tipped in favor of bone resorption over bone deposition. Let’s examine more thoroughly PTH’s actions in mobilizing Ca^{2+} from its labile and stable pools in bone.

The immediate effect of PTH is to promote the transfer of Ca^{2+} from bone fluid into plasma

Compact bone forms the dense outer portion of a bone. Interconnecting spicules of **trabecular bone** make up the more lacy-appearing inner core of a bone (Figure 7-29a). Compact bone is organized into **osteon** units, each of which consists of a **central canal** surrounded by concentrically arranged **lamellae** (Figure 7-29b). Lamellae are layers of osteocytes entombed within the bone they have deposited around themselves (Figure 7-29c). The osteons typically run parallel to the long axis of the bone. Blood vessels penetrate the bone from either the outer surface or the marrow cavity and run through the central canals. Osteoblasts are present along the outer surface of the bone and along the inner surfaces lining the central canals. Osteoclasts are also located on bone surfaces undergoing resorption. The surface osteoblasts and entombed osteocytes are connected by an extensive network of small, fluid-containing canals, the **canaliculi**, which allow substances to be exchanged between trapped osteocytes and the circulation. These small canals also contain long, filmy cytoplasmic extensions, or “arms,” of osteocytes and osteoblasts that are connected to one another, much as if these cells were “holding hands.” The “hands” of adjacent cells are connected by gap junctions, which permit communication and exchange of materials among these bone cells. The interconnecting cell network, which is called the **osteocytic-osteoblastic bone membrane**, separates the mineralized bone itself from the blood vessels within the central canals (Figure 7-30a). The small, labile pool of Ca^{2+} is in the **bone fluid** that lies between this bone membrane and the adjacent bone, both within the canaliculi and along the surface of the central canal.

PTH exerts its effects via cAMP. The earliest effect of PTH is to activate membrane-bound Ca^{2+} pumps located in the plasma membranes of the osteocytes and osteoblasts. These pumps promote movement of Ca^{2+} , without the accompaniment of PO_4^{3-} , from the bone fluid into these cells, which in turn transfer the Ca^{2+} into the plasma within the central canal. Thus, PTH stimulates the transfer of Ca^{2+} from the bone fluid across the osteocytic-osteoblastic bone membrane into the plasma. Movement of Ca^{2+} out of the labile pool across the bone membrane accounts for the fast exchange between bone and plasma (Figure 7-30b). Because of the large surface area of the osteocytic-osteoblastic mem-

brane, small movements of Ca^{2+} across individual cells are amplified into large Ca^{2+} fluxes between the bone fluid and plasma.

After Ca^{2+} is pumped out, the bone fluid is replenished with Ca^{2+} from the partially mineralized bone along the adjacent bone surface. Thus, the fast exchange of Ca^{2+} does not involve resorption of completely mineralized bone, and bone mass is not decreased. Through this means, PTH draws Ca^{2+} out of the “quick-cash branch” of the bone bank and rapidly increases the plasma Ca^{2+} level without actually entering the bank (that is, without breaking down mineralized bone itself). Normally, this exchange is much more important for maintaining plasma Ca^{2+} concentration than is the slow exchange.

PTH’s chronic effect is to promote localized dissolution of bone to release Ca^{2+} into plasma

Under conditions of chronic hypocalcemia, such as may occur with dietary Ca^{2+} deficiency, PTH influences the slow exchange of Ca^{2+} between bone itself and the ECF by promoting actual localized dissolution of bone. It does so by acting on osteoblasts, causing them to secrete RANKL, thereby indirectly stimulating osteoclasts to gobble up bone and increasing the formation of more osteoclasts while transiently inhibiting the bone-forming activity of osteoblasts. Bone contains so much Ca^{2+} compared to the plasma (more than 1,000 times as much) that even when PTH promotes increased bone resorption, there are no immediate discernible effects on the skeleton because such a tiny amount of bone is affected. Yet the negligible amount of Ca^{2+} “borrowed” from the bone bank can be lifesaving in terms of restoring free plasma Ca^{2+} level to normal. The borrowed Ca^{2+} is then redeposited in the bone at another time when Ca^{2+} supplies are more abundant. Meanwhile, the plasma Ca^{2+} level has been maintained without sacrificing bone integrity. However, prolonged excess PTH secretion over months or years eventually leads to the formation of cavities throughout the skeleton that are filled with very large, overstuffed osteoclasts.

When PTH promotes dissolution of the $\text{Ca}_3(\text{PO}_4)_2$ crystals in bone to harvest their Ca^{2+} content, both Ca^{2+} and PO_4^{3-} are released into the plasma. An elevation in plasma PO_4^{3-} is undesirable, but PTH deals with this dilemma by its actions on the kidneys.

PTH acts on the kidneys to conserve Ca^{2+} and to eliminate PO_4^{3-}

PTH promotes Ca^{2+} conservation and PO_4^{3-} elimination by the kidneys during urine formation. Under the influence of PTH, the kidneys can reabsorb more of the filtered Ca^{2+} , so less Ca^{2+} escapes into urine. This effect increases the plasma Ca^{2+} level and decreases urinary Ca^{2+} losses. (It would be counterproductive to dissolve bone to obtain more Ca^{2+} only to lose it in urine.) By contrast, PTH decreases PO_4^{3-} reabsorption, thus increasing urinary PO_4^{3-} excretion. As a result, PTH reduces plasma PO_4^{3-} levels at the same time it increases plasma Ca^{2+} concentrations.

An additional function of PTH on the kidneys (besides increasing Ca^{2+} reabsorption and decreasing PO_4^{3-} reabsorption) is to enhance the activation of vitamin D by the kidneys.

PTH indirectly promotes absorption of Ca^{2+} and PO_4^{3-} by the intestine

Although PTH has no direct effect on the intestine, it indirectly increases both Ca^{2+} and PO_4^{3-} absorption from the small intestine by means of its role in vitamin D activation. This vitamin, in turn, directly increases intestinal absorption of Ca^{2+} and PO_4^{3-} .

The primary signal for regulating PTH secretion is the plasma concentration of free Ca^{2+}

All the effects of PTH are aimed at raising the plasma Ca^{2+} levels. Appropriately, PTH secretion is increased in response to a fall in plasma Ca^{2+} concentration and decreased by a

rise in plasma Ca^{2+} levels. The secretory cells of the parathyroid glands are directly and exquisitely sensitive to changes in free plasma Ca^{2+} . Because PTH regulates plasma Ca^{2+} concentration, this relationship forms a simple negative-feedback loop for controlling PTH secretion without involving any nervous or other hormonal intervention, with the glands serving as sensing integrators much like a house thermostat (Figure 7-31).

Calcitonin lowers the plasma Ca^{2+} concentration, but may not be essential

Calcitonin (CT), the hormone produced by the C cells of the mammalian thyroid gland, is synthesized in anatomically distinct glands in most vertebrates. In birds the paired

FIGURE 7-30 Fast and slow exchanges of Ca^{2+} across the osteocytic–osteoblastic bone membrane. (a) Entombed osteocytes and surface osteoblasts are interconnected by long cytoplasmic processes that extend from these cells and connect to one another within the canaliculi. This interconnecting cell network, the osteocytic–osteoblastic bone membrane, separates the mineralized bone from the plasma in the central canal. Bone fluid lies between the membrane and the mineralized bone. (b) Fast exchange of Ca^{2+} between the bone and plasma is accomplished by Ca^{2+} pumps in the osteocytic–osteoblastic bone membrane that transport Ca^{2+} from the bone fluid into the plasma. Slow exchange of Ca^{2+} between the bone and plasma is accomplished by osteoclast dissolution of bone.

(a) Osteocytic–osteoblastic bone membrane

(b) Fast and slow exchange of Ca^{2+} between bone and plasma

- 1 In a fast exchange, Ca^{2+} is moved from the labile pool in the bone fluid into the plasma by PTH-activated Ca^{2+} pumps located in the osteocytic–osteoblastic bone membrane.
- 2 In a slow exchange, Ca^{2+} is moved from the stable pool in the mineralized bone into the plasma through PTH-induced dissolution of the bone by osteoclasts.

ultimobranchial glands lie posterior to the parathyroids, whereas in fish calcitonin secreting cells are located in connective tissue sheets around the heart. In fish, calcitonin has been suggested to promote bone formation by osteoblasts. Salmon CT is the most powerful form of calcitonin known in regulating calcium, and is administered to humans suffering from osteoporosis. However, its role in fish is still uncertain, and the most important hormone regulating calcium homeostasis in bony fish appears to be the hypocalcemic hormone, **stanniocalcin** (formerly called *hypocalcin*), which is synthesized in small organs termed the **corporacles of Stannius** located within the kidney. The ability to lower blood calcium is of greatest importance in seawater fishes, which are constantly exposed to the high levels of calcium present in seawater; PTH does not occur in these fishes. In response to the release of stanniocalcin, calcium uptake at the gills and intestine is rapidly reduced. In mammals, calcitonin exerts a comparatively weak effect on plasma Ca^{2+} levels.

Like PTH, CT has two effects on bone, but in this case both effects *decrease* plasma Ca^{2+} levels. First, on a short-term basis calcitonin decreases Ca^{2+} movement from the bone fluid into the plasma. Second, on a long-term basis CT decreases bone resorption by inhibiting the activity of osteoclasts. The suppression of bone resorption results in decreased plasma PO_4^{3-} levels as well as a reduced plasma Ca^{2+} concentration. CT only affects bone; it has no effect on the kidneys or intestine.

As with PTH, the primary regulator of calcitonin release is the free plasma Ca^{2+} concentration; an increase in plasma Ca^{2+} stimulates and a fall in plasma Ca^{2+} inhibits CT secretion (Figure 7-31). Because CT reduces plasma Ca^{2+}

FIGURE 7-31 Negative-feedback loops controlling parathyroid hormone (PTH) and calcitonin secretion.

FIGURE 7-32 Activation of vitamin D.

© Cengage Learning, 2013

levels, this system constitutes a second simple negative-feedback control over plasma Ca^{2+} concentration, one that is antagonistic to the PTH system. The effects of CT in birds and mammals are weak, however, and do not appear to be important in normal Ca^{2+} homeostasis. Most evidence suggests, that CT plays a critical role in protecting skeletal integrity when there is a large Ca^{2+} demand, such as during pregnancy or mammary-gland feeding.

Vitamin D is actually a hormone that increases calcium absorption in the intestine

The final factor involved in the regulation of Ca^{2+} metabolism in vertebrates is **cholecalciferol**, or vitamin D, a steroid-like compound that is essential for Ca^{2+} absorption in the intestine. The livers of marine teleosts are well known to contain high concentrations of vitamin D, which has traditionally been used as a nutritional supplement. Strictly speaking, vitamin D should be considered a hormone because it can be produced in the skin from a precursor related to cholesterol (7-dehydrocholesterol) on exposure to sunlight. It is subsequently released into the blood to act at a

distant target site, the intestine. The skin, therefore, is actually an endocrine gland and vitamin D is a prohormone. In 1931, the researcher H. C. Hou found that removing the *preen gland* from chicks caused rickets to develop even if the chicks were exposed to sunlight. From this observation he deduced that birds secrete a provitamin D from the preen gland onto their feathers, where it is converted into vitamin D. Traditionally, however, this chemical messenger has been named a vitamin—that is, a dietary supplement—for two reasons. First, scientists originally discovered and isolated it from a dietary source and tagged it as a vitamin. Second, even though the skin would be an adequate source of vitamin D if it were exposed to sufficient sunlight, indoor housing of production animals requires that it be supplemented in their diets.

Activation of Vitamin D Regardless of its source, vitamin D is biologically inactive when it first enters the blood from either the skin or the digestive tract. It must be activated by two sequential biochemical alterations that involve the addition of two hydroxyl ($-\text{OH}$) groups (Figure 7-32). The first of these reactions occurs in the liver and the second in the kidneys. The end result is production of the active form of vitamin D, **1,25-(OH) $_2$ -vitamin D $_3$** , also known as **calcitriol**. In response to a fall in plasma Ca^{2+} , PTH stimulates the kidney enzyme 1 α -hydroxylase that is involved in the second step of vitamin D activation. To a lesser extent, a fall in plasma PO_4^{3-} also enhances the activation process.

Function of Vitamin D The most dramatic and biologically important effect of activated vitamin D is to increase Ca^{2+} absorption in the intestine. Unlike most dietary constituents, dietary Ca^{2+} is not indiscriminately absorbed by the digestive system. In fact, the majority of ingested Ca^{2+} is typically not absorbed but is lost instead into the feces. When needed, more dietary Ca^{2+} is absorbed into the plasma under the influence of calcitriol. Calcitriol induces RNA transcription and synthesis of proteins including the calcium-binding protein, **calbindin D $_{28k}$** . For example, the onset of egg lay in birds coincides with increased 1,25-(OH) $_2$ -vitamin D $_3$ concentrations, which elevates concentrations of calbindin and increases intestinal calcium transport. Independent of its effects on Ca^{2+} transport, calcitriol also increases intestinal PO_4^{3-} absorption. Furthermore, calcitriol increases the responsiveness of bone to PTH. Thus, vitamin D and PTH have a closely interdependent relationship (Figure 7-33). Vitamin D may be used in some nonvertebrates; a role for steroids in Ca^{2+} absorption in the snail *Helix aspersa* has been demonstrated, with vitamin D shown to be more effective than cholesterol.

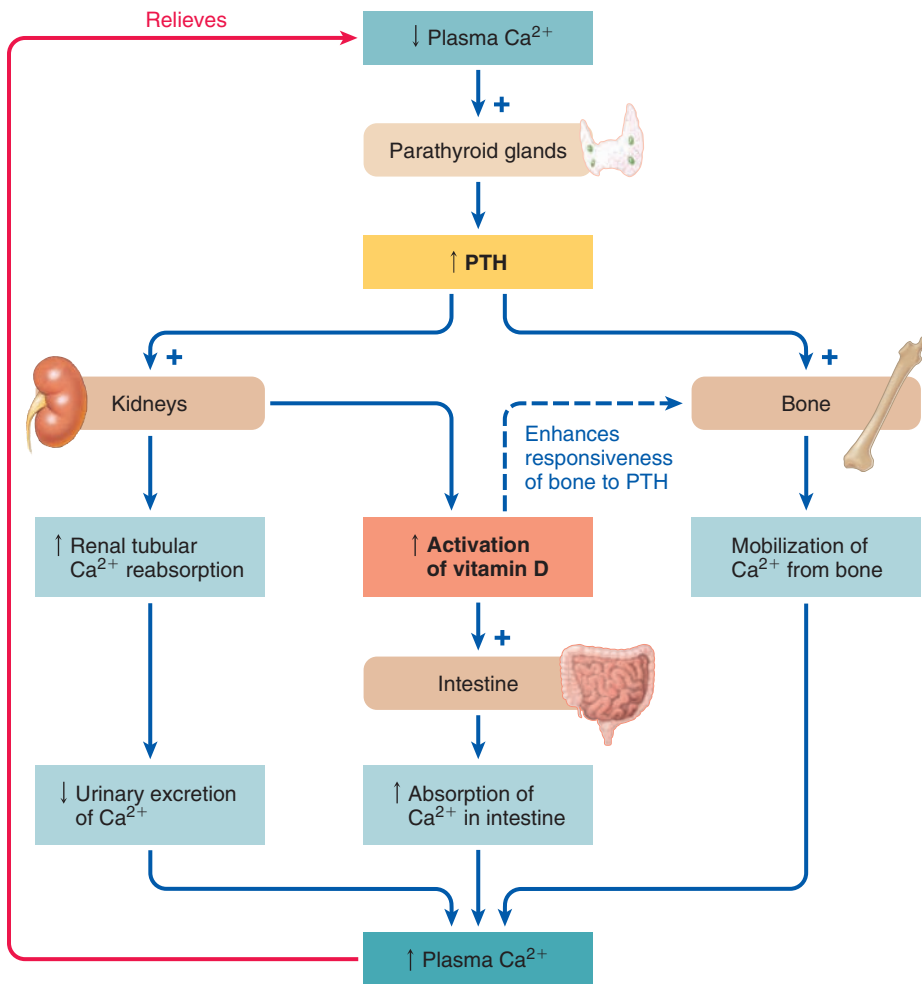

FIGURE 7-33 Interactions between PTH and vitamin D in controlling plasma calcium.

© Cengage Learning, 2013

PTH is principally responsible for controlling Ca^{2+} homeostasis, because the actions of calcitriol are too sluggish for it to contribute substantially to the minute-to-minute regulation of plasma Ca^{2+} concentration. However, both PTH and calcitriol are essential to Ca^{2+} balance, the process that ensures that, over the long term, Ca^{2+} input into the body is equivalent to Ca^{2+} output. When dietary Ca^{2+} intake is reduced, the resultant increase in PTH activates calcitriol, which increases the efficiency of uptake of ingested Ca^{2+} .

Phosphate metabolism is controlled by the same mechanisms that regulate Ca^{2+} metabolism

In the ECF, plasma PO_4^{3-} concentration is not as tightly controlled as plasma Ca^{2+} concentration. Phosphate is regulated directly by calcitriol and indirectly by the plasma Ca^{2+} –PTH feedback loop. To illustrate, a fall in plasma PO_4^{3-} concentration exerts a twofold effect to help restore the circulating PO_4^{3-} level back to normal (Figure 7-34). First, a fall in plasma PO_4^{3-} causes an increase in plasma Ca^{2+} , which directly suppresses PTH secretion. In the presence of reduced PTH, PO_4^{3-} reabsorption by the kidneys increases, returning plasma PO_4^{3-} concentration toward

normal. Second, a fall in plasma PO_4^{3-} also results in increased activation of vitamin D, which then promotes PO_4^{3-} absorption in the intestine. This further helps to alleviate the initial hypophosphatemia. Note that these changes do not compromise Ca^{2+} balance. Although the increase in activated vitamin D stimulates Ca^{2+} absorption, the concurrent fall in PTH produces a compensatory increase in urinary Ca^{2+} excretion because less of the filtered Ca^{2+} is reabsorbed. Therefore plasma Ca^{2+} remains unchanged while plasma PO_4^{3-} is being increased to normal.

Disorders in Ca^{2+} metabolism may arise from abnormal levels of parathyroid hormone or vitamin D

The primary disorders that affect Ca^{2+} metabolism are too much or too little PTH, a deficiency of vitamin D, or excessive demands on blood calcium concentrations. Let's look at three of these.

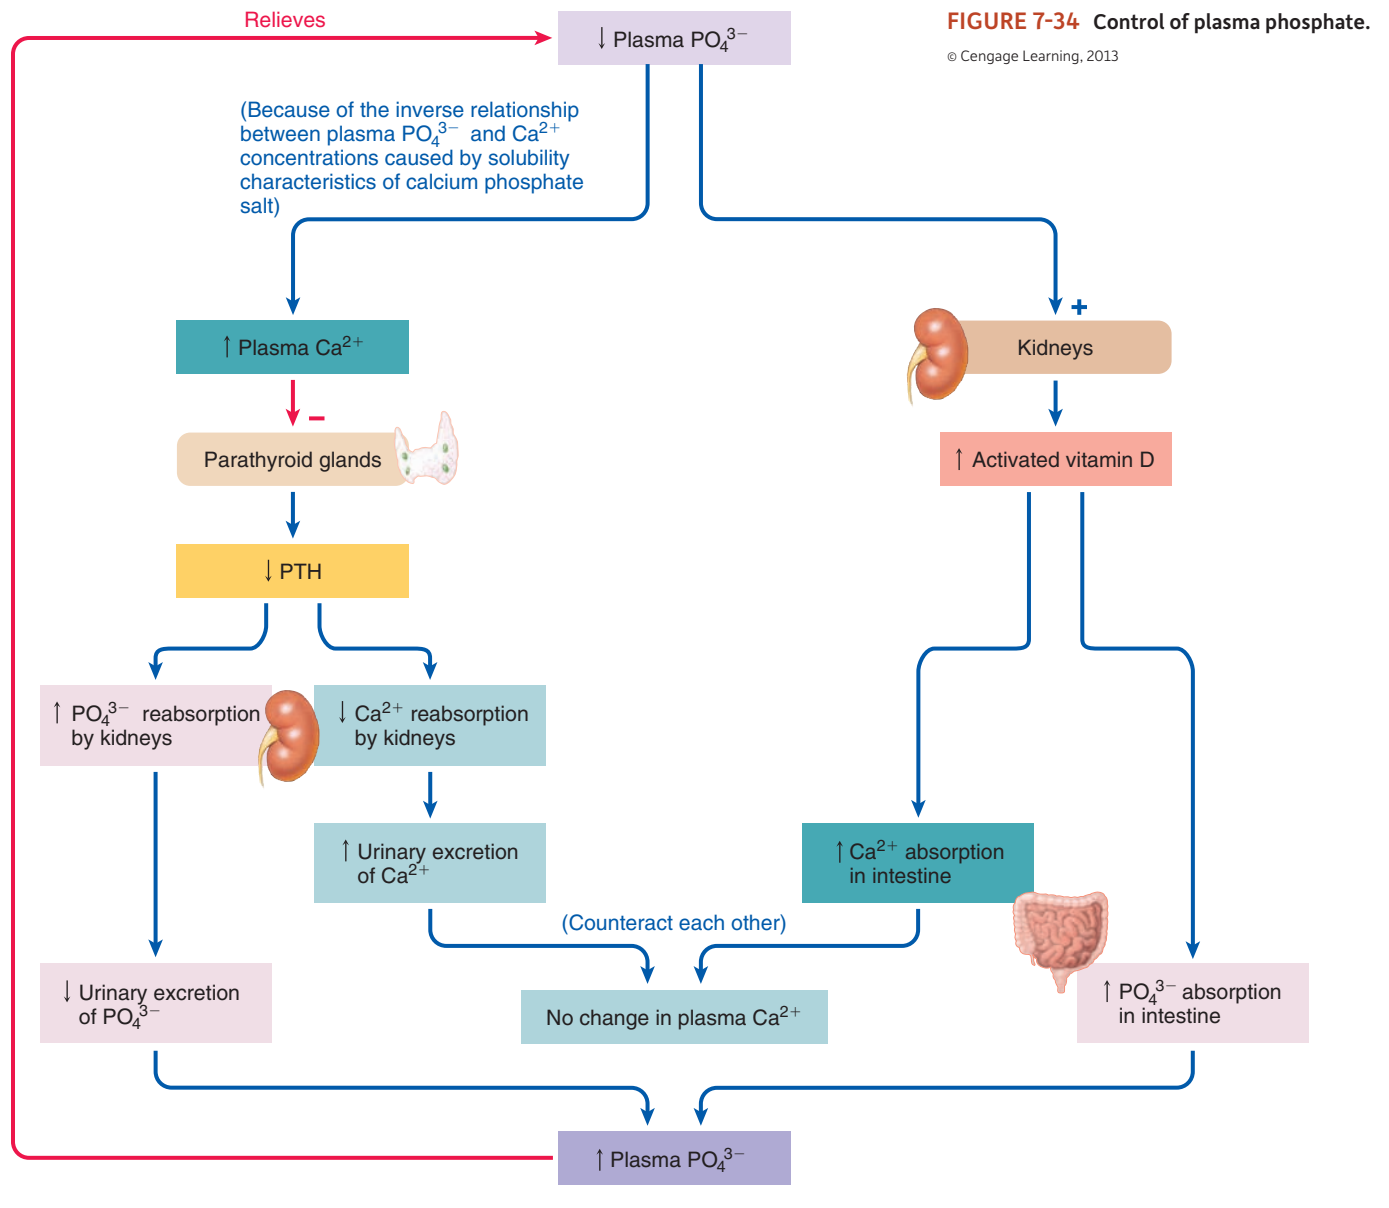

PTH Hypersecretion Excess PTH secretion, or hyperparathyroidism, occurs in domestic animals in response to diets low in calcium or vitamin D

content. These may be all-meat diets for carnivores, which are low in calcium, or inappropriate diets, such as those for horses that are high in phosphate relative to calcium. Less frequently there may be a hypersecreting tumor in one of the parathyroid glands. The affected animal can be asymptomatic or symptoms can be severe, depending on the magnitude of the problem. The following are among the possible consequences of the ensuing hypercalcemia and hypophosphatemia:

- *Reduced excitability of muscle and nervous tissue* leads to muscle weakness and neurological disorders. Cardiac disorders may also occur.
- *Excessive mobilization of Ca^{2+} and PO_4^{3-} from skeletal stores* leads to thinning of bone, which may result in skeletal deformities and increased incidence of fractures.
- *An increased incidence of Ca^{2+} -containing kidney stones* occurs because the excess quantity of Ca^{2+} being filtered through the kidneys may precipitate and form stones. These stones may impair renal function. Passage of the stones through the ureters causes extreme pain.

Because of these potential multiple consequences, hyperparathyroidism has been called a disease of “bones, stones, and abdominal groans.”

Vitamin D Deficiency The major consequence associated with vitamin D deficiency is impaired intestinal absorption of Ca^{2+} . In the face of reduced Ca^{2+} uptake, PTH maintains the plasma Ca^{2+} level at the expense of the bones. As a re-

sult, the bone matrix is not properly mineralized because Ca^{2+} salts are not available for deposition. The demineralized bones become soft and deformed, bowing to the pressures of weight bearing. This condition is known as **rickets** in prepubertal mammals and **osteomalacia** in adults. In the absence of vitamin D, amphibians (such as South African clawed toads) and reptiles are particularly susceptible to the development of rickets.

Excessive Demands for Calcium We end our discussion of disorders of calcium metabolism with a look at the effects of excessive demands. These occur most notably in farm animals bred for two specialized processes: milk production by dairy cows and egg laying by hens.

- *Parturient paresis (milk fever, or parturient hypocalcemia)*. This is the most common metabolic disorder affecting high-producing dairy cattle and provides a dynamic example of calcium metabolism during the immediate postpartum period. Because colostrum con-

tains high concentrations of calcium (2 g/L) and approximately 3 g of calcium are required per hour to produce colostrum, the inability of the dairy cow to adequately mobilize calcium reserves results in the characteristic symptoms of milk fever, which include restlessness, anxiety, anorexia, incoordination, and a lack of interest in their calves. The incidence of milk fever increases with age and yield of the animals. Affected cattle usually demonstrate symptoms within 72 hours following parturition. Without intervention the cow's progress to a second stage, which is manifested by recumbency: The cows lie on their sternums with their heads turned back toward their flanks, breathing is slow and labored, and body temperatures are below normal. In the final stage of parturient paresis the cows are stretched out on their sides as they progress from dullness to coma.

If the cows are fed an *increased level* of calcium in the diet during the *prepartum* period, then which hormone is predominant during the early lactation period?

Photo: Courtesy of USDA/Agricultural Research Service

Dairy cows can develop milk fever from the excessive demands for calcium in milk production.

The answer is *calcitonin*, which functions to block the resorption of calcium by PTH at the bone. Consider the profound impact on plasma calcium concentrations as colostrum begins to be produced. The sudden demand for calcium—more than all the calcium present in the blood—results in a dramatic decline in calcium concentrations in the blood, which triggers an enormous output of PTH from the parathyroid gland. Because of the elevated plasma-calcitonin concentrations, PTH can exert its effect primarily at the intestinal level, which cannot fill the increased demands placed on it. (Note that this does not necessarily reveal an important natural role for calcitonin, because this is an artificial situation of feeding calcium to a cow bred for high milk production.) However, if the cow is placed on a *low-calcium diet* (supplemented with vitamin D) during the prepartum period, then concentrations of PTH predominate during parturition and they are eminently more successful in mobilizing calcium from the bone reservoirs. Acting in concert with vitamin D to increase concentrations of calcium-binding protein in the intestinal epithelia and calcium transport across the intestine, PTH now acts uninhibitedly on bone to effectively combat the decline in blood calcium concentrations, and thus dramatically reduces the incidence of milk fever.

- *Egg lay in female birds.* Comparable to these events, which drain calcium from the blood of lactating dairy cows, is the situation in egg-laying birds. In the laying hen, an amount of calcium equivalent to 8 to 10% of the total calcium in her body is secreted into the shell each day on which an egg is laid (**oviposition**). Researchers believe the shell, composed primarily of calcium carbonate, evolved from the soft cover of eggs of ancestral reptiles into the calcareous shell to give a measure of protection from attacks by predators and pathogens (including soil organisms). PTH can rapidly mobilize calcium from the medullary bone whenever the rate at which calcium deposition on the shell exceeds the rate at which it is absorbed from the intestinal tract. Thus, as expected, there is a reciprocal relationship between the concentrations of PTH and Ca^{2+} during the egg cycle. During the two-week period prior to the onset of lay, a whole new system of secondary bone, medul-

lary bone (p. 324), is laid down in the marrow cavities of most bones under the combined influence of estrogens and androgens secreted from the developing follicles. Interestingly, calcitriol does not stimulate the synthesis of a calcium transporter (Ca^{2+} -ATPase) in the shell gland of a laying bird (unlike the situation in the intestinal epithelial cells) but rather its production is regulated by estrogen. When a bird goes “out of lay,” concentrations of estrogen decline in concert with the reduction in shell gland Ca^{2+} -ATPase activity.

How the Endocrine System Contributes to the Body as a Whole

The endocrine system is one of an animal’s two major control systems, the other being the nervous system (although, as you will see in Chapter 10, some physiologists consider the immune system a third major control system). Through its relatively slow-acting hormonal messengers, the endocrine system generally regulates activities that require duration rather than speed. Some endocrine systems are aimed at regulated changes such as these in vertebrates:

- Most aspects of postnatal development and growth are regulated by hormones such as GH and IGFs.
- The major hormone secreted by the adrenal medulla, epinephrine, generally reinforces activities of the sympathetic nervous system. It elevates blood pressure and also helps prepare the body for peak physical responsiveness in fight-or-flight situations. This includes increasing the plasma concentrations of glucose and fatty acids above normal, which provides additional energy sources for increased physical activity.
- The thyroid hormones, tetraiodothyronine (T_4) and triiodothyronine (T_3), increase the overall metabolic rate, influencing the rate at which cells use nutrient molecules and O_2 within the internal environment.

Other endocrine actions are directed toward maintaining homeostasis, as exemplified by the following in vertebrates:

- The actions of the thyroid hormones also produce heat, which helps maintain body temperature in endotherms.
- The adrenal cortex secretes cortisol, the primary glucocorticoid secreted by the adrenal cortex, which increases the plasma concentrations of glucose, fatty acids, and amino acids above normal. Although these actions change the concentrations of these molecules in the internal environment, they indirectly contribute to homeostasis by making the molecules readily available as energy sources or building blocks for tissue repair to help the body adapt to stressful situations.
- The two major hormones secreted by the endocrine pancreas, insulin and glucagon, are important in shifting metabolic pathways between the absorptive and postab-

sorptive states, which maintains the appropriate plasma levels of nutrient molecules, by regulating cellular uptake, storage, and release of these molecules (the crustacean hyperglycemic hormone is another example).

- Parathyroid hormone from the parathyroid glands is critical to maintaining plasma concentration of Ca^{2+} . PTH is essential for life because of Ca^{2+} 's effect on neu-

romuscular excitability. In the absence of PTH, death rapidly occurs from asphyxiation caused by pronounced spasms of the respiratory muscles.

Hormones often act in negative-feedback fashion to resist the change that induced their secretion, thus maintaining stability in the internal environment.

Chapter Summary

- The ability of cells to “communicate” with each other is ancient, preceding the evolution of multicellularity in the form of pheromones among unicellular organisms. In animals, pheromones gave rise to internal signal molecules used locally within a tissue. With the evolution of circulatory systems, which provided an effective route for delivering signal molecules to distant tissues, there arose endocrine systems, which consist of ductless glands that secrete hormones (signal molecules delivered by circulatory fluids), providing a second mechanism (in addition to nervous systems) for regulating and coordinating distant organs.
- Hormones are chemically classified into three categories: peptides and proteins, amines, and steroids. The mechanisms of hormone synthesis, storage, and secretion vary according to the class of hormone.
- Hydrophilic hormones are transported dissolved in the plasma, whereas lipid-soluble hormones are almost always transported bound to plasma proteins.
- Hormones exert a variety of regulatory effects throughout the body. Compared to neural responses that are brought about within milliseconds, hormone action is relatively slow and prolonged, taking minutes to hours for the response to take place after the hormone binds to its receptor.
- Nonnative or hormonelike substances termed endocrine-disrupting chemicals (EDCs), whose structures are similar to hormones, can sometimes disrupt endocrine communication by altering hormone secretion, transport, or action. These compounds are derived from the by-products of manufactured organic compounds.
- Hormones produce their effects by altering intracellular proteins through ion fluxes, second messengers, and transcription factors.
- The effective plasma concentration of a hormone is normally regulated by changes in its rate of secretion.
- The most common endocrine rhythm is the circadian (“around a day”) rhythm, which is characterized by repetitive oscillations in gene expression that correspond with changes in the physiology, metabolism, and behavior in nearly all organisms on Earth.
- The effective plasma concentration of a hormone can be influenced by the hormone’s transport, metabolism, and excretion. The responsiveness of a target cell to its hormone can be varied by regulating the number of its hormone-specific receptors.
- Endocrine disorders are attributable to hormonal excess, hormonal deficiency, or decreased responsiveness of the target cells.
- Nonvertebrate hormones are produced either by neurosecretory cells or glands in neural haemal organs where the axonal endings secrete the hormone into the haemolymph, which then can bind to specific receptors on peripheral organs.
- The pituitary has two anatomically and functionally distinct lobes, the posterior pituitary and the anterior pituitary. The hypothalamus and posterior pituitary form a neurosecretory system that secretes vasopressin and oxytocin. The anterior pituitary secretes six established hormones, many of which are tropic. In agnathans, amphibians, reptiles, and most mammals, the adenohypophysis includes a third, well-defined intermediate lobe (pars intermedia).
- Hypothalamic releasing and inhibiting hormones are delivered to the anterior pituitary by the hypothalamic–hypophyseal portal system to control anterior pituitary hormone secretion.
- Target gland hormones inhibit hypothalamic and anterior pituitary hormone secretion via negative feedback.
- To exert its metabolic effects, growth hormone (GH) binds directly with receptors on adipose tissue, skeletal muscles, and liver. GH’s indirect growth-promoting actions are mediated by Insulin-like growth factors (IGFs), which act on the target cells to cause growth of both soft tissues and bones. GH secretion is regulated by two hypophysiotropic hormones and influenced by a variety of other factors.
- Prolactin has a wide range of effects, including lactogenesis, reproductive behaviors, and ion regulation.
- Thyroid hormone is the primary determinant of overall metabolic rate and exerts other effects as well, such as amphibian development. Thyroid hormones are produced by a thyroid follicle in the thyroid gland. Most of the secreted thyroxine (T_4) is converted into triiodothyronine (T_3), or activated, by deiodinase enzyme (Type II) that strips off one of its iodines. T_3 is the major biologically active form of thyroid hormone at the cellular level.
- In most vertebrates, the adrenal gland consists of a steroid-secreting cortex intermingled with chromaffin tissue. The adrenal cortex secretes mineralocorticoids, glucocorticoids, and sex hormones.
- Glucocorticoids produced from the adrenal cortex exert metabolic effects and have an important role in adaptation to stress. Glucocorticoid secretion is directly regulated by the hypothalamic–pituitary–adrenal axis.
- Ganglionic cell bodies within the adrenal medulla release their chemical transmitter directly into the circulation on stimulation by the preganglionic fiber. Sympathetic stimulation of the adrenal medulla is solely responsible for epinephrine release.
- Epinephrine reinforces the sympathetic nervous system in “fight-or-flight” short-term stress, and exerts additional metabolic effects. The stress response is a generalized, nonspecific pattern of neural and hormonal reactions to any situation that threatens homeostasis.
- Fuel metabolism includes anabolism, catabolism, and interconversions among energy-rich organic molecules. Metabolic fuels are stored during the absorptive state and are mobilized during the postabsorptive state.
- The pancreatic hormones, insulin and glucagon, are most important in regulating fuel metabolism. Insulin lowers blood glucose, amino

acid, and fatty acid levels and promotes their storage. Glucagon in general opposes the actions of insulin. Glucagon promotes catabolism of nutrient stores between meals to keep up the blood nutrient levels, especially blood glucose.

- Plasma calcium must be closely regulated to prevent changes in neuromuscular excitability. Bone is the primary location of calcium; it is constantly remodeled by actions of osteoblasts (bone builders) and osteoclasts (bone destroyers). Three hormones—parathyroid hormone, calcitonin, and vitamin D—control calcium (Ca^{2+}) and

phosphate (PO_4^{3-}) metabolism after their ingestion from the diet and/or uptake from the gill. Parathyroid hormone raises free plasma calcium levels by its effects on bone, kidneys, and intestine. PTH acts on the kidneys to conserve Ca^{2+} and to eliminate PO_4^{3-} . On a long-term basis, calcitonin decreases bone resorption by inhibiting the activity of osteoclasts. Vitamin D is a hormone that increases calcium absorption in the intestine. Phosphate metabolism is controlled by the same mechanisms that regulate Ca^{2+} metabolism.

Review, Synthesize, and Analyze

1. Would you expect the concentration of hypothalamic releasing and inhibiting hormones in a systemic venous blood sample to be higher, lower, or the same as the concentration of these hormones in a sample of hypothalamic–hypophyseal portal blood?
2. Thinking about the feedback control loop among TRH, TSH, and thyroid hormone, would you expect the concentration of TSH to be normal, above normal, or below normal in an animal whose diet is deficient in iodine (an element essential for synthesizing thyroid hormone)?
3. An animal displays symptoms of excess cortisol secretion. What factors could be measured in a blood sample to determine whether the condition is caused by a defect at the hypothalamic/anterior pituitary level or the adrenal cortex level?
4. Discuss the release of hypophysiotropic hormones from the hypothalamus.
5. How is the multifaceted general stress response manifested in a mammal?
6. How is intermediary metabolism altered in the fed versus the fast-ing state?
7. Glucose homeostasis is altered in diabetes. Elaborate on the changes that result in chronic hyperglycemia?
8. How does parathyroid hormone adjust calcium and phosphate levels in the blood?
9. Explain the effect of a lack of activated vitamin D (due to inadequate exposure to sunlight) on an animal. How then are animals maintained indoors for the duration of their lifetime without developing these abnormalities?

Muscle Physiology

8.1 Introduction

Almost all living cells have rudimentary intracellular machinery for producing movement, including that associated with the redistribution of various cell components during cell division, other types of intracellular trafficking, and movement of whole cells (Chapter 2). For example, white blood cells and amoebas use intracellular contractile *microfilaments* (p. 62) to propel themselves through their environment with pseudopodia. Other cells such as sperm and paramecia move with *microtubule*-based propulsive structures called *cilia* and *flagella* (p. 60). As the first animals evolved, larger scale movements evolved from these intracellular ones. For example, Porifera (sponges) create large-scale water currents using numerous flagellated cells. Many aquatic larvae, flatworms, and even 1.5-meter comb jellies (ctenophores) move slowly through the environment by the beating of dozens to thousands of coordinated cilia. However, other (especially faster) locomotory movements of animals required the evolution of a highly organized microfilament-based structure called a **muscle**: a specialized cell that *contracts* to pull an external structure or squeeze a fluid. With the use of skeletons or fluids, the force produced by muscle can be transmit-

ted over a considerable distance and can generate large and often rapid movements (as you will see). In addition, the energy of muscle contraction can be stored temporarily in specialized elastic structures, and then released rapidly to create even faster movements. For example, even at near-freezing temperatures, ectothermic (“cold-blooded”) chameleons can capture prey by rapidly uncoiling tongues powered not by muscles that only weakly contract in the cold environment to retract the tongue but by energy stored during that contraction in a rubber-band-like sheath of collagen inside their tongue.

These combined innovations—contractile muscle cells, force-transmitting skeletons or fluids, and elastic storage structures—are very different from flagellar and ciliary mechanisms. Moreover, though muscles use microfilaments like pseudopodia, they power locomotion outside the cell rather than within it. All animal phyla above the Porifera (that is, sponges, which have no true organs) contain clearly identifiable muscle cells, often organized into muscle organs. By far, the most important effectors for animal *behavior* are muscle organs used in coordinated patterns.

Three types of muscle create a wide range of movements

Recall from Chapter 1 (p. 9) that there are three types of muscle: *skeletal muscle*, *cardiac muscle*, and *smooth muscle*. Through their highly developed microfilament system, muscle cells can shorten and develop tension, which enables them to produce force and do work. In contrast to sensory systems, which transform other forms of energy in the environment into electrical signals, muscles, in response to electrical signals, convert the chemical energy of ATP into mechanical energy that can act on the environment. Controlled contraction of muscles permits the following:

1. Purposeful *locomotory* movement of the whole body or parts of the body in relation to the environment (such as walking or flying)
2. Manipulation of external objects (such as a monkey poking a straw or stick into a termite mound, up which the termites then climb)
3. Propulsion of contents through various hollow internal organs (such as circulation of blood or movement of materials through the digestive tract)

- Emptying the contents of certain organs to the external environment (such as urination or parturition)
- Production of heat as a metabolic by-product, which may help to maintain internal body temperatures above ambient
- Production of sound

All muscles share numerous underlying characteristics, although there is considerable diversity among muscle cells from different animals requiring very different outputs. Examples of this diversity include fish sound-producing muscles that can contract at frequencies greater than 100 Hz (cycles per second), contraction frequencies unobtainable by their locomotory muscle counterparts. Hamlet, a species of coral-reef fish, broadcast a series of beeps and pulses ranging from 350 to 650 Hz at the critical moment when sperm and eggs are released into the environment. In contrast, the highest frequency for vertebrate locomotory muscles is an order of magnitude lower, 25 to 30 Hz for mouse and lizard so-called fast-twitch muscles at body temperatures of 35°C. You will discover that the ability to increase the speed of contraction is accomplished, in part, by reappportionment of key intracellular structures in addition to shifts in certain muscle isoforms (proteins with the same basic function but which differ slightly in their structures). Trade-offs that maximize performance of one function are usually at the expense of another. For this reason, muscles that operate at high frequencies are not effective at low frequencies and generate less force.

In most vertebrates, muscle is the largest group of tissues in the body, accounting, for example, for approximately half of the body's weight in humans. Skeletal muscle alone makes up about 40% of body weight in human males and 32% in females, with smooth and cardiac muscle making up another 10% of the total weight. Comparably, in most fishes, skeletal muscle mass varies from 20 to 50%, whereas in species noted for high rates of acceleration (such as barracudas), muscle mass ranges from 55 to 65%. In hummingbirds, flight muscles alone account for 25% of the animal's body weight.

Although the three muscle types are structurally and functionally distinct, they can be classified in two different ways according to their common characteristics (Figure 8-1). Muscles are categorized as **striated** (skeletal and cardiac muscle) or **unstriated** (smooth muscle), depending on whether alternating dark and light bands, or striations (which you will learn about), can be seen when the muscle is viewed under a light microscope.

Most of this chapter is devoted to a detailed examination of the most abundant and best understood muscle, skeletal muscle. Skeletal muscles make up the **muscular system**. Interestingly, arthropods and vertebrates share a common ancestor of striated muscle, although they diverged more than 700 million years ago. We begin by discussing skeletal muscle structure, then examine how it works from the molecular through the cellular level, and finally look at functions of the whole muscle. The chapter concludes with a discussion of the unique properties of smooth and cardiac muscle in comparison to skeletal muscle.

8.2 Skeletal Muscle

A basic understanding of the structural components of a skeletal muscle fiber is essential to understanding how muscles contract. In the 1830s William Bowman studied the basic structure and properties of skeletal muscle from more than 40 animal species and correctly noted that muscle shortening involved specific changes in the striation pattern during nerve-stimulated contractions. We now know that the striations arise from specialized protein arrays within each cell or fiber.

Skeletal muscle consists of muscle fibers lying parallel to each other

A single skeletal muscle cell, known as a **muscle fiber**, is relatively large, elongated, and cylindrical, measuring from 10 to 100 micrometers ($1\ \mu\text{m} = 1$ millionth of a meter) in diameter; they can be tens of centimeters in length in a large animal. A skeletal muscle (organ) consists of a number of muscle fibers lying parallel to each other and bundled together by connective tissue (Figure 8-2a). The fibers usually extend the entire length of the muscle. During embryonic development of vertebrates, the huge skeletal-muscle fibers are formed by the fusion of many smaller cells called **myoblasts** (*myo* means “muscle”; *blast* refers to a primitive cell that forms more specialized cells); thus, one striking feature is the presence of multiple nuclei in a single muscle cell. This multinucleate muscle cell, produced by a merging of cells, is termed a functional **syncytium** (*syn*, “together”; *cyt*, “cell”).

The most predominant structural feature of most skeletal muscle fibers is the presence of numerous **myofibrils**. These specialized contractile elements, which constitute up to 90% of the volume of the muscle fiber, are cylindrical intracellular organelles, typically $1\ \mu\text{m}$ in diameter, that extend the entire length of the muscle fiber (Figure 8-2b). The greater the volume of the fiber taken up by myofibrils, the greater the force per cross-sectional area that can be generated. Muscle fibers with a low percentage of myofibrils cannot generate high degrees of tension but are generally associated with the ability to turn muscles on and off quickly or to generate prolonged activity. For example, the aerobic sound-producing muscle of

FIGURE 8-2 Levels of organization in a skeletal muscle. Note in the cross section of a myofibril in part (c) that each thick filament is surrounded by six thin filaments, and each thin filament is surrounded by three thick filaments. Also note only a small portion of *titin* (which spans the whole sarcomere) is shown.

© Cengage Learning, 2013

male cicadas (insects that make loud mating “songs”) has a myofibrillar volume of only 22%; similarly, the high-frequency tail-shaker muscle of the rattlesnake contains only 31% myofibrils (the rest being *glycogen*, an energy store we will explore later). Conservation of function in this sound-producing muscle with those in cicadas is suggestive of convergent evolution, supporting the contention that these modifications are essential for high-frequency performance.

Each myofibril consists of a regular arrangement of highly organized cytoskeletal elements—the thick and thin

filaments (Figure 8-2c). The **thick filaments**, which are 0.012 to 0.018 μm in diameter and 1.6 μm in length, are special assemblies of the protein **myosin**, whereas the **thin filaments**, which are 0.005 to 0.008 μm in diameter and 1.0 μm long, are made up primarily of the protein **actin** (with other key proteins) (Figure 8-2d). These same proteins are found in all other cells but in smaller quantities and in a less organized fashion. The levels of organization in a skeletal muscle can be summarized as follows:

Structural Organization of the Sarcomere Viewed with a light microscope, a relaxed myofibril (Figure 8-3a) displays *striations*: alternating dark bands (the A bands) and light bands (the I bands). The bands of all the myofibrils lined up parallel to each other collectively lead to the striated appearance of a skeletal muscle fiber (Figure 8-3b). Alternate stacked sets of thick and thin filaments, the **myofilaments**, which slightly overlap each other, are responsible for the A and I bands (Figure 8-2c). An **A band** consists of a stacked set of thick filaments along with the portions of the thin filaments that overlap on both ends of the thick filaments. The thick filaments lie only within the A band and extend its entire width; that is, the two ends of the thick filaments within a stack define the outer limits of a given A band. The lighter area within the middle of the A band, where the thin filaments do not reach, is known as the **H zone**. Only the central portions of the thick filaments are found in this region. The **I band** consists of the remaining portion of the thin filaments that do not project into the A band.

Visible in the middle of each I band is a dense, vertical **Z line**. The area between two Z lines is called a **sarcomere**, which is the functional unit of skeletal muscle. A **functional unit** of any organ is the smallest component that can perform all the functions of that organ. Accordingly, a sarcomere is the smallest component of a muscle fiber that is capable of contraction. The Z line is a flat cytoskeletal disc (in three dimensions) made from a cytoskeletal protein complex that connects the thin filaments of two adjoining sarcomeres. Each relaxed sarcomere is about 2.5 μm in width and consists of one whole A band and half of each of the two I bands located on either side. During growth, a muscle increases in length by adding new sarcomeres, not by increasing the size of each sarcomere. Just as the Z line or discs hold the sarcomeres together in a chain along the myofibril's length, another system of supporting proteins holds the thick filaments together vertically within each stack. These proteins can be seen as the **M line**, which extends vertically down the middle of the A band within the center of the H zone.

Cross Bridges With an electron microscope, fine **cross bridges** can be seen extending from each thick filament toward the surrounding thin filaments in the regions where the thick and thin filaments overlap (Figure 8-2c). The thin filaments are arranged hexagonally around the thick filaments: Cross bridges project from each thick filament in all six directions toward the surrounding thin filaments. Each thin filament, in turn, is surrounded by three thick filaments (Figure 8-2c). To give you an idea of the magnitude of these filaments, a single muscle fiber may contain an estimated 16 billion thick and 32 billion thin filaments, all arranged in this very precise pattern within the myofibrils.

Myosin forms the thick filaments

Each thick filament consists of several hundred myosin molecules packed together in a specific arrangement. A **myosin** molecule is a protein consisting of two identical subunits, each shaped somewhat like a golf club with two heads (Figure

8-4a). The protein's *tail* ends are intertwined around each other, with the two globular *heads* projecting out at one end. The two halves of each thick filament are mirror images made up of myosin molecules lying lengthwise in a regular, staggered array, with their tails oriented toward the center of the filament and their globular heads protruding outward at regular intervals (Figure 8-4b). These heads form the cross bridges between the thick and thin filaments. Each head has two important sites crucial to the contractile process: an *actin binding site* and an *ATPase (ATP-splitting) site*. Myosin filaments are linked to the Z lines by the gigantic, elastic protein **titin** (Figure 8-2c), whose function is still being investigated (see the box, *Molecular Biology and Genomics: What Are the Functions of Titin?*).

Actin, along with tropomyosin and troponin, forms the thin filaments

Thin filaments consist of three proteins: *actin*, *tropomyosin*, and *troponin* (Figure 8-5). **Actin** molecules, the primary structural proteins of the thin filament, are spherical. The backbone of a thin filament is formed by actin molecules joined into two strands and twisted together, like two chains of pearls wrapped around each other. Each actin molecule

Molecular Biology and Genomics: What Are the Functions of Titin?

Titin, also known as **connectin**, is the largest protein known in any organism: The mouse homologue contains 35,213 amino acids and spans half the length of a sarcomere! A single gene for titin yields numerous different tissue-specific proteins through what is thought to be the most prolific example of *alternative RNA splicing* (p. 30). Discovered only in 1979, the roles titin plays in muscles are still not fully understood. It has been implicated in muscle development, perhaps acting as a scaffold

for sarcomere assembly. Titin is also believed to keep the thick filaments centered in the sarcomere during the contraction–relaxation cycle as it binds to the Z line and M line of the sarcomere. And there is evidence of springlike mechanical roles: It may act as a locomotory spring assisting in the return of the sarcomere to its relaxed conformation or in preventing harmful overextension of the sarcomere. Recent studies shed more light on this role: Differences in the elasticity of different titin isoforms lead

to high compliance (flexibility) in elephant muscle and to great stiffness in small mammals such as the shrew. Titin also has a mechanically activated *titin kinase* domain, which regulates nuclear transcription factors; these in turn control genes that may help remodel muscles to adapt to different levels of mechanical stresses. Deletion of these genes in turn leads to severe skeletal muscle *hypoplasia* (underdevelopment) during the perinatal period.

FIGURE 8-4 Structure of myosin molecules and their organization within a thick filament. (a) Each myosin molecule consists of two identical, golf-club-shaped subunits with their tails intertwined and with globular heads each containing an actin-binding site and a myosin ATPase site, projecting out at one end. (b) A thick filament is made up of myosin molecules lying lengthwise parallel to one another. Half are oriented in one direction and half in the opposite direction. The globular heads, which protrude at regular intervals along the thick filament, form the cross bridges.

has sites for both *weak* (primarily electrostatic, that is, the interaction between positively and negatively charged moieties) and *strong* myosin attachment with a myosin cross bridge. By a mechanism to be described shortly, binding of actin and myosin molecules at the cross bridges results in energy-consuming contraction of the muscle fiber. Accordingly, actin and myosin are often called **contractile proteins**, even though, as you will see, neither myosin nor actin actually contracts. Again, myosin and actin are not unique to muscle cells, but these proteins are more abundant and more highly organized in muscle cells.

In a relaxed muscle fiber, contraction does not take place; actin cannot bind with cross bridges because of the position of the two other types of protein within the thin filament—tropomyosin and troponin. **Tropomyosin** molecules are threadlike proteins that lie end-to-end alongside the groove of the actin spiral. In this position, tropomyosin covers the actin sites that bind with the cross bridges, thus blocking the inter-

action that leads to muscle contraction. The other thin-filament component, **troponin**, is a protein complex consisting of three polypeptide units: one that binds to tropomyosin, one that binds to actin, and a third that can bind with Ca^{2+} .

When troponin is not bound to Ca^{2+} , this protein complex stabilizes tropomyosin in its blocking position over actin's cross-bridge binding sites (Figure 8-6a). When Ca^{2+} binds to troponin, the shape of this complex is changed in such a way that tropomyosin is allowed to slide away from its blocking position (Figure 8-6b). With tropomyosin out of the way, the myosin head can bind to actin to form cross bridges, resulting (as you will see) in muscle contraction. Tropomyosin is a flexible molecule, and its positioning on the actin filament should be considered dynamic. Tropomyosin and troponin are often called **regulatory proteins** because of their role in covering (preventing contraction) or exposing (permitting contraction) the binding sites for cross-bridge interaction between actin and myosin.

FIGURE 8-5 Composition of a thin filament. The main structural component of a thin filament is two chains of spherical actin molecules that are twisted together. Troponin molecules (which consist of three small, spherical subunits) and threadlike tropomyosin molecules are arranged to form a ribbon that lies alongside the groove of the actin helix and physically covers the binding sites on actin molecules for attachment with myosin cross bridges. (The thin filaments shown here are not drawn in proportion to the thick filaments in Figure 8-4. Thick filaments are two to three times larger in diameter than thin filaments.)

check your understanding 8.2

What is the smallest component of a muscle fiber that is capable of contraction?

How is muscle contraction regulated?

8.3 Molecular Basis of Skeletal Muscle Contraction

How does cross-bridge interaction between actin and myosin bring about muscle contraction? How does a muscle action potential trigger this contractile process? What is the source of the Ca^{2+} that physically repositions troponin and tropomyosin to permit cross-bridge binding? We turn our attention to these topics in this section.

During contraction, cycles of cross-bridge binding and bending pull the thin filaments closer together between the stationary thick filaments, causing shortening of the sarcomeres

During contraction in mammalian striated muscle, the thin filaments on each side of a sarcomere were demonstrated to slide inward toward the A band's center (Figure 8-7). As they slide inward, the thin filaments pull closer together the Z discs to which they are attached, so the sarcomere shortens. Because all the sarcomeres throughout the muscle fiber's length shorten simultaneously, the entire fiber becomes shorter. This is known as the **sliding-filament mechanism** of muscle contraction, which was first proposed in 1954 by two separate teams, Hugh Huxley and Jean Hanson, and Andrew Huxley and R. Niedergerke. Nonvertebrate striated muscle, although considerably smaller in length, was also

demonstrated to operate on this same principle. The H zone, the region in the center of the A band where the thin filaments do not reach, becomes smaller as the thin filaments approach each other when they slide more deeply inward. The H zone may even disappear if the thin filaments meet in the middle of the A band. The I band, which consists of the portions of the thin filaments that do not overlap with the thick filaments, narrows as the thin filaments further overlap the thick filaments during their inward slide. The thin filaments themselves do not change length during muscle fiber shortening. The width of the A band remains unchanged during contraction because its width is determined by the length of the thick filaments, and the thick filaments do not change length during the shortening process. Note that neither the thick nor thin filaments decrease in length to shorten the sarcomere. Instead, contraction is accomplished by the thin filaments within each sarcomere sliding closer together between the thick filaments.

Power Stroke With the tropomyosin “blockers” pulled out of the way by the binding of Ca^{2+} , thin filaments are pulled inward relative to the stationary thick filaments by myosin cross-bridge activity. Myosin is a molecular motor, similar to kinesin and dynein. Recall that kinesin and dynein have little feet that “walk” along microtubules to transport specific products from one part of the cell to another (as in protein transport within a neuronal axon; p. 139) and to move microtubules in relation to one another (as in the beating of cilia or flagella; p. 60). In the same way, the myosin heads or cross bridges “walk” along an actin filament to pull it inward relative to the stationary thick filament. Let's concentrate on a single cross-bridge interaction (Figure 8-8a). The two myosin heads of each myosin molecule act independently, with only one head attaching to actin at a given time. When myosin and actin make contact at a cross bridge, the bridge changes shape, bending 45° inward as if it were on a hinge, “stroking” toward the center of the sarcomere, like

FIGURE 8-8 Cross-bridge activity. (a) During each cross-bridge cycle, the cross bridge binds with an actin molecule, bends to pull the thin filament inward during the power stroke, then detaches and returns to its resting conformation, ready to repeat the cycle. (b) The power strokes of all cross bridges extending from a thick filament are directed toward the center of the thick filament. (c) All six thin filaments surrounding each thick filament are pulled inward simultaneously through cross-bridge cycling during muscle contraction.

© Cengage Learning, 2013

the stroking of a boat oar. This so-called power stroke of a cross bridge pulls inward the thin filament to which it is attached. A single power stroke pulls the thin filament inward (approximately a micron), only a minute percentage of the total shortening distance, thus the need for repeated power strokes to achieve the desired extent of muscle shortening.

Complete shortening is accomplished by repeated cycles of cross-bridge binding and bending

At the end of one cross-bridge cycle, the link between the myosin cross-bridge and actin molecule is broken. Like a boat oar being lifted and returned to its starting point, the cross bridge returns to its original conformation and binds to the next actin molecule positioned behind its previous actin partner. The cross bridge bends once again to pull the thin filament in further, then detaches and repeats the cycle. Repeated cycles of cross-bridge binding and bending successively pull in the thin filaments.

Because of the orientation of the myosin molecules within a thick filament (Figure 8-8b), all the cross bridges' power strokes are directed toward the center of the sarcomere, so that all six of the surrounding thin filaments on each end of the sarcomere are pulled inward simultaneously (Figure 8-8c). The cross bridges aligned with given thin filaments do not all stroke in unison, however. At any time during contraction, some of the cross bridges are attached to the thin filaments and are stroking, while others are returning to their original conformation in preparation for binding with another actin molecule. Thus, some cross bridges are "holding on" to the thin filaments, whereas others "let go" to bind with new actin. Were it not for this asynchronous cycling of the cross bridges, the thin filaments would slip back toward their resting position between strokes.

How is this cross-bridge cycling switched on by muscle excitation? The term **excitation-contraction coupling** refers to the series of events linking muscle excitation (the presence of an action potential in a muscle fiber) to muscle contraction (cross-bridge activity that causes the thin filaments to slide closer together to produce sarcomere shortening). Now let's turn our attention to the mechanisms of this coupling.

Calcium is the link between excitation and contraction

Skeletal muscles are stimulated to contract by release of acetylcholine (ACh) at neuromuscular junctions between motor neuron terminals and muscle fibers (see Figure 4-19). Recall that the binding of ACh with the motor end plate of a muscle fiber brings about permeability changes in the muscle fiber that result in an action potential that is conducted over the entire surface of the muscle cell membrane. Recall also that the enzyme **acetylcholinesterase (AChE)** destroys ACh to shut off the signal. Two membranous structures within the muscle fiber play an important role in linking this excitation to contraction—**transverse tubules** and the **sarcoplasmic reticulum**. Let's examine the structure and function of each.

Spread of the Action Potential Down the T Tubules At each end of the A band (mammalian and reptilian muscles) or Z disc (amphibian muscle), the surface membrane dips deeply

FIGURE 8-9 The T tubules and sarcoplasmic reticulum in relationship to the myofibrils.

The transverse (T) tubules are membranous, perpendicular extensions of the surface membrane that dip deep into the muscle fiber at the junctions between the A and I bands of the myofibrils. The sarcoplasmic reticulum is a fine, membranous network that runs longitudinally and surrounds each myofibril, with separate segments encircling each A band and I band. The ends of each segment are expanded to form lateral sacs that lie next to the adjacent T tubules.

© Cengage Learning, 2013

into the large muscle fiber to form a transverse tubule (or **T tubule**), which runs perpendicularly from the surface of the muscle cell membrane into the central portions of the muscle fiber (Figure 8-9). Because the T tubule membrane is continuous with the surface membrane, an action potential on the surface membrane also spreads down into the T tubule, providing a means of rapidly transmitting the surface electric activity into the central portions of the fiber. The presence of a local action potential in the T tubules induces permeability changes in a separate membranous network within the muscle fiber, the sarcoplasmic reticulum.

Release of Calcium from the Sarcoplasmic Reticulum The sarcoplasmic reticulum is a modified endoplasmic reticulum (see p. 38) that is important for turning the muscle on and off. It consists of a fine network of interconnected tubules surrounding each myofibril like a mesh sleeve (Figure 8-9). This membranous network runs longitudinally down the myofibril (that is, encircles the myofibril throughout its length), but is not continuous. Separate segments of sarcoplasmic reticulum are wrapped around each A band and each I band. The ends of each segment expand to form saclike regions, the lateral sacs (alternatively known as terminal cisternae), which are separated from the adjacent T tubules by a slight gap (Figures 8-9 and 8-10). The sarcoplasmic reticulum's lateral sacs store Ca^{2+} with the aid of Ca^{2+} -ATPase pumps first discovered by Wilhelm Hasselbach in 1961. *Spread of an action potential down a T tubule triggers release of Ca^{2+} from the sarcoplasmic reticulum into the cytosol to trigger contraction, and the pumps later reuptake the Ca^{2+} for relaxation.* Performance of this pumping is affected by the number of pump units, that is, the density of the sarcoplasmic reticulum in the muscle fiber, as well as kinetic rates at which the pump isoforms operate. The time course of Ca^{2+} release and reuptake during contractions is related to the function of the muscle. Sarcoplasmic reticulum volume in a muscle fiber varies from 3 to 30% between

muscle fiber types; thus, the greater the speed of contraction, the greater the volume of the sarcoplasmic reticulum. Increases in cellular sarcoplasmic reticulum and mitochondrial volumes are generally associated with reduced myofibrillar volume, reducing force generation but permitting the muscle to operate at higher contraction frequencies. For example, sarcoplasmic volume in the shaker muscle fibers of rattlesnakes is approximately 26% (with mitochondrial volume also 26% and glycogen volume at 17%), thus leaving only 31% for the myofibrillar contents (as we noted earlier).

How is a change in T tubule potential linked with the release of Ca^{2+} from the sarcoplasmic reticulum's lateral sacs? An orderly arrangement of **foot proteins** extends from the sarcoplasmic reticulum and spans the gap between the lateral sac and T tubule. Each foot protein contains four subunits arranged in a specific pattern (Figure 8-10a). These foot proteins not only bridge the gap but also serve as Ca^{2+} -release channels. These foot protein Ca^{2+} channels are known as **L-type calcium channels** or **ryanodine receptors** because experimentally they can be locked in the open position by the plant chemical *ryanodine*.

Half of the sarcoplasmic reticulum's foot proteins are "zipped together" with complementary receptors or Ca^{2+} channels on the T tubule side of the junction. These T tubule channels, which are made up of four subunits in exactly the same pattern as the foot proteins, are located like mirror images in contact with every other foot protein protruding from the sarcoplasmic reticulum (Figure 8-10b and c). These T tubule channels are known as **dihydropyridine receptors** because they are blocked by the drug *dihydropyridine*. These Ca^{2+} channels are voltage-gated sensors. When an action potential is propagated down the T tubule, the local depolarization activates the voltage-gated dihydropyridine receptors. These activated T-tubule channels in turn trigger the opening of the directly abutting foot proteins in the adjacent lateral sacs of the sarcoplasmic reticulum. Opening of the half of these Ca^{2+} -release channels in direct contact with the

FIGURE 8-10 Relationship between dihydropyridine receptors on the T tubule and ryanodine receptors (Ca²⁺-release channels) on the adjacent lateral sacs of the sarcoplasmic reticulum.

© Cengage Learning, 2013

dihydropyridine channels triggers the opening of the other half that are not in direct contact.

Ca²⁺ moves down its electrochemical gradient into the surrounding cytosol from the sarcoplasmic reticulum's lateral sacs through all these open Ca²⁺-release channels. By slightly repositioning the troponin and tropomyosin molecules, this released Ca²⁺ exposes the binding sites on the actin molecules so that they can link with the myosin cross bridges at their complementary binding sites. The full coupling cycle (including relaxation, which we will discuss shortly) is summarized in Figure 8-11.

ATP-Powered Cross-Bridge Cycling Recall that a myosin cross bridge has both an actin-binding site and an ATPase site (Figure 8-4a). The latter is an enzymatic site that can bind the energy carrier *adenosine triphosphate* (ATP) and split it into *adenosine diphosphate* (ADP) and *inorganic phosphate* (P_i), releasing energy in the process. The breakdown of ATP occurs on the myosin cross bridge before the bridge ever links with an actin molecule (Figure 8-12, step 1). The ADP and P_i remain tightly bound to the myosin, and the generated energy is stored within the cross bridge to produce a high-energy form of myosin. To use an analogy, the cross bridge is

“cocked” like a gun, ready to be fired when the trigger is pulled. Recall that when the troponin–tropomyosin complex moves out of its blocking position, the energized (cocked) myosin cross bridge can bind with an actin molecule (step 2a). This contact between myosin and actin “pulls the trigger,” causing the cross-bridge bending that produces the *power stroke* (step 3). Researchers have not found the mechanism by which the chemical energy released from ATP is stored within the myosin cross bridge and then translated into the mechanical energy of the power stroke. Inorganic phosphate is released from the cross bridge during the power stroke. After the power stroke is complete, ADP is released.

When the muscle is not excited and Ca²⁺ is not released, troponin and tropomyosin remain in their blocking position so that actin and the myosin cross bridges do not bind and no power stroking takes place (step 2b).

When P_i and ADP are released from myosin following contact with actin and the subsequent power stroke, the myosin ATPase site is free for attachment of another ATP molecule. The actin and myosin remain linked at the cross bridge until a fresh molecule of ATP attaches to myosin at the end of the power stroke. Attachment of the new ATP molecule permits detachment of the cross bridge, which re-

FIGURE 8-11 Excitation–contraction coupling and muscle relaxation. Steps 1 through 7 show the events that couple neurotransmitter release and subsequent electrical excitation of the muscle cell with muscle contraction. At step 7, if Ca^{2+} is still present, the cross-bridge cycle returns to step 5 for another power stroke. If Ca^{2+} is no longer present as a consequence of step 8, relaxation occurs.

FIGURE 8-12 Cross-bridge cycle.

© Cengage Learning, 2013

turns to its unbent form, ready to start another cycle (step 4a). The newly attached ATP is then split by myosin ATPase, energizing the myosin cross bridge once again (step 1). On binding with another actin molecule, the energized cross bridge again bends, and so on, successively pulling the thin filament inward to accomplish contraction.

Removal of calcium is the key to muscle relaxation

As we noted earlier, **relaxation** is normally accomplished by the sarcoplasmic reticulum's Ca^{2+} -ATPase pumps. That is, the contractile process is turned off when Ca^{2+} is returned to the lateral sacs at cessation of local electrical activity (Figure 8-11). Recent research has demonstrated that the mitochondria also take up Ca^{2+} during a contraction-relaxation cycle. Each mitochondrion has a comparatively large surface area and is tightly wrapped around many myofibrils. Be-

cause the mitochondrial volume is approximately fivefold that of the sarcoplasmic reticulum in skeletal muscle fibers, their contribution to the relaxation cycle is significant. The mitochondria are positioned close to the Ca^{2+} release sites in the sarcoplasmic reticulum and, with only a few specific exceptions, keep up with the cytoplasmic Ca^{2+} transients with only a few milliseconds delay.

As we noted earlier for the rattlesnake shaker muscle, the speed at which Ca^{2+} is pumped back into the sarcoplasmic reticulum is critical in setting the maximum frequency at which a muscle can operate. In addition to increased density of Ca^{2+} -ATPase pump units, high-speed muscles also have elevated concentrations of calcium-binding proteins, such as **calsequestrin**, which help the sarcoplasmic reticulum store calcium. These calcium-binding proteins also play a critical role in reducing the duration of the twitch by rapidly lowering free (unbound) cytosolic Ca^{2+} .

Let's look at the steps more closely. When acetylcholinesterase removes ACh from the neuromuscular junction, the muscle fiber action potential ceases. When there is no longer a local action potential in the T tubules to trigger the release of Ca^{2+} , the ongoing activity of the sarcoplasmic reticulum's pumps returns the released Ca^{2+} back into its lateral sacs. Removal of cytosolic Ca^{2+} allows the troponin-tropomyosin complex to slip back into its blocking position so that actin and myosin can no longer bind at the cross bridges. The thin filaments, freed from cycles of cross-bridge attachment and pulling, can return to their resting position. The “elastic band” properties of titin may also help return the sarcomere to its unstimulated conformation. Relaxation has occurred.

Rigor Mortis Note that fresh ATP is needed not only for Ca^{2+} pumping but also for myosin to break the cross bridge link to actin at the end of a cycle, even though the ATP is not split during this dissociation process. The need for ATP

Beyond the Basics

Conversion of Muscle into Meat

The term *meat* is generally defined as those animal tissues suitable for use as food. However, it is the musculature that undergoes postmortem changes that determine palatability and therefore consumer acceptability. At the time of death, cessation of blood flow and thus the delivery of O_2 to muscle initiate a remarkable sequence of biochemical changes that explain the conversion of muscle to meat. As the oxygen supply is depleted, movement of electrons through the citric acid cycle (p. 49) and the electron transport chain ceases. The generation of ATP is shifted from the aerobic pathway to the anaerobic pathway, comparable to the situation that occurs in living muscle when oxygen debt arises in response to periods of intense activity. For a period of time after death, ATP is produced in sufficient quantities to maintain the structural integrity of the fibers. Recall that a major feature of anaerobic metabolism is the accumulation of lactate. When the oxygen supply is cut off, NADH generated in glycolysis cannot cycle through the TCA cycle and begins to accumulate in the muscle. NADH is then converted back to NAD^+ in conjunction with lactate generation from pyruvic acid, which permits glycolysis to proceed at a rapid rate (see p. 48). Because the circulatory system is no longer functioning, lactate remains in muscle fibers and increases in concentration as postmortem metabolism proceeds. Lactate accu-

mulation in the muscle lowers its pH, and at levels less than pH 6.0 the rate of glycolysis is reduced, along with ATP synthesis that had resulted from substrate-level phosphorylation. Mechanisms to regenerate ATP are now insufficient to prevent permanent cross-bridge formation between actin and myosin. Under these conditions, the postmortem onset of rigor mortis gets under way. As the stores of creatine phosphate are depleted, phosphorylation of ADP is insufficient to maintain the tissue in a relaxed state. Actin–myosin bridges begin to form, and this phase continues until all the creatine phosphate is exhausted and ATP can no longer be formed from ADP. This signals the completion of rigor mortis, which in chicken and fish requires less than an hour and as long as 6 to 12 hours in lamb and beef. Because the muscle glycogen content of fish is much lower than in mammals, the pH declines to only 6.8. “Resolution,” or the softening of rigor mortis, results from changes in the ultrastructure of the myofilaments. These structural changes result from the action of acid and alkaline proteases, enzymes that originate in lysosomes. Normally these acid proteases, called *cathepsins*, are maintained in an inactive state; but with the reduction in pH, loss of membrane integrity, and increase in ICF Ca^{2+} , these enzymes are activated and are responsible for much of the postmor-

tem structural changes and consequent improvement in meat tenderness.

With the advent of modern animal agriculture, generally only a few days elapse between the time when meat animals attain market weight and when they are slaughtered. Nonetheless, during this period certain factors can affect meat quality. For example, if an animal is stressed before slaughter, this may result in undesirable changes in postmortem metabolism. Glycogen deficiency in the muscle can occur in association with transport stress, fasting, or restraint. Consider also a serious injury to a deer sustained from a misdirected shot from a hunter that permitted the animal to run a considerable distance before blood loss sufficiently incapacitated its ability to run. If an injured or stressed animal dies or is slaughtered before it has replenished the glycogen, a *dark, firm, dry* muscle condition can result. Muscle glycogen deficiency results in a limited generation of lactate after death because the substrate of glycolysis, glycogen, was depleted before harvest. The resultant high pH (approximately 6.8) changes the muscle color development when these muscles are exposed to O_2 . This muscle tissue is dry and sticky because of its ability to bind water. Its unattractive appearance and decreased palatability result in a considerable monetary loss for the producer. In addition, its high pH makes it more susceptible to microbial degradation.

for both of these processes is amply demonstrated by the phenomenon of *rigor mortis*. This “stiffness of death” is a generalized locking-in-place of the skeletal muscles that begins sometime after death (3 to 4 hours in humans, becoming complete in about 12 hours). After death, cells stop making ATP, and the cytosolic concentration of Ca^{2+} begins to rise, most likely because the muscle-cell membrane cannot keep out extracellular Ca^{2+} and perhaps also because Ca^{2+} leaks out of the lateral sacs. This Ca^{2+} moves the regulatory proteins aside, permitting actin to bind with the myosin cross bridges, which were already charged with ATP before death. Without fresh ATP, actin and myosin, once bound, cannot detach. The thick and thin filaments thus remain linked together by the immobilized cross bridges, resulting in the stiffness of dead muscles (Figure 8-12, step 4b). During the next several days, rigor mortis gradually subsides as the proteins involved in the rigor complex begin to degrade (see *Beyond the Basics: Conversion of Muscle into Meat*).

Now let’s compare the duration of contractile activity to the duration of excitation, before we shift gears to discuss skeletal muscle mechanics.

Contractile activity far outlasts the electrical activity that initiated it

A single action potential in a skeletal muscle fiber lasts only 1 to 2 msec, resulting in a brief, weak contraction known as a **twitch**, which is too short and too weak to be useful (Figure 8-13). The onset of the resultant contractile response lags behind the action potential, because the entire excitation–contraction coupling process must take place before cross-bridge activity begins. In fact, the action potential is completed before the contractile apparatus even becomes operational. This time delay of a few milliseconds between stimulation and the onset of contraction is known as the **latent period**.

FIGURE 8-13 Relationship of an action potential to the resultant muscle twitch. The duration of the action potential is not drawn to scale but is exaggerated. Note that the resting potential of a skeletal muscle fiber is -90 mV, compared to a resting potential of -70 mV in a neuron.

© Cengage Learning, 2013

Time is also required for the generation of tension within the muscle fiber produced by means of the sliding interactions between the thick and thin filaments through cross-bridge activity. The time from the onset of contraction until peak tension is developed—the **contraction time**—averages about 50 msec in vertebrate locomotory muscles, although this time varies, depending on the type of muscle fiber. The contractile response does not cease until the lateral sacs have taken up all the Ca^{2+} released in response to the action potential. This reuptake of Ca^{2+} is also time consuming. Even after Ca^{2+} is removed, it takes time for the filaments to return to their resting positions. The time from peak tension until relaxation is complete, the **relaxation time**, usually lasts slightly longer than contraction time, another 50 msec or more. Consequently, the entire contractile response to a single action potential may last up to 100 msec or more; this is considerably longer than the duration of the action potential that initiated it (100 msec compared to 1 to 2 msec). These fundamental concepts are important in an

animal's ability to produce muscle contractions of variable strength, as you will discover in the next section.

check your understanding 8.3

How does the structure of the microfilaments allow for linear contraction of a whole muscle cell?

How does an event (action potential) on the outside of a muscle fiber trigger the contractile process on the inside?

Ryanodine receptors and dihydropyridine receptors are named for the specific drugs that bind to them, but physiologically, what is their function?

Defend the statement “Mitochondria may participate in calcium uptake but cannot be relied upon to deliver calcium when needed by the cell.” Under what circumstances are mitochondria unable to keep up with the Ca^{2+} transient?

8.4 Skeletal Muscle Mechanics

Thus far, we have described the contractile response in a single muscle fiber. In the body, groups of muscle fibers are organized into whole muscle organs. We now turn our attention to contraction of whole muscles. There are four major problems to be solved if muscle organs are to be useful to an animal.

First, each contraction must be precisely controlled. Tension must be developed and maintained at a level appropriate for the physiological response. There are essentially two evolutionary strategies for the gradation of tension generated in a muscle, one typified by vertebrates and the other by arthropods. Other nonvertebrates normally use variations of the solution found in arthropods.

Second, muscles typically contract linearly, but locomotory motions need more diverse motions. This is a major reason that most muscles exert force through external elements, for example, various forms of *skeletons*. For example, as we'll see later, hard skeletons with *joints* can act as levers to convert linear contraction into angular motion.

Third, muscles have a fundamental limit—the inability to expand actively due to the one-way nature of the myosin “rowing” mechanism. For a contracted muscle to expand, there are three basic mechanisms: (1) an *antagonistic* muscle typically found on the opposite side of a skeletal joint, whose contraction stretches out the other muscle (p. 350); (2) *fluid pressure* created by distant muscles that push on and re-extend a contracted muscle; and (3) **series elastic elements**: springlike structures that get stretched or compressed by a contracting muscle and that then “rebound” to release their stored energy and thereby stretch out that muscle. Titin may be one of these, but external springs are typically stronger and faster.

Fourthly, the sarcomere mechanism is too slow in strong muscles, due to trade-offs you saw earlier, to power some of the incredibly fast locomotory movements seen in the animal kingdom, like jumping fleas. This problem can also be solved by elastic mechanisms because a spring can move much faster than muscle can contract. This is the principle used in the bow-and-arrow invention of humans: Muscles are used to pull back the elastic bow cord (relatively

A Closer Look at Adaptation Muscles Evolved for Speed

Recent studies have investigated Ca^{2+} flux in one of the fastest known vertebrate muscle, the sound-producing swim-bladder muscle of the toadfish (*Opsanus tau*). To attract egg-laying females to his nest, the male toadfish sings a “boat whistle” mating call 10 to 12 times per minute. Vocalizations are generated by repetitive contractions (at about 200 Hz) of the muscles encircling the fish’s gas-filled swimbladder (see p. 539). High-frequency contractions of this muscle yield high-frequency sound production. If a muscle is to contract and relax rapidly, two conditions must apply:

1. Ca^{2+} , the trigger for muscle contraction, must both enter and leave the myoplasm rapidly (Ca^{2+} transient). To achieve this remarkable feat, researchers determined, the Ca^{2+} transient in the sonic muscle is the fastest ever measured for any fiber type, approximately 50-fold greater than the rate measured in comparable locomotory muscle. The importance of this observation is that the time course of Ca^{2+} uptake into the sarcoplasmic reticulum, comparable to that in a synapse, is so rapid that it has completely returned to baseline by the time of the next stimulus! In these superfast muscle fibers, this feat is achieved by (1) a maximal density of Ca^{2+} pumps in the sarcoplasmic reticulum, (2) different Ca^{2+} pump isoforms (which pump Ca^{2+} at different rates), (3) a high volume of sarcoplasmic reticulum, approaching 30% of the muscle volume, and (4) exclusion of mitochondria from the intermyofibrillar area where the Ca^{2+} release sites are located. Because mitochondria take up and release Ca^{2+} at rates different from the sarcoplasmic reticulum, their activity would hamper the rapid oscillations characteristic of the sarcoplasmic reticulum.

2. Myosin cross bridges must attach to actin and generate force soon after the Ca^{2+} concentrations rise and then must detach and stop generating force soon after the Ca^{2+} concentrations decline. A faster relaxing time also requires that troponin rapidly release its bound Ca^{2+} . In actuality, the release of Ca^{2+} from its troponin binding site in the sonic muscles is three times faster than in locomotory muscle. To permit faster cross-bridge cycling, modification in the molecular structure of troponin is required. Selection for isoforms of troponin with a lower affinity (attraction) for Ca^{2+}

helped increase beat frequency. In addition, the detachment rate of myosin–actin cross bridges in high-frequency muscles is approximately 70-fold faster than that measured in locomotory muscles, fast enough to account for the rapid relaxation rate. Because the detachment rate of cross bridges in swimbladder muscle is so fast, a low proportion of cross bridges are actually attached at any given instant. Although this represents a solution for speed, the consequences are that the muscles are weak. Fortunately, it does not require extraordinary power or force to produce sound.

slowly) to store energy in it; when released, the cord recoils and shoots the arrow at speeds much greater than a contracting muscle could. This is also the mechanism used in the chameleon tongue, mentioned at the beginning of the chapter. You’ll see locomotory examples later.

We will encounter each solution to these four problems after concluding our discussion on the structure of muscles as organs.

Muscle organs are groups of muscle fibers bundled together by connective tissue, often attached to skeletal elements in antagonistic pairs

Each muscle (organ) is covered by a sheath of connective tissue that penetrates from the surface into the muscle to envelop each individual fiber and divide the muscle into columns or bundles. In vertebrates, the connective tissue extends beyond the ends of the muscle to form tough, collagenous **tendons** that normally attach the muscle to bones (Figure 8-2). A tendon may be quite long, attaching to a

bone some distance from the fleshy portion of the muscle. For example, some of the muscles involved in digit movement are found in the forelimb, with long tendons extending down to attach to the bones of the digits. (You can readily observe the movement of these tendons on the top of your hand when you wiggle your fingers.) This arrangement permits greater dexterity; for example, in humans the fingers would be much thicker and more awkward if all the muscles involved in finger movement were actually located in the fingers.

In arthropods, muscles attach to **apodemes**, ridges that project from the inner face of the exoskeleton. The apodeme is considered the arthropod equivalent of a vertebrate tendon, although it is 50 times stiffer than a typical tendon. As you will see later, both apodemes and tendons can store and release elastic energy, acting as springs.

As we noted earlier and in Chapter 5, muscles are often arranged in **antagonistic pairs** to move a body part in two opposing directions. A common pairing is that of **flexors**, which bend a limb, and **extensors**, which typically straighten the limb out. Familiar examples are the *biceps* flexor and *triceps* extensor of a mammal’s limb (see Figure 5-21, p. 181). Similarly, a crab claw (a modified limb) is opened with an extensor and closed with a flexor.

Contractions of a whole muscle can be of varying strength

Recall that a **twitch** is too short and too weak to be useful (Figure 8-13). Muscle fibers are arranged into whole muscles where they can function cooperatively to produce contractions of variable grades of strength stronger than a twitch. The force produced by a single muscle can be made to vary and depends on the force required to move (or to carry an object). Most vertebrate muscle fibers contract in “all-or-none” fashion, such that a single fiber cannot produced graded contractions in a simple way. Thus, two primary factors are adjusted to accomplish gradation of whole-muscle tension: (1) *the number of muscle fibers contracting within a muscle* and (2) *the tension developed by each contracting fiber* (Table 8-1) by other than simple graded means. We discuss each of these factors in turn.

FIGURE 8-14 Motor units in a skeletal muscle.

© Cengage Learning, 2013

The number of fibers contracting within a vertebrate muscle depends on the extent of motor unit recruitment

Because the greater the number of fibers contracting, the greater the total muscle tension, larger muscles consisting of more muscle fibers can obviously generate more tension than can smaller muscles with fewer fibers. Each whole muscle is innervated by a number of different motor neurons. Typically, hundreds to thousands of motor neurons innervate a vertebrate muscle, whereas only 1 to 10 motor neurons innervate an arthropod muscle. When a vertebrate motor neuron enters a muscle, it branches, with each axon terminal supplying a single muscle fiber (Figure 8-14). *One motor neuron innervates a number of muscle fibers, but each vertebrate muscle fiber is supplied by only one motor neuron.* When a motor neuron is activated, all the muscle fibers it supplies are stimulated to contract simultaneously.

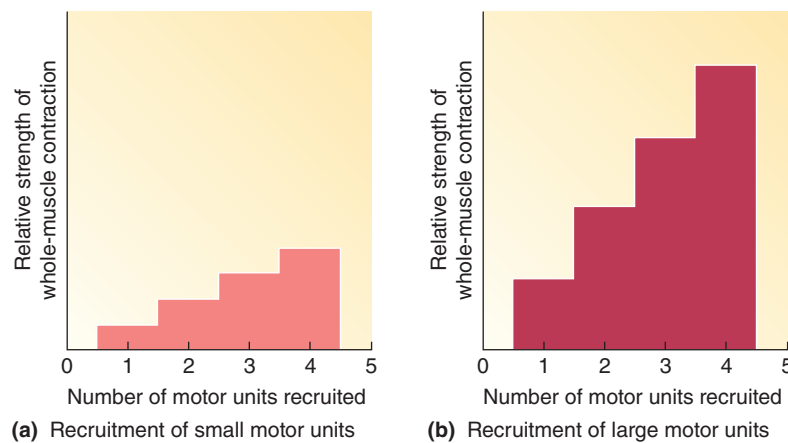

FIGURE 8-15 Comparison of motor unit recruitment in skeletal muscles with small motor units and muscles with large motor units. (a) Small incremental increases in strength of contraction occur during motor unit recruitment in muscles with small motor units because only a few additional fibers are called into play as each motor unit is recruited. (b) Large incremental increases in strength of contraction occur during motor unit recruitment in muscles with large motor units, because so many additional fibers are stimulated with recruitment of each additional motor unit.

© Cengage Learning, 2013

This team of concurrently activated components—one motor neuron plus all the muscle fibers it innervates—is called a **motor unit**. (We will examine a different arrangement in arthropods later.)

The muscle fibers that compose a vertebrate motor unit are dispersed throughout the whole muscle; thus, their simultaneous contraction results in an evenly distributed, although weak, contraction of the whole muscle. Each muscle consists of a number of intermingled motor units. For a weak contraction of the whole muscle, only one or a few of its motor units are activated. For stronger and stronger contractions, more and more motor units are recruited, or stimulated to contract, a phenomenon known as **motor unit recruitment**.

How much stronger the contraction will be with the recruitment of each additional motor unit depends on the size of the motor units (that is, the number of muscle fibers controlled by a single motor neuron) (Figure 8-15). The number of muscle fibers per motor unit and the number of motor units per muscle vary widely, depending on the specific function of the muscle. For muscles that produce precise, delicate movements, such as the external eye muscles, and the hand muscles in humans, a single motor unit may contain as few as a dozen muscle fibers. Because so few muscle fibers are involved with each motor unit, recruitment of each additional motor unit results in only a small additional increment in the whole muscle's strength of contraction. These small motor units allow a very fine degree of control over muscle tension. In contrast, in muscles used for powerful, coarsely controlled movement, such as those of most mammalian legs, a single motor unit may contain 1,500 to 2,000 muscle fibers. Recruitment of motor units in these muscles results in large incremental increases in whole-muscle tension. More powerful contractions occur at the expense of less precisely controlled gradations. Thus, the number of muscle fibers participating in the whole muscle's total contractile effort depends on the number of motor units recruited and the number of muscle fibers per motor unit in that muscle.

To delay or prevent **fatigue** (inability to maintain muscle tension at a given level) during a *sustained* contraction involving only a portion of a muscle's motor units, as is necessary in muscles supporting the weight of the body against the force of gravity, **asynchronous recruitment of motor units** takes place. The brain alternates motor unit activity, like shifts at a factory, to give motor units that have been active a chance to rest while others take over. Chang-

ing of the shifts is carefully coordinated, so that the sustained contraction is smooth rather than jerky. Asynchronous motor unit recruitment is possible only for submaximal contractions, during which only some of the motor units must maintain the desired level of tension. During maximal contractions, when all the muscle fibers must participate, it is impossible to alternate motor unit activity to prevent fatigue. This is one reason why you cannot support a heavy object as long as one that is light.

Furthermore, the type of muscle fiber that is activated varies with the magnitude of contraction. Most muscles consist of a mixture of fiber types that differ metabolically, some being more resistant to fatigue than others (as we'll discuss later). During weak or moderate endurance-type activities (aerobic activity), the motor units most resistant to fatigue are recruited first. The last fibers called into play in the face of demands for further increases in tension are those that fatigue rapidly. An animal can therefore engage in endurance activities for prolonged periods of time but can only briefly maintain bursts of all-out, powerful effort. Of course, even the muscle fibers most resistant to fatigue do eventually fatigue if required to maintain a certain level of sustained tension.

The frequency of stimulation can influence the tension developed by each vertebrate skeletal muscle fiber

Whole-muscle tension depends not only on the number of muscle fibers contracting but also on the tension developed by each contracting fiber. Various factors influence the extent to which tension can be developed. These factors, summarized in Table 8-1, include (1) frequency of stimulation; (2) length of the fiber at the onset of contraction; (3) extent of fatigue; and (4) thickness of the fiber. The other factors in Table 8-2 will be discussed later.

First let's examine the effect of frequency of stimulation.

Twitch Summation and Tetanus Even though a single action potential in a muscle fiber produces only an "all-or-none" twitch, contractions with longer duration and greater tension can be achieved by repetitive stimulation of the fiber. Let's see what happens when a second action potential occurs in a muscle fiber. If the muscle fiber has completely relaxed before the next action potential takes

FIGURE 8-16 Twitch summation and tetanus.

© Cengage Learning, 2013

place, a second twitch of the same magnitude as the first occurs (Figure 8-16a). The same excitation–contraction events take place each time, resulting in identical twitch responses. If, however, the muscle fiber is stimulated a second time before it has completely relaxed from the first twitch, a second action potential occurs that causes a second contractile response, which is added “piggyback” on top of the first twitch (Figure 8-16b). The two twitches resulting from the two action potentials add together, or summate, to produce greater tension in the fiber than that produced by a single action potential. This twitch summation is similar to temporal summation of EPSPs at the postsynaptic neuron (see p. 137).

Twitch summation is possible only because the duration of the action potential (1 to 2 msec) is much shorter than the duration of the resultant twitch (100 msec). Remember that once an action potential has been initiated, a brief refractory period occurs during which another action potential cannot be initiated (see p. 124). It is therefore impossible to achieve summation of action potentials. The membrane must return to resting potential and recover from its refractory period before another action potential can occur. However, because the action potential and refractory period are over long before the resultant muscle twitch is completed, the muscle fiber may be restimulated while some contractile activity still exists to produce summation of the mechanical response.

If the muscle fiber is stimulated so rapidly that it does not have a chance to relax at all between stimuli, a smooth, sustained contraction of maximal strength known as **tetanus** occurs (Figure 8-16c). (Not that a tetanus is a normal process; the disease with the same name causes uncontrollable tetanus, as we described on p. 143.) A tetanic contraction is usually three to four times stronger than a single twitch.

Twitch summation results from a sustained elevation in cytosolic calcium

What is the mechanism of twitch summation and tetanus at the cellular level? The tension produced by a contracting muscle fiber increases as a result of greater cross-bridge cycling. Connective tissue, as well as other components of the muscle, such as intracellular elastic proteins, exhibits a certain degree of passive elasticity. These noncontractile tissues are part of the *series-elastic component* we noted earlier; they behave like a stretchy spring placed between the internal tension-generating elements and the bone that is to be moved against an external load. The series-elastic component (connective tissue, titin, and tendons) must be stretched to transmit the tension generated in the muscle fiber to the bone, and it takes time to stretch these elastic elements. Accordingly, two factors contribute to twitch summation: (1) sustained elevation in cytosolic Ca^{2+} permitting greater cross-bridge cycling, and (2) more time to stretch the series-elastic component.

The most important factor in the development of twitch summation is sustained elevation in cytosolic Ca^{2+} as the frequency of action potentials increases. Sufficient Ca^{2+} is released in response to a single action potential to interact with all the troponin within the cell. As a result, all the cross bridges are free to participate in the contractile response. How then, can repetitive action potentials bring about a greater contractile response? The difference depends on how long sufficient Ca^{2+} is available.

The cross bridges remain active and continue to cycle as long as sufficient Ca^{2+} is present to keep the troponin–tropomyosin complex away from the cross-bridge binding sites on actin. Each troponin–tropomyosin complex spans a distance of seven actin molecules. Thus, binding of one Ca^{2+} ion to one troponin molecule leads to the uncovering of only seven cross-bridge binding sites on the thin filament.

As soon as Ca^{2+} is released in response to an action potential, the sarcoplasmic reticulum starts pumping Ca^{2+} back into the lateral sacs. As the cytosolic Ca^{2+} concentration declines with the reuptake of Ca^{2+} by the lateral sacs, less Ca^{2+} is present to bind with troponin, so some of the troponin-tropomyosin complexes slip back into their blocking positions. Consequently, not all the cross-bridge binding sites remain available to participate in the cycling process during a single twitch induced by a single action potential. Because not all the cross bridges find a binding site, the resulting contraction during a single twitch is not of maximal strength.

If action potentials and twitches occur far enough apart in time for all the released Ca^{2+} from the first contractile response to be pumped back into the lateral sacs between the action potentials, an identical twitch response occurs as a result of the second action potential. If, however, a second action potential occurs and more Ca^{2+} is released while the Ca^{2+} that was released in response to the first action potential is being taken back up, the cytosolic Ca^{2+} concentration remains elevated. This prolonged availability of Ca^{2+} in the cytosol permits more of the cross bridges to continue participating in the cycling process for a longer time. As a result, tension development increases correspondingly. As the frequency of action potentials increases, the duration of elevated cytosolic Ca^{2+} concentration increases, and contractile activity likewise increases until a maximum tetanic contraction is reached. With tetanus, the maximum number of cross-bridge binding sites remain uncovered so that cross-bridge cycling, and consequently tension development, are at their peak.

An additional factor contributing to twitch summation is related to the elastic element. During a single twitch, the contraction does not last long enough to completely stretch the series-elastic component and allow the full sarcomere-generated tension to be transmitted to the bone. At the end of the twitch, the elastic elements slowly relax, or recoil to their initial nonstretched state. If another twitch occurs before the elastic elements have completely relaxed, the tension from the second twitch adds to the residual tension in the series-elastic component remaining from the first twitch. With greater frequencies of action potentials and more frequent twitches, less time is available for the elastic elements to recoil between twitches. Consequently, despite the all-or-none nature of a twitch, as the frequency of action potentials increases, the tension in the series-elastic component transmitted to the bone progressively increases until it reaches its maximum during tetanus.

Because skeletal muscle must be stimulated by motor neurons to contract, the nervous system plays a key role in regulating the strength of contraction. The two main factors subject to control to accomplish gradation of contraction of a given muscle are the *number of motor units stimulated* and the *frequency of their stimulation*. The areas of the vertebrate brain responsible for directing motor activity use a combination of tetanic contractions and precisely timed shifts of asynchronous motor unit recruitment to execute smooth rather than jerky contractions.

Arthropod muscle tension is controlled by gradation of contraction within a motor unit

The mechanism by which tension is developed in arthropod muscle is somewhat different from that in vertebrate twitch muscle. Most nonvertebrate muscle fibers are innervated by

more than one motor neuron. Thus, an individual muscle fiber forms a part of several motor units! Because the nervous system of nonvertebrates consists of comparatively fewer neurons, a smaller number of such overlapping motor units must generate the complete range of tension necessary for the animal to move. In some arthropod muscles, one motor neuron innervates most, if not all, of the muscle fibers with numerous axons, such that the whole muscle acts much like a single unit. To examine the mechanism by which arthropods grade individual contractions, let's look at the example of crustacean skeletal muscle fibers.

The limb muscles of crayfish are innervated by very few efferent neurons. In crayfish, crabs, and other decapod crustaceans, two muscles of the terminal joints, the “opener” and “stretcher” (extensor) muscles share one single, common excitatory neuron. Recall that most vertebrate striated muscle fibers are innervated by only one or two end plates (see p. 134), but in many nonvertebrates motor control is achieved by **multiterminal innervation** of each muscle fiber. Synaptic terminals that run the entire length of the fiber, for example, repeatedly innervate most crustacean skeletal muscle fibers. Unlike the “all-or-none” contraction of most vertebrate fibers, contraction of the crustacean fiber depends on *graded depolarization* of the muscle fiber: The greater the frequency of action potentials arriving at the end plate region, the stronger the resulting contraction. In addition, unlike the situation for vertebrate muscle fibers, they also receive *separate* presynaptic inhibitory input on the excitatory nerve endings that permit the action of the two muscles to perform separately. Modulation of contraction and a graded response is thus achieved through *inhibitory* impulses, mostly at the presynaptic level. The release of the inhibitory neurotransmitter GABA (p. 138) onto presynaptic receptors increases Cl^- conductance. An excitatory nerve impulse arriving in the terminal button is then reduced in amplitude because a repolarizing leakage of Cl^- into the nerve terminal takes place when its membrane is depolarized by the nerve impulse. An impulse of reduced amplitude consequently releases less neurotransmitter at the excitatory synapse that results in a weaker contraction.

In addition to presynaptic inhibition of arthropod muscle, a second form of inhibitory control is common. In postsynaptic inhibition, the inhibitory nerve terminals form multiterminal neuromuscular synapses along the muscle fiber. Impulses generated in the inhibitory neuron produce IPSPs in the postsynaptic muscle fiber that oppose the membrane depolarization by EPSPs and reduce the force of the resultant contraction. Of these two mechanisms of inhibition, postsynaptic inhibition is the more common. Both mechanisms are important in controlling muscle tension and, in some situations, may speed the rate of relaxation of a contracted muscle.

There is an optimal muscle length at which maximal tension can be developed on a subsequent contraction

Additional factors not directly under nervous control also influence the tension developed during contraction (Table 8-1). Among these is the length of the fiber at the onset of contraction, to which we now turn.

A relationship exists between the length of the muscle before the onset of contraction, and the tetanic tension that

FIGURE 8-17 Length-tension relationship. Maximal tetanic contraction can be achieved when a muscle fiber is at its optimal length (l_0) before the onset of contraction, because this is the point of optimal overlap of thick-filament cross bridges and thin-filament cross-bridge binding sites (point A). The percentage of maximal tetanic contraction that can be achieved decreases when the muscle fiber is longer or shorter than l_0 before contraction. When it is longer, fewer thin-filament binding sites are accessible for binding with thick-filament cross bridges because the thin filaments are pulled out from between the thick filaments (points B and C). When the fiber is shorter, fewer thin-filament binding sites are exposed to thick-filament cross bridges because the thin filaments overlap (point D). Also, further shortening and tension development are impeded as the thick filaments become forced against the Z lines (point D). In the body, the resting muscle length is at l_0 . Furthermore, because of restrictions imposed by skeletal attachments, muscles cannot vary beyond 30% of their l_0 in either direction (the range screened in light green). At the outer limits of this range, muscles still can achieve about 50% of their maximal tetanic contraction.

© Cengage Learning, 2013

each contracting fiber can subsequently develop at that length. Every muscle has an **optimal length** (l_0) at which maximal force can be achieved on a subsequent tetanic contraction. More tension can be achieved during tetanus when beginning at the optimal muscle length than can be achieved when the contraction begins with the muscle less than or greater than its optimal length. This **length-tension relationship** can be explained by the sliding-filament mechanism of muscle contraction, which was first demonstrated on frog skeletal muscle fibers. Figure 8-16 shows the results of such a study: The tension generated by a muscle is measured after it was set at different lengths prior to stimulation (Points B, C, and D).

At Optimal Length (l_0) At l_0 when maximum tension can be developed (point A in Figure 8-17), the thin filaments optimally overlap the regions of the thick filaments from which the cross bridges project. At this length, a maximal number of cross-bridge sites are accessible to the actin molecules for binding and bending. The central region of thick filaments, where

the thin filaments do not overlap at l_0 , lacks cross bridges; only myosin tails are here.

At Lengths Greater Than l_0 At greater lengths, as when a muscle is passively stretched in our experiment (point B), the thin filaments have been pulled out from between the thick filaments, decreasing the number of actin sites available for cross-bridge binding; that is, some of the actin sites and cross bridges no longer “match up,” so they “go unused.” Thus, less cross-bridge activity can occur after stimulation, so less tension can be developed. In fact, when the muscle is stretched to about 70% longer than its l_0 (point C), the thin filaments are completely pulled out from between the thick filaments so that no cross-bridge activity and consequently no contraction can occur.

At Lengths Less Than l_0 If a muscle is compressed so that it is shorter than l_0 prior to stimulation (point D), less tension can be developed, for three reasons:

1. The thin filaments from the opposite sides of the sarcomere become overlapped, decreasing the number of actin sites exposed to the cross bridges.
2. The thick filaments become forced against the Z lines, so further shortening is impeded.
3. Besides these two mechanical factors, at muscle lengths less than 80% of l_0 , not as much Ca^{2+} is released during excitation-contraction coupling for reasons unknown. Furthermore, by an unknown mechanism the ability of Ca^{2+} to bind to troponin and pull the troponin-tropomyosin complex aside is reduced at shorter muscle lengths. Consequently, fewer actin sites are uncovered for participation in cross-bridge activity.

Limitations on Muscle Length The extremes in muscle length that prevent the development of tension occur only under experimental conditions, when a muscle is removed and stimulated at various lengths. *In vivo*, muscles are usually positioned such that their relaxed length is approximately their optimal length; thus, they can achieve near-maximal tetanic contraction most of the time. Because of limitations imposed by attachment to the skeleton, a muscle cannot be stretched or shortened more than 30% of its resting optimal length, and usually it deviates much less than 30% from normal length. Even at the outer limits (130 and 70% of l_0), the muscles can still generate half their maximum tension.

The factors discussed thus far that influence how much tension can be developed by a contracting muscle fiber—the frequency of stimulation and the muscle length at the onset of contraction—can vary from contraction to contraction. Other determinants of muscle fiber tension—the metabolic capability of the fiber relative to resistance to

FIGURE 8-18 Relationship between the contractile component and the series-elastic component in transmitting muscle tension to bone. Muscle tension is transmitted to the bone by means of the stretching and tightening of the muscle's elastic connective tissue and tendon (similar to the stretching spring) as a result of sarcomere shortening brought about by cross-bridge cycling.

© Cengage Learning, 2013

fatigue and the thickness of the fiber—do not vary from contraction to contraction but depend on the fiber type and can be modified over a period of time. After we finish discussing skeletal muscle mechanics, we will consider these other factors in the next section, on skeletal muscle metabolism and fiber types.

Muscle tension is transmitted to skeletal elements as the contractile component tightens the series-elastic component

Tension is produced internally within the sarcomeres, the contractile component of the muscle, as a result of cross-bridge activity and the resultant sliding of filaments. However, the sarcomeres are not attached directly to the skeleton. Instead, the tension generated by these contractile elements must be transmitted to the bone or exoskeleton via the connective tissue (such as tendons) before the skeletal element can be moved (Figure 8-18). This shortening of the sarco-

meres stretches the series-elastic component. Muscle tension is transmitted to the skeleton by this tightening of the series-elastic component. This externally applied tension is responsible for moving the skeleton against a load.

A vertebrate skeletal muscle is typically attached to at least two different bones across a joint by means of tendons that extend from each end of the muscle. When the muscle shortens during contraction, the position of the joint is changed as one bone is moved in relation to the other—for example, flexion of the elbow joint by contraction of the biceps (flexor) muscle and extension of the elbow by contraction of the triceps (extensor). The end of the muscle attached to the more stationary part of the skeleton is called the **origin**, and the end attached to the skeletal part that moves is the **insertion**.

For a muscle to shorten during contraction, the tension developed in the muscle must exceed the forces that oppose movement of the bone to which the muscle's insertion is attached. In the case of elbow flexion, the opposing force, or **load**, is the weight of an object being lifted. The force exerted by the muscle on the load is equivalent to the tension generated. If you flex your elbow without lifting any external object, there is still a load, albeit a minimal one—the weight of your forearm being moved against the force of gravity.

The two primary types of contraction are isotonic and isometric

Muscle accomplishes work in a physical sense only when an object is moved. **Work** is defined as force multiplied by distance. **Force** can be equated to the muscle tension required to overcome the load (the weight of the object being moved, such as a bone). The amount of work accomplished by a contracting muscle therefore depends on how much an object weighs and how far it is moved. There are two primary types of contraction, depending on whether the muscle changes length during contraction. In an **isotonic contraction**, muscle tension remains constant as the muscle changes length, doing work. In an **isometric contraction**, the muscle is prevented from shortening, so tension develops at constant muscle length; thus no work is done. The same internal events occur in both isotonic and isometric contractions: The tension-generating contractile process is turned on by muscle excitation; the cross bridges start cycling; and filament sliding shortens the sarcomeres, which stretches the series-elastic component to exert tension on the bone at the site of the muscle's insertion.

Considering the biceps as an example, assume a chimpanzee is going to lift an object (as in Figure 8-18). When the tension developing in the biceps becomes great enough to overcome the weight of the object, the animal can lift the object, with the whole muscle shortening in the process. Because the weight of the object does not change as it is lifted, the muscle tension remains constant throughout the

period of shortening. This is an *isotonic* (literally, “constant tension”) *contraction*. Isotonic contractions are used for body movements and for moving external objects. This type of isotonic contraction, in which the muscle shortens, is sometimes called a **concentric** one. However, another type called **eccentric** occurs when the *muscle lengthens* because it is being stretched by an external force, even while it is attempting to contract. An example is lowering a load to the ground. During this action, the muscle fibers in the biceps are lengthening but are still working in opposition to being stretched. This tension supports the weight of the object.

Not all vertebrate muscle contractions shorten muscles and move bones, however. What happens when lifting an object too heavy to move upwards (that is, if the tension in the muscles is just equal to that required to hold the load in place)? In this case, the muscle cannot shorten and lift the object but remains at constant length despite the development of tension, so an *isometric* (“constant length”) *contraction* occurs. In addition to occurring when the load is too great, isometric contractions also take place when the tension developed in the muscle is deliberately less than that needed to move the load. In this case, the goal is to keep the muscle at fixed length although it is capable of developing more tension. These submaximal isometric contractions are important for maintaining posture (such as keeping the legs stiff while standing) and for supporting objects in a fixed position. During a given movement, a muscle may shift between isotonic and isometric contractions. For example, when the animal picks up a banana to eat it, the biceps undergoes an isotonic contraction while the fruit is being lifted, but the contraction becomes isometric as the arm stops to hold the banana at the mouth.

Other Contractions An animal’s body is not limited to pure isotonic and isometric contractions. Muscle length and tension frequently vary throughout a range of motion. Think about drawing a bow and arrow. The tension of the biceps muscle continuously increases to overcome the progressively increasing resistance as the bow is stretched further. At the same time, the muscle progressively shortens as the bow is drawn farther back. Such a contraction occurs at neither constant tension nor constant length.

Some skeletal muscles do not attach to bones at both ends but still produce movement. For example, the muscles of the tongue are not attached at the free end. Isotonic contractions of the tongue muscles maneuver the free, unattached portion of the tongue to facilitate eating (and speech in humans). The external eye muscles attach to the skull at their origin but to the eye at their insertion. Isotonic contractions of these muscles produce the eye movements that enable an animal to track moving objects, for example. A few skeletal muscles that are completely unattached to bone actually prevent movement. These are the rings of skeletal muscles known as **sphincters** that guard the exit of urine and feces from the body by isotonically contracting. (Sphincters are examples of muscles that are expanded by fluid pressure as an antagonistic mechanism.)

The velocity of shortening is related to the load

The load is also an important determinant of the velocity, or speed, of shortening (Figure 8-19). During a concentric contraction, the greater the load, the lower the velocity at which

FIGURE 8-19 Load–velocity relationship in concentric contractions. The velocity of shortening decreases as the load increases.

© Cengage Learning, 2013

a single muscle fiber (or a constant number of contracting fibers within a muscle) shortens. The velocity of shortening is maximal when there is no external load, progressively decreases with an increasing load, and falls to zero (no shortening—*isometric contraction*) when the load cannot be overcome by maximal tetanic tension. You have frequently experienced this **load–velocity relationship**. You can quickly lift light objects requiring little muscle tension, whereas you can lift very heavy objects only slowly, if at all. This relationship between load and shortening velocity is a fundamental property of muscle, presumably because it takes the cross bridges longer to stroke against a greater load.

Whereas load and velocity for shortening are *inversely* related for *concentric* contractions, load and velocity for lengthening are *directly* related for *eccentric* contractions. The greater the external force (load) stretching a muscle that is contracting to resist the stretch, the greater the speed with which the muscle lengthens, likely because the load breaks some of the stroking cross-bridge attachments.

Skeletons include endoskeletons, exoskeletons, and hydrostatic skeletons

As you have seen, skeletal muscles typically create movement via skeletal elements. We have already mentioned the two major rigid skeletons: the *endoskeleton* of vertebrates and the *exoskeleton* of arthropods. However, there is a third kind common in the animal kingdom: the *hydrostatic* skeleton, which is based on the fact that water is essentially incompressible. A pressurized nonmoving fluid can produce rigid states, while a pressurized moving fluid can create large-scale movement and stretch out contracted muscles. In its simplest form, such as in a sea anemone (see Figure 5-2), a hydrostatic skeleton consists of a closed chamber of body fluid (in this case its digestive tract, sealed by a closed mouth) surrounded by two sets of muscles: *circular* muscles ringing the chamber and *longitudinal* muscles running the length of the chamber. In effect, these are antagonistic muscles but working through fluid pressure rather than a hard skeleton. When the circular muscles contract, the incompressible fluid builds up pressure against its walls, stiffening the body region around it. However, if the longitudinal

muscles are relaxed, the chamber and body region will become narrower and longer due to pressurized fluid movement. This is how a sea anemone extends its body and then keeps it upright, and how an earthworm extends its anterior into soil for burrowing.

The fluid being pressurized and moved can be that of a body cavity, a circulatory system, or the interior of cells. The latter is the case for an octopus's arms: Its muscles can (1) contract to pull on other muscles and connective tissue, (2) pressurize their own intracellular fluids to become stiff skeletal elements for other muscles to work on, and (3) relax to act as flexible joints pulled on by other muscles. These versions of hydrostatic skeletons are called *muscular hydrostats*. Hydrostatic skeletons and hydrostats provide little protection for body parts compared to hard skeletons, but they have one major advantage over the latter: They can switch between a static state to maintain rigidity and a mobile state that is more flexible than any jointed hard skeleton. An octopus, for example, can reach its arm into twisting rock crevices to find prey in a way no rigid limb can. And a cat-sized octopus can squeeze its entire body out of a box with only a 2 cm hole!

Hydrostatic skeletons (including muscular hydrostats) are also found in many animals with hard skeletons. Mammalian ones include the tongue, the erectile genitalia (penis, clitoris), and—perhaps the most sophisticated example—the highly dexterous trunk of an elephant, which can reach around and through dead brush to grab a live branch for food, pick up objects as small as a coin, and even shuck an ear of corn. Finally, as you'll see in Chapter 9, many spiders extend their exoskeletal legs rapidly for jumping not by extensor muscles but by circulatory fluid squeezed into the leg by muscles in the main body.

Interactive units of skeletal muscles, tendons, skeletons, and joints form lever systems

Let's return to the mechanics of rigid skeletons. Most skeletal muscles are attached to bones or exoskeleton segments across **joints**, forming lever systems. A **lever** is a rigid structure capable of moving around a pivot point known as a **fulcrum**. In the vertebrate body, the bones function as levers, the joints serve as fulcrums, and the skeletal muscles provide the force to move the bones. The part of a lever between the fulcrum and the point where an upward force is applied is called the **power arm**; the part between the fulcrum and the downward force exerted by a load is the **load arm** (Figure 8-20a).

The most common type of lever system in the mammalian body is exemplified by flexion of the human elbow joint. Skeletal muscles, such as the biceps whose contraction flexes the elbow joint, consist of many parallel (side-by-side) tension-generating fibers that can exert a large force at their insertion but shorten only a small distance and at a relatively slow velocity. The lever system of the elbow joint amplifies the slow, short movements of the biceps to produce more rapid movements of the hand that cover a greater distance.

Consider how an object weighing 5 kg is lifted by the human hand (Figure 8-20b). When the biceps contracts, it exerts an upward force at the point where it inserts on the forearm bone about 5 cm away from the elbow joint, the fulcrum. Thus, the power arm of this lever system is 5 cm long. The length of the load arm, the distance from the elbow joint to the hand, averages 35 cm. In this case, the load arm is seven times longer than the power arm, which enables

The octopus *Octopus aculeatus* uses its hydrostat arms to walk along the seafloor and to mimic algae.

the load to be moved a distance seven times greater than the shortening distance of the muscle and at a velocity seven times greater (the hand moves 7 cm during the same length of time the biceps shortens 1 cm).

The disadvantage of this lever system is that at its insertion the muscle must exert a force seven times greater than the load. The product of the length of the power arm times the upward force applied must equal the product of the length of the load arm times the downward force exerted by the load. Because the load arm times the downward force is $35 \text{ cm} \times 5 \text{ kg}$, the power arm times the upward force must be $5 \text{ cm} \times 35 \text{ kg}$ (the force that must be exerted by the muscle to be in mechanical equilibrium). Thus, some skeletal muscles typically work at a mechanical disadvantage in that they must exert a considerably greater force than the actual load to be moved. Nevertheless, the amplification of velocity and distance afforded by the lever arrangement enables muscles to move loads faster over greater distances than would otherwise be possible. This amplification provides valuable maneuverability and speed.

In contrast, some muscles are arranged to amplify load lifting, at the expense of speed. An example is the “calf” muscle or *gastrocnemius* in the hind limbs of terrestrial vertebrates (used for lifting or jumping the body up on the toes). This muscle pulls on the heel bone at a distance farther from the fulcrum—the toe joints—than the load being lifted. That load is the weight of the body being supported by the foot, usually centered over the middle of the foot. A modest force produced by the muscle can lift a body weight greater than that force, but as a trade-off, speed is de-amplified; that is, the lifting muscle moves a greater distance than the body being lifted.

Elastic storage structures can greatly increase the efficiency and speed of locomotion

Finally, recall that elastic “spring” elements can store muscle-generated energy, not only to help stretch out contracted muscles but also for rapid locomotion, such as the chameleon tongue's feeding strike, or a flea's rapid jump to distances

FIGURE 8-20 Lever systems of muscles, bones, and joints. Note that the lever ratio (length of the power arm to length of the load arm) is 1:7 (5 cm:35 cm), which amplifies the distance and velocity of movement seven times (distance moved by the muscle [extent of shortening] = 1 cm, distance moved by the hand = 7 cm, velocity of muscle shortening = 1 cm/unit of time, hand velocity = 7 cm/unit of time), but at the expense of the muscle having to exert seven times the force of the load (muscle force = 35 kg, load = 5 kg).

© Cengage Learning, 2013

over 100 times its body length. Let's look at the latter more closely. Fleas are thought to jump by first using muscles to compress a pad with a highly elastic rubberlike protein called **resilin**. Once compressed, resilin releases almost all of its stored energy to extend the leg for a fast, powerful push-off. Elastic apodemes are similarly used by jumping locusts and grasshoppers, and resilin springs are also key to the rapid wing beats of some flying insects, as you will see later. Resilin contains coiled peptide chains in a three-dimensional network stabilized by tyrosines cross-linked to form *dityrosine* and *trityrosine*. The network stores and releases a higher percentage of energy (97%) than any other known elastic substance, and is currently being tested for uses in springy athletic shoes and restoring elasticity to damaged arteries.

Elastic springlike mechanisms also increase energy efficiency. For example, ligaments of a human's arched foot and the gastrocnemius tendon of most mammals are important energy components of running and jumping. Consider what happens when you run. First, you push with one leg to create thrust, but also have to use energy to lift it off the ground. That energy could be lost, but when gravity pulls the foot down to the ground, much of that energy is captured by ligaments in your foot arch (stretched as your foot flattens slightly) and your gastrocnemius (Achilles) tendon, stretched as your lower leg bends forward. Now, when that foot pushes off again with the gastrocnemius muscle, it is aided by its tendon and arch ligaments rebounding. This mechanism is perhaps most effectively used in hopping animals like kangaroos (see photograph at the chapter start). Their large tendons

store large amounts of energy as they hit the ground, much more forcefully in a hop than during running. In fact the faster a kangaroo hops, the *less* energy it uses to cover a given distance! This is not the case during running.

Elastic storage and release are also found in fluid-based locomotory systems. This is how a jellyfish's bell and a squid's mantle reopen after muscles contract to create a jet of water.

We now shift our discussion from muscle mechanics to the metabolic means by which muscles power these movements.

check your understanding 8.4

A mussel is attempting to avoid being eaten by a starfish by tightly closing its shell. Is this an isometric contraction or an isotonic contraction? Explain.

A person eating a crab claw usually picks out only one—very large—muscle. Is it the flexor or the extensor, and why? And why is the other muscle—extensor or flexor—usually too small to bother eating?

8.5 Skeletal Muscle Metabolism and Fiber Types

Recall that three different steps in the contraction–relaxation process require ATP:

1. Splitting of ATP by myosin ATPase provides (indirectly) the energy for the power stroke of the cross bridge.
2. Binding (but not splitting) of a fresh molecule of ATP to myosin permits detachment of the bridge from the actin filament at the end of a power stroke so that the cycle can be repeated (see p. 346). This ATP is subsequently split to provide energy for the next stroke of the cross bridge (step 1).
3. The active transport of Ca^{2+} back into the sarcoplasmic reticulum during relaxation depends on energy derived from the breakdown of ATP.

Muscle fibers have alternate pathways for forming ATP

Because ATP is the only energy source that can be directly used for these activities, for contraction and relaxation to continue ATP must constantly be supplied. Only limited stores of ATP are immediately available in muscle tissue, but three pathways supply additional ATP as needed during muscle contraction: (1) transfer of a high-energy phosphate from a *phosphagen* to ADP, (2) *oxidative phosphorylation* (the citric acid cycle and electron transport system), and (3) *glycolysis*. We discussed these at length in Chapter 2 (pp. 48–53) and give only a brief overview here.

Phosphagens The phosphagens *creatine phosphate* and *arginine phosphate*, described on p. 55, are often the first energy storehouse tapped at the onset of contractile activity (Figure 8-21, step 3a). Like ATP, the phosphagens contain a high-energy phosphate group, which can be donated directly to ADP to form ATP. This reaction is reversible; energy and phosphate from ATP can be transferred to creatine or arginine to form the phosphate. In vertebrates, which use creatine phosphate, the reaction is catalyzed by the muscle cell enzyme creatine kinase:

In accordance with the law of mass action (see p. 533), as the energy reserves are built up in a resting muscle, the increased concentration of ATP favors the transfer of the high-energy phosphate group to the phosphagen. By contrast, at the onset of contraction when myosin ATPase splits the meager reserves of ATP, the resultant fall in ATP favors transfer of the high-energy phosphate group from stored creatine phosphate to form more ATP. A rested vertebrate muscle contains about five times as much creatine phosphate as ATP. Thus, most energy is stored in vertebrate muscle in creatine phosphate pools. Because only one enzymatic reaction is involved in this energy transfer, ATP can be formed rapidly (within a fraction of a second) by using creatine phosphate.

Muscle ATP levels actually remain fairly constant early in contraction, but phosphagen stores become depleted. In fact, short bursts of high-intensity contractile effort are supported primarily by ATP derived at the expense of phosphagen. Other energy systems do not have a chance to become operable before the activity is over.

Oxidative Phosphorylation If the energy-dependent contractile activity is to be continued, most animal muscles shift

to the pathways of oxidative phosphorylation and glycolysis to form ATP. These multistep pathways require time to pick up their rates of ATP formation to match the increased demands for energy, time provided by the immediate supply of energy from the one-step phosphagen system.

If enough O_2 is present, oxidative phosphorylation (see p. 51) takes place within the muscle mitochondria. Oxygen is required to support the mitochondrial electron-transport system, which, together with chemiosmosis by ATP synthase, efficiently harnesses energy captured from the breakdown of nutrient molecules and uses it to generate ATP. This pathway is fueled by glucose or fatty acids, depending on the intensity and duration of the activity (Figure 8-21, step 3b). Although it provides a rich yield of ~30 ATP molecules for each glucose molecule processed, oxidative phosphorylation is relatively slow because of the number of steps involved, and it requires a constant supply of O_2 and nutrient fuel.

During light activity (such as walking) to moderate activity (such as flight or swimming), muscle cells can form sufficient amounts of ATP through oxidative phosphorylation to keep pace with the modest energy demands of the contractile machinery for prolonged periods of time. To sustain ongoing oxidative phosphorylation, the exercising muscles depend on delivery of adequate O_2 (such as by circulatory systems or tracheae) and nutrient supplies. Activity that can be supported in this way is known as **aerobic** (“with O_2 ”) or **endurance-type** activity. The O_2 required for oxidative phosphorylation in vertebrates is primarily delivered by the blood. Increased O_2 is made available to vertebrate muscles during exercise by several mechanisms: Enhanced breathing brings in more O_2 (Chapter 11), the heart contracts more rapidly and forcefully to pump more oxygenated blood to the tissues, more blood is diverted to the exercising muscles by dilation of the blood vessels supplying them (Chapter 9), and the **hemoglobin** molecules that carry the O_2 in the blood release more O_2 in exercising muscles (Chapter 11). Furthermore, some types of muscle fibers have an abundance of **myoglobin (Mb)**, which is similar to hemoglobin. Myoglobin can store amounts of O_2 , akin to a storage tank, but it also increases the rate of O_2 transfer from the blood into muscle fibers.

Glucose and fatty acids, ultimately derived from ingested food, are also delivered to the muscle cells by the circulatory fluid. Excess ingested nutrients not immediately used are stored (such as in vertebrate liver and adipose tissue, and fat bodies in insects; pp. 685–690). In addition, muscle cells can store limited quantities of glucose in the form of glycogen. Only a small volume of the muscle fiber is normally committed to fuel storage, with the combined volume of lipids and glycogen usually less than 3%, although storage of glycogen is an extraordinary 17% in the shaker muscle of the rattlesnake.

Insects have an advantage in that concentrations of **trehalose** (diglucose) in their hemolymph occur at concentrations around 2% (0.06 M), in contrast to mammals, where blood concentrations of glucose are only 0.1% (0.005 M). These high concentrations of disaccharide represent a substantial source of fuel for muscle contractions, particularly in flying insects. Trehalose has an advantage over glucose and other reducing sugars in being nonreducing and consequently is less toxic; it does not exhibit the damaging reactions that glucose has with tissue proteins in diabetes in mammals (see p. 564).

FIGURE 8-21 Metabolic pathways producing ATP used during muscle contraction and relaxation.

Glycolysis There are respiratory and cardiovascular limits to the amount of O₂ that can be delivered to a vertebrate muscle. In near-maximal contractions, the blood vessels that course through the muscle are compressed almost closed by the powerful contraction, severely limiting the O₂ available to the muscle fibers. Furthermore, even when O₂ is available, the relatively slow oxidative-phosphorylation system may not be able to produce ATP rapidly enough to meet the muscle's needs during intense activity. A skeletal muscle's energy consumption may increase up to 100-fold when going from rest to high-intensity exercise. When O₂ delivery or oxidative phosphorylation cannot keep pace with the demand for ATP formation as the intensity of activity increases, the muscle fibers rely increasingly on glycolysis (Figure 8-21, step 3c) to generate ATP (see p. 48). Glycolysis alone has two advantages over the oxidative-phosphorylation pathway: (1) glycolysis can form ATP in the absence of O₂ (operating anaerobically, that is, "without O₂"), and (2) it can proceed much more rapidly than oxidative phosphorylation because it requires fewer steps and can work with only local cellular molecules (that is, no external oxygen is needed). Although glycolysis extracts considerably fewer ATP molecules from each nutrient molecule processed, it can proceed so much more rapidly that it can out produce oxidative phosphorylation in ATP yield over a given period of time if enough glucose is present. Activity that can be supported in this way is **anaerobic** or **high-intensity**.

However, there is a disadvantage of the low efficiency of glycolysis (recall that glycolysis yields a net of 2 ATP molecules for each glucose molecule degraded, whereas the oxidative-phosphorylation pathway can extract up to about 30 ATP molecules from each glucose; see p. 56). Muscle cells can store limited quantities of glucose in the form of glycogen, but anaerobic glycolysis rapidly depletes the muscle's glycogen supplies to produce ATP rapidly but with this low efficiency.

Another aspect of glycolysis is the end products it yields, which must be produced from pyruvic acid to regenerate NAD⁺ (see p. 55). There are different end products in different animal groups (p. 56), but the best studied are the following:

1. **Lactate.** The end product of anaerobic glycolysis, pyruvic acid, is converted in most vertebrates to **lactate** (by the enzyme **lactate dehydrogenase**; p. 55):

Lactate leads to acidosis (low pH/high acidity). Lactate is also produced in many nonvertebrates such as insects.

2. **Octopine.** As we noted in Chapter 2, some nonvertebrates produce other glycolytic end products, some with less impact on pH than lactate. In many mollusks, **octopine** is produced by the enzyme octopine dehydrogenase, by combining an acid (pyruvic acid) and a basic amino acid (arginine):

In the cuttlefish, *Sepia officinalis*, for example, one study found octopine to be the primary end product in mantle muscle (used for jetting) during hypoxia (low oxy-

gen) and exhaustive swimming. As octopine concentration increased, there was a corresponding decrease in muscle glycogen and arginine phosphate. This reaction, in addition to regenerating NAD⁺, detoxifies arginine, a solute that, at the high concentrations produced by phosphagen breakdown, can perturb structures of proteins. Octopine, in contrast, has little effect on protein structures and is known as a *compatible solute* (see Chapter 13).

Lactate picked up by the blood produces the metabolic acidosis accompanying intense activity. Therefore, anaerobic high-intensity activity can be sustained for only a short duration, in contrast to the body's prolonged ability to sustain aerobic endurance-type activities. Both depletion of energy reserves and the fall in muscle pH caused by lactate accumulation in vertebrates are believed to play a role in the onset of muscle fatigue, a topic to which we turn next.

Fatigue may be of muscle or central origin

Contractile activity in a particular skeletal muscle cannot be maintained at a given level indefinitely. Eventually, the tension in the muscle declines as fatigue sets in. There are two different types of fatigue: muscle fatigue and central fatigue.

Muscle fatigue occurs when an exercising muscle can no longer respond to stimulation with the same degree of contractile activity. Muscle fatigue is a defense mechanism that protects a muscle from reaching a point at which it can no longer produce ATP. An inability to produce ATP would result in rigor mortis (obviously not an acceptable outcome of exercise). The underlying causes of muscle fatigue are unclear. The primary implicated factors include the following:

1. The *local increase in ADP and inorganic phosphate* from ATP breakdown may directly interfere with cross-bridge cycling and/or block Ca²⁺ release and uptake by the sarcoplasmic reticulum.
2. *Accumulation of lactate* may inhibit key enzymes in the energy-producing pathways and/or excitation-contraction coupling process.
3. The *accumulation of extracellular K⁺* that occurs in the muscle when the Na⁺/K⁺ pump cannot actively transport K⁺ back into the muscle cells as rapidly as this ion leaves during the falling phase of repeated action potentials (see p. 120) causes a local reduction in membrane potential. This altered potential may decrease the release of Ca²⁺ intracellularly by impairing the coupling of voltage-gated dihydropyridine receptors in the T tubules and Ca²⁺-release channels in the sarcoplasmic reticulum.
4. *Depletion of glycogen energy reserves* may lead to muscle fatigue in exhausting exercise.
5. The time of onset of fatigue varies with the *type of muscle fiber*, some fibers being more resistant to fatigue than others, and with the intensity of the exercise, more rapid onset of fatigue being associated with high-intensity activities.

Central fatigue occurs when the CNS no longer adequately activates the motor neurons supplying the working muscles. The animal slows down or stops exercising even though the muscles are still able to perform. The mechanisms involved in central fatigue are poorly understood. In some cases, central fatigue may be psychological or may stem from biochemical insufficiencies within the brain.

Increased oxygen consumption is necessary to recover from activity

An animal continues to breathe deeply and rapidly for a period of time after exhaustive activity. The necessity for the elevated O_2 uptake during recovery from exercise is due to a variety of factors. The best known is repayment of an **oxygen deficit** incurred during the activity, when ATP derived from nonoxidative sources such as creatine phosphate and anaerobic glycolysis was supporting contractile activity. During the activity, phosphagen stores of active muscles are reduced, lactate may accumulate, and glycogen stores may be tapped; the extent of these effects depends on the intensity and duration of the activity. Oxygen is needed for recovery of the energy systems. During the recovery period, fresh supplies of ATP are formed by oxidative phosphorylation using the newly acquired O_2 , which is provided by the sustained increase in respiratory activity after the activity has stopped. Much of this ATP is used to resynthesize phosphagen to restore its reserves. This can be accomplished in a matter of a few minutes in mammals. Any accumulated lactate (or octopine) is converted back into pyruvic acid, part of which is used by the oxidative-phosphorylation system for ATP production (some of this takes place in other organs such as vertebrate liver and heart, which take up lactate from the bloodstream). The remainder of the pyruvic acid is converted back into glucose (primarily by the liver in vertebrates). Most of this glucose in turn is used to replenish the glycogen stores drained from the muscles and liver during exercise. These biochemical transformations involving pyruvic acid require O_2 and take several hours for completion. Thus, as the O_2 debt is repaid, the phosphagen system is restored, lactate (or octopine) is removed, and glycogen stores are at least partially replenished.

Unrelated to increased O_2 uptake is the need to restore nutrients after grueling activity, such as a fight between two males competing for females, or fleeing from a predator. In such cases, glycogen stores are severely depleted, and long-term recovery can take a day or more because the exhausted energy stores require nutrient intake for full replenishment. Therefore, depending on the type and duration of activity, recovery can be complete within a few minutes or can require more than a day.

Part of the extra O_2 uptake during recovery is not directly related to the repayment of energy stores but instead is the result of a general metabolic disturbance after exercise. For example, the local increase in muscle temperature arising from heat-generating contractile activity speeds up the rate of all chemical reactions in the muscle tissue, including those dependent on O_2 . Likewise, the secretion of epinephrine, a vertebrate hormone that increases O_2 consumption, is elevated during moderate activity. Until the circulating level of epinephrine returns to its pre-exercise state, O_2 uptake is above normal.

Although muscles can accomplish work, much of the energy is converted to heat

One of the limits to muscle energy is its relatively low efficiency. In an isotonic contraction, it is only about 25%. That is, of the ATP consumed by the muscle during the contraction, 25% is realized as external work whereas the remaining 75% is converted to heat, in part due to friction.

Recall that in an isometric contraction, when no object is moved, external work is zero. All energy consumed by the muscle during contraction is converted to heat. However, this is not all wasted energy since holding a limb in place can obviously be very useful.

Muscle heat is not always wasted in another way, because it is important in some animals in maintaining elevated core-body temperatures (such as tunas, bumblebees, birds, and mammals). In fact, shivering, a form of involuntarily induced skeletal muscle contraction in mammals, birds, and some insects, is a well-known mechanism for increasing heat production on a cold day or to fight infections with a fever. Heavy exertion on a hot day, in contrast, may overheat the body, because the normal heat-loss mechanisms may be unable to compensate for this increase in heat production (see Chapter 15).

We have been looking at the contractile and metabolic activities of skeletal muscle in general. Yet not all skeletal muscle fibers use these mechanisms to the same extent. We are next going to examine the different types of muscle fibers, based on their speed of contraction and how they are metabolically equipped to generate ATP.

There are three types of skeletal muscle fibers, which differ in ATP hydrolysis and synthesis

No one muscle-fiber type can perform all the activities essential for an animal to survive. For this reason, muscle fibers show the greatest diversity of any tissue in an animal's body. Based on their biochemical capacities and physiological requirements, vertebrate skeletal muscle fibers have been classified into three major groups (Table 8-2):

1. Slow-oxidative (SO) fibers or "slow" fibers (Type I)
2. Fast-oxidative (FO) fibers or "FR": Fast Resistant fibers (Type IIa)
3. Fast-glycolytic (FG) fibers or "FF": Fast Fatigable fibers (Type IIb, IId or IIx) (In addition, there is a type IIc fiber, an undifferentiated form that can become other type II forms).

As their names imply, the two main differences between these fiber types are their speed of contraction (slow or fast) and the type of enzymatic machinery they primarily use for ATP formation (oxidative or glycolytic). There also exist a small number of muscle fibers that do not obviously belong to those groups listed above that are termed "Fast Intermediate." These fibers are characterized by a fast contraction time but are unable to maintain their initial force production in response repeated stimulation.

Fast versus Slow Fibers As is well known, compared with large animals, small ones have a much higher power output when normalized to body weight. Correspondingly, fast twitch muscles of these animals have a larger unloaded shortening velocity than their counterparts in very large animals. Fast fibers have higher myosin-ATPase (ATP-splitting) activity than slow fibers because of different myosin isoforms (see *Molecular Biology and Genomics: Myosin Family Genetics*). The higher the ATPase activity, the more rapidly ATP is split and the faster the rate at which energy is made available for cross-bridge cycling. The result is a fast twitch, compared to the slower twitches of those fibers that split ATP more slowly. On average, the time to peak twitch ten-

TABLE 8-2 Characteristics of Skeletal Muscle Fibers

Characteristic	TYPE OF FIBER		
	Slow-Oxidative (Type I)	Fast-Oxidative (Type IIa)	Fast-Glycolytic (Type IIx)
Myosin-ATPase Activity	Low	High	High
Speed of Contraction	Slow	Fast	Fast
Resistance to Fatigue	High	Intermediate	Low
Oxidative Phosphorylation Capacity	High	High	Low
Enzymes for Anaerobic Glycolysis	Low	Intermediate	High
Mitochondria	Many	Many	Few
Capillaries	Many	Many	Few
Myoglobin Content	High	High	Low
Color of Fiber	Red	Red	White
Glycogen Content	Low	Intermediate	High

© Cengage Learning, 2013

sion for fast fibers is 20–40 msec compared to 60–100 msec for slow fibers. Thus, two factors determine the speed with which a muscle contracts: the load (load-velocity relationship) and the myosin ATPase activity of the contracting fibers (fast or slow twitch).

Oxidative versus Glycolytic Fibers Fiber types also differ in ATP-synthesizing ability. Those with a greater capacity to form ATP are more resistant to fatigue. Some fibers are better equipped for oxidative phosphorylation, whereas others rely primarily on anaerobic glycolysis for synthesizing ATP. Because oxidative phosphorylation yields considerably more ATP from each nutrient molecule processed, it does not readily deplete energy stores. Furthermore, it does not result in lactate accumulation. Oxidative types of muscle fibers are therefore more resistant to fatigue than are glycolytic fibers.

Other related characteristics distinguishing these three fiber types are summarized in Table 8-2. As would be expected, the oxidative fibers, both slow and fast, contain an abundance of mitochondria, the organelles that house the enzymes involved in the oxidative-phosphorylation pathway. Mitochondrial volume in most skeletal-muscle fibers lies between 4 and 42%, with low values found in muscles relying on anaerobic metabolism (so-called white muscle), and high values in those relying on aerobic metabolism (so-called red muscle; we discuss the details of white and red muscle shortly). For example, mitochondrial volume of the

tail-shaker muscle in rattlesnakes (*Crotalus*) is 26%. However, there are extreme values, as low as 1% in some white fish muscle and as much as 50% in the flight muscle of locusts.

Oxidative fibers (type I) are richly supplied with capillaries and also have a high myoglobin (Mb) content. The highest known myoglobin contents are those in swimming muscles of diving penguins and mammals; for example, the pectoralis muscle (which operates the wings) of a king penguin has 4.3 g of Mb per 100 g of muscle, whereas a gull's pectoralis has only 0.55 g Mb/100g and a chicken's pectoralis only 0.03 g Mb/100g. Myoglobin not only helps support oxidative fibers' O₂ dependency but also imparts a red color to them, just as oxygenated hemoglobin is responsible for the red color of arterial blood. Accordingly, these muscle fibers are referred to as **red fibers**.

In contrast, the fast fibers specialized for glycolysis (IIb, IId, IIx) contain few mitochondria but have a high content of glycolytic enzymes instead. Also, to supply the large amounts of glucose necessary for glycolysis, they contain an abundance of stored glycogen. Because the glycolytic fibers need relatively less O₂ to function, they receive only a meager capillary supply compared with the oxidative fibers. The glycolytic fibers contain very little myoglobin and therefore are pale in color, so they are sometimes called **white fibers**. (The most readily observable comparison between red and white fibers is the dark and white meat in poultry, and the red meat of a tuna compared to the white meat of a halibut.) In addition to their higher myosin ATPase content, these fibers are also larger in diameter than the slow-oxidative fibers because of a greater abundance of actin and myosin filaments. With these additional power-generating filaments, the fast-glycolytic fibers are capable of rapidly producing large amounts of tension, but only for a short duration because of their dependence on glycolysis for energy release. For example, the explosive "burst" of flapping flight in many species of galliform birds (such as grouse) is used to escape predators but can be sustained for only a few minutes. Appropriately, these species of birds have relatively small heart masses and a reduced capacity to supply the flight muscles with oxygen. For these reasons, galliform birds are restricted to anaerobic flights of short duration and are adapted to a largely ground-based life.

Finally, fast-oxidative fibers share characteristics with each of the other two types. They have high ATPase activity like the fast-glycolytic fibers and high oxidative capacity like the slow-oxidative fibers. They contract more rapidly than the slow-oxidative fibers and can maintain the contraction for a longer period of time than the fast-glycolytic fibers. However, because their rate of ATP production by oxidative phosphorylation cannot keep pace with the high rate of ATP splitting, they rely partially on glycolysis and are more prone to fatigue than the slow-oxidative fibers. Thus, the flight muscles of migratory birds contain an abundance of fast-oxidative glycolytic fibers. Normally, the flight muscles of small birds are composed entirely of this muscle type, whereas larger birds have a mixture of different fiber types.

Consider as well the energy requirements of the muscle fibers in a horse as its gait changes from a walk into a canter. While the horse is walking, Type I fibers are recruited because the muscle contracts slowly and energy requirements are minimal. During this phase the muscle fibers rely primarily on fat as an energy source. However, as speed increases

Molecular Biology and Genomics

Myosin Family Genetics

As noted in the text, there are at least three different functional categories of muscle fibers: In humans, these are termed slow-oxidative or Type I, fast-oxidative or Type IIa, and fast-glycolytic or Type IIx. Scientists have known for some time that each of these expresses a different myosin protein from its own myosin gene; each myosin has catalytic properties suited to its muscle type. Thus, researchers long suspected that there are at least three different myosin genes. Genetic analysis has revealed that there is indeed a large variety of related myosins, with as many as 16 different myosin gene types in muscles among different mammals and among different muscle tissues. Key examples are designated as follows:

- Embryonic
- Neonatal
- Cardiac α
- Cardiac β or slow type I (in skeletal muscle)
- Fast type IIa
- Fast type IIx

- Fast type IIc
- Fast type IIb
- Extraocular
- Mandibular or masticatory (m-MHC)
- Smooth muscle type (SMMHC)

All these are considered to be *isoforms* of myosin *class II*, the type in muscle (not to be confused with subtype IIa, and so on). In addition, there are numerous nonmuscle myosin classes such as myosin class VI, associated with movements of single cells. Mutations in the myosin VI gene in mice lead to deafness because the stereocilia used in hearing (p. 219) are nonfunctional. Including all classes, the human genome has a total of 39 myosin genes!

The class II muscle myosins have played important roles in evolutionary adaptations. For example, fast-glycolytic types termed IIb and IIc are found in rodents, animals that scurry around at high limb velocities, and are faster than type IIx, the fastest type found in skeletal muscles of large mammals (including humans). (Type IIb gene is expressed in eye muscles in some

large mammals, but in others such as horses it has become a pseudogene.) As another example, nonhuman primates have an active mandibular (m-MHC) gene (also called MYH16) that produces very strong jaw muscles. In humans, the gene is mutated, leading to our relatively small, weak jaws. It is speculated that this mutation allowed for finer jaw control needed for speech.

The expression of myosin genes changes with activity and other environmental factors related to muscle use, in concert with changes in muscle fiber types (see main text). In human muscles repeatedly loaded, as in weight training, the genes of fast IIx fibers stop transcribing the IIx myosin and begin transcribing the IIa myosin, as the fibers convert from IIx type to IIa type. (In rodents subjected to the equivalent of weight training, fibers convert from IIb to IIx.) In contrast, in sedentary people, much of the limb muscle converts to type IIx (which fits the way their muscles are used: quiet most of the time, with intermittent short bursts of usage).

(a) Icelandic horses standing and moving. As these animals increase their activity from resting to higher and higher speeds, more motor units are activated and different fiber types are recruited. While standing or walking, Type I (aerobic) dominates, while in burst activity, such as rearing, Type IIx (anaerobic) dominates. Unlike most horses, which have four gaits, these have five: walk, trot, tölt, gallop, and a smooth flying pace.

© Paul H Yancey

(b) A deep-sea cusk eel (with muscles under the skin shown at the right). This fish cruises slowly in the deep using thin bands of red Type I (aerobic) muscle, then bursts occasionally to escape or catch prey using white Type IIx (anaerobic) muscle (seen here as light pink).

to a trot, Type I fibers can no longer contract rapidly enough to propel the horse. Type IIa fibers are now recruited. Because fat cannot be metabolized anaerobically, glycogen serves as the primary energy source for ATP production. As the speed of the horse increases to a gallop, Type IIx muscle

fibers are recruited. ATP production is now almost exclusively generated through anaerobic pathways. However, although ATP is rapidly generated, it is associated with the generation of lactate, which results in a decline in muscle pH and the onset of fatigue.

Genetic Endowment of Muscle Fiber Types The muscles of most terrestrial vertebrates contain a mixture of all three fiber types because almost all must cope with gravity using red fibers, while also producing faster movements. However the type of activity for which the muscle is specialized largely determines the percentage of each type. Accordingly, a high proportion of slow-oxidative fibers are found in muscles specialized for maintaining low-intensity contractions for long periods of time without fatigue, such as the muscles of the back and legs that support an animal's weight against the force of gravity. The deep layers of the pectoralis muscles of birds adapted for soaring and gliding modes of flight contain more slow-oxidative fibers (red). Fast-glycolytic fibers are preponderant in the arm muscles of primates, adapted for rapid, forceful movements. In fish, which do not need to cope with gravity, muscle fibers are often completely separate. In species that are inactive much of the time (such as a halibut), almost all the muscle is fast glycolytic (white), used for burst activity, with red muscle forming a distinct, small band under the lateral line (p. 218).

Muscle fibers adapt considerably in response to the demands placed on them

Not only is the nerve supply to a skeletal muscle essential for initiating contraction, but the motor neurons supplying a skeletal muscle are also important in maintaining the muscle's integrity and chemical composition. Different types of activity produce different patterns of neuronal discharge to the muscle involved. Depending on the pattern of neural activity, long-term adaptive changes occur in the muscle fibers, enabling them to respond most efficiently to the types of demands placed on the muscle. Therefore, skeletal muscle has a high degree of *plasticity* (see p. 171). Three types of changes can be induced in muscle fibers: changes in their ATP-synthesizing capacity, in myosin isoforms and thus contractile speed and force, and in their diameter.

Improvement in Oxidative Capacity Regular endurance (aerobic) activities, such as flight or swimming, induce metabolic changes within the oxidative fibers, which are the ones primarily recruited during aerobic exercise. These changes enable the muscles to use O₂ more efficiently. For example, the number of mitochondria and the number of capillaries supplying blood to these fibers both increase. Muscles so adapted are better able to endure prolonged activity without fatiguing, but they do not enlarge. In the example of the horse whose gait is increased from a walk to a canter, sufficient endurance training ultimately enhances the aerobic ability of its muscle to use fuels through oxidation. Blind mole rats, with most of their muscle mass located in the anterior end of the body, find themselves digging in tunnels with scant oxygen supplies. Researchers found that, as an adaptation to these extreme conditions, capillary density was approximately 30% higher in mole rat muscles compared to white rat muscles. Although mole rats have less muscle mass than white rats, mitochondrial density is about 50% higher.

Muscle Hypertrophy The actual size of the muscles can also be increased by regular bouts of anaerobic, short-duration, high-intensity training. The resulting muscle enlargement comes primarily from an increase in diameter (hypertrophy)

of the fast-glycolytic fibers that are called into play during such powerful contractions. Most of the fiber thickening is a consequence of increased synthesis of myosin and actin filaments, which permits a greater opportunity for cross-bridge interaction and subsequently increases the muscle's contractile strength. The resultant bulging muscles are better adapted to activities that require intense strength for brief periods, but endurance has not improved.

Influence of Hormones Muscle fibers of many mammalian males are thicker, and accordingly, their muscles are larger and stronger than those of females because of the actions of testosterone, a steroid hormone secreted primarily in males. Testosterone promotes the synthesis and assembly of myosin and actin and is responsible for the naturally larger muscle mass of males. Consider the effect of the photoperiod-induced increase in testosterone on the development of muscle in the necks of male deer prior to the onset of the rutting season. Only the fittest males (those that dominate in battles that involve clashes with the head and antlers) have access to the harem and can reproduce. While testosterone increases male-specific muscle mass, IGF-1 production from the liver as induced by growth hormone (p. 292) increases muscle mass associated with normal growth in both males and females with overexpression of the IGF-1 gene in transgenic mice resulting in muscle hypertrophy. **Myostatin**, a growth factor secreted primarily by skeletal muscle, is a negative regulator of muscle growth. Mutations in the myostatin gene in mice, sheep, and cattle lead to gross muscle hypertrophy as a result of hyperplasia (increased cell number) and hypertrophy (increased cell size).

Interconversion between Fast Muscle-Fiber Types All the muscle fibers within a single vertebrate motor unit are of the same fiber type. This pattern usually is established early in life, but the two types of fast-twitch fibers are interconvertible, depending on usage. Regular endurance activities can convert fast-glycolytic fibers into fast-oxidative fibers, whereas fast-oxidative fibers can be shifted to fast-glycolytic fibers in response to power events such as weight training. Slow and fast fibers are not interconvertible, however, but the proportions can change to some extent with activity. Adaptive changes that take place in skeletal muscle gradually reverse to their original state over a period of months if the regular exercise program that induced these changes is discontinued. During these changes, the type of myosin isoform that is expressed also changes (see *Molecular Biology and Genomics: Myosin Family Genetics*).

Although training can induce changes in muscle fibers' metabolic support systems, whether a fiber is fast or slow twitch depends on the fiber's nerve supply. Slow-twitch fibers are supplied by motor neurons that exhibit a low-frequency pattern of electrical activity, whereas fast-twitch fibers are innervated by motor neurons that display intermittent rapid bursts of electrical activity. Experimental switching of motor neurons supplying slow muscle fibers with those supplying fast fibers gradually reverses the speed at which these fibers contract. Innervation of muscle fibers by motor neurons is also responsible for differentiation.

Muscle Atrophy At the other extreme, if a muscle is not used or an animal undergoes metamorphosis, its organelles, cytoplasm, and protein content decreases, its fibers become

smaller, and the muscle accordingly **atrophies** (decreases in mass) and becomes weaker. Muscle atrophy can take place in two ways. **Disuse atrophy** occurs when a muscle experiences metamorphosis or if it is not used for a long period of time even though the nerve supply is intact. Sarcomeric proteins are also normally rapidly lost during periods of fasting. **Denervation atrophy** occurs after the nerve supply to a muscle is lost. If the muscle is stimulated electrically until innervation can be reestablished, such as during regeneration of a severed peripheral nerve, atrophy can be diminished but not entirely prevented. Contractile activity itself obviously plays an important role in preventing atrophy; however, poorly understood factors released from active nerve endings, perhaps packaged with the ACh vesicles, apparently contribute to the integrity and growth of muscle tissue.

In contrast, **aestivation** (“summer sleep”) and **hibernation** (“winter sleep”), periods of an animal’s life when it experiences prolonged inactivity as a result of inhospitable environmental conditions (e.g., aridity or excessive temperature), do not result in any significant muscle atrophy for reasons that include the marked reduction in the animal’s metabolic rate. A well-studied example is the aestivation of the Australian green-striped burrowing frog (*Cyclorana alboguttata*), which escapes its cocoon of shed skin and mucus to greet the seasonally heavy summer rains with muscles capable of force production comparable to when they initially burrowed underground. Similarly, prolonged hibernation of black bears results in only marginal declines in muscle performance, which suggests that animals have evolved specialized mechanisms to reduce the effects of disuse atrophy. In the case of the black bear, researchers have suggested that these animals may use occasional bouts of shivering as an isometric exercise to maintain a low-level register of activity. These animals may also preserve skeletal muscle by recycling the nitrogen from *urea* (see Chapter 12) back into amino acids that can be used in protein synthesis.

As exemplified by metamorphosis in the gastropod mollusk, *Helix rufescens*, specific larval muscles can also undergo rearrangement and biogenesis of the new juvenile muscle system. The larval retractor muscle, by far the major muscle of the larva, reorganizes at metamorphosis, with the ventral cells of the muscle degenerating, while the dorsal cells become part of developing juvenile mantle musculature. Associated with these changes in myofibrillar structure, tropomyosin mRNA prevalence declines until becoming undetectable in the ventral cells, concurrent with an increase in the dorsal cells. Programmed cell death is a common fate of redundant larval tissues at metamorphosis in a wide range of animal taxa. Regulatory mechanisms operating at both transcriptional and posttranscriptional levels ultimately control the biogenesis and atrophy of the various larval and postlarval muscles during this process.

Limited Repair of Muscle When a muscle is damaged, limited repair is possible, even though muscle cells cannot divide mitotically to replace lost cells. Small populations of inactive muscle-specific stem cells called satellite cells are located close to the muscle surface. When a muscle fiber is damaged, locally released factors activate the satellite cells, which divide to give rise to **myoblasts**, the same undifferentiated cells that formed the muscle during embryonic development. A group of myoblasts fuse to form a large, multinucleated cell, which immediately

begins to synthesize and assemble the intracellular machinery characteristic of the muscle, ultimately differentiating completely into a mature muscle fiber. With extensive injury, this limited mechanism is not adequate to completely replace all the lost fibers. In that case, the remaining fibers often hypertrophy to compensate.

unanswered Questions | What signals trigger changes in muscle mass and fiber type?

As you have seen, muscle features change considerably under different patterns of neural stimulation and usage. But what are the actual signals involved? The answers are not complete, but neural stimulation of muscles causes changes in several candidate signal mechanisms: titin kinase (p. 339), neurotrophic growth factors, cAMP, calcium, and nitric oxide. *Nitric oxide*, a widespread paracrine (p. 93), is produced in skeletal muscle in relation to the load on the muscle, and may thus trigger changes involved in hypertrophy. Calcium, in contrast, builds up in chronically stimulated muscle cells and activates the protein *calcineurin*. Its role was suggested with mice that were genetically engineered to overexpress calcineurin. Researchers found that these mice were converting fast fibers to slow ones, with no hypertrophy. Calcineurin appears to lead to activation of a transcription factor that in turn activates genes involved in slow-muscle fiber development. Thus, two distinct signaling pathways may be involved in hypertrophy and fiber specification, respectively. <<

What is the first energy storehouse to be tapped at the onset of contractile activity?

Which energy storehouse is utilized in brief *anaerobic* activity versus ongoing *aerobic* activity? Explain why each fuel is appropriate for the particular metabolic needs.

8.6 Adaptations for Flight: Continuous High Power at High Contraction Frequencies

Consider the price a flying animal has to pay in order to fly. Bats and birds must be lightweight, and so have evolved very lightweight hollow bones. For this reason bats hang from their feet when not flying: Their leg bones are simply too thin to support their body weight. But even with this skeletal adaptation, it is not immediately clear how muscles are up to the task of flying. Recall that muscle used to generate high power is anaerobic (and thus is used intermittently) and is most effective at low-frequency output, whereas muscle that operates continuously at high frequency is aerobic, but generates low power output. Given this contradiction, that high-force output

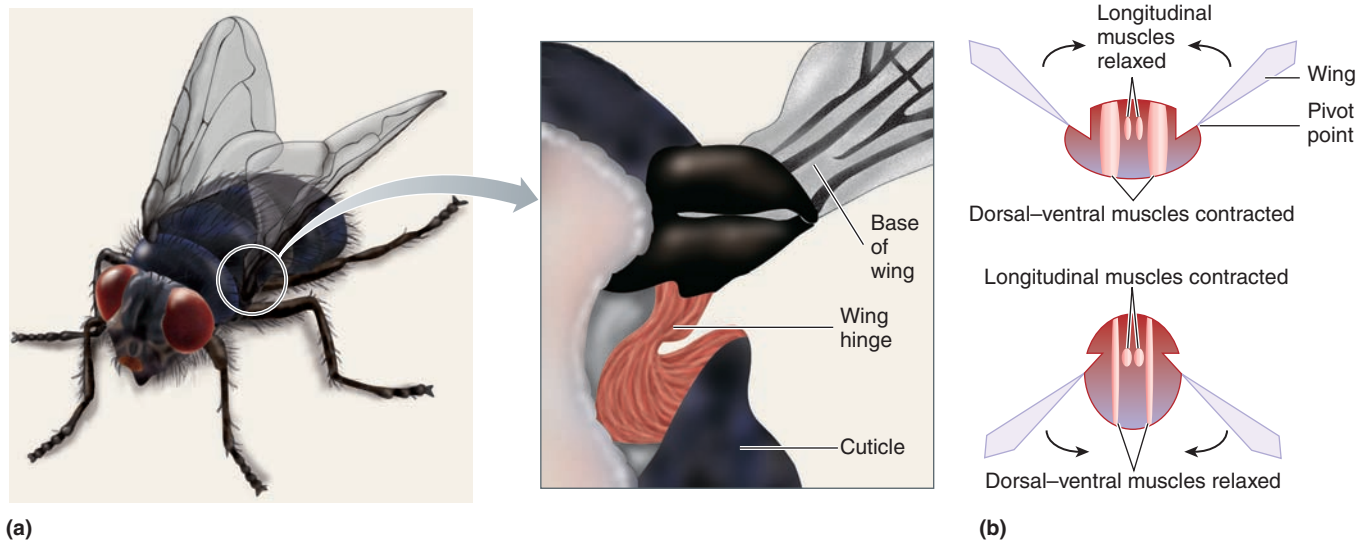

FIGURE 8-22 Mechanics of flight in the housefly. (a) The exoskeleton of insects relying on asynchronous flight muscles is hinged. Each wing is moved through an elastic, hingelike structure as a result of changes in the shape of the thorax. (b) Flight muscles do not attach directly to the hinges or to the wings but rather pull on the sides of the thorax to which they are attached. The two sets of flight muscles are arranged perpendicular to each other. Upward movement of the wings occurs when the vertical dorsoventral muscles contract and pull the flexible dorsal roof downward, flicking the wings up. The downstroke occurs when the longitudinal muscles contract, distorting the roof upward and forcing the wings down. Only the up or down positions are stable, and because of the elasticity of the hinge, much of the energy used to power muscle wing movement is recycled into the subsequent stroke. Smaller muscles acting directly on the hinge allow the wings to move at an angle, resulting in forward movement, so that a complete wing cycle actually involves the wingtip performing a figure-eight pattern.

© Cengage Learning, 2013

and high-frequency operation are mutually exclusive, it would seem impossible for an animal to have both attributes. Yet this is precisely what animals must have in order to fly. What evolutionary developments have arisen to solve this problem?

To provide for faster contraction rates, the mechanics of contraction need to speed up. One factor that increases reaction times is an increase in muscle temperature. Increasing body temperature from 30 to 40°C results in a 2.2-fold increase in the rate of ATP synthesis, equivalent to doubling the effectiveness of the mitochondria within each cell. Birds have higher body temperatures than mammals, a subtle but effective adaptation to increasing reaction times and an important adaptation for flight. Many insects cannot fly without warming up because they cannot supply ATP at a sufficient rate to power the flight muscles; thus, some (such as butterflies) bask in the morning sun before takeoff, whereas others (such as honey bees) shiver their muscles to warm up before flight. An increase in body temperature also permits Ca^{2+} pumps to work more efficiently, resulting in faster clearance of Ca^{2+} from the cytoplasm, which permits muscles to relax more rapidly. In birds and insects the structure of mitochondria is altered such that the inner mitochondrial membrane has twice the packing of cristae (folds of the inner membranes) compared to mammalian mitochondria. Thus, each mitochondrion consumes O_2 at approximately twice the rate (7 to 10 versus 4 to 5 mL O_2 per cm^{-3} per min) measured in mammals. Combined, each of these factors contributes to the ability of flight muscle to operate at higher frequencies. This is exemplified by the high wing-beat frequency of hummingbirds (70 wing beats per second) as well

as for large insects that use **direct** or **synchronous** muscle contractions to power flight muscle.

High-speed synchronous skeletal muscles are those in which each muscle action potential evoked by incoming neuronal activity results in a single mechanical contraction. For example, cicadas generate a calling song by vibrating a pair of resilin-based elastic cuticular plates termed **tymbals**. Contraction of the tymbal muscle bends the tymbals inward, which then recoil outward when the muscle relaxes. Each distortion cycle results in a burst of resonant sound vibration with a frequency of approximately 550 Hz.

Synchronous muscle arrangements are also found in butterflies, moths, locusts, and dragonflies and consist of attachment of the flight muscle directly to the wing. Each signal from a motor neuron triggers contraction of the flight muscle, so that the contractions that raise and lower the wing are synchronous. As has been discussed, muscle fibers are activated by the release of Ca^{2+} and deactivated by the reuptake of Ca^{2+} . However, animals cannot fly at frequencies of greater than 100 Hz with synchronous muscles. How have some animal groups found a solution to this problem?

Asynchronous muscle contractions are characterized by a nearly constant myoplasmic Ca^{2+} concentration

The most significant space- as well as energy-saving solution for flight is the development of **asynchronous** muscle contractions (Figure 8-22). For muscles that operate at extraordinarily

high frequencies, their design results in the generation of more power, although capacity for fine neural control declines. Asynchronous muscles are believed to have evolved from synchronous ones and represent a design breakthrough.

Asynchronous or “indirect” muscles are associated with the flight muscle of approximately three quarters of known insect species including Hemiptera (true bugs, cicadas, aphids, and bedbugs), Diptera (flies), and Hymenoptera (bees and wasps). In these animals, wing beat frequency is too great to be controlled directly by neuronal activation. For example, wing beat frequencies greater than 1,000 per second have been recorded for midges, although for most species the number of muscle contractions ranges from 100 to 300 per second. Associated with the rapid wing-beat frequency is a lowered number of nerve impulses that are now asynchronous with muscle contraction. In these circumstances, a single Ca^{2+} pulse maintains the muscle in an activated state for numerous successive cycles. In addition, the flight muscles are attached to the walls of the thorax rather than directly to the wings.

Flight muscles consist of two sets of large antagonistic power muscles oriented more or less perpendicular to each other: the **dorsal ventral muscles** and the **dorsal longitudinal muscles**. Contraction of asynchronous flight muscle is normally triggered by stretch (“stretch activation”) and deactivated by “shortening deactivation” both in the presence of elevated myoplasmic Ca^{2+} concentrations. With the flight muscles antagonistically situated, a contraction or relaxation changes the shape of the thorax—which has *resilin*-based elasticity in some species (p. 358)—into one of two stable positions: one with the wings elevated and the thorax depressed and the other with the wings depressed and the thorax elevated. Let’s examine the situation as the fruit fly (*Drosophila melanogaster*) prepares itself for flight. The fruit fly must beat each wing up to 240 times per second to achieve enough power for lift. Just before takeoff, intermittent nervous stimulation primes the two muscle sets with increased intracellular Ca^{2+} . The fly then leaps into the air and becomes airborne. Contraction of dorsal ventral muscles lengthens the dorsal longitudinal flight muscles simultaneously. These longitudinal muscles respond to the stretch with a delayed rise in tension (the stretch activation response), causing it to contract. This in turn causes an antagonistic reciprocal stretch and delayed contraction in the dorsal ventral muscles. As the two sets of muscles alternately contract and relax, the thorax rapidly oscillates between the two stable set points, causing deformations at the wing hinges that make the wings beat at the appropriate resonant frequency. The release of the catecholamine octopamine further increases both the force and efficiency of flight muscle contractions. At the same time, octopamine stimulates the oxidation of carbohydrate and fat in the flight muscle. Wing movements are ended when action potentials are no longer initiated, permitting muscle fiber repolarization and Ca^{2+} uptake into the sarcoplasmic reticulum.

Insects having an asynchronous arrangement of flight muscle conserve cellular volume in two ways. The first is achieved by a marked reduction in the volume of the sarcoplasmic reticulum. As an example, the sound-producing synchronous muscles of cicadas have approximately 34% sarcoplasmic reticulum, whereas an asynchronous flight muscle has a sarcoplasmic volume less than 4%. Secondly, intracellular space is saved by the reduced requirement for

ATP-producing mitochondria. Synchronous muscles require a substantial volume of mitochondria in order to supply ATP for the recycling of Ca^{2+} into sarcoplasmic reticulum. Thus, the reduction in Ca^{2+} cycling in asynchronous muscle reduces the requirement for mitochondria, which translates into a substantial space savings. Those mitochondria that are present are committed to supplying ATP for the cross bridges, whereas the force-generating myofibrils can instead use the volume not occupied by mitochondria. As a rule of thumb, muscle fibers in all flying animals contain a minimum of 50% myofibrils. Also, the reduction in amount of ATP used to power Ca^{2+} cycling reduces energy costs, which lessens the direct expenses of flight, making the entire process more efficient.

For the remaining section on skeletal muscle, we will examine the central and local mechanisms involved in regulating the motor activity performed by these muscles.

check your understanding 8.6

How does asynchronous flight muscle differ from that of synchronous? Which is capable of faster wing-beat frequency and why?

Compare the composition of flight muscles with a powerful locomotive muscle in terms of mitochondria, myofibrils, or sarcoplasmic reticulum (assume that these three components make up 100% of the muscle volume). Explain your answer.

8.7 Control of Motor Movement

Particular patterns of motor unit output govern vertebrate motor activity, ranging from maintenance of posture and balance to stereotypical locomotory movements such as walking or swimming, to individual, highly skilled motor activity such as swinging and leaping through trees. Control of any motor movement, no matter what its level of complexity, depends on converging input to the motor neurons of specific motor units. The motor neurons in turn trigger contraction of the muscle fibers within their respective motor units by means of the events that occur at the neuromuscular junction.

Multiple motor inputs influence vertebrate motor unit output

Three levels of input control motor neuron output in vertebrates (Figure 8-23):

1. *Input from afferent neurons*, usually through intervening interneurons, at the level of the spinal cord—that is, spinal reflexes (see p. 182).
2. *Input from the primary motor cortex*. Fibers originating from neuronal cell bodies known as **pyramidal cells** within the primary motor cortex (see p. 189) descend directly without synaptic interruption to terminate on motor neurons (or on local interneurons that terminate on motor neurons) in the spinal cord. These fibers make up the **corticospinal** (or pyramidal) motor system.
3. *Input from the brain stem* as part of the multineuronal motor system. The pathways composing the **multi-**

neuronal (or extrapyramidal) motor system include a number of synapses that involve many regions of the brain (*extra* means “outside of;” *pyramidal* refers to the pyramidal system). The final link in multineuronal pathways is the brain stem, especially the reticular formation, which in turn is influenced by motor regions of the cortex, the cerebellum, and the basal nuclei. In addition, the motor cortex itself is interconnected with the thalamus as well as with premotor and supplementary motor areas, all part of the multineuronal system.

The only brain regions that directly influence motor neurons are the primary motor cortex and brain stem; the other involved brain regions indirectly regulate motor activity by adjusting motor output from the motor cortex and brain stem. A number of complex interactions take place between these various brain regions; the most important are represented in Figure 8-23. (See Chapter 5 for further discussion of the specific roles and interactions of these brain regions.)

Spinal reflexes involving afferent neurons are important in maintaining posture and in executing basic protective movements, such as the withdrawal reflex (see Figure 5-22). The corticospinal system primarily mediates performance of fine, discrete movements of the hands and digits (such as in primates). Premotor and supplementary motor areas, with input from the cerebocerebellum, plan the voluntary motor command that the primary motor cortex issues to the appropriate motor neurons through this descending system. The multineuronal system, in contrast, is primarily concerned with regulation of overall body posture involving involuntary movements of large muscle groups of the trunks and limbs. Considerable complex interaction and overlap of function exist between these two systems.

Muscle spindles and the Golgi tendon organs provide afferent information essential for controlling skeletal muscle activity

Coordinated, purposeful skeletal muscle activity depends on afferent input from a variety of sources. At a simple level, afferent signals indicating that a foot is touching a hot ember (see Figure 5-21) triggers reflex contractile activity in appropriate limb muscles to withdraw the foot from the injurious stimulus. At a more complex level, if a dog is going to catch a stick thrown in the air by a human, the motor systems of the dog's brain must program sequential motor commands that will move and position its body correctly for the catch, using predictions of the stick's direction and rate of movement provided by visual input (see p. 185 for a discussion on predictions made by brain regions such as the cerebellum). Many muscles acting simultaneously or alternately at different joints rapidly shift the dog's location and position while maintaining balance. It is critical to have ongoing input about body position with respect to the surrounding environment, as well as about the position of various body parts in relationship to each other. This information is necessary for establishing a neuronal pattern of activity to perform the desired movement. The dog's CNS must know the starting position of the dog's body to appropriately program muscle activity. Further, it must be constantly appraised of the progression of movement it has initiated so it can adjust as needed. An animal receives this information, which is known as *proprioceptive input*, from **proprioceptors** (see p. 192) in the eyes, joints, vestibular apparatus, and skin, as well as from the muscles themselves. For example, you can demonstrate your joint and muscle proprioceptive receptors in action by closing your eyes and bringing the tips of your right and left index fingers together at any point in space. You can do so without seeing where your hands are, because afferent input from the joint and muscle receptors inform your brain at all times about the position of your hands and other body parts.

Two types of muscle proprioceptors—**muscle spindles** and **Golgi tendon organs**—monitor changes in muscle length and tension. This information is used in two ways: (1) to apprise motor areas of the brain about muscle length and tension and (2) to control muscle length and tension in negative-feedback fashion by means of local spinal reflexes. Muscle length is monitored by muscle spindles, whereas changes in muscle tension are detected by Golgi tendon organs. Both these receptor types are activated by muscle stretch, but they convey different types of information. Let's see how.

Muscle Spindle Structure Muscle spindles, which are distributed throughout the fleshy part of a skeletal muscle, are collections of specialized muscle fibers known as **intrafusal fibers** (*fusus*, “spindle”), which lie within spindle-shaped connective tissue capsules parallel to the “ordinary” **extrafusal fibers** (Figure 8-24). Unlike an ordinary skeletal muscle fiber, which contains contractile elements (myofibrils) throughout its entire length, an intrafusal fiber has a non-contractile central portion, with the contractile elements being limited to both ends. The structure of the spindle varies among vertebrate classes with Amphibia considered the most primitive vertebrate to possess this sensory organ. In fish (*Oncorhynchus masoni*) the well-developed jaw muscle contains a simple muscle spindle composed of a single intrafusal fiber. A comparable **muscle receptor organ (MRO)** has been described in the mandible of a pierce-sucking insect *Oncopeltus fasciatus*.

Each muscle spindle has its own private efferent and afferent nerve supply. The efferent neuron that innervates a muscle spindle's intrafusal fibers is known as **gamma (γ) motor neuron**, whereas the motor neurons that supply the ordinary extrafusal fibers are designated as **alpha (α) motor neurons**. Two types of afferent sensory endings terminate on the intrafusal fibers and serve as muscle spindle receptors, both of which are activated by stretch. The **primary (annulospiral) endings** are wrapped around the central portion of the intrafusal fibers; they detect changes in the length of the fibers during stretching as well as the speed with which it occurs. The **secondary (flower-spray) endings**, which are clustered at the end segments of many of the intrafusal fibers, are sensitive only to changes in length. Muscle spindles play a key role in the stretch reflex.

Stretch Reflex Whenever the whole muscle is passively stretched, the intrafusal fibers within its muscle spindles are likewise stretched, increasing the rate of firing in the afferent nerve fibers whose sensory endings terminate on the stretched spindle fibers. The afferent neuron directly synapses on the α motor neuron that innervates the extrafusal fibers of the same muscle, resulting in contraction of that muscle (Figure 8-25a, pathway 1 \rightarrow 2). This stretch reflex serves as a local negative-feedback mechanism to resist any passive changes in muscle length so that optimal resting length can be maintained.

The classic example of the stretch reflex is the **patellar tendon**, or **knee-jerk**, reflex in humans (Figure 8-26). The extensor muscle of the knee is the *quadriceps femoris*, which forms the anterior (front) portion of the thigh and is attached just below the knee to the tibia (shinbone) by the *patellar tendon*. Tapping this tendon with a rubber mallet passively stretches the quadriceps muscle, activating its spindle receptors. The resultant stretch reflex brings about contraction of this extensor muscle, causing the knee to extend and raise the foreleg in the well-known knee-jerk fashion. This test is routinely performed as a preliminary assessment of nervous system function.

The primary purpose of the stretch reflex is to resist the tendency for the passive stretch of extensor muscles caused by gravitational forces when a person is standing upright. Whenever the knee joint tends to buckle because of gravity, the quadriceps muscle is stretched. The resultant enhanced contraction of this extensor muscle brought about by the stretch reflex quickly straightens out the knee, holding the limb extended so that the person remains standing.

FIGURE 8-24 Muscle receptors. (a) A muscle spindle consists of a collection of specialized intrafusal fibers that lie within a connective tissue capsule parallel to the ordinary extrafusal skeletal muscle fibers. The muscle spindle is innervated by its own gamma motor neuron and is supplied by two types of afferent sensory terminals, the primary (annulospiral) endings and the secondary (flower-spray) endings, both of which are activated by stretch. (b) The Golgi tendon organ is entwined with the collagen fibers in a tendon and monitors changes in muscle tension transmitted to the tendon.

© Cengage Learning, 2013

Coactivation of γ and α Motor Neurons Gamma (γ) motor neurons initiate contraction of the muscular end regions of intrafusal fibers (Figure 8-25a, pathway 3). This contractile response is too weak to have any influence on whole-muscle tension, but it does have an important localized effect on the muscle spindle itself. If there were no compensating mechanisms, shortening of the whole muscle by α motor-neuron stimulation of extrafusal fibers would cause slack in the spindle fibers so that they would be less sensitive to stretch and therefore not as effective as muscle length detectors (Figures 8-25b and c). Co-activation of the γ -motor-neuron system along with the α -motor-neuron system during reflex and voluntary contractions (Figure 8-25, pathway 4) takes the slack out of the spindle fibers as the whole muscle shortens, permitting these receptor structures to maintain their high sensitivity to stretch over a wide range of muscle lengths. When γ motor-neuron stimulation triggers simultaneous contraction of both end muscular portions of an in-

trafusal fiber, the noncontractile central portion is pulled in opposite directions, tightening this region and taking out the slack (Figure 8-25d). Whereas the extent of α -motor-neuron activation depends on the intended strength of the motor response, the extent of simultaneous γ motor-neuron activity to the same muscle depends on the anticipated distance of shortening.

Golgi Tendon Organs In contrast to muscle spindles, which lie within the belly of the muscle, Golgi tendon organs are located in the tendons of the muscle, where they can respond to changes in the muscle's externally applied tension rather than to changes in its length. Because a number of factors determine the tension developed in the whole muscle during contraction (for example, frequency of stimulation or length of the muscle at the onset of contraction), it is essential that motor control systems be apprised of the tension actually achieved so that adjustments can be made if necessary.

(a) Pathways involved in monosynaptic stretch reflex and coactivation of alpha and gamma motor neurons

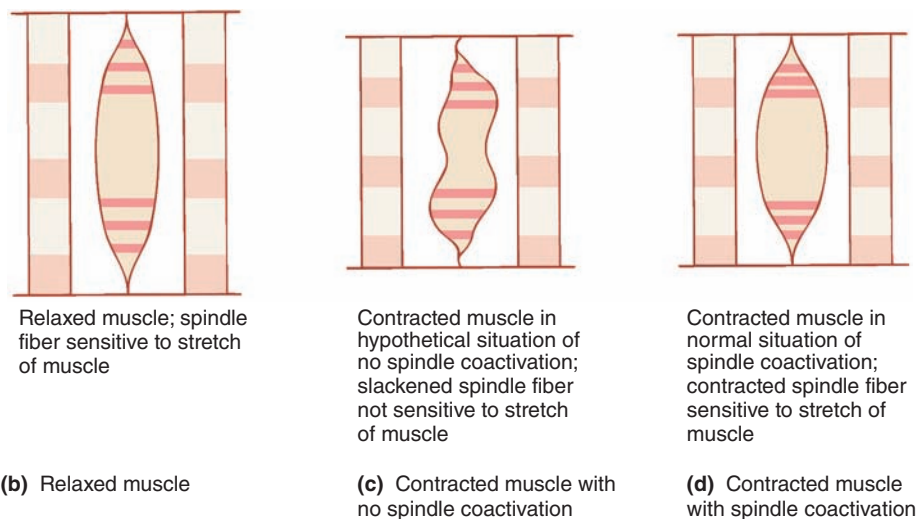

FIGURE 8-25 Muscle spindle function.

© Cengage Learning, 2013

Golgi tendon organs consist of endings of afferent fibers entwined within bundles of connective tissue fibers that make up the tendon. When the extrafusal muscle fibers contract, the resultant pull on the tendon tightens the connective tissue bundles, which in turn increase the tension exerted on the bone to which the tendon is attached. In the process, the entwined Golgi organ afferent-receptor endings are stretched, causing the afferent fibers to fire; the frequency of firing is directly related to the tension developed. This afferent information is sent to the brain for processing, much of which is used subconsciously for smoothly executing motor activity. Unlike afferent information from the muscle spindles, afferent information from the Golgi tendon organ reaches the level of conscious awareness, at least in humans. You are aware of the tension within a muscle, but you are not aware of its length.

Traditionally, physiologists thought the Golgi tendon organ triggered a protective spinal reflex that halted further contraction and brought about sudden reflex contraction when the muscle tension became great enough, thus helping prevent damage to the muscle or tendon from excessive, tension-developing muscle contraction. Scientists now believe, however, that this receptor is a pure sensor and does not initiate any reflexes. Other unknown mechanisms are apparently involved in inhibiting further contraction to prevent tension-induced damage.

How do muscle spindles differ from Golgi tendon organs?

Is the stretch reflex monosynaptic or polysynaptic? Explain.

FIGURE 8-26 Patellar tendon reflex (a stretch reflex) in a human leg. Tapping the patellar tendon with a rubber mallet stretches the muscle spindles in the quadriceps femoris muscle. The resultant monosynaptic stretch reflex results in contraction of this extensor muscle, causing the characteristic knee-jerk response.

8.8 Smooth Muscle and Cardiac Muscle

Having completed our discussion of skeletal muscle, we will finish with an examination of the other two types.

Smooth and cardiac muscle share some basic properties with skeletal muscle

The other types of muscle—smooth muscle and cardiac muscle—share some basic properties with skeletal muscle, but each also displays unique characteristics (Table 8-3). For example, smooth muscle evolved independently from the skeletal and cardiac muscles and is found in all vertebrates as well as some nonvertebrates. However, the three muscle types do have several features in common. First, they all have a specialized contractile apparatus made up of thin actin filaments that slide relative to stationary thick myosin filaments in response to a rise in cytosolic Ca^{2+} to accomplish contraction. Second, they all directly use ATP as the energy source for cross-bridge cycling. However, the structure and organization of fibers within these different muscle types vary, as do their mechanisms of excitation and the means by which excitation and contraction are coupled. Furthermore, there are important distinctions in the contractile response itself. We spend the remainder of this chapter highlighting unique features of smooth and cardiac muscle as compared with skeletal muscle, reserving a more detailed discussion of their function for chapters devoted to organs containing these muscle types.

Smooth muscle cells are small and unstriated

The majority of smooth muscle cells in vertebrates lie in the walls of hollow organs and tubes. Their contraction exerts pressure on and regulates the forward movement of the contents of these structures.

Both smooth and skeletal muscle cells are elongated, but in contrast to their large, cylindrical, multinucleated skeletal muscle counterparts, smooth muscle cells are spindle-shaped, have a single nucleus, and are considerably smaller (2 to 10 μm in diameter and 50 to 400 μm long). Also unlike skeletal muscle cells, a single smooth-muscle cell does not extend the full length of a muscle. Instead, groups of smooth muscle cells are typically arranged in sheets (Figure 8-27a).

A smooth muscle cell has three types of filaments: (1) thick myosin filaments, which are longer than those found in skeletal muscle; (2) thin actin filaments, which contain tropomyosin but lack the regulatory protein troponin; and (3) filaments of intermediate size, which are unique to smooth muscle and which do not directly participate in the contractile process but serve as part of the cytoskeletal framework that supports the shape of the cell. Smooth muscle filaments do not form myofibrils and are not arranged in the sarcomere pattern found in skeletal muscle. Thus, smooth muscle cells do not display the banding or striation found in skeletal muscle, hence the term “smooth” for this muscle type.

Lacking sarcomeres, smooth muscle does not have Z lines as such, but **dense bodies** containing the same protein constituent found in Z lines are present (Figure 8-27b). Dense bodies are positioned throughout the smooth muscle

TABLE 8-3 Comparison of Muscle Types

Characteristic	TYPE OF MUSCLE			
	Skeletal	Multiunit Smooth	Single-Unit Smooth	Cardiac
Location	Attached to skeleton	Large blood vessels, eye, and hair follicles	Walls of hollow organs in digestive, reproductive, and urinary tracts and in small blood vessels	Heart only
Function	Movement of body in relation to external environment	Varies with structure involved	Movement of contents within hollow organs	Pumps blood out of heart
Mechanism of Contraction	Sliding filament mechanism	Sliding filament mechanism	Sliding filament mechanism	Sliding filament mechanism
Innervation	Somatic nervous system (alpha motor neurons)	Autonomic nervous system	Autonomic nervous system	Autonomic nervous system
Level of Control	Under voluntary control; also subject to subconscious regulation	Under involuntary control	Under involuntary control	Under involuntary control
Initiation of Contraction	Neurogenic	Neurogenic	Myogenic (pacemaker potentials and slow-wave potentials)	Myogenic (pacemaker potentials)
Role of Nervous Stimulation	Initiates contraction; accomplishes gradation	Initiates contraction; contributes to gradation	Modifies contraction; can excite or inhibit; contributes to gradation	Modifies contraction; can excite or inhibit; contributes to gradation
Modifying Effect of Hormones	No	Yes	Yes	Yes
Presence of Thick Myosin and Thin Actin Filaments	Yes	Yes	Yes	Yes
Striated by Orderly Longitudinal Arrangement of Filaments	Yes	No	No	Yes
Presence of Troponin and Tropomyosin	Yes	Tropomyosin only	Tropomyosin only	Yes
Presence of T Tubules	Yes	No	No	Yes
Level of Development of Sarcoplasmic Reticulum	Well developed	Poorly developed	Poorly developed	Moderately developed
Cross Bridges Turned on by Ca^{2+}	Yes	Yes	Yes	Yes
Source of Increased Cytosolic Ca^{2+}	Sarcoplasmic reticulum	ECF and sarcoplasmic reticulum	ECF and sarcoplasmic reticulum	ECF and sarcoplasmic reticulum
Site of Ca^{2+} Regulation	Troponin in thin filaments	Myosin in thick filaments	Myosin in thick filaments	Troponin in thin filaments
Mechanism of Ca^{2+} Action	Physically repositions troponin–tropomyosin complex to uncover actin cross-bridge binding sites	Chemically brings about phosphorylation of myosin cross bridges so they can bind with actin	Chemically brings about phosphorylation of myosin cross bridges so they can bind with actin	Physically repositions troponin–tropomyosin complex

Characteristic	TYPE OF MUSCLE			
	Skeletal	Multiunit Smooth	Single-Unit Smooth	Cardiac
Presence of Gap Junctions	No	Yes (very few)	Yes	Yes
ATP Used Directly by Contractile Apparatus	Yes	Yes	Yes	Yes
Myosin ATPase Activity; Speed of Contraction	Fast or slow, depending on type of fiber	Very slow	Very slow	Slow
Means by which Gradation Accomplished	Varying number of motor units contracting (motor unit recruitment) and frequency at which they are stimulated (twitch summation)	Varying number of muscle fibers contracting and varying cytosolic Ca^{2+} concentration in each fiber by autonomic and hormonal influences	Varying cytosolic Ca^{2+} concentration through myogenic activity and influences of the autonomic nervous system, hormones, mechanical stretch, and local metabolites	Varying length of fiber (depending on extent of filling of the heart chambers) and varying cytosolic Ca^{2+} concentration through autonomic, hormonal, and local metabolite influence
Presence of Tone in Absence of External Stimulation	No	No	Yes	No
Clear-Cut Length-Tension Relationship	Yes	No	No	Yes

cell as well as being attached to the internal surface of the plasma membrane. The dense bodies are held in place by a scaffold of intermediate filaments. The actin filaments are anchored to the dense bodies. Considerably more actin is present in smooth muscle cells than in skeletal muscle cells, with 10 to 15 thin filaments for each thick myosin filament in smooth muscle and two thin filaments for each thick filament in skeletal muscle.

The thick- and thin-filament contractile units are oriented slightly diagonally from side to side within the smooth muscle cell in an elongated, diamond-shaped lattice, rather than running parallel with the long axis as myofibrils do in skeletal muscle (Figure 8-28a). Relative sliding of the thin filaments past the thick filaments during contraction causes the filament lattice to reduce in length and expand from side to side. As a result, the whole cell shortens and bulges out between the points where the thin filaments are attached to the inner surface of the plasma membrane (Figure 8-28b).

Unlike in skeletal muscle, myosin molecules are arranged in a smooth-muscle thick filament so that cross bridges are present along the entire filament length (that is, there is no bare portion in the center of a smooth-muscle thick filament). As a result, the surrounding thin filaments can be pulled along the thick filaments for longer distances than in skeletal muscle. Also dissimilar to skeletal muscle, the myosin proteins in smooth-muscle thick filaments are organized so that half of the surrounding thin filaments are pulled in one direction and the other half are pulled in the opposite direction (Figure 8-28b).

Smooth muscle cells are turned on by Ca^{2+} -dependent phosphorylation of myosin

The thin filaments of smooth muscle cells do not contain troponin, and tropomyosin does not block actin's cross-bridge binding sites. What, then, prevents actin and myosin from binding at the cross bridges in the resting state, and how is cross-bridge activity switched on in the excited state? Lightweight chains of proteins are attached to the heads of myosin molecules, near the "neck" region. These so-called **light chains** are only of secondary importance in skeletal muscle, but they have a crucial regulatory function in smooth muscle. The smooth muscle myosin heads can interact with actin only when the myosin light chain is *phosphorylated* (that is, has an inorganic phosphate from ATP attached to it). During excitation, the increased cytosolic Ca^{2+} acts as an intracellular messenger, initiating a chain of biochemical events that results in phosphorylation of the myosin light chain (Figure 8-29). Smooth muscle Ca^{2+} binds with **calmodulin**, an intracellular protein found in most cells that is structurally similar to troponin (see p. 339). This Ca^{2+} -calmodulin complex binds to and activates another protein, **myosin light chain kinase (MLC kinase)**, which in turn phosphorylates the myosin light chain. Note that this inorganic phosphate on the myosin light chain is in addition to the inorganic phosphate accompanying ADP on the myosin cross-bridge ATPase site. The P_i on the ATPase site is part of the energy-supplying cycle that powers cross-bridge bending. The P_i on the light chain permits the myosin cross bridge to bind with actin so that cross-bridge cycling can

begin. Therefore, smooth muscle is triggered to contract by a rise in cytosolic Ca^{2+} similar to what happens in skeletal muscle, but in smooth muscle, Ca^{2+} ultimately turns on the cross bridges by inducing a *chemical* change in myosin in the *thick* filaments, whereas in skeletal muscle it exerts its effects by invoking a *physical* change at the *thin* filaments (Figure 8-30). Recall that in skeletal muscle Ca^{2+} moves troponin and tropomyosin from their blocking position, so actin and myosin are free to bind with each other.

Phasic smooth muscle contracts in bursts of activity; tonic smooth muscle maintains an ongoing level of contraction

The means by which cytosolic Ca^{2+} concentration increases in smooth muscle cells to turn on the cross bridges also differs from that for skeletal muscle and even varies among the highly diversified smooth muscle found in different organs.

Smooth muscle can be classified in various ways, depending on the timing and means of increasing cytosolic Ca^{2+} : phasic or tonic, multiunit or single-unit, and neurogenic or myogenic smooth muscle. Each smooth muscle belongs to one class of each of these three categories. That is, the smooth muscle in one organ might be phasic, multiunit, and neurogenic, and the smooth muscle in another organ might be tonic, single-unit, and myogenic. Let's examine each of these categories.

Smooth muscle can be grouped into two categories depending on how its cytosolic Ca^{2+} concentration increases and its level of ongoing contractile activity: *phasic smooth muscle* and *tonic smooth muscle*. **Phasic smooth muscle** contracts in bursts, triggered by action potentials that lead to increased cytosolic Ca^{2+} . These bursts in contraction are characterized by pronounced increases in contractile activity. Phasic smooth muscle is most abundant in the walls of hollow organs that push contents through them, such as the digestive organs. Phasic digestive contractions mix the food with digestive juices and propel the mass forward for further processing. **Tonic smooth muscle** is usually partially contracted at all times. This state of partial contraction is called **tone**. Tone exists because this type of smooth muscle has a relatively low resting potential of -55 mV to -40 mV. Some surface-membrane voltage-gated Ca^{2+} channels are open at these potentials. The resultant Ca^{2+} entry maintains a state of partial contraction. Therefore, maintenance of tone in tonic smooth muscle does not depend on action potentials. Tonic smooth muscle does not display bursts of contractile activity but instead incrementally varies its extent of contraction above or below this tonic level in response to regulatory factors, which alter the cytosolic Ca^{2+} concentration. The smooth muscle in walls of arterioles is an example of tonic smooth muscle. The ongoing tonic contraction in these small blood vessels squeezes down on the blood flowing through them and is one of the major contributing factors to maintenance of blood pressure.

A smooth muscle cell has no T tubules and a poorly developed sarcoplasmic reticulum. In phasic smooth muscle, the increased cytosolic Ca^{2+} that triggers depolarization and contraction comes from two sources: Most Ca^{2+} enters from the ECF, but some is released intracellularly from the sparse sarcoplasmic reticulum stores. Unlike their role in skeletal muscle cells, C-type Ca^{2+} channels (voltage-gated dihydropyridine receptors) in the plasma membrane of smooth muscle cells function as Ca^{2+} channels. When these surface-membrane channels are opened in response to an action potential, Ca^{2+} enters down its concentration gradient from the ECF. The entering Ca^{2+} triggers the opening of Ca^{2+} channels in the sarcoplasmic reticulum so that small additional amounts of Ca^{2+} are released intracellularly from this meager source. Because smooth muscle cells are so much smaller in diameter than skeletal muscle fibers, most Ca^{2+} entering from the ECF can influence cross-bridge activity, even in the central portions of the cell, without requiring an elaborate T tubule-sarcoplasmic reticulum mechanism.

One of the major means of increasing cytosolic Ca^{2+} concentration and thus increasing contractile activity in tonic smooth muscle is binding of an extracellular chemical messenger, such as norepinephrine or various hormones, to a G-protein coupled receptor, which activates the $\text{IP}_3/\text{Ca}^{2+}$ second-messenger pathway (see p. 98). The membrane of the sarcoplasmic reticulum in tonic smooth muscle has IP_3 receptors, which like ryanodine receptors, are Ca^{2+} -release channels. IP_3 binding leads to release of contractile-inducing

© Cengage Learning, 2013

Ca^{2+} from this intracellular store into the cytosol. This is how norepinephrine released from the sympathetic nerve endings acts on arterioles to increase blood pressure.

Relaxation is accomplished by removal of Ca^{2+} as it is actively transported out across the plasma membrane and back into the sarcoplasmic reticulum. When Ca^{2+} is removed, myosin is dephosphorylated (the phosphate is removed) and can no longer interact with actin, so the muscle relaxes.

We still have not addressed the question of how smooth muscle becomes excited to contract; that is, what opens the Ca^{2+} channels in the plasma membrane and sarcoplasmic

reticulum? Smooth muscle is grouped into two categories—*multiunit* and *single-unit smooth muscle*—based on differences in how the muscle fibers become excited. Let's compare these two types of smooth muscle.

Multiunit smooth muscle is neurogenic

Multiunit smooth muscle exhibits properties partway between skeletal muscle and single-unit smooth muscle. As the name implies, a multiunit smooth muscle consists of multiple discrete units that function independently of each other

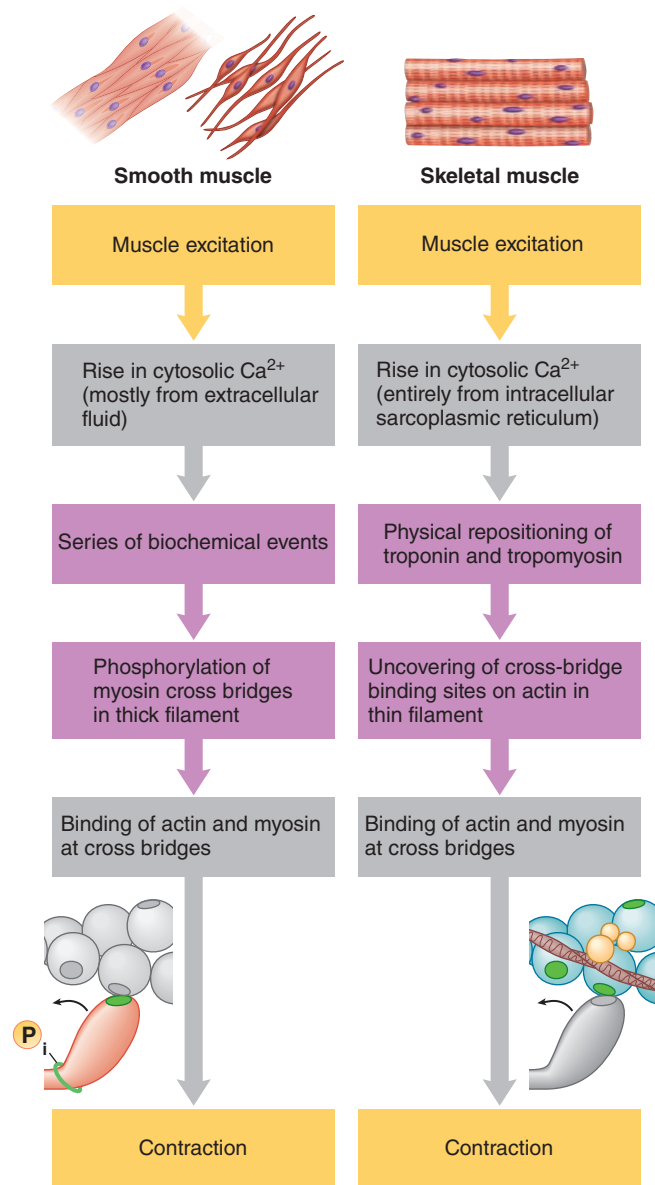

FIGURE 8-30 Comparison of the role of calcium in bringing about contraction in smooth muscle and skeletal muscle.

© Cengage Learning, 2013

and must be separately stimulated by nerves to contract, similar to skeletal muscle motor units. Thus, contractile activity in both skeletal muscle and multiunit smooth muscle is **neurogenic** (“nerve-produced”). All multiunit smooth muscle is phasic, contracting only when neurally stimulated. Whereas skeletal muscle is innervated by the voluntary somatic nervous system (motor neurons), multiunit (as well as single-unit) smooth muscle is supplied by the involuntary autonomic nervous system.

Mammalian multiunit smooth muscle is found (1) in the walls of large blood vessels; (2) in large airways to the lungs; (3) in the muscle of the eye that adjusts the lens for near or far vision; (4) in the iris of the eye, which alters the size of the pupil to adjust the amount of light entering the eye; and (5) at the base of hair follicles, contraction of which causes raising of hairs in response to fear or cold.

Single-unit smooth muscle cells form functional syncytia

Most smooth muscle is **single-unit** muscle, alternatively called **visceral smooth muscle** because it is found in the walls of the hollow organs or viscera (for example, the digestive, reproductive, and urinary tracts and small blood vessels). The term *single-unit smooth muscle* derives from the fact that the muscle fibers that make up this type of muscle become excited and contract as a single unit. Gap junctions electrically link the muscle fibers in single-unit smooth muscle (see p. 66). When an action potential occurs anywhere within a sheet of single-unit smooth muscle, it is quickly propagated via these special points of electrical contact throughout the entire group of interconnected cells, which then contract as a single coordinated unit. This group of interconnected muscle cells that function electrically and mechanically as a unit is a *functional syncytium* (see p. 336 for skeletal muscle version).

Thinking about the role of the uterus during the process of labor in a mammal can help you appreciate the significance of this arrangement. Muscle cells composing the uterine wall act as a functional syncytium. They repetitively become excited and contract as a unit during labor, exerting a series of coordinated “pushes” that are eventually responsible for delivering the neonate. Independent, uncoordinated contractions of individual muscle cells in the uterine wall would not exert the uniformly applied pressure needed to expel the neonate. Single-unit smooth muscle elsewhere in the body is arranged in similar functional syncytia.

Single-unit smooth muscle is myogenic

Single-unit smooth muscle is **self-excitable**, so it does not require nervous stimulation for contraction. Clusters of specialized smooth-muscle cells within a functional syncytium display spontaneous electrical activity; that is, they can undergo action potentials without any external stimulation. In contrast to the other excitable cells we have been discussing (such as neurons, skeletal muscle fibers, and multiunit smooth muscle), the self-excitable cells of single-unit smooth muscle do not maintain a constant resting potential. Instead, their membrane potential inherently fluctuates without any influence by factors external to the cell. Two major types of spontaneous depolarizations displayed by self-excitable cells are *pacemaker potentials* and *slow-wave potentials*.

Pacemaker Potentials With pacemaker potentials (Figure 8-31a), the membrane potential gradually depolarizes on its own because of shifts in passive ionic fluxes accompanying automatic changes in channel permeability. When the membrane has depolarized to threshold, an action potential is initiated. After repolarizing, the membrane potential once again depolarizes to threshold, cyclically continuing in this manner to self-generate action potentials.

Slow-Wave Potentials Slow-wave potentials are gradually alternating hyperpolarizing and depolarizing swings in potential caused by automatic cyclic changes in the rate at which sodium ions are actively transported across the membrane (Figure 8-31b). The potential moves farther from threshold during each hyperpolarizing swing and closer to threshold during each depolarizing swing. If

(a) Pacemaker potential

(b) Slow-wave potential

FIGURE 8-31 Self-generated electrical activity in smooth muscle.

(a) With pacemaker potentials, the membrane gradually depolarizes to threshold on a regular periodic basis without any nervous stimulation. These regular depolarizations cyclically trigger self-induced action potentials. (b) In slow-wave potentials, the membrane gradually undergoes self-induced hyperpolarizing and depolarizing swings in potential. A burst of action potentials occurs if a depolarizing swing brings the membrane to threshold.

© Cengage Learning, 2013

threshold is reached, a burst of action potentials occurs at the peak of a depolarizing swing. Threshold is not always reached, however, so the oscillating slow-wave potentials can continue without generating action potentials. Whether threshold is reached depends on the starting point of the membrane potential at the onset of its depolarizing swing. The starting point, in turn, is influenced by neural and local factors.

Myogenic Activity Self-excitable smooth muscle cells are specialized to initiate action potentials, but they are not equipped to contract. Only a very small proportion of the total number of cells in a functional syncytium are noncontractile, pacemaker cells. Pacemaker cells are typically clustered together in a specific location. The vast majority of smooth muscle cells in a functional syncytium are specialized to contract but cannot self-initiate action potentials. However, once an action potential is initiated by a self-initiating smooth muscle cell, it is conducted to the remaining contractile, nonpacemaker cells of the functional syncytium via gap junctions, so that the entire group

of cells contracts without any nervous input. Such nerve-independent contractile activity initiated by the muscle itself is called myogenic (“muscle-produced”) activity, in contrast to the neurogenic activity of skeletal muscle and multiunit smooth muscle. Recall that tonic, single-unit smooth muscle cells have sufficient levels of cytosolic Ca^{2+} to maintain a low level of tension even in the absence of action potentials, so they too are myogenic. (Thus, multi-unit smooth muscles are all neurogenic and phasic; single-unit smooth muscles are all myogenic and may be phasic or tonic.)

Gradation of single-unit smooth muscle contraction differs considerably from that of skeletal muscle

Single-unit smooth muscle differs from skeletal muscle in the way gradation of contraction is accomplished. Gradation of skeletal muscle contraction is entirely under neural control, primarily involving motor unit recruitment and twitch summation. In smooth muscle, the gap junctions ensure that an entire smooth-muscle mass contracts as a single unit, making it impossible to vary the number of muscle fibers contracting. Only the tension of the fibers can be modified to achieve varying strengths of contraction of the whole organ. The portion of cross bridges activated and the tension subsequently developed in single-unit smooth muscle can be graded by varying the cytosolic Ca^{2+} concentration. A single excitation in smooth muscle does not cause all the cross bridges to switch on, in contrast to skeletal muscles where a single action potential triggers the release of enough Ca^{2+} to permit all cross bridges to cycle. As Ca^{2+} concentration increases in smooth muscle, more cross bridges are brought into play, and greater tension develops.

Smooth Muscle Tone Many single-unit smooth muscle cells have sufficient cytosolic Ca^{2+} to maintain a low level of tension, or tone, even in the absence of action potentials. A sudden drastic change in Ca^{2+} , such as accompanies a myogenically induced action potential, brings about a contractile response superimposed on the ongoing tonic tension. Besides self-induced action potentials, a number of other factors, including autonomic neurotransmitters, can influence contractile activity and the development of tension in smooth muscle cells by altering their cytosolic Ca^{2+} concentration.

Smooth muscle activity can be modified by the autonomic nervous system

Both branches of the vertebrate autonomic nervous system typically innervate smooth muscle. In single-unit smooth muscle (both phasic and tonic), this nerve supply does not *initiate* contraction, but it can *modify* the rate and strength of contraction, either enhancing or retarding the inherent contractile activity of a given organ. Recall that the isolated motor end-plate region of a skeletal muscle fiber interacts with ACh released from a single axon terminal of a motor neuron. In contrast, the receptor proteins that bind with autonomic transmitters are dispersed throughout the entire surface membrane of a smooth muscle cell. Smooth muscle cells are sensitive to varying degrees and in

FIGURE 8-32 Innervation of smooth muscle by autonomic postganglionic nerve terminals.

© Cengage Learning, 2013

varying ways to autonomic transmitters, depending on their distribution of cholinergic and adrenergic receptors (see p. 164).

Each terminal branch of a postganglionic autonomic fiber travels across the surface of one or more smooth muscle cells, releasing transmitter from the vesicles within its multiple **varicosities** (bulges) as an action potential passes along the terminal (Figure 8-32). The neurotransmitter diffuses to the many receptor sites specific for it on the cells underlying the terminal. Thus, in contrast to the discrete one-to-one relationship at motor end plates, a given smooth muscle cell can be influenced by more than one type of neurotransmitter, and each autonomic terminal can influence more than one smooth muscle cell.

Other Factors Influencing Smooth Muscle Activity Other factors (besides autonomic neurotransmitters) can influence the rate and strength of both multiunit and single-unit smooth muscle contraction, including certain hormones, local metabolites, mechanical stretch, and specific drugs. Recent evidence suggests that the abundant caveolae found in smooth muscle may serve as sites of integration of the extracellular signals that modify smooth muscle contractility (see p. 89). All these factors ultimately act by modifying the permeability of Ca^{2+} channels in the plasma membrane, the sarcoplasmic reticulum, or both, through a variety of mechanisms. Thus, smooth muscle is subject to more external influences than is skeletal muscle, even though smooth muscle can contract on its own, whereas skeletal muscle cannot.

For now, we are going to consider only the effect of mechanical stretch on smooth muscle contractility in more detail as we look at the length–tension relationship in smooth muscle. We defer an examination of the extracellular chemical influences on smooth muscle contractility to other chapters, where we discuss regulation of the various organs that contain smooth muscle.

Smooth muscle can still develop tension, yet inherently relaxes when stretched

The relationship between the length of the muscle fibers before contraction and the tension that can be developed on a subsequent contraction is less closely linked in smooth muscle than in skeletal muscle. The range of lengths over which a smooth muscle fiber can develop near-maximal tension is much greater than for skeletal muscle. Smooth muscle can still develop considerable tension even when stretched up to 2.5 times its resting length, for two probable reasons. First, in contrast to skeletal muscle, in which the resting length is at l_0 , in smooth muscle the resting (nonstretched) length is much shorter than the l_0 . Therefore, smooth muscle can be stretched considerably before even reaching its optimal length. Second, the thin filaments still overlap the much longer thick filaments even in the stretched-out position, so that cross-bridge interaction and tension development can still take place. In contrast, the thick and thin filaments of skeletal muscle are completely pulled apart and no longer able to interact when the muscle is stretched only three fourths longer than its resting length.

The ability of a considerably stretched smooth-muscle fiber to still develop tension is important because the smooth muscle fibers within the wall of a hollow organ are progressively stretched as the volume of the organ's contents increases. Consider the urinary bladder as an example. Even though the muscle fibers in the urinary bladder are stretched as the bladder gradually fills with urine, they still maintain their tone and are even capable of developing further tension in response to inputs regulating bladder emptying. If considerable stretching prevented development of tension, as in skeletal muscle, a filled bladder could not contract to empty.

Stress Relaxation Response When a smooth muscle is suddenly stretched, it initially increases its tension, much like the tension in a stretched rubber band. The muscle quickly

adjusts to this new length, however, and inherently relaxes to the tension level prior to the stretch, probably from rearrangement of cross-bridge attachments. Smooth muscle cross bridges detach comparatively slowly. Physiologists speculate that on sudden stretching, any attached cross bridges would strain against the stretch, contributing to a passive (not actively generated) increase in tension. As these cross bridges detach, the filaments would be permitted to slide into an unstrained stretched position, restoring the tension to its original level. This inherent property of smooth muscle is called the stress relaxation response.

Advantages of the Smooth-Muscle Length–Tension Relationship These two responses of smooth muscle to being stretched—being able to develop tension even when considerably stretched and inherently relaxing when stretched—are highly advantageous. They enable smooth muscle to exist at a variety of lengths with little change in tension. As a result, a hollow organ enclosed by smooth muscle can accommodate variable volumes of contents with little change in the pressure exerted on the contents except when the contents are to be pushed out of the organ. At that time, the tension is deliberately increased by fiber shortening. It is possible for smooth muscle fibers to contract to half their normal length, enabling hollow organs to dramatically empty their contents on increased contractile activity; thus, smooth-muscle viscera can easily accommodate large volumes but can empty to practically zero volume. This length range in which smooth muscle normally functions (anywhere from 0.5 to 2.5 times the normal length) is considerably greater than the limited length range within which skeletal muscle remains functional.

Smooth muscle contains abundant connective tissue, which resists being stretched. Unlike skeletal muscle in which the skeletal attachments restrict how far the muscle can be stretched, this connective tissue prevents smooth muscle from being overstretched and thus places an upper limit on the volume capacity of a smooth-muscle hollow organ.

Smooth muscle is slow and economical, especially in latch and catch types

A smooth muscle contractile response proceeds at a more leisurely pace than does a skeletal muscle twitch. The rate of ATP splitting by myosin ATPase is much slower in smooth muscle, so cross-bridge activity and filament sliding occur about 10 times more slowly compared to striated muscle. A single smooth muscle contraction may last as long as 3 seconds (3,000 msec), compared to the maximum of 100 msec required for a single contractile response in skeletal muscle. Smooth muscle also relaxes more slowly because of a slower rate of Ca^{2+} removal. Slowness should not be equated with weakness, however. Smooth muscle can generate the same contractile tension per unit of cross-sectional area as skeletal muscle, but it does so more slowly and at considerably less energy expense. Because of the low rate of cross-bridge cycling, cross bridges are maintained in the attached state for a longer period of time during each cycle compared with skeletal muscle.

Some smooth muscles are specialized to carry this low-cycling attached state to an extreme known as a **latch state** in vertebrates, and a **catch state** in nonvertebrates (Figure 8-33). In these states, the cross bridges “latch onto” the thin fila-

FIGURE 8-33 Model for the regulation of the catch state in the byssus retractor muscle of the common mussel *Mytilus*. The energy-saving catch state occurs in certain specialized smooth muscles of mollusks after cessation of ACh stimulation. During catch, force is maintained for prolonged periods in the absence of elevated ICF Ca^{2+} concentrations. In this model, the chainlike protein twitchin (which resembles the giant vertebrate protein titin) is the key structure that maintains catch force during contraction due to its linkages between the thick and thin filaments. Dephosphorylation of twitchin induces catch, whereas phosphorylation of twitchin inhibits the catch state. Dephosphorylation of twitchin is induced by a Ca^{2+} -dependent phosphatase. Relaxation of contraction occurs in response to the release of serotonin from synapses of catch-terminating neurons. Serotonin increases intracellular cAMP concentrations, which activates a cAMP-dependent protein kinase (PKA). In turn, PKA phosphorylates the thick filament protein twitchin with the result that catch is now inhibited.

Source: Avrova, J. (2009). Twitchin of mollusc smooth muscles can induce “catch”-like properties in human skeletal muscle: support for the assumption that the “catch” state involves twitchin linkages between myofilaments. *Comp. Physiol. B* 179:945–950.

ments for minutes to hours, enabling the smooth muscle to maintain tension with very low ATP consumption (because each cross-bridge cycle uses up one molecule of ATP). The mechanisms for this are unclear, and may be different in different types of animals, but some evidence is emerging. Let’s look at a bivalve mollusk’s **adductor muscle** as an example. Bivalve shells have elastic elements that spring the shells open in the absence of muscle activity. The adductor muscle contains smooth muscle that must hold the two shells closed for long periods (such as when the tide is out, or a predator is attacking). The adductor also contains some white skeletal-type muscle to close the shell rapidly, as during an initial disturbance, or in the jet-propelled swimming of a scallop (which rapidly opens and closes its shell to draw in and squirt out water). Acetylcholine (ACh) stimulates smooth muscle contraction and the catch state, whereas serotonin triggers relaxation. The rate at which the myosin heads detach from the actin is greatly slowed by the presence of **twitchin**, a titin-like protein associated with the myosin. Phosphorylation of twitchin by protein kinase A, perhaps because of the actions of serotonin, inhibits the catch state by allowing the myosin heads to detach at a faster (noncatch) rate.

Because of its slowness and the less ordered arrangement of its filaments, smooth muscle has often been mistakenly viewed as a poorly developed version of skeletal

A scallop has an adductor muscle to close its shell. In a *catch* state, the shell can be closed for long periods of time. The muscle can also be contracted and relaxed rapidly for jet-propelled swimming.

muscle. Actually, smooth muscle is just as highly specialized for the demands placed on it—that is, being able to economically maintain tension for prolonged periods without fatigue and being able to accommodate considerable variations in the volume of contents it encloses with little change in tension. It is an extremely adaptive, efficient tissue.

Nutrient and O_2 delivery are generally adequate to support the smooth-muscle contractile process. Smooth muscle can use a wide variety of nutrient molecules for ATP production. There are no energy storage pools comparable to creatine phosphate in smooth muscle; they are not necessary. Oxygen delivery is usually adequate to keep pace with the low rate of oxidative phosphorylation needed to provide ATP for the energy-efficient smooth muscle. If necessary, anaerobic glycolysis can sustain adequate ATP production if O_2 supplies are diminished.

Cardiac muscle is striated but also has some smooth-muscle characteristics

Cardiac muscle, found only in the heart, shares structural and functional characteristics with both skeletal and single-unit smooth muscle. Like skeletal muscle, cardiac muscle is striated, with its thick and thin filaments highly organized into a regular banding pattern. Cardiac thin filaments contain troponin and tropomyosin, which constitute the site of Ca^{2+} action in turning on cross-bridge activity, as in skeletal muscle. Also similar to skeletal muscle, cardiac muscle has a clear length–tension relationship. Like the oxidative skeletal muscle fibers, cardiac muscle cells have an abundance of mitochondria and myoglobin. They also have T tubules and a moderately well-developed sarcoplasmic reticulum.

As in smooth muscle, Ca^{2+} enters the cytosol from both the ECF and the sarcoplasmic reticulum during cardiac excitation. Ca^{2+} entry from the ECF through voltage-gated dihydropyridine receptors, alias Ca^{2+} channels, in the T tubule membrane triggers the release of Ca^{2+} intracellularly from the sarcoplasmic reticulum. Like single-unit smooth muscle, the heart displays pacemaker (but not slow-wave) activity, initiating its own action potentials without any external influence. Cardiac cells are interconnected by gap junctions that enhance the spread of action potentials throughout the heart,

just as in single-unit smooth muscle. Also similarly, the heart is innervated by the autonomic nervous system, which, along with certain hormones and local factors, can modify the rate and strength of contraction. In contrast to skeletal muscle, the heart's output is graded by controlling contraction frequency and modulating mechanical output of each cell, not the number of activated cells.

Unique to cardiac muscle, the cardiac fibers are joined together in a branching network, and its action potentials have a much longer duration before repolarizing. Further details and the importance of cardiac muscle's features are addressed in the next chapter.

How Muscle Physiology Contributes to the Body as a Whole

The skeletal muscles make up the muscular system itself. Cardiac and smooth muscle are part of the organs that comprise other body systems. Cardiac muscle is found only in the heart, which is part of the circulatory system. Smooth muscle is found in the walls of vertebrate hollow organs and tubes, including the blood vessels in the circulatory system, airways in the respiratory system, bladder in the urinary system, stomach and intestines in the digestive system, and uterus and ductus deferens (the duct that provides a route of exit for sperm from the testes) in the reproductive system.

Muscles contribute to both desirable changes as well as homeostasis. Contraction of skeletal muscles moves the body parts in relation to each other and moves the whole body in relation to the external environment. Thus, these muscles permit movement through and manipulation of the external environment. Some of these movements are aimed at maintaining homeostasis, such as moving the body toward a food source or away from predators, the chewing and swallowing of food for further breakdown in the digestive system into usable energy-producing nutrient molecules (the mouth and throat muscles are all skeletal muscles), and breathing to obtain O_2 and eliminate CO_2 (the gill and respiratory muscles are all skeletal muscles). In some species the generation of heat by contracting skeletal muscles also helps maintain body temperature.

All the other systems of the body, except the immune (defense) system, depend on their nonskeletal muscle components to enable them to accomplish their homeostatic functions. For example, contraction of cardiac muscle in the vertebrate heart pushes life-sustaining blood forward into the blood vessels, and contraction of smooth muscle in the stomach and intestines pushes the ingested food through the digestive tract at a rate appropriate for the digestive juices secreted along the route to break down the food into usable units.

Chapter Summary

- Whole muscles are groups of muscle fibers (cells) bundled together by connective tissue, often attached to skeletal elements in antagonistic pairs. Skeletal muscle consists of muscle fibers lying parallel to each other, while smooth muscle cells are small and unstriated.
- Each fiber is striated by a highly organized internal arrangement and consists of thick filaments, which are mostly myosin. Actin, along with tropomyosin and troponin, forms the thin filaments. Binding of calcium to troponins causes tropomyosin to move so that myosin “heads” can form cross bridges with actin.
- During contraction, cycles of cross-bridge binding and bending pull the thin filaments closer together between the stationary thick filaments, causing shortening of the sarcomeres, while complete shortening is accomplished by repeated cycles of cross-bridge binding and bending. ATP triggers the release of myosin and energizes it.
- Excitation of muscle begins with neurotransmitter at a synapse. The consequent depolarization is carried by T-tubules, which penetrate deep into the muscle fiber. Calcium is the link between excitation and contraction, and the removal of calcium is the key to muscle relaxation.
- The number of fibers contracting within a vertebrate muscle depends on the extent of motor unit recruitment. The frequency of stimulation can influence the tension developed by each vertebrate skeletal muscle fiber. Twitch summation results from a sustained elevation in cytosolic calcium.
- Arthropod muscle tension is controlled by gradation of contraction within a motor unit, with the strength of contraction dependent on the summation of postsynaptic potentials. Asynchronous muscle contractions are characterized by a nearly constant myoplasmic Ca^{2+} concentration.
- There is an optimal muscle length at which maximal tension can be developed on a subsequent contraction. The two primary types of contraction are isotonic and isometric.
- Muscle tension is transmitted to skeletal elements as the contractile component tightens the series-elastic component.
- There are three types of skeletal muscle fibers, which differ in ATP hydrolysis and synthesis and fatigue rate: fast glycolytic (for short but powerful bursts), slow oxidative (for long, endurance actions), and the fast oxidative (for rapid, sustained actions).
- Muscle spindles and the Golgi tendon organs provide afferent information essential for controlling skeletal muscle activity.
- Smooth muscle cells are turned on by Ca^{2+} -dependent phosphorylation of myosin. Phasic smooth muscle contracts in bursts of activity; tonic smooth muscle maintains an ongoing level of contraction.
- Smooth muscle is slow and economical, especially in latch and catch types. Its activity can be modified by the autonomic nervous system.

Review, Synthesize, and Analyze

1. Until the 1930s, it was hypothesized that an increase in lactate neutralized the negative charges inside the muscle fiber, which then resulted in shortening. Design a study to show that this was indeed not the case.
2. What advantages are there of setting the resting length of smooth muscle lower than l_0 ?
3. How do the structures associated with the series-elastic component of muscle contribute to the production of a tetanic force?
4. In most fish, the bulk of the trunk muscles are fast glycolytic, which are not used for steady cruising. Explain.
5. A rattlesnake spies you walking along the trail, which elicits contraction of the shaker muscle. List three roles for ATP in the shaker muscle.
6. Why can neither red nor white *swimming* muscles produce sound?
7. In your view, what is the best technology to increase the muscle mass of production farm animals? Explain.
8. An emerging concept in muscle biology is that signals dependent on muscle activity, specifically the muscle load, may arise in the sarcomere and be transmitted to the nucleus to affect gene expression. Explain the putative role of titin in this process.
9. How does the entry of Ca^{2+} into the inner mitochondrial matrix affect the mitochondrial membrane potential? How might this affect the energy available for the operation of the ATP synthase?

Circulation serves as an animal's internal transport system. Moving fluid transports and distributes O_2 , nutrients, wastes, hormones, and heat. The fluid is usually moved under pressure created by a heart or other pump. As an extreme example, consider a giraffe. Its heart must generate high pressures in order to overcome gravity to provide adequate blood flow to its brain. It also has tight-fitting skin on its legs that helps prevent blood pooling there, as occurs in humans who sit or stand immobile for extended periods.

Circulatory Systems

9.1 Evolution of Circulation

Most multicellular organisms with specialized cells need some form of internal transport to move important molecules (and often cells) from one tissue to another in a reasonable amount of time. Transported molecules in animals include gases, nutrients, wastes, and hormones. Heat may also be usefully transported, especially in *endothermic* animals (“warm-blooded” ones such as birds and mammals that regulate body temperature via internal heat production), but also in some *ectothermic* animals (“cold-blooded” ones whose body temperatures depend on external sources). For example, many reptiles (ectotherms) speed up the heating process when they move into the sun, simultaneously increasing their heart rate and rapidly shunting the heat from the skin to the body core (see Chapter 15 for details on thermoregulation). In this situation, the increase in heart rate clearly costs energy. Why doesn't the animal just let heat conduct on its own throughout the body? Similarly, why not just let oxygen diffuse in through the skin rather than expend energy pumping it around the body?

Circulatory systems evolved to overcome the limits of diffusion

It is important to realize that diffusion of molecules, and to a lesser extent conduction of heat, are slow processes. For example, it takes a glucose molecule in calm water only about 0.06 microseconds (μsec) to diffuse across a membrane (about 10 nanometers, or 10^{-8} meters thick), but it takes about 20 years to diffuse 1 meter (3.3 feet)! (Recall Fick's law, p. 76, and the physics of diffusion in Chapter 3.) For single-celled organisms and very small animals such as rotifers, movement of molecules occurs primarily by diffusion, since distances are quite small and metabolic demands are not high. Similarly, flatworms (though they may be quite large in body length) are—as their name implies—thin enough to rely on diffusion, aided by an internal branching digestive tract that brings digested materials close to all cells.

However, as animals evolved thicker and larger bodies and higher

metabolic rates, the need for internal circulatory systems became paramount because of diffusion limits. Briefly, circulatory systems overcome the slowness of diffusion by the much faster process of **bulk transport**: the movement of the medium that contains the molecules (and cells) of interest. We begin our examination of these systems with some general features and principles.

Circulatory systems have up to three distinct components: fluid, pump, and vessels

From a functional standpoint, a circulatory system can have the following components:

1. The *fluid* itself, which carries the transported molecules and cells; typically called *blood* or *hemolymph*. Terms associated with circulatory fluid often contain the root *hemo* or *emia* (from the Greek for blood).

FIGURE 9-1 Diagram of the circulatory systems of a sponge, Cnidarian, and nematode. (a) Circulation of external medium in a gastrovascular cavity of a sponge; (b) Circulation of external medium in a gastrovascular cavity of a cnidarian; (c) Circulation of fluid in the pseudocoelom of a nematode.

Source: P. Withers. (1992). *Comparative Animal Physiology*. Belmont, CA: Brooks/Cole, p. 667.

2. A *pump* to move the fluid; dedicated pumps are usually called *hearts*, and terms associated with them often contain the root *cardio* (Greek for heart).
3. *Vessels* to carry the fluid between the pump and body tissues; these are called *vascular* (Latin, relating to small vessels) components.

A system with all three components should be quite familiar to you. For example, a city water supply typically has pumps (at reservoirs, wells, and water towers) that move a vital fluid, water, through pipes to your house and other buildings. However, not all three components are necessary for some types of circulation. In particular, completely enclosed vessels are absent in many animal groups. Also, biological pumps are not always distinct dedicated organs (hearts). The simplest example is that of the water canal system of a sponge (Figure 9-1a). A sponge has no true internal circulatory fluid; rather, environmental water is pumped through hundreds of pores and internal chambers by thousands of collar cells (*choanocytes*) with beating flagella. Thus, water with food items and oxygen is brought close to most cells, whereas water with wastes leaves a large exit pore. In large Cnidarians (jellies, sea anemones, and so on; Figure 9-1b), materials move by a combination of diffusion and muscle-driven movement of ambient water in and out of the digestive cavity (*coelenteron*) that takes up most of their interiors. Pumping as such is accomplished as part of the digestive process. The tissues are generally thin, and all cells are close enough to the ambient water (outside) and the digestive cavity to survive on diffusion.

Circulatory systems can be open or closed

Most other animals have an internal extracellular fluid (ECF) that is separate from the environment. Small animals with an internal fluid-filled body cavity, such as nematodes (roundworms), may move materials through body motions that simply move the internal fluid (Figure 9-1c). But more complex animals have dedicated pumps and vessels that actively circulate the fluid. Traditionally, internal circulation of fluids is divided into two broad categories:

- **Open** systems (Figure 9-2a and b), in which the fluid—called **hemolymph**—moves via pumping through vessels that open like garden hoses into extracellular spaces among the tissues, bathing them directly for molecular exchanges with cells. The entire space filled with hemo-

lymph is called the **hemocoel**, which may be subdivided into smaller spaces called **sinuses**. The fluid may be moved by body movements, by cilia, or by hearts; the latter may have outflowing vessels called *arteries*, and intake pores called *ostia* or intake vessels called *veins*. This design is similar to your home water system: Water arrives in pipes; emerges into the open spaces in your shower, toilet, sinks, dishwasher, and so on; then re-enters pipes through drains (although the analogy fails at this point, because whereas the water does not return to its starting point, hemolymph does).

Various versions of open systems are found in many animal groups, including most mollusks and all arthropods (an example is shown in Figure 9-2b).

- **Closed** systems (Figure 9-2c and d), in which the fluid—called **blood**—exits a heart through vessels that are continuous all the way back to the intake side of the heart. The delivery (outgoing) vessels branch and become smaller and smaller until they become tiny leaky **capillaries**, where flow slows down and exchange of materials occurs with body cells (Figure 9-2c). These vessels then merge and become larger in size and fewer in number as blood is returned to the heart. Capillaries are widely regarded as the primary structure distinguishing a closed from an open system because, while some open systems have delivery vessels that branch into quite small ones, they are not contiguous with return vessels. An analogy is the cooling system in your refrigerator, in which a compressor pumps fluid out to coiled tubes and back again. (The open–closed distinction is not clear-cut: As you’ll see, blood fluid may leak out of capillaries and bathe nearby cells much as hemolymph does before returning to nearby vessels.) Closed systems are found in several animal groups, including cephalopod mollusks, annelids, and vertebrates (e.g., Figure 9-2d).

Now let’s examine each of the three circulatory system components individually. Then we will examine how pumps and vessels are integrated and regulated as one system.

check your understanding 9.1

How do circulatory systems overcome the limits of diffusion?

What are the differences between open and closed circulatory systems?

FIGURE 9-2 Flow through open and closed circulatory systems. (a, b) Open system of a grasshopper. A “heart” pumps blood through a vessel (aorta). Blood moves into tissue spaces and mingles with fluid bathing cells, then reenters the heart at opening (ostia) in the heart wall. (c, d) Closed system of an earthworm. Blood is confined within several pairs of muscular “hearts” near the head end and within blood vessels.

9.2 Circulatory Fluids and Cells

Circulatory fluids are traditionally divided into two components: a liquid called **plasma**, primarily water containing a variety of dissolved and dispersed molecules, and **cellular elements**, of which there may be several specialized kinds. In hemolymph, various cell types are called *hemocytes*, which are responsible for immune functions (Chapter 10), clotting (see below), and sometimes oxygen transport (Chapter 11). In vertebrates, these functions belong to three types of specialized cellular elements suspended in the plasma: (1) *erythrocytes* (or red blood cells, for oxygen transport; see below), (2) *leukocytes* (or white blood cells, for immunity; Chapter 10), and (3) *thrombocytes* or *platelets* (for clotting; see below).

Methodology: The Hematocrit If a sample of whole blood or hemolymph is placed in a test tube, treated to prevent clotting, and centrifuged, the heavier cellular elements move to the bottom and the lighter plasma rises to the top. This gives the **hematocrit**, or **packed cell volume** (Figure 9-3). Hematocrit values in vertebrates give a good indication of the oxygen delivery capacity of a species or individual; for example, well over 90% of the packed cells are erythrocytes in mammals. Stressed animals often have abnormal values. Vertebrates evolutionarily adapted or acclimatized to higher aerobic demands or low oxygen usually have higher values. Here are some examples:

- Human, *Homo sapiens*: 45% in males, 42% in females (average values; often higher in athletes), can increase dangerously by 20% in dengue fever
- Weddell seal, *Leptonychotes weddellii* (a deep-diving species): 46.5% in pups; 63.5% in adults

- Pekin duck, *Anas domestica*: 45% at sea level, 56% after four weeks acclimation at 5,640 meters.
- Striped bass, *Morone saxatilis*: 39% if acclimated to 5°C, 53% if acclimated to 25°C (note that warm water cannot dissolve as much oxygen as cold water).
- Icefish of Antarctica (Channichthyidae family): <1% (see box on p. 532).
- Ark snails (Arcidae family): 6–7%.

Plasma accounts for the remaining volume. Let’s first consider the properties of this component before turning to the cellular elements.

Plasma is an aqueous medium for inorganic ions, gases, and numerous organic solutes

Plasma typically consists of 90% or more water, which serves as a medium for a large number of organic and inorganic substances being carried in the fluid. In mammals, the most plentiful organic constituents are the *plasma proteins*, which compose 6 to 8% of plasma’s total weight, compared to about 1% for inorganic constituents. The most abundant electrolytes (ions) in virtually all animal plasmas are Na^+ and Cl^- (see p. 103). There are smaller amounts of HCO_3^- , K^+ , Ca^{2+} , and others. The most notable functions of these ECF ions are their roles in membrane potential, osmotic distribution of fluid between the ECF and cells, and buffering of pH; these functions are discussed elsewhere (Chapters 3, 4, and 13). The remaining small percentage of plasma is occupied by nutrients (for example, glucose, amino acids, lipids, and vitamins); waste products (such as creatinine, bilirubin, and urea in mammals); dissolved gases (O_2 and CO_2); and hormones. Most of these substances are merely being transported and have no functions in the plasma.

FIGURE 9-3 Hematocrit and types of blood cells. The values given are for human males. Other examples are given in the main text. Note the biconcave shape of the erythrocytes.

Plasma proteins carry out many of the functions of plasma

The **plasma proteins** are the one group of plasma constituents not present just for the ride. Here are the two of the most important nonspecific functions:

1. **Colloid osmotic pressure.** Unlike other plasma constituents that are dissolved in the plasma water, the plasma proteins exist in a colloidal dispersion. Furthermore, as largest in size of the plasma constituents, plasma proteins usually do not exit through the pores in capillary walls (of closed systems) to enter the interstitial fluid. Thus, plasma proteins establish an osmotic gradient between the blood (where they are present) and interstitial fluid (where they are absent). This **colloid osmotic pressure** is the primary force responsible for limiting the loss of plasma from the capillaries into the interstitial fluid, which helps maintain plasma volume (see p. 444). In open systems, plasma proteins create part of the osmotic pressure of the entire ECF but not the ICF.
2. **Buffering.** Plasma proteins are partially responsible for the plasma's capacity to buffer changes in pH (see Chapter 13, p. 641).

In addition to these nonspecific functions, each plasma protein has its own specific role(s).

Arthropods Insects, crustaceans, and arachnids also have a variety of plasma proteins in their hemolymph. There are clotting factors as well as proteins involved in exoskeleton production, because arthropods periodically molt their exoskeletons so that they can grow in size. Making new exoskeleton involves, in part, the polymerization of *phenols*

from the plasma. Three major protein classes found in arthropod plasma are as follows:

1. **Coagulogens** are key proteins in clotting (see p. 399).
2. **ProPOs** are inactive forms of **phenoloxidases (POs)** that are activated during exoskeletal synthesis (after molting, and during wound repair). POs in turn polymerize phenols. ProPOs are also involved in arthropod immune responses (p. 462).
3. **Hexamerins** and other hemolymph proteins in insects are thought to transport phenols to exoskeletal-producing epithelial cells.

Vertebrates These have three major groups of plasma proteins, which are classified according to their various physical and chemical properties:

1. **Fibrinogen**, like coagulogen, is a key factor in the blood-clotting process (see Figure 9-11, p. 397).
2. **Albumins**, the most abundant of mammalian plasma proteins, bind many substances (for example, bilirubin, bile salts, and fatty acids) for transport through the plasma and contribute most extensively to the colloid osmotic pressure by virtue of their numbers.
3. **Globulins** come in three forms—**alpha (α)**, **beta (β)**, and **gamma (γ)**—which act as:
 - **Transporters.** Specific α - and β -globulins bind and transport a number of substances in the plasma, such as thyroid hormone, cholesterol, and iron. The most common is **transferrin**, which binds and transports iron atoms.
 - **Clotting agents.** Many of the factors involved in the process of blood clotting, which will be described shortly, are α - or β -globulins.

- **Regulators.** Inactive proteins that are precursors of regulators such as hormones, and that are activated as needed by specific signals, belong to the α -globulin group (for example, the α -globulin angiotensinogen is activated to angiotensin, which plays an important role in regulating blood pressure and salt balance in the body; p. 587).
- **Immune effectors.** The γ -globulins are the immunoglobulins (antibodies), which are crucial to vertebrate defense mechanism.

These proteins are predominately synthesized by the liver. Some are produced by vascular endothelial (lining) cells. The functions of some of these proteins are elaborated on elsewhere in the text; for example, the γ -globulins in immune responses are covered in Chapter 10.

Lipoprotein complexes carry energy lipids and structural lipids for biosynthesis

Because lipids are hydrophobic, they are not very soluble in blood or hemolymph. For this reason, most lipids in circulation are converted into droplets attached to specific plasma-protein carriers called **apolipoproteins**. The resulting droplets called **lipoproteins** can disperse in circulatory fluids and then transport lipids between tissues.

Cells of most animals need such lipids for two purposes: (1) **energy** lipids, such as *triglycerides*, form large stores of chemical energy (p. 26), while (2) **structural** lipids are used for making membranes. There are two types of the latter: *phospholipids* for constructing the primary bilayer itself, and *cholesterol* for stabilizing the membrane (see Chapter 3). In addition, a few special cell types use cholesterol as a precursor for the synthesis of secretory products, such as steroid hormones and bile salts. Most cells cannot manufacture enough of these lipids and therefore must rely on the circulation to deliver supplemental lipid. There are two sources for that: *dietary* intake, with animal tissues being especially rich in cholesterol compared to plant tissues; and *biosynthesis* by other organs, for example, the liver in vertebrates.

Now let's look at key examples of lipoproteins:

Arthropods Except for Crustacea, arthropods have **lipophorins** in their hemolymph that deliver energy lipids, phospholipids, and cholesterol to all cells. These droplets have lipids with apolipoproteins called *apolipophorins*. The lipoproteins are named for their densities based on lipid-protein ratios. As shown in Figure 9-4a for an insect:

1. **High-density lipophorins (HDLp)** and the apolipophorin *apoLp-III* in the hemolymph pick up lipids, primarily energy-rich *diacylglycerides* from the gut (step 1a, DAG) and from triacylglyceride breakdown in the fat body (equivalent to a liver; step 1b, TAG and DAG). The apolipophorin helps keep the droplet dispersible in the hemolymph and can be recognized by muscle receptors.
2. The droplets are now **low-density lipophorins (LDLp)** because they contain more lipid (which is less dense than protein). LDLp delivers lipids primarily to muscles (step 2).
3. Muscles use lipids for energy storage or immediate usage as free fatty acids (step 3, FFA).

4. With many lipids removed, the droplets become HDLp again and release the apolipoprotein; both recycle to start the transport over again (steps 4a, b).

Vertebrates These have four major lipoproteins also named by density properties:

- **Chylomicrons (CM)**, produced by intestinal absorptive cells, which transport triglycerides, cholesterol, and phospholipids after a meal.
- **High-density lipoproteins (HDL)**, which contain the most protein, some phospholipids, and least cholesterol.
- **Low-density lipoproteins (LDL)**, which contain less protein, some phospholipids, and more cholesterol.
- **Very-low-density lipoproteins (VLDL)**, which contain the least protein and most lipid, but the lipid they carry is triglyceride for energy.

Let's look at these in more detail; note that all the transport droplets have apolipoproteins (Figure 9-4b; see Chapter 14 for more on chylomicrons):

1. Lipids in the diet for energy (triglycerides) and structures (phospholipids, cholesterol) are packaged by the small intestine into *chylomicrons* that enter the lymph and blood (step 1).
2. Some tissues as adipose extract some of the triglycerides as free fatty acids (step 2a; FFA) to be reconverted into triglycerides for storage; then the leftovers—*chylomicron remnants*—go to the liver (step 2b).
3. The liver repackages the lipids into *VLDLs*, which are then transported into blood (step 3a); VLDLs deliver energy lipids to adipose and other body cells (step 3b).
4. The leftovers become intermediate-density lipoproteins (IDLs) and then *LDLs*, which are dominated by structural lipids (steps 4a, b).
5. LDLs deliver cholesterol and phospholipids to most body cells (step 5), including those lining the blood vessel walls. LDL is often called “bad” cholesterol because *plaques*—pathological accumulations of LDL cholesterol in blood vessel walls—are a leading cause of cardiovascular disease in humans, many domestic mammals such as pigs, and may possibly occur in some wild vertebrates such as salmon.
6. In contrast, cholesterol carried in HDL complexes is dubbed “good” cholesterol, because HDL removes excess cholesterol *from* the cells and transports it to the liver (step 6).
7. There the excess is partly eliminated as bile (step 7). Bile enters the intestinal tract, where bile salts participate in the digestive process (Chapter 14). Most of the secreted cholesterol and bile salts are later reabsorbed from the intestinal tract into the blood to be recycled to the liver, but the cholesterol molecules not reclaimed by absorption are eliminated in the feces.

Cells accomplish phospholipid and cholesterol uptake from the blood by receptor proteins in their plasma membranes specifically capable of binding the apolipoprotein of LDLs (Figure 9-4b). When an LDL particle binds to one of the membrane receptors, the cell engulfs the particle by endocytosis. Within the cell, lysosomal enzymes break down the LDLs to free the lipids, making them available to the cell for synthesis of new cellular membrane.

(a) Lipid transport in insect hemolymph

(b) Lipid transport in mammalian blood

FIGURE 9-4 Role of the circulating lipoproteins in lipid transport. (a) Insects. High-density lipoproteins (HDLp) and low-density lipoproteins (LDLp) complexed with an apolipoprotein *apoLp-III* and are involved in hemolymph transport of energy lipids (DAG—diacylglycerides) to muscles from the gut and fat body (converted there from TAG—triacylglycerides). See text for description of each step. (b) Mammals. Chylomicrons (CM), very-low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL) deliver lipids (such as FFA, free fatty acid; PL, phospholipids; Chol, cholesterol) to various tissues. The small colored spheres are apolipoproteins, proteins that bind to the droplets to make them dispersible in the blood and recognizable by cell receptors. See text for description of each step.

(1998). Discovery of the lipoproteins, their role in fat transport and their significance as risk factors. *Journal of Nutrition* 128:439S–443S.

Respiratory pigments carry oxygen

In many animals, other crucial types of circulatory proteins function as **respiratory pigments**. These are oxygen-binding proteins critical for transporting O_2 for cellular respiration. Respiratory pigments in animals vary considerably by phylum and may exist as one or more isoforms in a particular species, as you will see in detail in Chapter 11; we give a brief summary here. The two most common ones are **hemoglobins**, proteins in vertebrates and many nonvertebrates that use an iron atom to bind an O_2 molecule; and **hemocyanins**, proteins in many mollusks and arthropods such as crustaceans, that use two copper atoms to bind one oxygen molecule. Most insects do not have a respiratory pigment, because their tracheal system (Chapter 11) carries O_2 directly to tissues. However, arachnids do have hemocyanin because some species lack tracheae (using book lungs, for example; see Chapter 11), whereas others have tracheae that do not extend into the tissues. Hemocyanins circulate in arachnid hemolymph to transfer O_2 between the lungs or tracheal termini to muscles and other organs.

The pigment proteins may be dissolved in the hemolymph or blood, which is the case for most annelids, arthropods, and some other nonvertebrates. In many animals, however, these proteins are not in the plasma itself but are contained in specialized cells. If they contain hemoglobin, which is reddish when oxygen is bound, these cells are called **erythrocytes** (*erythro*, “red”), to which we now turn our attention.

Erythrocytes serve primarily to transport oxygen

Each milliliter (mL) of vertebrate blood contains numerous erythrocytes (or *red blood cells*), for example, about 3 billion per mL in chickens, 7 billion per mL in cows and pigs, 10 billion per mL in horses, and 15 billion per mL in llamas (which live at high altitude in the Andes). The main function of erythrocytes is to transport O_2 from the lungs or gills to the tissues. In most vertebrates, these cells are oblong oval (ovoid) shapes (Figure 9-5), with amphibians and lungfish having the largest. In contrast, mammalian erythrocytes are flat, disc-shaped (biconcave) cells without nuclei, indented in the middle on both sides like a doughnut with a flattened center instead of a hole (Figure 9-3). See *Unanswered Questions: Why are erythrocytes in birds and mammals so different?* for details.

unanswered Questions | Why are erythrocytes in birds and mammals so different?

Mammalian red cells are unique in having a biconcave shape and no nucleus; they are also the smallest of vertebrate erythrocytes and so more can be packed into a given blood volume. The mammalian red cell's small size and shape is thought to aid O_2 transport by (1) providing a larger surface area for diffusion of O_2 across the membrane than would a spherical cell of the same volume; (2) enabling O_2 to diffuse rapidly between the exterior and innermost regions of the cell due to its thinness; (3) having more room for hemoglobin due to the lack of a nucleus; and (4) allowing the cell to squeeze through mammalian capillaries, which are the narrowest among all verte-

FIGURE 9-5 Anatomic characteristics of chicken erythrocytes (and thrombocytes). Compare these to the mammalian biconcave shape in Figure 9-3.

brates (this narrowness presumably evolved to support the high metabolism of mammals). The cells, each with a diameter of 6 μm , can deform amazingly without rupturing as they squeeze single file through capillaries as narrow as 3 μm in diameter.

In other vertebrates, erythrocytes are at lower densities, have a larger ovoid shape, and keep their nuclei, although in aging birds the red cells become progressively condensed (and unused). However, birds, which typically have higher oxygen requirements than mammals, have ovoid red cells twice the diameter of mammalian ones. Correspondingly, bird capillaries, though smaller than those of most vertebrates, are twice as wide as mammals'. Yet oxygen delivery obviously functions quite well in birds. Why these differences evolved is uncertain; might the faster circulation or more efficient lung of birds be the answer? See pp. 414, 515, and 527. <<

Vertebrate erythrocytes also play a role in returning carbon dioxide (CO_2) to the lungs or gills. As you will see shortly, both the cytoplasm and hemoglobin contribute to CO_2 transport.

Oxygen Transport To maximize its hemoglobin content, a mammalian erythrocyte is stuffed with several hundred million hemoglobin molecules, to the exclusion of almost everything else including nucleus, other organelles, or ribosomes. These structures are extruded during the cell's development to make room for more hemoglobin. Maturation of erythrocytes is aided by immune cells called *macrophages* (p. 465), which bind to the immature nucleated erythrocytes (erythroblasts) to form “islands” consisting of a central macrophage that extends cytoplasmic protrusions to a ring of maturing erythroblasts. The macrophages nurture red cell development and aid in the loss of their nuclei. Ultimately then, a mammalian red blood cell is mainly a plasma-membrane-enclosed sac full of hemoglobin. Ironically, these mammalian cells cannot use the O_2 they are carrying for energy production since they lack the mitochondria. Instead, they rely entirely on glycolysis for ATP formation (see p. 48).

Because of its iron content, hemoglobin appears red-dish when combined with O_2 and bluish when deoxygenated, acidified, and combined with CO_2 . Thus, fully oxygenated arterial blood is red in color, and venous blood, which has lost some O_2 and gained some CO_2 , has a bluish cast.

Carbon Dioxide Transport Erythrocytes contribute to CO_2 transport in two ways:

1. *Bicarbonate production:* Though lacking most enzymes, the mature mammalian erythrocyte retains glycolytic enzymes and **carbonic anhydrase (CA)**. CA is crucial in CO_2 transport (see also Chapter 11, p. 541). It catalyzes a key reaction that ultimately leads to the conversion of metabolically produced CO_2 into **bicarbonate ion (HCO_3^-)**, which is the primary form in which CO_2 is transported in the blood. (This bicarbonate is a major pH buffer in the extracellular fluid—see p. 640)
2. *Hemoglobin* also contributes by binding CO_2 , although it does not carry as much of this gas as it carries O_2 . CO_2 binds to the protein itself (the globin), not the iron (p. 540).

Hemoglobins and erythrocytes have additional transport functions

In addition to carrying CO and O_2 , hemoglobin and erythrocytes can also transport or regulate the following:

- *Bicarbonate (HCO_3^-)*. In crocodiles, hemoglobin binds this ionic form of carbon dioxide, which in turn enhances oxygen release (Chapter 11).
- *H^+ from ionized carbonic acid*, generated at the tissue level from CO_2 . Hemoglobin binds to and thus buffers this proton so that it minimally alters the pH of the blood (Chapter 13).
- *Nitric oxide (NO)*. In mammalian lungs, the vasodilator nitric oxide (see p. 93) binds to a sulfur atom within the hemoglobin molecule to form SNO. This nitric oxide is released at the tissues, where it relaxes and dilates the local arterioles. This vasodilation helps ensure that the O_2 -rich blood can make its vital rounds and also helps stabilize blood pressure.
- *Hydrogen sulfide (H_2S)*. Mammalian erythrocytes generate small amounts of this “rotten egg” gas that is toxic at high levels. H_2S , like NO, stimulates vessel dilation. This may be one reason garlic is thought to aid cardiovascular health in humans: it contains organic sulfur compounds that erythrocytes convert into H_2S . A very different animal, the giant annelid tubeworm *Riftia*, needs H_2S to live. This animal, found at deep-sea hydrothermal vents in the Pacific Ocean, lives exclusively off sulfide-oxidizing bacterial symbionts in its *trophosome* (a saclike structure that replaces the gut). *Riftia* has a hemoglobin that transports both H_2S (from the hot waters of the vents) and O_2 (from cold ocean water) to its symbionts, via a closed circulatory system with a heart. In the trophosome, the symbionts oxidize H_2S using O_2 to provide the energy for conversion of CO_2 into glucose, which then powers metabolism of both the bacteria and their animal host.

Hemopoietic tissues continuously replace worn-out erythrocytes

Avian and mammalian erythrocytes have a short life span, presumably because they have nonfunctioning nuclei (in birds) or no nuclei (in mammals). For example, they survive an average of only about 100 to 110 days in domestic mammals, and only 28 days in a parrot and 30 days in a chicken. During this short life span, the cell’s plasma membrane, which cannot be repaired, becomes fragile as the cell repeatedly squeezes through capillaries.

One organ involved with erythrocyte regulation is the **spleen**. It has two important roles:

1. *Removal of old red cells.* Most old red-blood cells meet their final demise in the spleen, because this organ’s narrow, winding, capillary network is a tight fit for these fragile cells. Macrophages engulf and destroy the dying cells.
2. *Red cell reservoir.* The spleen can store healthy erythrocytes in its pulpy interior; it also serves as a reservoir site for platelets and contains an abundance of lymphocytes, a type of white blood cell. In many mammals, the stored erythrocytes form a reserve of oxygen that can be released (by contraction of the organ) during locomotory activity. In horses, for example, splenic contraction during exercise can double the hematocrit. This also occurs in many marine mammals during a dive (p. 545).

Because erythrocytes cannot divide to replenish their own numbers, the old ruptured cells must be replaced by new cells produced in an erythrocyte factory, called **hemopoietic tissues**. The **kidney** and **spleen** produce these cells in bony fishes. In birds and mammals, it is the **bone marrow**—the soft, highly cellular tissue that fills the internal cavities of bones. Regions of bone marrow called *red bone marrow* normally generate new red blood cells, a process known as **erythropoiesis**, to keep pace with the demolition of old cells (at the amazing rate of 2 to 3 million per second in humans). In adult humans, red bone marrow is found in the sternum (breastbone), vertebrae (backbone), ribs, base of the skull, and upper ends of the long limb bones. Red marrow not only produces red blood cells but is the ultimate source for leukocytes and platelets as well. Undifferentiated **pluripotent stem cells** reside in the red marrow (or in blood of lower fishes, and the kidney and spleen in bony fishes), where they continuously divide and differentiate to give rise to each of the types of blood cells. Regulatory factors act on the *hemopoietic* (“blood-producing”) marrow to govern the type and number of cells generated and discharged into the blood. Of the blood cells, the mechanism for regulating red blood cell production is the best understood. Let’s consider it now for vertebrates.

Erythropoiesis in mammals and probably other vertebrates is controlled by erythropoietin from the kidneys

The number of circulating erythrocytes normally remains fairly constant in an animal living with consistent oxygen supply, indicating that erythropoiesis must be closely regulated in negative-feedback fashion. If O_2 delivery to the tissues is reduced (due to loss of erythrocytes or lower

FIGURE 9-6 Control of erythropoiesis.

© Cengage Learning, 2013

environmental O₂), increased erythropoiesis is indeed stimulated. However, low O₂ delivery does not cause this directly, but rather it triggers the *kidneys* to secrete the hormone **erythropoietin** (EPO) into the blood. This hormone in turn stimulates erythropoiesis by the hemopoietic tissues (Figure 9-6). (Synthetic EPO was developed to treat humans with kidney failure and other causes of anemia, but you may be more familiar with EPO due to its illegal use by some human athletes; it is also sometimes illegally injected into racing animals such as horses.) EPO has been mostly studied in mammals but is found in other vertebrates including some bony fish; for example, in zebrafish, the gene is regulated by low-oxygen conditions just as it is in mammals. EPO acts on derivatives of undifferentiated stem cells that are already committed to becoming red blood cells, stimulating their proliferation and maturation into mature erythrocytes (Figure 9-7). This increased erythropoietic activity elevates the number of circulating red blood cells, thereby restoring O₂ delivery to the tissues to normal. Once normal O₂ delivery is achieved, EPO secretion is turned down until needed again. In this way, erythrocyte production is normally balanced against loss of these cells so that the O₂-carrying capacity in the blood remains fairly constant. In response to severe loss of erythrocytes, as in hemorrhage, or to prolonged impairment of O₂ delivery, such as livestock being taken to high altitude or a fish entering low-O₂ water, the rate of erythropoiesis is upregulated.

Leukocytes are key components of vertebrate immune systems

Leukocytes, or white blood cells, are the mobile units of vertebrate immune systems. We leave a more detailed discussion of their names and functions for Chapter 10. For now, note that all leukocytes ultimately originate from the

same undifferentiated pluripotent stem cells that also give rise to erythrocytes and platelets (Figure 9-7). To direct the differentiation and proliferation of each cell type, specific hormones analogous to erythropoietin are required.

Thrombocytes and platelets function in clotting

The third type of blood cell or cell derivative is the **thrombocyte** (a living cell) or **platelet** (a cell fragment), which serves in the clotting mechanism. Thrombocytes are cells found in all vertebrates except mammals; these cells circulate in an inactive state, and when activated by an injury to nearby tissue, they begin to break up into platelet-like fragments. Mammals are different in that the precursor cells become platelets, which become the primary inactive form that circulates in the blood. Specifically, platelets are small cell fragments (about 2 to 4 μm in diameter) that are shed off the outer edges of extraordinarily large (up to 60 μm in diameter), bone-marrow-bound cells known as **megakaryocytes** (Figure 9-8), each of which typically produces about 1,000 platelets. Megakaryocytes are derived from the same stem cells that give rise to the erythrocytic and leukocytic cell lines (Figure 9-7). Platelets are essentially detached vesicles containing portions of cytoplasm wrapped in plasma membrane.

Platelets remain functional for less than two weeks, at which time they are removed from circulation by macrophages, especially those in the spleen and liver, and are replaced. The hormone **thrombopoietin**, made by hepatocytes (*hepato*, “liver”), increases the number of megakaryocytes in the bone marrow and stimulates each megakaryocyte to produce more platelets (Figure 9-7). Platelets lack nuclei, but they can produce secretory products from storage granules, and contain the contractile proteins actin and myosin (Chapters 2 and 8) to enable them to contract. These features are important in hemostasis, our next topic.

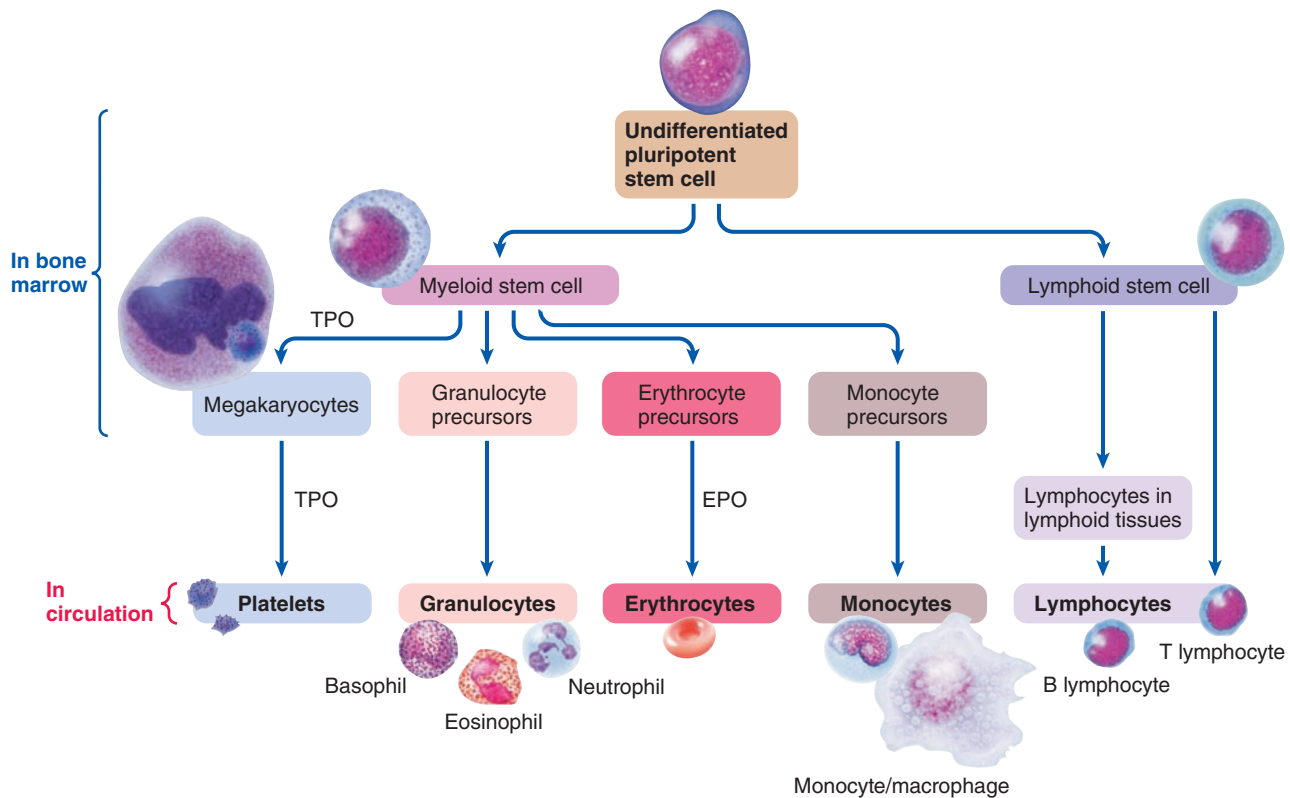

FIGURE 9-7 Blood cell production (hemopoiesis) in a mammal. All the blood cell types ultimately originate from the same undifferentiated pluripotent stem cells in the red bone marrow. The hormones EPO and TPO (thrombopoietin) stimulate cell differentiation and production where indicated; see main text for details.

What is the basic composition of plasma?

Discuss the roles of HDLs and LDLs in mammals.

What are the major transport functions of vertebrate erythrocytes?

9.3 Circulatory Fluids: Hemostasis

Hemostasis is the arrest of bleeding. (Be sure not to confuse this with the term *homeostasis*.) Bleeding occurs when there is a rupture in a vessel or hemocoel wall, and the pressure inside is greater than the pressure outside. Hemostatic mechanisms in vertebrates normally are adequate to seal tears and stop loss of blood through small damaged capillaries, arterioles, and venules (pp. 429–448), small vessels that are frequently ruptured by minor traumas. The much rarer occurrence of bleeding from medium- to large-size vessels usually cannot be stopped by the hemostatic mechanisms alone. Bleeding from a severed artery is more profuse and therefore more dangerous than venous bleeding because the driving pressure is greater in the arteries than in the veins (as you will see later).

Here we focus primarily on the mammalian system, which involves three major steps: (1) *vascular spasm*, (2)

formation of a platelet plug, and (3) blood coagulation (clotting).

Vascular spasm reduces blood flow through an injured vessel

A cut or torn blood vessel in a vertebrate immediately constricts as a result of an inherent vascular response to injury, release of chemicals by platelets or thrombocytes (described shortly), and sympathetically induced vasoconstriction. This constriction slows blood flow through the defect and thus minimizes blood loss. Also, as the opposing endothelial (inner) surfaces of the vessel are pressed together by this initial **vascular spasm**, they become sticky and adhere to each other, further sealing off the damaged vessel. These physical measures are important in minimizing blood loss until the other hemostatic measures can actually plug up the defect.

Platelets aggregate to form a plug at a vessel defect by positive feedback

Platelets and thrombocytes normally do not adhere to the smooth endothelial surface of blood vessels, but when this lining is disrupted because of vessel injury, platelets in mammals—or, in other vertebrates, platelet-like fragments that begin to form from thrombocytes—can now attach to the exposed collagen, a fibrous protein present in the underlying connective tissue. Once platelets or fragments start aggregating at the site of the defect, they release several important chemicals from their storage granules (Figure 9-9). Among these chemicals is *adenosine diphosphate* (ADP), which causes the surface of nearby circulating platelets to become sticky, so that they adhere to the first layer of aggregated platelets. These newly aggregated platelets release more ADP, which causes more platelets to pile on, and so on. Thus, a **platelet plug** is rapidly built up at the defect site in a *positive-feedback* fashion. The actin-myosin protein complex within the aggregated platelets contracts to compact and strengthen what was originally a fairly loose plug.

Given the self-perpetuating nature of platelet aggregation, why is the platelet plug limited to the site of vessel injury once it is initiated? (In other words, why doesn't the platelet plug continue to expand over the surface of the adjacent normal vessel lining?) A key reason why this does not happen is that ADP and other chemicals released by the activated platelets stimulate the release of *prostacyclin* and *nitric oxide* (NO) from the adjacent normal endothelium. Both chemicals profoundly inhibit platelet aggregation. Thus, the platelet plug is limited to the defect and does not spread to normal tissue (Figure 9-9).

The aggregated platelet plug not only physically seals the break in the vessel but also performs other important roles. (1) The chemicals released from the platelet plug include *serotonin*, *epinephrine*, and *thromboxane* A₂, which induce profound constriction of the affected vessel to reinforce the vascular spasm. (2) The aggregated platelets secrete a chemical that helps promote the invasion of fibroblasts ("fiber formers") from the surrounding connective tissue into the wounded area of the vessel to repair it, forming a scar at the vessel defect. (3) The platelet plug releases other chemicals that enhance blood coagulation, the next step of hemostasis.

A triggered chain reaction and positive feedback involving clotting factors in the plasma results in blood coagulation

Although the platelet-plugging mechanism alone is often sufficient to seal the myriad minute tears in capillaries that occur daily, larger holes in the vessels require the formation of a *clot* to completely stop the bleeding. **Blood coagulation**, or **clotting**, is the transformation of blood from a liquid into a solid gel. Formation of a clot on top of the platelet plug strengthens and supports the plug, reinforcing the seal over a break in a vessel. Furthermore, as blood in the vicinity of the vessel defect solidifies, it can no longer flow. Clotting is the most powerful hemostatic mechanism, and it works as follows.

Clot Formation The ultimate step in clot formation is the conversion of **fibrinogen**, a large, soluble plasma protein produced by the liver and normally always present in the plasma, into **fibrin**, an insoluble, threadlike molecule. This conversion into fibrin is catalyzed by the enzyme **thrombin** at the site of the injury. Fibrin molecules adhere to the damaged vessel surface, forming a loose, netlike meshwork that traps blood cells, including aggregating platelets. The resulting mass, or **clot**, typically appears red because of the abundance of trapped red cells, but the foundation of the clot is formed of fibrin (Figure 9-10).

The original fibrin web is rather weak because the fibrin strands are only loosely interlaced. However, chemical linkages rapidly form between adjacent strands to strengthen and stabilize the clot meshwork. This cross-linkage process is catalyzed by a clotting factor known as **factor XIII** (**fibrin-stabilizing factor**), which normally is present in the plasma in inactive form.

Fibrin is one of the stretchiest proteins that scientists have ever studied. On average fibrin fibers can be passively stretched to 2.8 times their original length and still snap back to their starting length and can be stretched to 4.3 times their original length before they break. This highly elastic property accounts for the extraordinary stretchiness of blood clots.

Roles of Thrombin Thrombin, in addition to converting fibrinogen into fibrin (step 1a in Figure 9-11) also activates factor XIII to stabilize the resultant fibrin mesh (step 1b), acts in a *positive-feedback* fashion to facilitate its own formation (step 1c), and enhances platelet aggregation (step 1d), which in turn is essential to the clotting process (step 2).

Because thrombin converts the ever-present fibrinogen molecules in the plasma into a blood-stanching clot, thrombin must normally be absent from the plasma except in the vicinity of vessel damage. Otherwise, blood would always be coagulated—a situation incompatible with life. How can thrombin normally be absent from the plasma, yet be readily available to trigger fibrin formation when a vessel is injured? The solution lies in thrombin's existence in the plasma in the form of an inactive precursor called **prothrombin**. What converts prothrombin into thrombin when blood clotting is desirable? This conversion involves the clotting cascade.

The Clotting Cascade Yet another activated plasma clotting factor, **factor X**, converts prothrombin to thrombin; factor X itself is normally present in the blood in inactive form and

FIGURE 9-9 Formation of a platelet plug. Platelets aggregate at a vessel defect through a positive-feedback mechanism involving the release of adenosine diphosphate (ADP) and thromboxane A_2 from platelets, which stick to exposed collagen at the site of the injury. Platelets are prevented from aggregating at the adjacent normal vessel lining by the release of prostacyclin and nitric oxide from the undamaged endothelial cells.

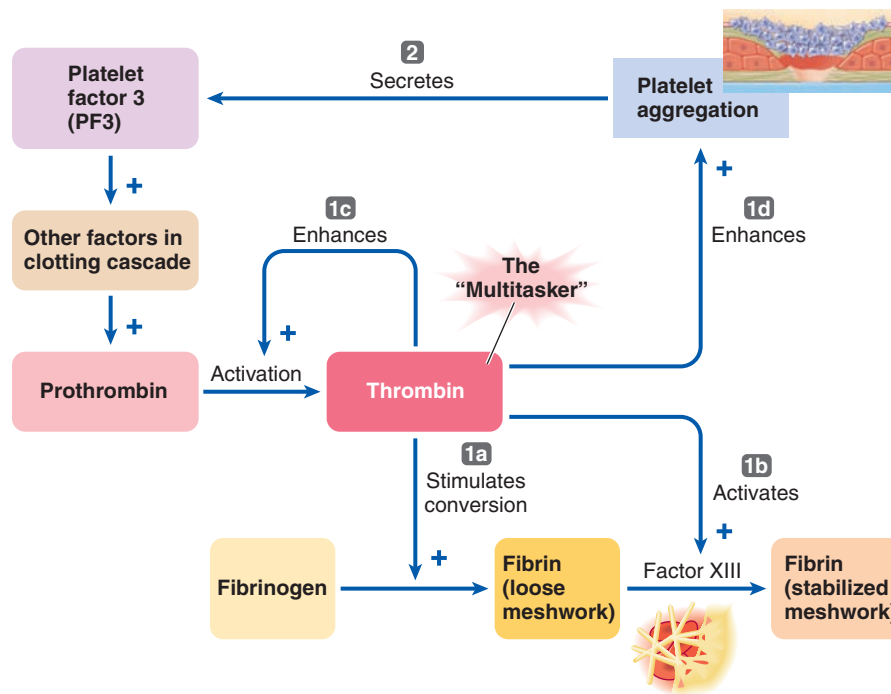

FIGURE 9-10 Erythrocytes trapped in the fibrin meshwork of a clot.

must be converted into its active form by still another activated factor, and so on. Altogether, 12 plasma-clotting factors participate in essential steps that lead to the final conversion of fibrinogen into a stabilized fibrin mesh (Figure 9-12). These factors are designated by Roman numerals in the order in which the factors were discovered, not the order in which they participate in the clotting process. (The term *factor VI* is no longer used, as it has now been determined to be an activated form of factor V.) Most of these clotting factors are plasma proteins synthesized by the liver. Normally, they are always present in the plasma in an inactive form, such as fibrinogen and prothrombin. In contrast to fibrinogen, which is converted into insoluble fibrin strands, prothrombin and the other precursors, when converted to their active form, act as *proteolytic* (protein-splitting) enzymes. These enzymes activate another specific factor in the clotting sequence. Once the first factor in the sequence is activated, it in turn activates the next factor, and so on, in a series of sequential reactions known as the **clotting cascade**, until thrombin catalyzes the final conversion of fibrinogen into fibrin. Several of these steps require the presence of plasma Ca^{2+} and *platelet factor 3* (PF3), a phospholipid secreted by the aggregated platelet plug. Thus, platelets also contribute to clot formation.

1 Thrombin, a component of the clotting cascade, plays multiple roles in hemostasis:

1a stimulates conversion of fibrinogen to fibrin

1b activates factor stabilizing fibrin meshwork of clot

1c enhances activation of more prothrombin into thrombin through positive feedback

1d enhances platelet aggregation

2 Through positive feedback, aggregated platelets secrete PF3, which stimulates clotting cascade that results in thrombin activation.

FIGURE 9-11 Roles of thrombin in hemostasis.

© Cengage Learning, 2013

The clotting cascade may be triggered by the intrinsic pathway or the extrinsic pathway

Two distinct clotting cascades called the *intrinsic* and *extrinsic* mechanisms usually operate simultaneously. When tissue injury involves rupture of vessels, the intrinsic mechanism stops blood in the injured vessel, whereas the extrinsic mechanism clots the blood that escaped into the tissue before the vessel was sealed off.

- The **intrinsic pathway** precipitates clotting within damaged vessels as well as clotting of blood samples in test tubes. This pathway, which involves seven separate steps (shown in blue in Figure 9-12), is set off when **factor XII** is activated by coming into contact with a negatively charged surface, especially exposed collagen in an injured vessel (or a foreign surface such as a glass test tube). Remember that exposed collagen also initiates platelet aggregation, so formation of a platelet plug and the chain reaction leading to clotting are simultaneously set in motion. Positive feedback further contributes: The aggregated platelets secrete PF3, which is essential for the clotting cascade that in turn enhances further platelet aggregation (Figures 9-11 and 9-13).
- The **extrinsic pathway** takes a shortcut and requires only four steps (shown in gray in Figure 9-12). This pathway, which requires contact with tissue factors external to the blood, initiates clotting of blood that has escaped into the tissues. When a tissue is traumatized, it releases a protein complex known as **tissue thromboplastin**. Tissue thromboplastin directly activates factor X, thereby bypassing all preceding steps of the intrinsic pathway. From this point on, the two pathways are identical. Indeed, it is not clear whether the intrinsic pathway with factor XII is essential. Non-avian reptiles have it, but birds have lost it. Some marine mammals (dolphins, whales) have lost it as well.

unanswered Questions | Why is mammalian clotting so complex?

The complex multistep clotting process in mammals clearly evolved from simpler beginnings, as revealed by genomic analysis. All vertebrates use the fibrinogen–fibrin mechanism, but fishes lack many of the mammalian clotting factors and steps. Some of these steps appeared later in the first land vertebrates, but only mammals have the full system described above. This addition of clotting steps in vertebrate evolution occurred in part by the process of **gene duplication** (in which an error in meiosis produces a second copy of a gene, which may mutate to yield new functions), as revealed by closely related gene sequences among many of the clotting factors.

Clotting clearly works in the simpler systems of nonmammals, so why did the complexity in mammals evolve? For one, **cascade amplification** is accomplished during many of the steps. One molecule of an activated factor can activate perhaps a hundred molecules of the next factor in the sequence, each of which can activate many more molecules of the next factor, and so on. This increases the speed of clotting, which may be crucial in the higher-pressure circulation that birds and mammals have compared to other vertebrates. (A similar amplification occurs in second-messenger systems, p. 99.) Also, Russell Doolittle (the biochemist who has documented the stepwise evolution of vertebrate clotting) speculates that mammalian complexity, in addition to boosting amplification, allows for more versatile regulation of clotting over a wider range of environments including a larger range of blood pressures, higher metabolic rates, and additional organs such as placentas. <<

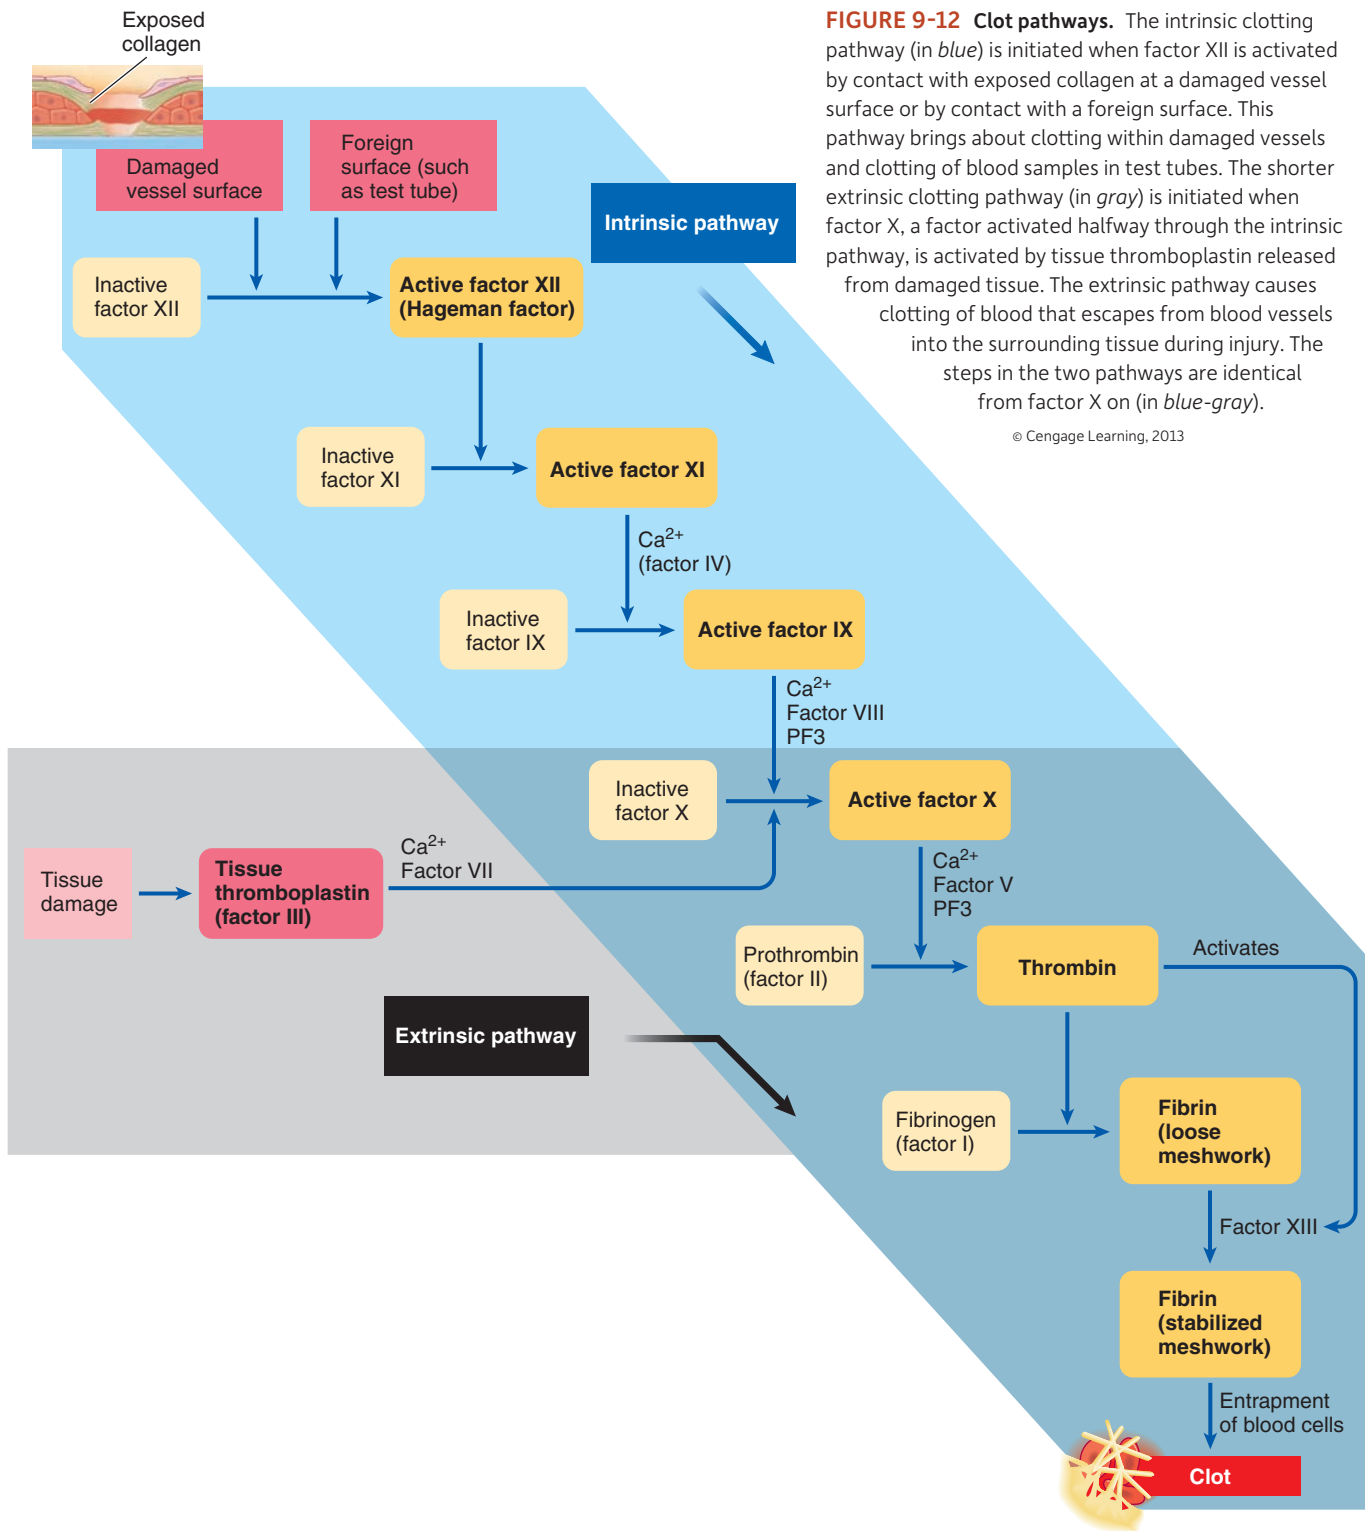

FIGURE 9-12 Clot pathways. The intrinsic clotting pathway (in blue) is initiated when factor XII is activated by contact with exposed collagen at a damaged vessel surface or by contact with a foreign surface. This pathway brings about clotting within damaged vessels and clotting of blood samples in test tubes. The shorter extrinsic clotting pathway (in gray) is initiated when factor X, a factor activated halfway through the intrinsic pathway, is activated by tissue thromboplastin released from damaged tissue. The extrinsic pathway causes clotting of blood that escapes from blood vessels into the surrounding tissue during injury. The steps in the two pathways are identical from factor X on (in blue-gray).

Fibrinolytic plasmin dissolves clots and prevents inappropriate clot formation

A clot is not meant to be a permanent solution to vessel injury. It is a transient device to stop bleeding until the vessel can be repaired. Moreover, because positive feedback is involved, clotting could get out of control and spread beyond

the wound. Thus, there are crucial anticlotting regulatory processes.

Clot Dissolution Simultaneous with the healing process, the clot, which is no longer needed to prevent hemorrhage, is slowly dissolved by a fibrinolytic (fibrin-splitting) enzyme called **plasmin**. If clots were not removed after they per-

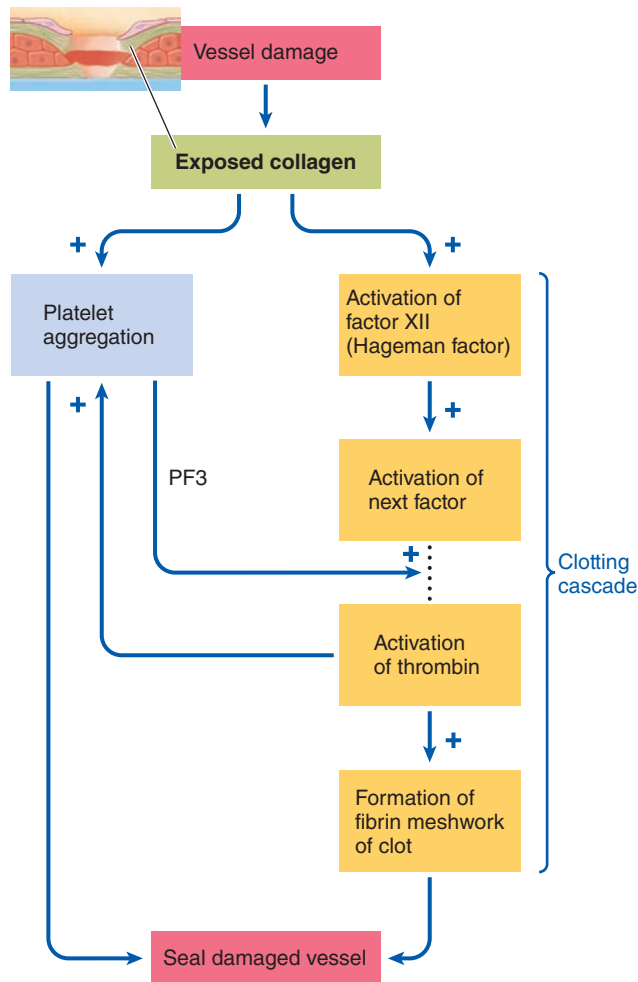

FIGURE 9-13 Concurrent platelet aggregation and clot formation. Exposed collagen at the site of vessel damage simultaneously initiates platelet aggregation and the clotting cascade. These two hemostatic mechanisms positively reinforce each other as they seal the damaged vessel.

© Cengage Learning, 2013

formed their hemostatic function, the vessels, especially the small ones that endure tiny ruptures on a regular basis, would eventually become obstructed by clots.

Plasmin, like the clotting factors, is a plasma protein produced by the liver and present in the blood in an inactive precursor form, **plasminogen**. Plasmin is activated in a fast cascade of reactions involving many factors, among them factor XII, which also triggers the chain reaction leading to clot formation (Figure 9-14). When a clot is rapidly being formed, activated plasmin becomes trapped in the clot and later dissolves it by slowly breaking down the fibrin meshwork. Phagocytic white blood cells gradually remove the products of clot dissolution.

Preventing Inappropriate Clot Formation In addition to removing clots that are no longer needed, plasmin functions continually to prevent clots from forming inappropriately. Throughout the vasculature, small amounts of fibrinogen are constantly being converted into fibrin, triggered by unknown mechanisms. Clots do not develop, however, because the fibrin is quickly disposed of by plasmin activated by tis-

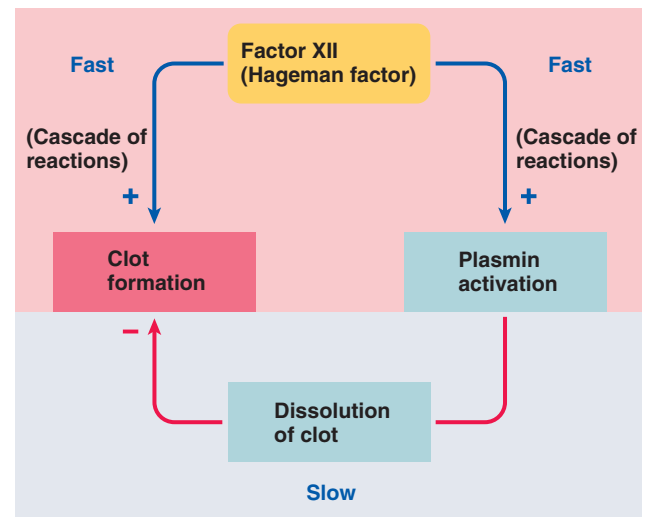

FIGURE 9-14 Role of factor XII in clot formation and dissolution.

Activation of factor XII (Hageman factor) simultaneously initiates a fast cascade of reactions that result in clot formation and a fast cascade of reactions that result in plasmin activation. Plasmin, which is trapped in the clot, subsequently slowly dissolves the clot. This action removes the clot when it is no longer needed after the vessel has been repaired.

© Cengage Learning, 2013

sue plasminogen activator (tPA) from the tissues, especially the lungs. Normally, the low level of fibrin formation is counterbalanced by a low level of fibrinolytic activity, so inappropriate clotting does not occur. Only when a vessel is damaged do additional factors precipitate the explosive chain reaction that leads to more extensive fibrin formation and results in local clotting at the site of injury.

Inhibition of clotting is also a predatory adaptation in blood-sucking parasites. See *A Closer Look at Adaptation: Vampires and Medicine* (p. 400).

Hemocytes and hemolymph proteins provide hemostasis in arthropods

Hemostasis mechanisms also exist in animals with hemolymph systems, but these processes are not nearly as well understood. In arthropods such as insects and horseshoe crabs, wounds in the exoskeleton trigger coagulation of the hemolymph in part by the conversion of the hemolymph protein *coagulogen* into *coagulin* in a mechanism similar to fibrinogen–fibrin conversion. Hemolymphs contain a variety of cells collectively called **hemocytes** (about 30 to 50 million per milliliter). Some of these (called *hyaline hemocytes*), when triggered by a wound, release enzymes for coagulin formation and protein strands, which interact with a variety of dissolved hemolymph proteins to form insoluble clots at the wound site. Molecular analysis reveals that one of these proteins is related to mammalian clotting factor XIII (the cross-linking enzyme), but the other proteins are different. Remarkably, recent analysis of barnacle glue by Daniel Rittschof and colleagues has found that one of its key proteins is also very similar to the same cross-linking factor XIII. Barnacles apparently use a clotlike cross-linking of proteins to adhere the animals tightly to rocks, whale skin, and the hulls of ships.

A Closer Look at Adaptation

Vampires and Medicine

Most animals have hemostatic mechanisms involving coagulation or clotting of circulatory fluids. This is clearly a crucial survival mechanism because wounds to the skins or exoskeletons of animals are a common occurrence. But there are certain animals whose survival depends on thwarting hemostasis. These are the external parasites and predators that latch onto the outer surface of another (usually larger) animal and suck its blood as a source of nutrition. These include ticks, mosquitoes, kissing bugs, leeches, and vampire bats. Such parasites must prevent clotting, or they will not get much of a meal. Thus, these blood-

suckers have evolved anticlotting substances. These compounds are of great interest to medical researchers because many strokes and heart attacks in humans are caused by pathological clots. These natural anticlotting agents may help stop or dissolve these life-threatening clots. For example, the medical leech *Hirudo medicinalis* makes a compound called **hirudin**, which inhibits the enzymatic activity of **thrombin** (see main text). Hirudin is being used to treat stroke victims. The most recent discovery involves the Australian vampire bat, *Desmodus rotundus*. This animal, which latches onto its prey and sucks large quanti-

© Michael & Patricia Fogden/CORBIS

A vampire bat.

ties of blood, makes a salivary **plasminogen activator** called **desmoteplase**. By activating plasmin, it leads to the destruction of fibrin at a rate hundreds of times faster than existing drugs. Desmoteplase is currently being tested in human stroke patients. To learn how kissing bugs use yet another anti-clotting mechanism, see p. 568.

The arthropod clot system can also be induced by bacterial invasion. Because of this, a horseshoe crab's hemolymph extract is required by U.S. law to be used by the pharmaceutical and medical device industries to test their products for bacterial contamination. Exposure of a contaminated drug, for example, to horseshoe crab extract will rapidly cause the extract to gel into a clot, making a testing process that is much faster and more reliable than other methods.

check your understanding 9.3

Describe the key events of clotting (without naming every step) and the role of positive feedback.

What mechanisms keep platelet plugs and clots from spreading inappropriately?

Paul Yanney

A grasshopper has a heart with an open circulatory system, but its main heart stops pumping when the animal is moving. This is because movements of the body wall and limbs are sufficient to pump the blood during locomotion.

9.4 Circulatory Pumps: Evolution

Circulating body fluids require some form of pump. Here we will look at different types.

Pumping mechanisms include flagella, extrinsic skeletal muscles, peristaltic muscular pumps, and hearts (chamber muscle pumps)

At least four different types of pumping mechanisms have evolved, as follows:

1. **Flagella:** Internal fluids may be moved slowly by beating flagella on epithelial cells. We have seen how flagella do this in sponges, where the fluid is environmental water (Figure 9-1a). In echinoderms such as sea urchins, which have an internal fluid in their main body cavity, the *coelom*, flagella of epithelial cells create slow currents.
2. **Extrinsic muscle or skeletal pumps:** Fluids may be moved by motions of muscles or skeletal elements that are not part of the circulatory system itself. Most often, extrinsic pumping occurs only during locomotion. For example, a seastar's body-wall muscles function mainly to move the flexible arms, but they also cause the coelomic fluid to move. Various body-wall and exoskeletal muscle movements in arthropods similarly enhance circulation of hemolymph. In fact, in grasshoppers the primary heart only beats when the animal is inactive! Apparently, it is not needed when extrinsic pumping is working. Active skeletal muscles of vertebrates can also push circulatory fluids in vessels adjacent to or within them (Figure 9-15a). This is an important mechanism in tails of hagfish and legs of tall animals such as humans, for example. In both, flow is aided by active skeletal muscles squeezing blood through one-way valves in

veins and by the action of the respiratory muscles in breathing. We discuss both processes later (p. 448).

A final example of extrinsic pumping involves skeletal and connective elements. Some mammals with hooves (*perissodactyls* such as rhinoceros and horse) have a cartilaginous plate, the “frog” or *cuneus ungulae*, at the base of the hoof that is flexed upward with each footstep (Figure 9-15b). This flexing pushes on an overlying elastic cushioning tissue that is compressed and moves outward, expanding nearby cartilage and the hoof walls. It also compresses nearby veins, sending blood into the leg above. When the foot is lifted, elastic rebound of these tissues draws blood into the local veins. This pumping action is particularly important in horses, with their long, thin legs, because they do not have enough skeletal muscle mass below the knee to act as extrinsic muscle pumps. Gravity provides the direct energy for flexing the plate, although this gravitational energy originated from upper limb muscles, which lift the limb off the ground.

3. **Peristaltic (tubular) muscle pumps:** Peristaltic pumping occurs when muscles in the walls of vessels contract in a moving wave that pushes fluid in front of it. By repeated cycles of this action, fluid is moved in one direction. These pumps are called “hearts” if they occur in specialized sections of vessels. This is the pumping method in many annelids such as earthworms, where regions of dorsal blood vessels are specialized for this purpose (Figure 9-15c). Many arthropods also have peristaltic hearts.
4. **Chamber muscle pumps:** These are the more familiar form of hearts, consisting of a chamber or chambers with muscles to squeeze the fluid within. Chamber hearts are the primary pumps in all vertebrates and many arthropods and mollusks. Unlike directional peristaltic pumps, chamber pumps usually need one-way valves to create flow in one direction to prevent back-flow when the pump relaxes (Figure 9-15d). In some animals such as arthropods, the heart has a single chamber. But many chamber hearts such as those of most mollusks and all vertebrates have (at a minimum) two types of chambers: an **atrium**, which collects returning fluid, and a **ventricle** that provides the primary force for outgoing fluid. (As you will see, there are three or more chambers in more complex hearts.)

FIGURE 9-15 Types of pumps in animals. (a) External muscle pump expands and compresses a blood vessel (double-headed arrows) and forces blood to flow along the vessel (right-pointing arrows); valves maintain a unidirectional flow, e.g., in nematodes, scaphopod mollusks, and some leeches with no heart to propel blood flow, and the skeletal muscle pump of vertebrates. (b) Structure of the horse foot. The cartilaginous “frog” is pushed by the weight of the horse to aid pumping of the blood (see main text). (c) Peristaltic tubular heart forces blood along a vessel (which may have valves to ensure one-way flow) by peristaltic contractions, e.g., insect heart. (d) A chambered heart propels blood by a coordinated contraction of the muscular wall; valves ensure a one-way flow of blood, e.g., most mollusk and vertebrate hearts.

Many animals have primary hearts aided by auxiliary pumps

Peristaltic or chamber hearts are found in most animal groups more advanced than flatworms (although there are major exceptions, such as nematodes and echinoderms, which have no hearts). Interestingly, most of these animals have both a primary (often called **systemic**) heart that drives the initial, usually oxygenated fluid to most organs, and one or more **auxiliary** pumps that aid flow returning to the primary heart or flow going to critical organs. We have already noted how extrinsic pumping by body walls, skeletal muscles, and skeletal elements can aid flow during locomotion. But some animals have true nonextrinsic auxiliary hearts:

- *Cephalopods*, the only mollusks with a closed system, have a systemic heart and two auxiliary hearts that boost flow to their gills (Figure 9-16a).
- Most *vertebrates* have two or more *lymph hearts* (Figure 9-16b), part of a separate circulatory pathway, the *lymphatic system*, which we discuss later (p. 444). *Hagfish* have several auxiliary hearts; the *caudal heart* in their tails has a chamber that is squeezed by a cartilaginous rod, which in turn is pushed by extrinsic skeletal muscles.
- *Insects* often have auxiliary hearts at the base of legs, wings, and antennae (Figure 9-16c).

FIGURE 9-16 Examples of auxiliary hearts. (a) Diagram of the closed circulatory system of a cephalopod circulatory system. These animals have two branchial hearts that pump blood to the gills, in addition to a main systemic heart. (b) Diagram of a lymph heart in an eel. Muscles in the heart wall push lymph from the caudal lymphatic sinus into the caudal venous sinus. (c) Diagram of the open circulatory system of an insect. A main dorsal vessel (aorta) carries blood from the heart into side channels and open spaces. Flow to the wings is boosted by auxiliary pumps called *pulsatile organs* (PO). Septa (S) in the limbs channel flow through the spaces in specific directions.

Arthropod systemic hearts are dorsally located and have many valved openings

Crustaceans, insects, and arachnids (the major arthropod groups) have many similarities in their primary hearts. Each is located in a dorsal region of the body, and each has one or more porelike openings called **ostia** (singular, **ostium**), which allow hemolymph to reenter the heart after passing

through the body (Figure 9-2b). The ostia often have **one-way valves** to prevent backflow (you will see how this type of valve works in a mammalian example later).

However, there are some differences. Crustacean hearts, present mainly in larger species such as decapods (lobsters, crabs, and so on), are single-chamber pumps, whereas insect and arachnid hearts are tubular (modified vessels) and can have peristaltic pumping.

Vertebrate systemic hearts evolved from a two-chambered to a four-chambered structure

The primitive systemic heart of vertebrates is thought to have begun with two chambers, one atrium to collect returning blood and one ventricle to pump to the body. Fishes have this basic design, but one or two auxiliary chambers have evolved. Blood of all jawless and jawed fishes first enters a chambered extension of the atrium called the **sinus venosus**, which collects blood from the veins before entering the adjacent atrium. In jawed fishes, blood leaving the ventricles enters an extension forming a fourth chamber, the **conus arteriosus** (in cartilaginous fish) or **bulbus arteriosus** (in bony fish), which dampens the pulsatile pressure output of the ventricle (a function taken over by the **aorta** in reptiles (including birds) and mammals, in a process we describe on p. 430). Although these fish hearts have four chambers, they are considered to have two primary chambers with two auxiliary chambers (see Figure 9-17 for a cartilaginous fish).

A significant change in vertebrate hearts began when the first air-breathing fishes evolved. The crucial feature that drove this change was the evolution of a separate circuit, called the **pulmonary circulation**, from the heart to the newly evolved lungs and back. The two primary chambers began to subdivide with internal septa to support this separate circuit, with one side of the atrium collecting blood from the body and one side collecting from the lungs, and with one side of the ventricle pumping blood to the lungs and one side pumping to the body. This culminated in the hearts of birds and mammals, which have two completely separate atrium-ventricle pairs, which pump to the pulmonary circulation to the lungs and the **systemic circulation** to the rest of the body. We describe these evolutionary changes and the flow patterns in more detail in the next section of this chapter, on circulatory pathways and vessels.

Avian and mammalian hearts are dual pumps

Even though anatomically the heart is a single organ, in birds and mammals there are separate right and left sides that act as two separate pumps (we examine the hearts of other vertebrates later). Indeed they begin in embryos as *two separate hearts that fuse together*. These hearts have four chambers, an upper and a lower one, within each half (Figure 9-18a). The upper chambers, the **atria** (singular, **atrium**), receive blood returning to the heart and transfer it to the lower chambers, the **ventricles**, which pump the blood from

FIGURE 9-17 Diagram of an elasmobranch heart. Venous blood enters the sinus venosus (upper right) and is then pumped by the atrium, ventricle, and bulbus cordis into the aorta (lower left).

Source: P. Withers. (1992). *Comparative Animal Physiology*. Belmont, CA: Brooks/Cole; as modified from A. J. Waterman, B. E. Frye, K. Johansen, et al. (1971). *Chordate Structure and Function*. New York: Macmillan.

the heart. The vessels that return blood from the tissues to the atria are **veins**, and those that carry blood away from the ventricles to the tissues are **arteries**. The two halves of the heart are separated by the **septum**, a continuous muscular partition that prevents mixture of blood from the two sides of the heart. This separation is extremely important, because the right half of the heart is receiving and pumping O_2 -depleted CO_2 -rich blood whereas the left side of the heart receives and pumps O_2 -rich CO_2 -poor blood.

Let's examine how the heart functions as a dual pump by tracing a drop of blood through one complete circuit in a mammal (Figure 9-18b). Blood returning from the systemic circulation enters the right atrium via large veins known as the **venae cavae**. The drop of blood entering the right atrium has returned from the body tissues, where O_2 has been extracted from it and CO_2 has been added to it. This partially deoxygenated blood flows from the right atrium into the right ventricle, which pumps it out through the **pulmonary artery** to the lungs. Thus, *the right side of the heart pumps blood into the pulmonary circulation*. Within the lungs, the drop of blood loses its extra CO_2 and picks up a fresh supply of O_2 before being returned to the left atrium via the **pulmonary veins**. This O_2 -rich blood returning to the left atrium subsequently flows into the left ventricle, the pumping chamber that propels the blood to all body systems except the pulmonary circulation of the lungs; that is, *the left side of the heart pumps blood into the systemic circulation*. The large artery carrying blood away from the left ventricle is the **aorta** (Figure 9-18a). Major arteries branch from the aorta to supply the various tissues of the body.

Both sides of the heart simultaneously pump equal amounts of blood. The pulmonary circulation is a low-pressure, low-resistance system, whereas the systemic circulation is a high-pressure, high-resistance system. Therefore, even though the right and left sides of the heart pump the same amount of blood, the left side performs more work

because it pumps an equal volume of blood at a higher pressure into a higher-resistance system. Accordingly, the heart muscle on the left side is much thicker than the muscle on the right side, making the left side a stronger pump (Figure 9-18c).

This left–right difference leads to difficulties in rapidly growing animals, such as broiler chickens. Oxygen usage by the growing tissues reduces oxygen in the blood. In response, the volume of blood pumped by the left ventricle increases to restore oxygen delivery. The right ventricle must in turn work harder, and it hypertrophies (grows larger). However, for unclear reasons, the right ventricle's growth does not keep pace with the growth of the body, so the ventricle becomes unable to maintain sufficient pressure to propel the entire blood flow. Eventually, the overstressed right ventricle is unable to take in and pump returning blood, resulting in life-threatening **edema** (fluid accumulation) in various organs, a condition termed **ascites syndrome**. Current research is focused on selecting strains of chickens resistant to developing this condition. A similar phenomenon, called **brisket disease**, occurs in cattle and horses that spend some time at high altitudes and then return to low altitude.

Heart valves ensure that the blood flows in the proper direction through the heart

As you have seen, blood flows through vertebrate hearts in one fixed direction through the heart. The presence of one-way valves ensures this unidirectional flow of blood. Heart valves are positioned so that they open and close passively because of pressure differences, similar to a one-way door (Figure 9-19). A forward pressure gradient (that is, a greater pressure behind the valve) forces the valve open, much as you open a door by pushing on one side of it, whereas a backward pressure gradient (that is, a greater pressure in front of the valve) forces the valve closed, just as you apply pressure to the opposite side of the door to close it. (Functionally similar valves are found in arthropod heart ostia, as you saw earlier.)

These valves are in all vertebrate hearts; two are shown in a cartilaginous fish in Figure 9-17. Let us examine these valves more closely in mammals, which have four (Figure 9-20). The **right** and **left atrioventricular (AV) valves** are positioned between the atrium and the ventricle on the right and left sides, respectively. These valves allow one-way flow from the atria into the ventricles during ventricular filling (when atrial pressure exceeds ventricular pressure). The other two valves, the **aortic** and **pulmonary valves**, are located at the juncture where the major arteries leave the ventricles. They are known as **semilunar** (“half-moon”) valves because they consist of three cusps, each resembling a shallow half-moon-shaped pocket. These valves are forced open when the left and right ventricular pressures exceed the pressure in the aorta and pulmonary arteries, respectively, during ventricular contraction and emptying. Closure results when the ventricles relax and ventricular pressures fall below the aortic and pulmonary artery pressures.

Even though there are no valves between the atria and veins, backflow into the veins usually is not a significant problem, because (1) atrial pressures are not much higher than venous pressures, and (2) the junctions of the veins and atria are partially compressed during atrial contraction.

Vertebrate heart walls are composed primarily of spirally arranged cardiac muscle fibers interconnected by intercalated discs

The bulk of the vertebrate heart wall is the **myocardium** (*myo*, “muscle”), a middle layer of cardiac muscle lying between an endothelial layer (the **endocardium**) and a thin outer sheath, the **epicardium**. In mammals, the myocardium consists of interlacing bundles of cardiac muscle fibers arranged spirally around the heart circumference. As a result of this arrangement, when the ventricular muscle contracts, the diameter of the ventricular chambers is reduced while

the apex is simultaneously pulled upward toward the top of the heart in a rotating manner. This “wringing” effect efficiently exerts pressure on the blood within the chambers and directs it upward to the arteries that exit the ventricles.

The individual cardiac muscle cells are interconnected to form branching fibers, with adjacent cells joined end-to-end at specialized structures known as **intercalated discs**. Within an intercalated disc are two types of membrane junctions we saw in Chapter 2: *desmosomes* and *gap junctions* (Figure 9-21). Recall that desmosomes are a type of adhering junction that mechanically holds cells together under high mechanical stress, whereas gap junctions are channels

FIGURE 9-21 Organization of mammalian cardiac muscle fibers. Bundles of cardiac muscle fibers are arranged spirally around the ventricle. Adjacent cardiac muscle cells are joined end to end by intercalated discs, which contain two types of specialized junctions: desmosomes, which act as spot rivets mechanically holding the cells together, and gap junctions, which permit action potentials to spread from one cell to adjacent cells.

that allow action potentials to spread from one cardiac cell to the next (see pp. 65–67).

As we explore later, electrical impulses trigger heart contraction. Once initiated, an impulse spreads to all the other cells that are joined by gap junctions so that they contract as a single functional **syncytium** (a group of joined cells acting as one functional unit). Vertebrate atrial and ventricular muscles form separate syncytia; each contracts synchronously to produce the force necessary to eject the enclosed blood. However, an impulse starting in the right atrium will spread to the rest of the heart. Therefore, unlike skeletal muscle, where graded contractions can be produced by varying the number of muscle cells that are contracting within the muscle (recruitment of motor units), either all the cardiac muscle fibers contract or none do. A “half-hearted” contraction is not possible.

Cardiac muscle cells in most vertebrates have two features that indicate how much the energy for contraction relies on aerobic metabolism: (1) 30–50% by volume of mitochondria, the O_2 -dependent energy organelles (see p. 47); and (2) an abundance of *myoglobin* (p. 533), which stores limited amounts of O_2 for immediate use, and also facilitates the diffusion of O_2 arriving at the cell to the mitochondria for rapid processing.

What are intercalated discs and their functions?

9.5 Circulatory Pumps: Heart Electrical Activity

Now that you’ve learned the basic anatomy of hearts, we turn to the electrical control of beating. Contraction of cardiac muscle cells to bring about ejection of blood is triggered by *action potentials* (p. 116) sweeping across the muscle cell membranes. Many animal hearts have a small number of **autorhythmic** or **pacemaker cells**, which do not contract but instead are specialized for repeatedly initiating the action potentials responsible for contraction of the contractile cells. Hearts that have pacemaker cells are called **myogenic** (“generating from muscle”), and are found in many animals including all vertebrates, tunicates (Urochordates), insects, and some mollusks and crustaceans. They are presumably advantageous because they ensure blood or hemolymph flow even if there is severe neural trauma. (However, myogenic insect hearts appear to be largely under the control of external neural stimuli under normal circumstances.) Some crustaceans such as decapods (crabs, lobsters, and so on) have **neurogenic** hearts, which do not beat without an external neural stimulus. This type of regulation may allow for a heart to be stopped completely in animals that do not need continuous circulatory flow in some situations (see also the grasshopper on p. 400).

Pacemaker cells have channels that cyclically move them to “firing” threshold

Let's examine the role of the pacemaker cells in the origin and spread of a heartbeat. In contrast to most nerve and skeletal muscle cells, in which the membrane remains at constant resting potential unless the cell is stimulated (see p. 116), the cardiac pacemaker cells do not have a stable resting potential. Instead, their membrane potential slowly depolarizes, or drifts, between action potentials until threshold is reached, at which time the membrane “fires,” that is, has an action potential (Figure 9-22). Through repeated cycles of drifting and firing, these autorhythmic cells cyclically initiate action potentials, which then spread throughout the heart to trigger rhythmic beating without any nervous stimulation.

Consider how this coordinates pumping in an insect (as in Figure 9-16c). Pacemaker activity dominates in the most posterior segment of the dorsal heart and spreads forward into the anterior aorta. This ensures that contraction moves in a wave from posterior to anterior for proper hemolymph flow.

Pacemaker Potential and Action Potential in Autorhythmic Cells Complex interactions of several different ionic mechanisms are responsible for the **pacemaker potential**, which is an autorhythmic cell membrane's slow drift to threshold. The most important changes in ion movement that give rise to the mammalian pacemaker potential are (1) an increased inward Na^+ current, (2) a decreased outward K^+ current, and (3) an increased inward Ca^{2+} current (Ca^{2+} influx is also essential to cardiac action potentials in insects). Let's examine the details:

1. The initial phase of the slow depolarization to threshold is caused by net Na^+ entry through a type of voltage-gated Na^+ channel—an **HCN** or **hyperpolarization-activated cyclic nucleotide-gated channel**—found only in cardiac pacemaker cells and some neurons. Most ion channels open when the membrane becomes less negative (depolarizes), but these unique channels open when the potential becomes more negative (hyperpolarizes) at the end of repolarization from the previous action potential. Because of their unusual behavior, currents through HCN channels are called **funny**, or I_f , currents (recall that “I” refers to current in Ohm's Law, p. 115). When one action potential ends and the HCN channels open, the resultant inward I_f Na^+ current starts immediately moving the pacemaker cell's membrane potential toward threshold once again.
2. At the same time, a progressive reduction occurs in the passive outward flux of K^+ . Unlike in neurons and skeletal muscles, the cardiac K^+ channels that opened during the falling phase of the preceding action potential slowly close at negative potentials. This slow closure gradually diminishes the outflow of positive potassium ions down their concentration gradient. Thus, K^+ efflux slowly declines at the same time as the inward leak of Na^+ , adding to the drift toward threshold.
3. Finally, increased Ca^{2+} entry occurs in the second half of the pacemaker potential, as the HCN channels close and **transient** Ca^{2+} channels (**T-type Ca^{2+} channels**) open before the membrane reaches threshold. The resultant brief influx of Ca^{2+} further depolarizes the membrane, bringing it to threshold, at which time these Ca^{2+} channels close. At threshold, the rapid rising phase of the

FIGURE 9-22 Pacemaker activity of mammalian cardiac autorhythmic cells. The first half of the pacemaker potential (1) is the result of simultaneous opening of the funny (f or HCN) channels, which permit inward Na^+ current, and closure of the K^+ channels, which reduce outward K^+ current. The second half of the pacemaker potential (2) is the result of opening of T-type Ca^{2+} channels. Once threshold is reached (green dashed line), the action potential rise (3) results from opening of L-type Ca^{2+} channels; the falling phase (4) results from the opening of K^+ channels.

© Cengage Learning, 2013

action potential occurs from voltage-activation of a second class of Ca^{2+} channel, the **long-lasting (L-type Ca^{2+} channel)** type, which produces a large influx of Ca^{2+} (in contrast to the rising phase resulting from Na^+ influx in neurons and skeletal muscles).

The falling phase is the result, as usual, of the K^+ efflux that occurs when K^+ permeability increases on activation of voltage-gated K^+ channels, coupled with closure of the L-type Ca^{2+} channels. (Inhibited function of these K^+ channels, resulting from a genetic mutation or drugs such as *erythromycin*, interferes with repolarization and has been shown to cause sudden cardiac arrest in horses and humans.)

The sinoatrial node is the normal pacemaker of the vertebrate heart

The specialized, noncontractile cardiac cells capable of autorhythmicity are found in several locations in vertebrate hearts (Figure 9-23a). The main sites are as follows:

- The **sinoatrial node (SA node)**, a small, specialized region in the right atrial wall in reptiles (including birds) and mammals. In fishes and amphibians, the equivalent of the SA node lies in the wall of the **sinus venosus**.
- The **atrioventricular node (AV node)**, a small bundle of specialized cardiac muscle cells located at the base of the right atrium near the septum, just above the junction of the atria and ventricles.

FIGURE 9-23 Specialized conduction system of the mammalian heart and spread of cardiac excitation.

An action potential initiated at the SA node first spreads throughout both atria. Its spread is facilitated by two specialized atrial conduction pathways, the interatrial and internodal pathways. The AV node is the only point where an action potential can spread from the atria to the ventricles. From the AV node, the action potential spreads rapidly throughout the ventricles, hastened by a specialized ventricular conduction system consisting of the bundle of His and Purkinje fibers.

© Cengage Learning, 2013

In all vertebrates, the **SA node** (or sinus venosus node) normally exhibits the fastest rate of autorhythmicity, inherently at 90 to 100 action potentials per minute in humans, and drives the rest of the heart at this rate. Thus, it is the main pacemaker of the heart, which excites the entire heart, triggering the contractile cells to contract (and thus the heart to beat) at the pace set by pacemaker autorhythmicity. The AV node does not assume its own naturally slower rate, because it is activated by action potentials generated from the SA node before it reaches threshold at their own slower rhythm.

The spread of cardiac excitation is coordinated to ensure efficient pumping

Once initiated in the SA node, an action potential spreads throughout the rest of the heart. For efficient cardiac function, the spread of excitation achieves the following:

1. **Atrial excitation and contraction is complete before the onset of ventricular contraction.** This ensures complete ventricular filling. During cardiac relaxation, the AV valves are open so that venous blood entering the atria continues to flow directly into the ventricles. Most ventricular filling occurs by this means prior to atrial contraction. When the atria do contract, additional blood is squeezed into the ventricles to complete ventricular filling. Only then does ventricular contraction eject blood into the arteries.
2. **Excitation of cardiac muscle fibers is coordinated to ensure that each heart chamber contracts as a unit to accomplish efficient pumping.** If the muscle fibers in a heart chamber were to become excited and contract randomly rather than contracting simultaneously in a

coordinated fashion, they would be unable to eject blood. A smooth, uniform ventricular contraction is essential. In contrast, random, uncoordinated excitation and contraction is known as **fibrillation**. Ventricular fibrillation rapidly causes death because the heart cannot pump blood into the arteries.

3. **The pair of atria and pair of ventricles are coordinated so that both members of the pair contract simultaneously.** This permits synchronized pumping of blood into the pulmonary and systemic circulation.

The normal spread of cardiac excitation is carefully orchestrated to achieve these three events, as described next (Figure 9-23b):

1. **Atrial excitation:** An action potential originating in the SA node first spreads throughout both atria, primarily from cell to cell via gap junctions. The signal appears to spread symmetrically, ensuring synchronized atrial contraction.
2. **Transmission between the atria and the ventricles:** The AV node is the only point of electrical contact between the atria and ventricles; other connections consist of electrically nonconductive fibrous tissue. In the AV node, the impulse is delayed about 0.1 second (the **AV nodal delay**), which enables the atria to become completely depolarized and to contract, emptying their contents into the ventricles, before ventricular contraction occurs.
3. **Ventricular excitation:** After the AV nodal delay, the impulse travels rapidly along two specialized tracts (Figure 9-23b):
 - The **bundle of His** (atrioventricular bundle), a tract of specialized autorhythmic cells that originates at

the AV node and enters the interventricular septum, where it divides to form the right and left bundle branches that travel down the septum, curve around the tip of the ventricular chambers, and travel back toward the atria along the outer walls.

- **Purkinje fibers**, small terminal fibers that extend from the bundle of His and spread through some (in most mammals) or all (in ruminants) of the ventricular myocardium, much like small twigs of a tree branch.

The network of fibers in this ventricular conduction system is specialized for rapid propagation of action potentials to ensure that the ventricles contract as a unit. Although this system carries the action potential rapidly to a large number of cardiac muscle cells, it does not terminate on every cell. The impulse quickly spreads from the excited cells to the remainder of the ventricular muscle cells by means of gap junctions. Altogether, these conduction steps lead to almost simultaneous activation of the ventricular myocardial cells in both ventricular chambers, efficiently ejecting blood into the systemic and pulmonary circulations simultaneously.

The action potential of contractile cardiac muscle cells shows a characteristic plateau

The action potential in contractile cardiac muscle cells, although initiated by the nodal pacemaker cells, varies considerably in ionic mechanisms and shape from the SA node potential (compare Figures 9-22 and 9-24). Unlike autorhythmic cells, contractile cells remain essentially at rest until excited by electrical activity from the pacemaker. Once a myocardial contractile cell is excited, an action potential is generated by a complicated interplay of permeability changes and membrane potential changes as follows (Figure 9-24):

1. During the rising phase of the action potential, the membrane potential rapidly climbs to about +20 mV to +30 mV as a result of activation of voltage-gated Na^+ channels. At peak potential, the Na^+ permeability then rapidly plummets. This is essentially identical to events in neurons and skeletal muscle, using the same channels (see pp. 117–120).
2. At peak potential, another subclass of K^+ channels transiently opens. The resultant limited efflux of K^+ through these transient channels brings about a brief, small repolarization as the membrane becomes slightly less positive.
3. Unique to cardiac muscle cells, the membrane potential is maintained at this near peak positive level for several hundred msec (compared to 1 to 2 msec in neurons and skeletal muscles), producing a **plateau phase**. This plateau, which prolongs contraction for squeezing the heart chambers, is maintained by two voltage-dependent permeability changes triggered by the sudden voltage change during the rising phase of the action potential: activation of “slow” L-type Ca^{2+} channels and a marked decrease in K^+ permeability. Because Ca^{2+} is in greater concentration in the ECF, opening of the L-type Ca^{2+} channels results in a slow, inward diffusion of Ca^{2+} that prolongs the positivity inside the cell. This effect is enhanced by the concomitant decrease in K^+ permeability on closure of both the briefly opened transient K^+ channels and the leaky K^+ channels open at resting potential.

FIGURE 9-24 Action potential in mammalian contractile cardiac muscle cells. The action potential in cardiac contractile cells differs considerably from the action potential in cardiac autorhythmic cells (compare with Figure 9-22). The rapid rising phase of the action potential in contractile cells is the result of Na^+ entry on opening of fast Na^+ channels at threshold. The early, brief repolarization after the potential reaches its peak is because of limited K^+ efflux on opening of transient K^+ channels, coupled with inactivation of the Na^+ channels. The prolonged plateau phase is the result of slow Ca^{2+} entry on opening of L-type Ca^{2+} channels, coupled with reduced K^+ efflux on closure of several types of K^+ channels. The rapid falling phase is the result of K^+ efflux on opening of ordinary voltage-gated K^+ channels, as in other excitable cells. Resting potential is maintained by opening of leaky K^+ channels.

© Cengage Learning, 2013

4. The rapid falling phase of the action potential results from inactivation of the Ca^{2+} channels and delayed activation of “ordinary” voltage-gated K^+ channels, yet another subclass of K^+ channels identical to the ones in neurons and skeletal muscle cells. As the inward movement of Ca^{2+} stops, the sudden increase in K^+ permeability simultaneously promotes rapid outward movement of positive K^+ . Thus, as in other excitable cells, the cell returns to resting potential as K^+ leaves the cell. At resting potential, the voltage-gated K^+ channels close and the leaky K^+ channels open once again.

Let’s now see how this action potential brings about contraction.

Ca^{2+} entry from the ECF induces a much larger Ca^{2+} release from the sarcoplasmic reticulum

In cardiac contractile cells, the L-type Ca^{2+} channels lie primarily in the *T tubules* (p. 343), opening during a local action potential. Thus, unlike in skeletal muscle, Ca^{2+} moves into the cytosol from the ECF across the T tubule membrane in cardiac muscle. This entering Ca^{2+} triggers the opening of

nearby *ryanodine* Ca^{2+} -release channels in the lateral sacs of the sarcoplasmic reticulum (SR; see p. 343). By means of this so-called **Ca^{2+} -induced Ca^{2+} release**, Ca^{2+} entering the cytosol from the ECF induces a much larger release of Ca^{2+} from the intracellular stores into the cytosol. The resultant local bursts of Ca^{2+} release, known as *Ca^{2+} sparks*, collectively increase the cytosolic Ca^{2+} pool sufficiently to turn on the contractile machinery. Ninety percent of the Ca^{2+} needed for muscle contraction comes from the SR. This extra supply of Ca^{2+} , coupled with slow Ca^{2+} removal processes, causes the prolonged period of cardiac contraction, which lasts about three times longer than the contraction of a single skeletal muscle fiber (300 msec compared to 100 msec).

As in skeletal muscle, Ca^{2+} within the cytosol binds with the troponin-tropomyosin complex and causes it to move aside to allow cross-bridge cycling (p. 344). However, unlike skeletal muscle, in which sufficient Ca^{2+} is always released to turn on all the cross bridges, in cardiac muscle the extent of cross-bridge activity varies with the amount of cytosolic Ca^{2+} . As you will learn, various regulatory factors can alter the amount of cytosolic Ca^{2+} . Removal of Ca^{2+} from the cytosol by active transport in both the plasma membrane and SR restores the blocking action of troponin and tropomyosin so that contraction ceases and the heart muscle relaxes.

Tetanus of cardiac muscle is prevented by a long refractory period

Like other excitable tissues, cardiac muscle has a *refractory period*. Recall that this occurs immediately after an action potential and makes it impossible or very difficult for another action potential to be generated (p. 124). In skeletal muscle, the refractory period is very short compared with the duration of the resultant contraction, so the fiber can be restimulated again before the first contraction is complete to produce summation of contractions, resulting in a sustained, maximal contraction known as *tetanus* (see Figure 8-16, p. 352).

In contrast, cardiac muscle has a long refractory period that lasts about 250 msec. This is almost as long as the period of contraction (Figure 9-25). Consequently, cardiac muscle cannot be restimulated until contraction is almost over, making summation of contractions and tetanus of cardiac muscle impossible. This is a valuable protective mechanism because a prolonged tetanic contraction would prove fatal. (Think about why.)

The chief factor responsible for the long refractory period is inactivation, during the plateau phase, of the Na^+ channels that were activated during the initial Na^+ influx of the rising phase. Not until the membrane recovers from this inactivation process (when the membrane has already repolarized to resting), can the Na^+ channels be activated once again to begin another action potential (compare to neurons, pp. 124–125).

Methodology: The Electrocardiogram (ECG) The electrical currents generated by cardiac muscle during depolarization and repolarization spread into the tissues surrounding the heart and are conducted through the body fluids. A small portion of this electrical activity reaches the body surface, where it can be detected using recording electrodes on the skin, generally on limbs (Figure 9-26a) and/or chest (al-

FIGURE 9-25 Relationship of an action potential and the refractory period to the duration of the contractile response in cardiac muscle.

© Cengage Learning, 2013

though on horses they may be placed on the neck and shoulder). It can also be detected with internally implanted devices. The record produced is an **electrocardiogram**, or **ECG**. (Alternatively, the term **EKG** is used, from the ancient Greek “kardia” instead of “cardia” for *heart*.) Two important points should be remembered when analyzing an ECG:

1. It is a recording of that portion of the electrical activity induced in the body fluids by the cardiac impulse that reaches the surface of the body, not a direct recording of the actual electrical activity of the heart.
2. It is a complex recording representing the sum of electrical activity spreading throughout all of the heart's muscle cells during depolarization and repolarization.

A normal vertebrate ECG exhibits three distinct wave-forms (Figure 9-26b and d), as follows:

- The **P wave** represents atrial depolarization.
- The **QRS complex** represents ventricular depolarization.
- The **T wave** represents ventricular repolarization.

(These letters do not signify anything; the founder of the technique simply started in the middle of the alphabet when naming the waves.) The following important points about the ECG record should also be noted:

1. Firing of the SA node does not generate sufficient electrical activity to reach the surface of the body, so no wave is recorded for SA nodal depolarization. Therefore, the first recorded wave, the P wave, occurs when the impulse spreads across the atria.
2. No separate wave is detected for atrial repolarization, because that normally occurs simultaneously with ventricular depolarization and is masked by the QRS complex.

Source: L. A. Geddes. (2002). Electrocardiograms from the turtle to the elephant that illustrate interesting physiological phenomena. *Pacing and Clinical Electrophysiology* 25:1762–1770, Figure 12.

3. The P wave is much smaller than the QRS complex because the atria have a much smaller muscle mass than the ventricles and thus generate less electrical activity.
4. There are three times when no current is flowing in the heart musculature and the ECG remains at baseline:
 - a. *During the AV nodal delay.* This delay is the interval of time between the end of the P wave and the onset of the QRS wave, and is termed the **PR segment**. (It is not called the PQ segment because the Q deflection is small and sometimes absent.) Current is flowing through the AV node, but it is too weak to be detected by the ECG electrodes.
 - b. *When the ventricles are completely depolarized and the cardiac contractile cells are undergoing the plateau phase of their action potential before they repolarize.* This is represented by the **ST segment**, the interval between QRS and T; during this time, ventricular activation is complete and the ventricles are contracting and emptying.
 - c. *When the heart muscle is completely at rest and ventricular filling is taking place, after the T wave and before the next P wave.* This is called the **TP interval**.

ECG measurements are conducted on humans and domestic animals such as horses to diagnose certain heart problems. For example, a P wave with no subsequent QRST events (a skipped beat) is called an “AV block,” and may be due to damaged conduction fibers. Horses may exhibit such skipped beats occasionally during rest, but a healthy horse never has one during exercise. ECGs are also measured on a variety of other vertebrates as part of physiological monitoring during studies on behavior and effects of temperature, drugs, stress, exercise, and so on (see the example for a goldfish in Figure 9-26c and d).

ECGs have also been measured in arthropods, although the PQRST pattern is not present. One study, using electrodes under the cuticle, demonstrated cephalic control of the housefly’s heart. The ECG of an anesthetized fly had rhythmic variations averaging 133 beats/min. However, when neural input to the heart was eliminated the pattern became highly regular, at a steady 120 beats/min. Thus, the brain was apparently modulating an intrinsic mechanism.

9.6 Circulatory Pumps: Heart Mechanics and the Cardiac Cycle

Now that we've seen the electrical control of the mammalian heart, we turn to the mechanical features, which (usually due to pacemaker activity) occur in a cycle.

Hearts alternately contract in systole to empty and relax in diastole to fill

The *cardiac cycle* in all chamber hearts consists of alternate periods of **systole** (contraction and emptying) and **diastole** (relaxation and filling). In vertebrates, the atria and ventricles go through separate cycles of systole and diastole. Contraction occurs as a result of the spread of excitation (started by the pacemaker) across the heart, whereas relaxation follows the subsequent repolarization of the musculature. The following discussion, again focusing on the mammalian heart, correlates various events that occur concurrently during the cardiac cycle, including pressure changes, volume changes, and valve activity. Look at Figure 9-27 to understand this discussion. Only the events on the left side of the heart are described, but keep in mind that identical events are occurring on the right side of the heart, except that the pressures are lower. Our discussion follows one full cardiac cycle.

Early Ventricular Diastole During early *ventricular* diastole, the atrium is also in diastole. This stage corresponds to the TP interval on the ECG—the resting stage. Because of the continuous inflow of blood from the venous system into the atrium, atrial pressure slightly exceeds ventricular pressure (point 1, Figure 9-27). Because of this differential, the AV valve is open, and blood flows directly from the atrium into the ventricle (heart *a* in Figure 9-27). As a result, the ventricular volume slowly continues to rise even before atrial contraction takes place (point 2).

Late Ventricular Diastole Late in ventricular diastole, the SA node reaches threshold and fires. The depolarization impulse spreads throughout the atria (the ECG P wave) (point 3), triggering atrial contraction, which causes a rise in the atrial pressure curve (point 4) and squeezes more blood into the ventricle. The corresponding rise in ventricular pressure (point 5) is due to this additional blood added from the atria (point 6) (heart *b*). Throughout atrial contraction, atrial pressure still slightly exceeds ventricular pressure, so the AV valve remains open.

End of Ventricular Diastole Ventricular diastole ends at the onset of ventricular contraction. By this time, atrial contraction and ventricular filling are completed. The volume of blood in the ventricle at the end of diastole (point 7) is known as the **end-diastolic volume**, which we will discuss in detail later.

Ventricular Excitation and Onset of Ventricular Systole Following atrial excitation, the impulse passes through the AV node and specialized tracts to excite the ventricle (the ECG QRS complex) (point 8). The ventricular pressure curve sharply increases shortly after the QRS complex, signaling the onset of ventricular systole (point 9). As ventricular contraction begins, ventricular pressure immediately exceeds atrial pressure. This backward pressure differential forces the AV valve closed (point 9).

Isovolumetric Ventricular Contraction After the AV valve has closed, the ventricular pressure must continue to increase before it can open the aortic valve. Therefore, there is a brief period of time when the ventricle remains a closed chamber (point 10). Thus, no blood can enter or leave the ventricle during this time. This interval is termed the period of **isovolumetric ventricular contraction** (*isovolumetric* means “constant volume”) (heart *c*). The muscle fibers remain at constant length, similar to an isometric contraction in skeletal muscle. During this period, ventricular pressure continues to increase as volume remains constant (point 11).

Ventricular Ejection When ventricular pressure finally exceeds aortic pressure (point 12), the aortic valve is forced open and ejection of blood begins (heart *d*). The aortic pressure curve rises as blood is forced into the aorta from the ventricle faster than blood is draining off into the smaller vessels at the other end (point 13). The ventricular volume decreases substantially as blood is rapidly pumped out (point 14). Ventricular systole includes the periods of both isovolumetric contraction and ventricular ejection.

End of Ventricular Systole The ventricle does not empty completely during ejection. Normally, about half the blood contained within a ventricle at the end of diastole is pumped out during the subsequent systole. The amount of blood remaining in the ventricle at the end of systole is known as the **end-systolic volume** (point 15). This is the least amount of blood that the ventricle will contain during this cycle. The amount of blood pumped out of each ventricle with each contraction is known as the **stroke volume**; it is equal to the end-diastolic volume minus the end-systolic volume. As an example, in some horses the end-diastolic volume is 800 mL, the end-systolic volume is 350 mL, and the stroke volume is 450 mL.

Ventricular Repolarization and Onset of Ventricular Diastole The T wave signifies ventricular repolarization occurring at the end of ventricular systole (point 16). As the ventricle starts to relax on repolarization, ventricular pressure falls below aortic pressure and the aortic valve closes (point 17). Closure of the aortic valve produces a disturbance or notch on the aortic pressure curve known as the **dicotic notch** (point 18). No more blood leaves the ventricle during this cycle.

FIGURE 9-27 Mammalian cardiac cycle.

This graph depicts various events that occur concurrently during the cardiac cycle. Follow each horizontal strip across to see the changes that take place in the electrocardiogram; aortic, ventricular, and atrial pressures; ventricular volume; and heart sounds throughout the cycle. Late diastole, one full systole and diastole (one full cardiac cycle), and another systole are shown for the left side of the heart. Follow each vertical strip downward to see what happens simultaneously with each of these factors during each phase of the cardiac cycle. See the text (pp. 412 and 414) for a detailed explanation of the circled numbers. The sketches of the heart illustrate the flow of O_2 -poor (dark blue) and O_2 -rich (bright red) blood in and out of the ventricles during the cardiac cycle.

© Cengage Learning, 2013

Isovolumetric Ventricular Relaxation When the aortic valve closes, the AV valve is not yet open, because ventricular pressure still exceeds atrial pressure, so no blood can enter the ventricle from the atrium. Therefore, all valves are once again closed for a brief period of time known as **isovolumetric ventricular relaxation** (point 19) (heart *e*). The muscle fiber length and chamber volume (point 20) remain constant. No blood moves as the ventricle continues to relax; pressure steadily falls.

Ventricular Filling When the ventricular pressure falls below the atrial pressure, the AV valve opens (point 21), and ventricular filling occurs once again. Ventricular diastole includes the periods of both isovolumetric ventricular relaxation and ventricular filling. Blood continues to flow from the pulmonary veins into the left atrium. As this incoming blood pools in the atrium, atrial pressure rises continuously (point 22); When the AV valve opens at the end of ventricular systole, the blood that accumulated in the repolarizing atrium during ventricular systole pours rapidly into the ventricle (heart *a* again). Ventricular filling thus occurs rapidly at first (point 23) because of the increased atrial pressure resulting from the accumulation of blood in the atria. Then ventricular filling slows down (point 24) as the accumulated blood has already been delivered to the ventricle, and atrial pressure starts to fall. During this period of reduced filling, blood continues to flow from the pulmonary veins into the left atrium and through the open AV valve into the left ventricle. During late ventricular diastole, the SA node fires again (point 25), and the cardiac cycle starts over.

9.7 Circulatory Pumps: Cardiac Output and Its Control

Now that we have examined the heart itself, we turn to its role in the animal body. The most important physiological parameter of a heart is undoubtedly the **cardiac output (C.O.)**: the volume of blood per minute pumped by a heart to the body. (*Note:* Do not confuse C.O. with the gas CO, carbon monoxide.) This flow is responsible for transport needs.

Cardiac output is a product of heart rate and stroke volume

C.O. is a product of two simple factors: *how fast* the heart beats and *how much* volume it pumps per beat. The key formula in any animal is:

C.O. = heart rate × stroke volume
(volume (beats per (volume
per minute) pumped per
minute) beat or stroke)

C.O. values vary tremendously with activity state of an individual animal, and across the animal kingdom. Larger

animals tend to have slower heart rates (see the discussion on scaling in Chapter 15) but larger stroke volumes. To illustrate, let us compare typical values for mammals of different sizes, and a bird and a fish of similar size. (By convention, the C.O. value is that of one ventricle, not the sum of both, in animals having two ventricles; during any period of time, the volume of blood flowing through the pulmonary circulation is equivalent to the volume flowing through the systemic circulation.) As you can see, cardiac output is related to body size and is generally lower in ectotherms, here represented by rainbow trout:

Animal	Cardiac Output	=	Heart Rate	×	Stroke Volume
Blue Whale:	2,100,000 mL/min	=	6 beats/min*	×	350,000 mL/beat
Horse:	13,500 mL/min	=	30 beats/min	×	450 mL/beat
Human:	4,900 mL/min	=	70 beats/min	×	70 mL/beat
Shrew:	1 mL/min	=	1,000 beats/min	×	0.001 mL/beat
Pigeon:	195.5 mL/min	=	115 beats/min	×	1.7 mL/beat
Trout (10°C):	17.4 mL/min	=	37.8 beats/min	×	0.46 mL/beat

*A whale’s heart rate declines even lower when diving; see Chapter 11, p. 544.

Now consider a yellowfin tuna, a partly endothermic fish with high metabolic rates (see p. 750). While they are able to warm various tissues including some skeletal muscles, their hearts remain near ambient temperature because the *coronary* circulation (that which goes to the heart; see p. 418) receives blood directly from the gills, which are at ambient temperature. As the following table shows, this fish suffers a fivefold drop in heart rate in low-speed swimming at 10° C compared to 25° C. Interestingly, stroke volume shows an inverse temperature dependence, so that the cardiac output decreases only a little more than twofold:

Yellowfin Tuna	Cardiac Output	=	Heart Rate	×	Stroke Volume
25°C:	43.5 mL/min	=	106 beats/min	×	0.41 mL/beat
10°C:	19.8 mL/min	=	19.6 beats/min	×	1.01 mL/beat

Although the tuna’s C.O. at 10°C is similar to the trout’s at 10°C, the tuna does not do well at this temperature, presumably because of its higher metabolic demands.

Cardiac output also changes with development. For example, in young broiler chicks, stroke volume (but not heart rate) almost doubles in a two-week period:

Broiler Chicks	Cardiac Output	=	Heart Rate	×	Stroke Volume
4 weeks old:	253 mL/min	=	362 beats/min	×	0.70 mL/beat
6 weeks old:	434 mL/min	=	328 beats/min	×	1.33 mL/beat

The preceding numbers are resting values; cardiac output also changes with activity, often by large amounts (fivefold or more). The following are some values that have been

TABLE 9-1 Effects of the Autonomic Nervous System on the Heart and Structures That Influence the Heart

Area Affected	Effect of Parasympathetic Stimulation	Effect of Sympathetic Stimulation
SA Node	Decreases the rate of depolarization to threshold; decreases the heart rate	Increases the rate of depolarization to threshold; increases the heart rate
AV Node	Decreases excitability; increases the AV nodal delay	Increases excitability; decreases the AV nodal delay
Ventricular Conduction Pathway	No effect	Increases excitability; hastens conduction through the bundle of His and Purkinje cells
Atrial Muscle	Decreases contractility; weakens contraction	Increases contractility; strengthens contraction
Ventricular Muscle	No effect	Increases contractility; strengthens contraction
Adrenal Medulla (an Endocrine Gland)	No effect	Promotes adrenomedullary secretion of epinephrine, a hormone that augments the sympathetic nervous system's actions on the heart
Veins	No effect	Increases venous return, which increases the strength of cardiac contraction through the Frank-Starling mechanism

measured at maximal activity levels (running, flying, swimming):

Thoroughbred Horse:	300,000 mL/min
Human (Untrained):	25,000 mL/min
Human (Athlete):	40,000 mL/min
Pigeon:	1,072 mL/min
Rainbow Trout (10°C):	53 mL/min
Yellowfin Tuna (10°C):	26 mL/min
Yellowfin Tuna (25°C):	99 mL/min

How can cardiac output vary so tremendously, depending on the demands of the animal body? The regulation of cardiac output depends on antagonistic control of both heart rate and stroke volume, topics that are discussed next.

Heart rate is determined primarily by antagonistic regulation of autonomic influences on the SA node

Most vertebrate hearts are innervated by both divisions of the autonomic nervous system, which can modify the rate (as well as the strength) of contraction in antagonistic fashion. Again, we focus on mammals. The “rest-and-digest” parasympathetic nerve to the mammalian heart, the *vagus nerve* (p. 183), primarily supplies the atrium, especially the SA and AV nodes, in order to reduce C.O. “Fight-or-flight” sympathetic nerves also supply the atria, including the SA and AV nodes, and—unlike the vagus nerve—richly innervate the ventricles as well in order to boost C.O.

Both the parasympathetic and sympathetic nervous system affect C.O. and stroke volume by altering the activity of

ion channels and the cyclic AMP second-messenger system in the innervated cardiac cells, as follows:

- The parasympathetic neurotransmitter **acetylcholine (ACh)** from the vagus nerve binds to *muscarinic* receptors which open up K^+ channels via a G protein, and to another inhibitory G protein which reduces activity of the cyclic AMP pathway (see pp. 97 and 164).
- The sympathetic neurotransmitter **norepinephrine (NE)** binds with a β_1 -adrenergic receptor that is coupled to a stimulatory G protein, which accelerates the cyclic AMP pathway.

Let's examine the specific effects that these neurotransmitters have on the heart.

Effect of Parasympathetic Stimulation on the Mammalian Heart

Parasympathetic stimulation *reduces cardiac output* through these effects:

1. *ACh decreases heart rate* (Figure 9-28 and Table 9-1). Enhanced K^+ permeability because of ACh hyperpolarizes the SA node membrane (in most vertebrates), because more K^+ leaves than normal, making the inside even more negative. Inhibition of the cAMP pathway depresses both the inward movement of Na^+ and Ca^{2+} through the HCN- I_f and T-type channels, respectively, further slowing the depolarization to threshold. The “resting” potential starts even farther away from threshold, so it takes longer to reach threshold.
2. *ACh decreases excitability of the AV node*, prolonging transmission of impulses to the ventricles even longer than the usual AV nodal delay.
3. *Parasympathetic stimulation of the atrial contractile cells shortens the action potential*, reducing the slow inward current carried by Ca^{2+} ; that is, the plateau phase is shortened.

KEY

- = Inherent SA node pacemaker activity
- = SA node pacemaker activity on parasympathetic stimulation
- = SA node pacemaker activity on sympathetic stimulation

(a) Autonomic influence on SA node potential

(b) Control of heart rate by autonomic nervous system

FIGURE 9-28 Autonomic control of SA node activity and heart rate.

(a) Parasympathetic stimulation decreases the rate of SA nodal depolarization so that the membrane reaches threshold more slowly and has fewer action potentials, whereas sympathetic stimulation increases the rate of depolarization of the SA node so that the membrane reaches threshold more rapidly and has more frequent action potentials.

(b) Because each SA node action potential ultimately leads to a heartbeat, increased parasympathetic activity decreases the heart rate, whereas increased sympathetic activity increases the heart rate.

© Cengage Learning, 2013

Thus, the heart is more “leisurely” under parasympathetic influence—it beats less rapidly, the time between atrial and ventricular contraction is stretched out, and atrial contraction is weaker. These actions are appropriate in relaxed situations when a high cardiac output is not needed, and in the *dive reflex* in air-breathing diving animals such as many seals and cetaceans (Chapter 11). These effects are similar in other vertebrates as well.

Effect of Sympathetic Stimulation on the Mammalian Heart

Through the following effects, *sympathetic stimulation increases C.O.* (Figure 9-28 and Table 9-1):

1. *NE increases heart rate* through its effect on cAMP, which increases the influx of Na^+ and Ca^{2+} . The resulting swifter drift to threshold permits a greater frequency of action potentials and a correspondingly more rapid heart rate.
2. *NE reduces the AV nodal delay* at the AV node by increasing conduction velocity, by enhancing the slow, inward Ca^{2+} current.
3. *NE speeds up the spread of the action potential* throughout the specialized conduction pathway.
4. *NE increases contractile strength* of the atrial and ventricular contractile cells, both of which have numerous sympathetic nerve endings, so that the heart beats more forcefully and squeezes out more blood (a higher stroke volume). This effect is produced by increasing inward Ca^{2+} movement through prolonged opening of L-type Ca^{2+} channels, which enhances the slow Ca^{2+} influx and intensifies Ca^{2+} participation in excitation–contraction coupling.

The overall effect of sympathetic stimulation on the heart, therefore, is to increase pumping by increasing the heart rate, decreasing the delay between atrial and ventricular contraction, decreasing conduction time throughout the heart, and increasing the force of contraction. These actions are appropriate for emergency or exercise situations.

Control of Heart Rate Thus, as is typical of the autonomic nervous system, parasympathetic and sympathetic effects on heart rate are an example of antagonistic regulation (p. 16). At any given moment, the heart rate is determined largely by the existing balance between the inhibitory effects of the vagus nerve and the stimulatory effects of the cardiac sympathetic nerves. The relative level of activity in these two branches in turn is primarily coordinated by the *cardiovascular control center* located in the brain stem (p. 437).

Although autonomic innervation is the primary means by which heart rate is regulated, other factors can affect it as well. The most important is *epinephrine*, a hormone that is secreted into the blood from the adrenal medulla (p. 308) on sympathetic stimulation and that acts in a manner similar to norepinephrine (NE) to increase the heart rate.

Stroke volume is determined by the extent of venous return and by sympathetic activity

Note that both autonomic systems affect heart rate, but the sympathetic also boosts stroke volume, the amount of blood pumped out by each ventricle during each beat. Actually, there are two types of controls that influence stroke volume: (1) *intrinsic control* related to the extent of *venous return*, which increases during activity and (2) *extrinsic control* from sympathetic stimulation. Recall that intrinsic/extrinsic control is part of the hierarchical regulation we described in Chapter 1 (p. 19). Both factors increase stroke volume by increasing the strength of contraction of the heart (Figure 9-29). Let’s examine each of these factors’ effects in detail.

FIGURE 9-29 Control of cardiac output. Cardiac output equals heart rate times stroke volume. Heart rate in turn is increased by sympathetic activity and decreased by parasympathetic activity, while stroke volume is increased by sympathetic activity and higher venous return.

© Cengage Learning, 2013

Increased end-diastolic volume intrinsically results in increased stroke volume

Intrinsic control of stroke volume refers to the heart's inherent ability to vary the stroke volume, based on a direct correlation between end-diastolic volume (EDV) and stroke volume (SV). That is, *as more blood is returned to the vertebrate heart, the heart pumps out more blood*. However the relationship is not quite as simple as it appears, because the heart does not eject all the blood it contains. This control depends on the *length–tension* relationship of cardiac muscle, which is similar to that of skeletal muscle. For skeletal muscle, the resting muscle length is approximately the optimal length at which maximal tension can be developed during a subsequent contraction. When the skeletal muscle is longer or shorter than this optimal length, the subsequent contraction is weaker (see Figure 8-17, p. 354). For cardiac muscle, the resting cardiac muscle-fiber length is less than optimal. Therefore, an increase in cardiac muscle-fiber length increases the contractile tension of the heart on the following systole (Figure 9-30). Unlike in skeletal muscle, there is another more important effect: As a cardiac muscle fiber is stretched from greater ventricular filling, its myofilaments are pulled closer together. Because of this reduced distance between filaments, more cross-bridge interactions between myosin and actin can take place during contraction. Thus, the length–tension relationship in cardiac muscle depends not on muscle fiber length per se but on the resultant variations in the lateral spacing between the myosin and actin filaments.

Frank-Starling Law of the Heart What causes cardiac muscle fibers to vary in length before contraction without being attached to any bones? The main determinant of cardiac muscle-fiber length is the *degree of diastolic filling*. An analogy is a balloon filled with water—the more water you put in, the larger the balloon becomes, and the more it is stretched. Likewise, the greater the extent of diastolic filling, the larger the volume, the more the heart is stretched, and the longer the initial cardiac-fiber length is before contraction. The increased length results in a greater force on the subsequent cardiac contraction and, consequently, a greater SV. This intrinsic relationship between EDV and SV is known as the **Frank-Starling law of the heart**. Stated simply, the law says that *the greater the volume of blood entering the heart during diastole, the greater the volume of blood ejected during systole*. In Figure 9-30, assume that the EDV increases from point A to point B, due to increased venous return. You can see that this increase in EDV is accompanied by a corresponding increase in SV from point A¹ to point B¹. This effect is not unique to vertebrates; for example, mollusk hearts also respond in this way to increased filling (they also beat faster in response).

The built-in relationship matching SV with venous return has two important advantages. First, this intrinsic mechanism equalizes output between the right and left sides of the avian and mammalian hearts so that the blood pumped out by the heart is equally distributed between the pulmonary and systemic circulation. If, for example, the right side of the heart ejects a larger SV, more blood enters the pulmonary circulation, so venous return to the left side of the heart is increased accordingly. The increased EDV of the left side of the heart causes it to contract more forcefully, so it too pumps out a larger SV. In this way, equality of output of the two ventricular chambers is maintained.

The contractility of the heart and venous return are increased by sympathetic stimulation

In addition to intrinsic control, stroke volume is also subject to extrinsic control, the most important of which are actions of the cardiac sympathetic nerves and epinephrine. Sympathetic NE and epinephrine act in two ways:

1. As we noted earlier, both enhance the heart's **contractility**, which is the strength of contraction at any given EDV; that is, the heart contracts more forcefully and squeezes out a greater percentage of the blood it contains on sympathetic stimulation. This increased contractility is due to the increased Ca^{2+} influx triggered by NE and epinephrine. The extra cytosolic Ca^{2+} allows the myocardial fibers to generate more force through greater cross-bridge cycling than they would without sympathetic influence. Normally, the human EDV 135 mL and the end-systolic volume (ESV) is 65 mL for a SV of 70 mL (Figure 9-31a). Under sympathetic influence, for the same EDV the ESV might be 35 mL, yielding an SV of 100 mL (Figure 9-31b).
2. Sympathetic stimulation increases stroke volume also by constricting veins, squeezing more blood from the veins to the heart and thus *enhancing venous return* (Figure 9-31c). A value of about 140 mL may be achieved in humans. The resultant increase in EDV automatically increases SV correspondingly.

FIGURE 9-30 Intrinsic control of stroke volume (Frank-Starling curve). The cardiac muscle fiber's length, which is determined by the extent of venous filling, is normally less than the optimal length for developing maximal tension. Therefore, an increase in end-diastolic volume (that is, an increase in venous return), by moving the cardiac muscle fiber length closer to optimal length, increases the contractile tension of the fibers on the next systole. A stronger contraction squeezes out more blood. Thus, as more blood is returned to the heart and the end-diastolic volume increases, the heart automatically pumps out a correspondingly larger stroke volume.

© Cengage Learning, 2013

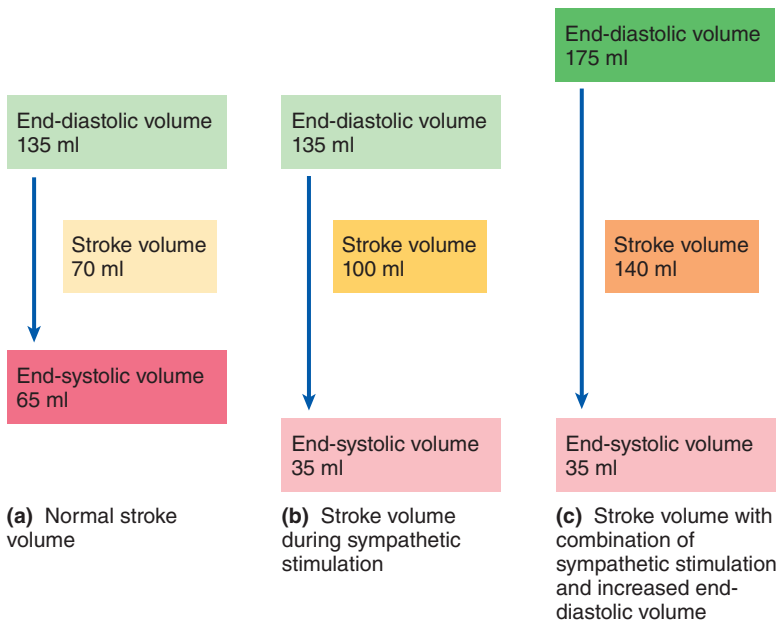

FIGURE 9-31 Effect of sympathetic stimulation on stroke volume. Values are for average human heart.

© Cengage Learning, 2013

The strength of cardiac muscle contraction and, accordingly, the stroke volume can thus be varied. Because activity also increases heart rate, these two factors act together to increase the C.O. so that more blood can be delivered to the active muscles. All the factors that determine the cardiac output by influencing the heart rate or stroke volume are summarized in Figure 9-29.

The heart receives most of its own blood supply through the coronary circulation

Although all the blood passes through the heart, the heart muscle cannot extract O_2 or nutrients from the blood within its chambers, in part because the walls are too thick to permit diffusion of O_2 and other supplies from the blood in the chamber to all the cardiac cells. Therefore, like most tissues, heart muscle must receive blood through blood vessels, specifically by means of the **coronary circulation**, which first evolved in active fishes (this circulation is lacking in most sedentary fishes). The coronary arteries branch in fishes from the branchial arteries leaving the gills, in mammals from the aorta just beyond the aortic valve.

During locomotory activity, the rate of coronary blood flow

increases several-fold above its resting rate. This is accomplished primarily by vasodilation, or enlargement, of the coronary vessels, which allows more blood to flow through them. Coronary blood flow is adjusted primarily in response to changes in the heart's O_2 requirements. The major link that coordinates coronary blood flow with myocardial O_2 needs is *adenosine*, which is formed from adenosine triphosphate (ATP) during cardiac metabolic activity. Increased formation and release of adenosine from the cardiac cells occur (1) when there is a cardiac O_2 deficit or (2) when cardiac activity is increased and the heart accordingly requires more O_2 for ATP production. The adenosine induces dilation of the coronary blood vessels, allowing more O_2 -rich blood to flow to the more active cardiac cells to meet their increased demand. This is a negative-feedback process, summarized as follows:

Reduced O_2 in cardiac myocytes → adenosine release → vasodilation of coronary vessels → increased blood flow and O_2 delivery to myocytes

This matching of O_2 delivery with O_2 needs is critical, because the heart muscle depends on oxidative processes, not anaerobic, to generate energy. The heart primarily uses free fatty acids and, to a lesser extent, glucose and lactate as fuel sources, depending on their availability, and it can shift metabolic pathways to use whatever nutrient is available. The primary danger of insufficient coronary blood flow is not fuel shortage but O_2 deficiency.

Obstruction of coronary arteries is a leading cause of death in humans. Hardening called **arteriosclerosis** occurs in the artery walls for a variety of reasons, such accumulation of cholesterol plaques (p. 389) following damage from high

blood pressure (hypertension). Curiously, arteriosclerotic lesions in the coronary vessels of migratory salmonids (Pacific and Atlantic salmon and steelhead trout) are very common and increase with age, affecting up to 100% of adults. These lesions are absent or less severe in nonmigratory salmonids and other fish. It is not certain why this is; researchers speculate that the damage arises from various natural stresses, such as migrating, feeding, and avoiding predation. As in humans, stress leads to *hypertension* (p. 449), which may cause the initial damage. Another possible factor relates to the anatomy of the coronary artery: It lies on top of the bulbus arteriosus (recall its pressure storage-release function, p. 402) that overly expands during stress. This may cause damaging distortion of the coronary artery.

Now that we have concluded the discussion of circulatory pumps and circulatory fluids, we turn our attention to circulatory pathways and vessels.

9.8 Circulatory Pathways and Vessels: Hemodynamics and Evolution

Now that we have discussed the fluids and pumps of circulatory systems, we turn to the details of the flow pathways. As we discussed at the beginning of this chapter, most animals have an *open* (hemolymph) or *closed* (blood) systems (or both). Before we examine these in detail, we begin with the physics of fluid flow.

Flow of fluid obeys certain physical laws called *hemodynamic laws*, which are important to understanding how flow is controlled. Here we focus on flow through vessels.

Blood flow varies directly with the pressure gradient and inversely with resistance

The **flow rate** of blood through a vessel (that is, the volume of blood passing through per unit of time) is expressed in the **hemodynamic flow law**, one of the key hemodynamic equations:

$$Q = \Delta P/R$$

where

Q = flow rate of fluid through a vessel
(quantity per unit time)

ΔP = pressure gradient, or $P_1 - P_2$, where

P_1 = pressure at the inflow end of a vessel

P_2 = pressure at the outflow end of a vessel

R = resistance of blood vessels

This equation might look familiar; it is similar to *Ohm's law* for electrical current (current $\Delta I = \Delta V/R$; p. 115). In both,

A crocodile and impala both have four-chambered hearts. But their plumbing is different. The crocodile's heart and vessels allow flow to be diverted away from the lungs when the animal is underwater, while the impala's blood must always go to the lungs before going to the rest of the body.

flow changes in direct proportion to the driving force (pressure or voltage gradient) and inversely with resistance. Let's look at these factors.

Pressure Gradient The **pressure gradient**—the difference in pressure between the beginning and end of a vessel—is the main driving force for flow through the vessel; that is, blood flows from an area of higher pressure (P_1) to an area of lower pressure (P_2) down a pressure gradient (ΔP). Contraction of the heart imparts pressure to the blood, but because of frictional losses (resistance), the pressure decreases as blood flows through a vessel, so it is higher at the beginning than at the end. This maintains a positive ΔP for forward flow of blood through the vessel. The greater the pressure gradient forcing blood through a vessel, the greater the rate of flow through that vessel (Figure 9-32, vessels 1 versus 2). Think of a garden hose attached to a faucet. If you turn on the faucet slightly, a small stream of water flows out of the end of the hose because the pressure is only slightly greater at the beginning than at the end of the hose. If you open the faucet all the way, the pressure gradient increases tremendously so that the rate of water flow through the hose is much greater, and water spurts forth from the end of the hose. Note that the *difference* in pressure (hence the delta symbol in ΔP) between the two ends of a vessel, not the absolute pressures, determines flow rate (Figure 9-32, vessels 2 versus 3).

Gravity is another major factor in establishing the pressure gradient. This is particularly important in a tall terrestrial animal such as a human or a giraffe (Figure 9-33). Continuing with the garden hose analogy, if you point a spurting hose upward, the water will not travel as great a distance from the hose as it does if you point the hose horizontally. To push a column of water upward 1 m requires a pressure of about 70 mm Hg. In effect, gravity increases the P_2 (the pressure at the end of the flow being measured), so that a higher initial P_1 is needed to maintain a given flow. Thus, to maintain a reasonable pressure well above zero in the brain, the average driving pressure from the heart in

FIGURE 9-32 Relationship of flow to the pressure gradient in a vessel. As the difference in pressure (ΔP) between the two ends of a vessel increases, the flow rate increases proportionately (vessel 1 versus 2). Flow rate is determined by the *difference* in pressure between the two ends of a vessel, not the magnitude of the pressures at each end (vessel 2 versus 3).

humans needs to be about 100 mm Hg, whereas in a giraffe with its brain about 2 m above its heart (Figure 9-33b), driving pressure needs to be about 200 mm Hg! In contrast, fishes (in which gravity effects are minimal) have lower pressures: 2 to 14 mm Hg in hagfish, and up to about 40 mm Hg in bony fish.

unanswered Questions | How could a brachiosaur pump blood to its brain?

The giraffe heart generates 200 mm Hg to ensure oxygen supply to its brain. But consider the large dinosaurs such as brachiosaurs and barosaurs, which had necks of 25 m or more in length! Pressures of 700 mm Hg or more would be needed from a heart in the chest to create sufficient flow to the brain. Is this likely to have been the case, or can you think of another mechanism to create adequate blood flow to the head? After generating your own hypotheses, read the article by Choy and Altman (1992) in the Suggested Readings. <<

Resistance The other factor influencing flow rate through a vessel is the **resistance** (R), which is a measure of the hindrance to blood flow through a vessel caused by friction between the moving fluid and the stationary vascular walls. As R increases, it is more difficult for blood to pass through

the vessel, so flow decreases (as long as the pressure gradient remains unchanged). When resistance increases, the pressure gradient ΔP must increase correspondingly to maintain the same flow rate. Accordingly, when the vessels offer more resistance to flow, the heart must work harder to maintain adequate circulation.

Resistance to blood flow depends on several factors. For an idealized smooth flow known as **laminar flow** (where layers of the fluid slide smoothly over each other), there are three key factors: (1) *viscosity* of the fluid, η ; (2) vessel *length*, L ; and (3) vessel *radius*, r , which is by far the most important. The exact relationship, for idealized laminar, nonpulsatile flow in a rigid tube, is

$$R = 8\eta L / \pi r^4$$

Viscosity (η) arises from friction developed between the molecules of a fluid as they slide over each other during flow of the fluid. Thus, higher viscosity creates higher resistance to flow. In general, the thicker a liquid, the more viscous it is. For example, molasses flows more slowly than water because molasses has greater viscosity. Viscosity of blood is determined by two factors: the concentration of plasma proteins and, more importantly, the number of red blood cells per unit volume. Normally, these two factors are relatively constant for a species and are not important in the control of resistance. Occasionally, however, blood viscosity and, accordingly, resistance are altered by an abnormal number of red blood cells. Recall that increased synthesis of EPO increases number of red blood cells (p. 393), which thus increases blood viscosity. Blood flow can be more sluggish than normal when excessive red blood cells are present; this is a consequence, for example, of a migratory bird or mammal acclimatizing to a high elevation (from a low elevation) or EPO injections.

Because blood “rubs” against the lining of the vessels as it flows past, the greater the vessel surface area in contact with the blood, the greater the resistance to flow. Surface area is determined by both the length (L) and radius (r) of the vessel. At a constant radius, the longer the vessel, the greater the surface area and the greater the resistance to flow. Because vessel length is typically constant in an adult body, it is not a variable in the control of vascular resistance. *Therefore, the major determinant of resistance to flow is the vessel’s radius.* Fluid passes more readily through a large vessel than through a smaller vessel because a given volume of blood comes into contact with much more of the surface area of a small-radius vessel than of a larger-radius vessel, resulting in greater resistance (Figure 9-34a). Furthermore, a slight change in the radius of a vessel brings about a notable change in flow because the resistance is inversely proportional to the *fourth power* of the radius:

$$R \propto 1/r^4$$

Thus, doubling the radius (Figure 9-34b) decreases R 16-fold and therefore increases flow through the vessel 16-fold (at the same pressure gradient). The converse is also true. Only 1/16th as much blood flows through a vessel at the same driving pressure when its radius is halved. As you will see the radius of *arterioles* is subject to regulation and is the most important factor in the control of resistance.

The factors that affect the flow rate through a vessel are integrated in an idealized way in the **Poiseuille-Hagen law**, as follows:

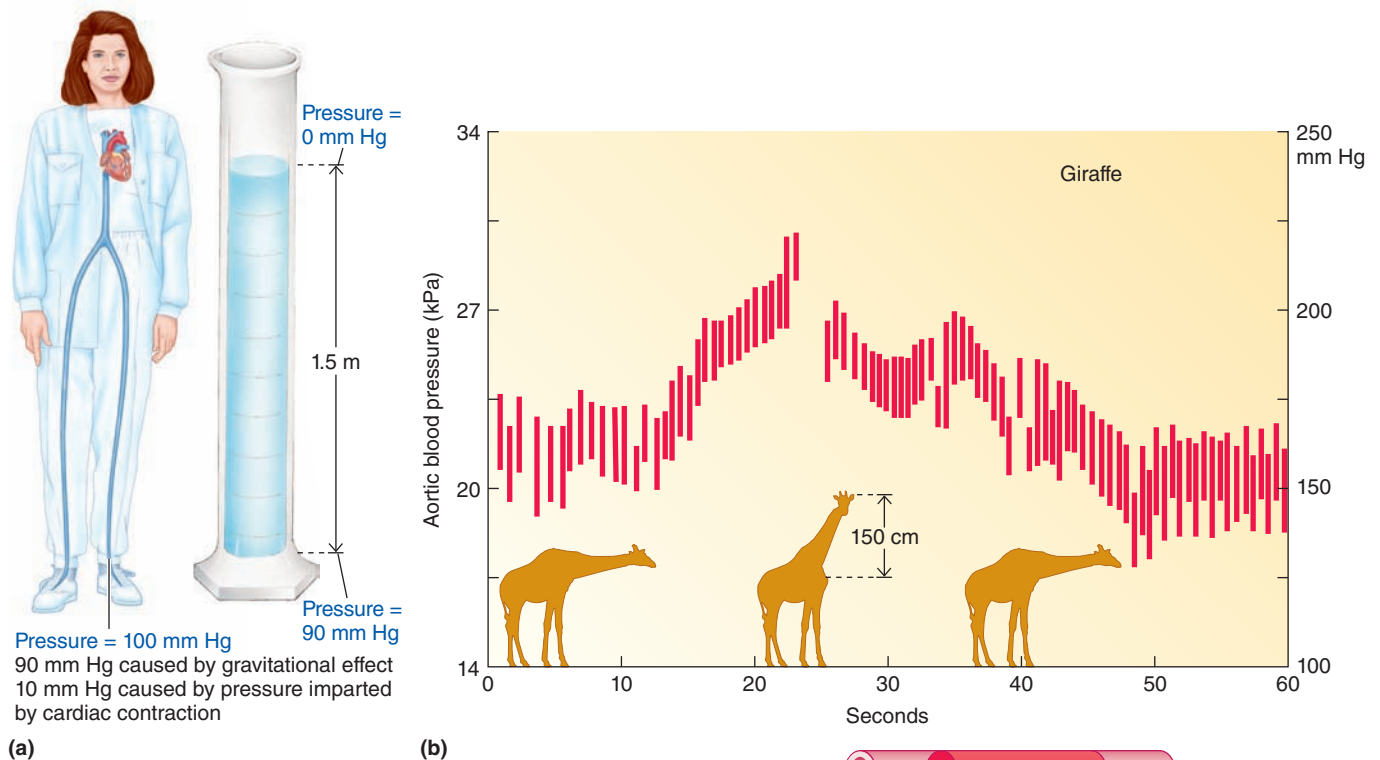

FIGURE 9-33 Effect of gravity on venous pressure. (a) In an upright adult, the blood in the vessels extending between the heart and foot is equivalent to a 1.5 m column of blood. The pressure exerted by this column of blood as a result of the effect of gravity is 90 mm Hg. The pressure imparted to the blood by the heart has declined to about 10 mm Hg in the lower-leg veins because of frictional losses in preceding vessels. The pressure caused by gravity (90 mm Hg) added to the pressure imparted by the heart (10 mm Hg) produces a venous pressure of 100 mm Hg in the ankle and foot veins. Similarly, the capillaries in the region are subjected to these same gravitational effects. (b) Effect on aortic blood pressure of raising a giraffe's head.

$$Q = \pi \Delta P r^4 / 8 \eta L$$

Although blood vessels are not rigid tubes with nonpulsatile flow (to which this law applies), it works reasonably well for some blood vessels (small arteries and veins). But even where the law is not wholly accurate, the simplified version, $Q = \Delta P/R$, is correct. For the most part, we use this version, noting viscosity and radius effects where appropriate. These factors will come more into focus when we later embark on a voyage through animal circulation.

Circulatory fluids transport materials in a parallel manner, especially in closed systems

Now that we have seen the basic physics of flow, let's see how flow is directed and regulated. There are two important structural features in closed, and often in open, systems:

1. Closed systems always have initial *parallel* branching in arteries, and many open systems do as well (see Figure 9-2; you will see more detailed figures shortly). Parallel

(b) Influence of vessel radius on resistance and flow

FIGURE 9-34 Relationship of resistance and flow to the vessel radius. (a) The same volume of blood comes into contact with a greater surface area of a small-radius vessel compared to a larger-radius vessel. Accordingly, the smaller-radius vessel offers more resistance to blood flow, because the blood “rubs” against a larger surface area. (b) Doubling the radius decreases the resistance to 1/16 and increases the flow 16 times because the resistance is inversely proportional to the fourth power of the radius.

plumbing allows all organs or body regions to obtain *fresh* blood (or hemolymph). That is, part of the fluid pumped out by the heart can go to a particular muscle, part to another muscle, part to a kidney, part to the brain, and so on. Thus, the same circulatory fluid does not pass sequentially from one tissue to another tissue (*series* flow).

2. There can be muscular *valves* on some of the branching parallel vessels. These appear universally in closed systems and occur in some open ones. They allow the animal to regulate circulatory flow to specific organs, for example, so that gas and nutrient supplies can be boosted for active tissues that need more.

Thus, blood, and in some cases hemolymph, is carried by arteries until very close to target tissues. Moreover, hemolymph can sometimes be channeled in specific directions by body wall muscles or discrete channels even if not contained in vessels as such. However, closed systems are often said to have evolved in the most metabolically active animals because they allow more rapid and more precise control of oxygen delivery to the tissues that need it the most. (Another advantage is that closed circulation can achieve the same or better delivery rates with a much lower fluid volume that has to be pumped; for example, blood may be only 5% of body fluids in a vertebrate or squid, whereas hemolymph can be 30 to 50% in a noncephalopod mollusk.) This “active animal” hypothesis may explain why the most active mollusks (cephalopods) evolved a closed system, whereas other, more sluggish mollusks did not. Similarly, vertebrates with their closed systems are generally more active than most nonvertebrates. (Highly active flying insects are an exception because they have a separate tracheal system for oxygen delivery.) This explanation for closed systems is compelling, but certain exceptions seem to contradict it; for example, nemerteans (ribbon worms) and most annelids (segmented worms) have closed systems but are not more active than many other animals with open systems (such as crustaceans). However, it does appear that the most highly active animals that use circulation for oxygen transport do have closed systems. (And as you will see, large active crustaceans have open systems that approach closed ones in terms of parallel flow.)

Circulatory fluids are driven by pressure and can transmit useful force

Directing the fluid flow in a parallel manner can serve another purpose—that of *force transmission* to specific organs. To move from one point to another, circulatory fluids must be pressurized, as we discussed earlier. In addition to creating circulation, pressure can be used to exert a force for other functions, including the following (Figure 9-35):

- **Movement.** For example, hemolymph pressure (rather than skeletal muscle) is used to extend the legs in arachnids such as spiders. Arteries branch to the legs and flow to them can be controlled. Hemolymph entering into a bent leg at high pressure (from an open artery) makes the leg straighten out (Figure 9-35a), much as a coiled water hose may straighten out when high-pressure water enters it. Cephalothorax muscles, not the spider’s heart, create the pressure. The same process is used to extend the foot in mollusks, such as in a clam burrowing into

sand (Figure 9-35b). These animals have hemolymph sinuses with valves to control flow direction in the foot. Researchers have discovered that blue crabs, which like all arthropods must molt their exoskeletons in order to grow, also use fluid pressure when they are in the soft-shell stage. In this stage, after molting but before growing a new exoskeleton, there are no skeletal elements for muscles to act on, so muscles must push internal fluid to move the limbs.

- **Ultrafiltration.** Blood pressure can force water and small, dissolved solutes out of pores in capillary linings. This is used in the initial process of urine formation in vertebrate kidneys (Chapter 12), and for interactions with the ECF in many tissues (see p. 443).
- **Erection.** Blood can enter a flaccid organ under high pressure, and if the exiting blood is restricted, the force of the pressure will inflate that organ. This occurs during arousal of erectile genitalia (penis, clitoris; see Chapter 16). Scientists also think it inflates the sensitive snout of the echidna (a monotreme or egg-laying mammal of Australia), which pokes its snout into termite and ant nests to feed (Figure 9-35c).

Why is parallel flow important in circulatory systems?

In what ways can circulatory fluid be used in force transmission?

9.9 Circulatory Pathways and Vessels: Open Circulation

Now that you’ve seen common principles and features of circulation, let’s look at details in specific animals, starting with those having open circulation. There are many similarities but also significant differences among the various systems. For example, some nonvertebrates have two or more separate ECF compartments. In echinoderms, the ECF is divided into the main body cavity or *coelom*, a *water-vascular* system of canals to operate their unique tube feet, plus a *perihemal* system and a *hemal* system of connected spaces with uncertain functions. However, the most widely studied animals with open circulations are dominated by a single hemolymph space. Let’s look at three examples—mollusks, insects, and crustaceans.

Mollusks (Noncephalopods) Most mollusks—snails, chitons, bivalves, and so on—have open circulations with myogenic chamber hearts (Figure 9-36a). (Recall that cephalopods have closed systems.) Although there are no capillaries in the non-cephalopods, hemolymph flow is not completely random. As you saw earlier, burrowing clams can control hemolymph for burrowing. Also, flow to individual organs in at least one species, the black abalone (*Haliotis cracheroidii*), matches each organ’s metabolic demands, clearly indicating some directionality in hemolymph flow.

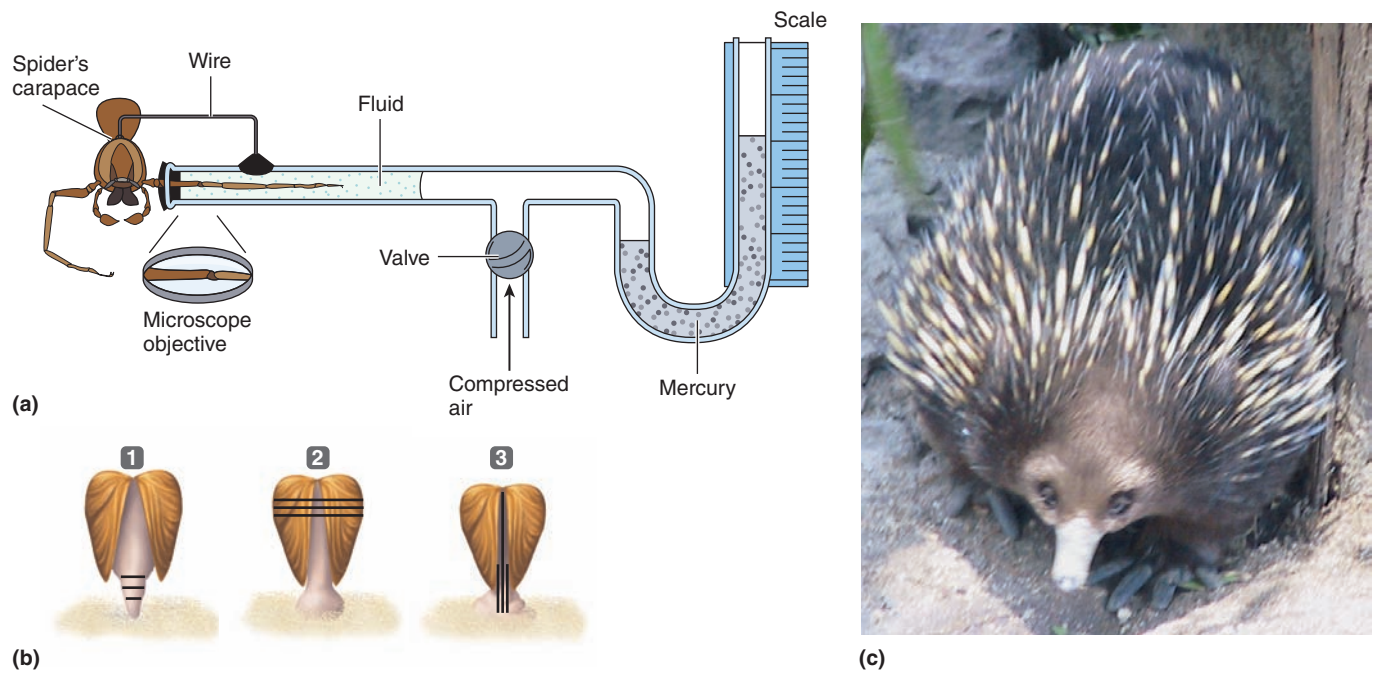

FIGURE 9-35 Examples of the use of circulatory fluid pressure for force transmission. (a) An experiment measuring hemolymph pressure in a spider's leg. Spiders use hemolymph pressure to extend their legs. In the experiment, a living spider (*Tegenaria*) is held with one leg sealed into a tube. While watching the turgid membrane of one joint of the leg, through a microscope, the experimenter slowly raises the pressure in the tube by admitting compressed air. When the external pressure in the tube just exceeds the internal pressure of the leg, the membrane is seen to collapse. Normal pressures in a quiet spider were approximately 5 cm mercury. When the spider was stimulated, pressures up to 45 cm mercury were recorded. Intermediate pressures extend the legs during normal walking. (b) A bivalve uses its foot to burrow into sand. Black lines represent muscles being used. In step 1, foot muscles squeeze the hemolymph to extend the foot, while the shells remain open to form an anchor. In step 2, adductor muscles contract and squeeze more hemolymph into the foot, which flares to form an anchor. In step 3, other foot muscles contract to pull the shell downwards. (c) The spiny echidna uses blood pressure to stiffen its snout for probing into the ground for insects.

Crustacea Larger crustaceans such as decapods (lobsters, crabs, crayfish, and so on) have a well-developed circulatory system with numerous parallel structures (Figure 9-36b). At least some decapods have fine, highly branched capillary-sized arteries within target tissues (see the remarkable crab system in Figure 9-36c). These capillary-like arteries open up into local **lacunae** (very small meshlike spaces), and the larger sinuses that collect the fluid for return to the heart are defined channels rather than random open spaces. Thus, the circulation in these animals blurs somewhat the distinction between open and closed systems. Flow can be characterized as (Figure 9-36b):

Dorsal heart → anterior and posterior aortas → arteries branching in parallel into capillary-like ends → tissue lacunae → sinuses → gills → dorsal heart via ostia

The various branching arteries have valves to control flow to different regions. Later you will see how such valves work for vertebrates. Note that all the hemolymph flows to the gills before returning to the heart. This is part of the flow *in series* rather than in parallel, the significance of which is explained shortly.

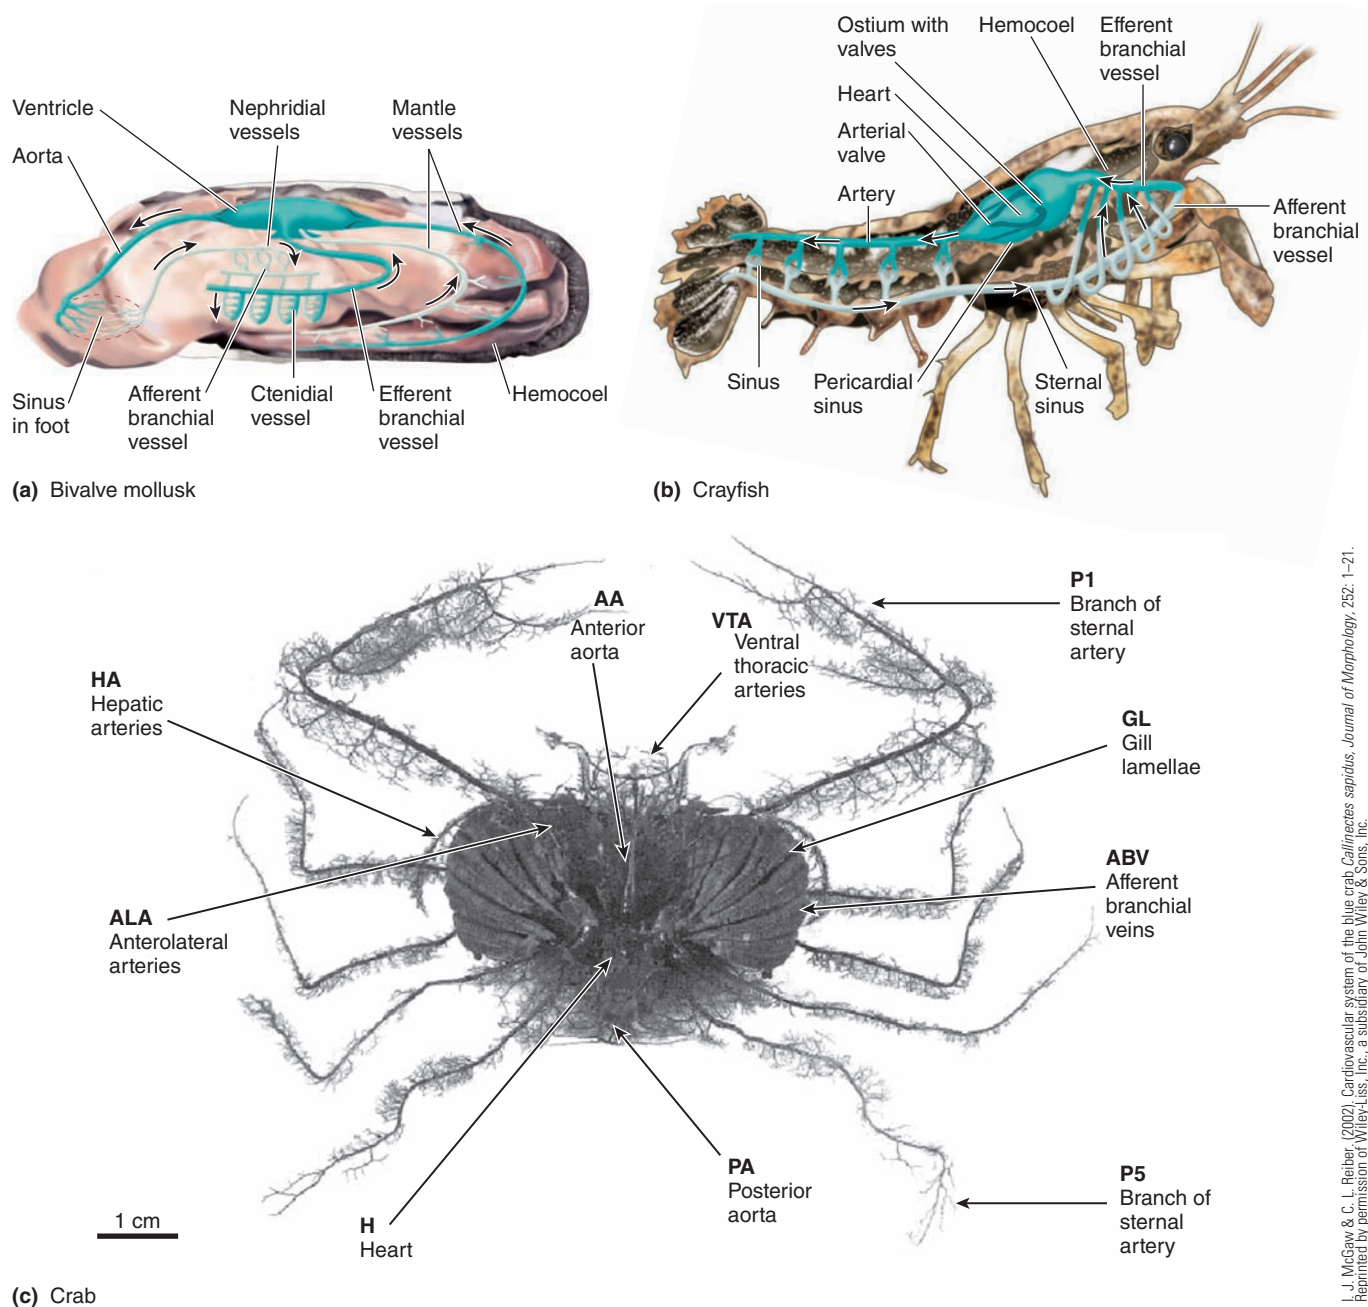

Insects Flow in insects is in some sense cruder than in decapods, with a tubular rather than chamber heart, and with much less parallel branching and control. Recall that insects do not rely on circulation for oxygen delivery, which probably explains why they have not evolved more complex, crustacean-like vessels. Flow can be characterized as (Figure 9-2b and 9-16c):

Posterior dorsal heart → dorsal aorta and arterial branches → head and other anterior regions → open spaces throughout body → abdomen → dorsal heart via ostia

Flow through the open spaces is not completely random. In the limbs, for example, longitudinal sheaths channel the hemolymph in specific directions. Thus, some parallel flow is evident.
