DMSO is approved for topical application in horses suffering from acute swelling caused by trauma and in the treatment of acute or chronic otitis. In humans DMSO is approved for interstitial cystitis. Although not approved, DMSO has been recommended for therapy in male cats suffering from urinary tract obstruction.³⁷³ Other reported applications of DMSO include facilitation of healing of skin wounds (including habronemiasis of horses), acral lick dermatitis in dogs, postoperative fibrous adhesions, acute CNS trauma, inflammation, edema or ischemia, intervertebral disc disease, fibrocartilaginous embolization, ischemic insults, postoperative myositis, rheumatic diseases, myasthenia gravis, and chronic musculoskeletal conditions. DMSO also inhibits alcohol dehydrogenase and thus has been recommended for the treatment of ethylene glycol toxicity.³⁷³

Methylsulfonylmethane

Methylsulfonylmethane is a naturally occurring metabolite of DMSO that has also received attention as a food additive for control of musculoskeletal inflammation. Limited data³⁶⁴ are available to support the use of this compound for therapy of osteoarthritis.

USE OF MODULATORS OF INFLAMMATION IN THE TREATMENT OF SHOCK AND CENTRAL NERVOUS SYSTEM TRAUMA

A number of drugs that modulate the inflammatory response have been studied for their effect in the patient suffering from shock, particularly that associated with the release of bacterial toxins such as endotoxin (septic shock). Because of the oxygen radical scavenging ability of some of these drugs, studies have also focused on their use in treatment of damage to the CNS.

Pathophysiology of Septic Shock

The pathophysiology of septic shock is addressed in Chapter 8. This discussion focuses on the inflammatory mediators associated with the syndrome. Increasingly, sepsis is recognized to reflect an exaggerated systemic inflammatory response to infectious organisms. Mediators of the response include lipopolysaccharide of gram-negative bacteria, lipoteichoic acid of gram-positive bacteria, and peptidoglycan from both. Cytokines released by host cells (macrophages and circulating monocytes) play a pivotal role in the pathyophysiology.

Gram-positive bacteria appear to secrete superantigens, which bind to both major histocompatibility complex molecules and T-cell receptors, initiating massive cytokine production. Lipoteichoic acid and endotoxin both stimulate cytokine production. The lipid A component of lipopolysaccharide, endotoxin, found on the surface of gram-negative organisms, is a highly conserved molecule responsible for the sequelae of endotoxic shock. The manifestation begins as endotoxin released from dying gram-negative organisms interacts with receptors on cells of the host defense system: macrophages, neutrophils, platelets, and lymphocytes. Endotoxin also directly interacts with vascular endothelial cells. In response, cells either release the mediators of endotoxic shock or render other cells more reactive to cellular signals and subsequent mediator release. Mediators of endotoxic shock are grouped as cytokines, lipid mediators, or secondary mediators.^{377,378} Cytokines are small polypeptides released from inflammatory cells, especially macrophages. TNF and IL-1 are the two cytokines that appear to be primarily responsible for the cascade of endotoxemia. Their effects in turn are often mediated by nitric oxide. Lipid mediators are derived from AA, located in the phospholipids of cell membranes, particularly those of neutrophils, platelets, vascular endothelium, and vascular smooth muscle. Examples include PGs (including thromboxane), LTs, and platelet-activating factor.

Both cytokines and the lipid mediators act as signaling mechanisms among inflammatory cells, platelets, and the vascular endothelium through negative and positive feedback mechanisms. When the positive feedback loops overwhelm the negative feedback loops, the pathophysiology of endotoxic shock becomes a clinical reality. The pathophysiology reflects, in part, the direct effects of endotoxin (e.g., it directs activation of Hageman factor and complement components) and the combined or individual effects of the mediators. Secondary mediators (e.g., histamine, serotonin, vasopressin, angiotensin II, catecholamines, and opioids) are released in response to cytokines and lipid mediators, resulting in the general signs of endotoxic shock. Adhesion molecules, selectins, and leukocyte integrins are among the humoral mediators associated with the pathophysiology. Disruption in hemostasis balance also is affected by inflammatory cytokines. Interleukins 1α , 1 β , and TNF- α activate tissue factor and subsequent coagulation; endotoxin also increased the activity of fibrinolytic inhibitors, contributing to an imbalance in the coagulation cascade. Changes in peripheral vasculature (i.e., constriction and dilation) coupled with activation of clotting factors and inhibition of fibrinolysis, results in widespread coagulopathy, microbembolization, and vascular endothelial damage. The clinical signs associated with each stage of shock depend on the mediators released during that stage and vary among species. The complex interactions of these mediators, however, if allowed to progress, can result in multiple organ failure in any species simply because of the cumulative effects of hypoxia: oxygen radical, lysosomal enzymes, thrombosis, and metabolic derangements.

Drug therapy is most likely to be successful when initiated early during the course of endotoxic shock. The role of steroidal compounds in the treatment of shock in animals was reviewed by Howe.³⁷⁹ A number of investigators have recently reviewed the role of mediator-specific antiinflammatory agents in the prevention and treatment of septic shock.^{380,381} Examples of these drugs include antibiodies to TNF, soluble TNF receptors, agonists of IL-1or platelet activating receptors, and drugs that target bradykinin or PGs. Thus far, these drugs appear to have demonstrated efficacy in clinical trials. Metaanalyses indicate that their use should be associated with clinical benefits in the individual patient.³⁸¹ However, because the targets of these drugs play complex roles in the pathophysiology of septic shock, their general use should be discouraged; rather their use should be matched to patient conditions that are more likely to benefit from treatment.

Role of Lipid Peroxidation in Tissue Injury

Lipid peroxide formation is the result of free radical-mediated cell and tissue injury caused by lipid peroxides within cell membranes and organelles. Both structure and function of the membranes and organelles are disrupted by lipid peroxide formation. Lipid peroxidation is a potentially geometrically progressing reaction that spreads over the surface of cell membranes, impairing phospholipid-dependent enzymes; ionic gradients across the cell membrane,;and, if sufficiently severe, membrane lysis (Figure 29-15). Its importance, along with the generation of oxygen radicals, is evident early in the pathophysiology of CNS trauma. Lipid peroxidation is only one of several sources of oxygen radial formation. Other sources include the AA cascade; catecholamine oxidation; mitochondrial "leak"; oxidation of extravasated hemoglobin; and, as the inflammatoryprocess proceeds, infiltrating neutrophils.

Lipid peroxidation is initiated by a reactive oxygen molecule. After CNS trauma, the generation of oxygen radicals during the normal reduction of oxygen overwhelms normal control mechanisms. Xanthine/xanthine oxidase, PG synthetase, and other mechanisms result in superoxide anion formation. Although superoxide anion is not in itself very reactive, it becomes more so by accepting a proton, thereby becoming more able to penetrate cell membranes. Other sources of superoxide anion include catecholamines; ascorbic acid and glutathione act to inhibit superoxide anion. The superoxide anion can also become more dangerous by conversion by way of superoxide dismutase to hydrogen peroxide. Inflammatory cells are an important source of hydrogen peroxide, as is degradation of monoamines mediated by monoamine oxidase. Mitochondria contain high concentrations of superoxide dismutase. Although hydrogen peroxide is not very damaging to intact tissues, it can easily penetrate cell membranes unless destroyed first by catalase. In the cell membrane, hydrogen peroxide interacts with iron to yield the highly reactive hydroxyl radical.

Normally, the conversion of oxygen to water is well controlled by the presence of superoxide dismutase, catalase, and endogenous antioxidants, with vitamin E being one of the most important membrane-bound antioxidants. After CNS trauma, normal control mechanisms are lost, and lipid peroxidase formation begins. Iron plays a crucial role in this process. Free iron released from hemoglobin, transferrin, or ferritin in the presence of a lowered tissue pH or oxygen radicals catalyzes radical-initiated peroxidation (see Figure 29-15). Iron–oxygen complexes probably initiate lipid peroxidase formation; damage during ischemic injury from

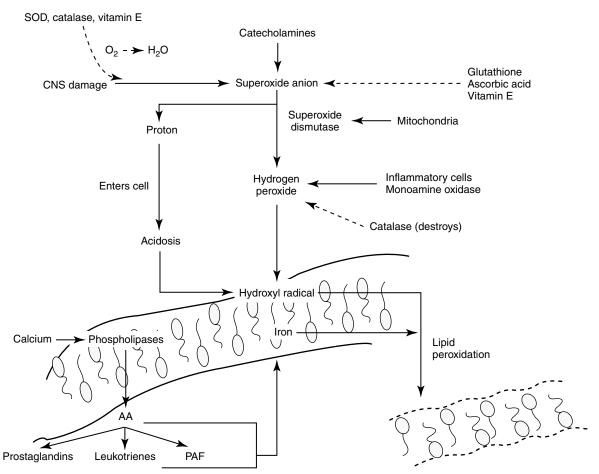

Figure 29-15 Lipid peroxidation of cell membranes reflects a cascade of events that begins with neurologic damage. Oxygen radical formation is potentiated in the presence of iron and is inhibited by endogenous protectants such as superoxide dismutase (SOD) (which converts the superoxide radical to hydrogen peroxide) and catalase. Catecholamine release can contribute to damage. The ability of the radicals to move down the cell membrane is facilitated by the fluidity of the membrane. Calcium influx accompanying cell membrane damage contributes to the formation of arachidonic acid metabolites and subsequent inflammation. *AA*, Arachidonic acid; *CNS*, central nervous system; *PAF*, platelet-activating factor.

radicals will be affected by the amount and location of iron (and copper) ions. Unfortunately, these ions become more available during injury. Acidosis, which often accompanies ischemia (anaerobic environment and lactic acidosis), increases the solubility of iron. Free calcium released during the injury stimulates phosopholipase A_2 and the AA cascade. Metabolites of AA are important sources of reactive oxygen species. Inflammatory cells become an important source of continued AA metabolism. Decreased concentrations of vitamin E, ascorbic acid, and glutathione (induced by scavenging of oxygen radicals) predicate the occurrence of lipid peroxidation.

Drugs That Impair Mediators of Sepsis

Nonsteroidal Antiinflammatory Drugs

A number of NSAIDs have been studied for their ability to block response to mediators of endotoxic shock. Indomethacin and ibuprofen have shown efficacy in human patients.^{380,382} Flunixin meglumine has been studied in horses and dogs.^{141,383} As with glucocorticoids, however, the effects of NSAIDs must be realized within the first 2 hours of the onset of endotoxic shock—that is, before mediators have been able to stimulate response. The use of NSAIDs may shunt AA substrate to the lipoxygenase pathway, which may cause detrimental effects. Thus drugs that impair both arms of the AA cascade may prove more useful. The efficacy of ketoprofen, an NSAID that appears to inhibit both PGs and LTs, has been shown to ameliorate many of the effects of endotoxin infusion.³⁸⁴ The combined use of NSAIDs with LT antagonists apparently has not been reported in endotoxic shock, but the advent of dual inhibitors warrants further studies. Prolonged therapy with NSAIDs is not advisable because of toxic effects. Although gastrointestinal toxicity is the major concern in most animals, the patient suffering from endotoxic shock may be more predisposed.

Glucocorticoids

Glucocorticoids are discussed in Chapter 17. Glucocorticoids inhibit the enzyme phospholipase A_2 and the release of TNF and IL-2 from activated macrophages.³⁸⁵ Glucocorticoids also alter synthesis of and biologic response to collagenase, lipase, and plasminogen activator. The immunosuppressive actions of glucocorticoids are more pronounced on the cellular arm than the humoral arm of the immune system. Glucocorticoids have minimal effects on plasma immunoglobulin concentrations but can modulate immunoglobulin function. Immunosuppressive actions of glucocorticoids, like their antiinflammatory actions, involve disruption of intercellular communication of leukocytes through interference with lymphokine production and biological action; however, these effects are largely transrepressive (see Chapter 17). Glucocorticoids block the effects of macrophage-inhibiting factor and interferon- γ (IFN- γ) on macrophages. IFN-y, which is released from activated T cells, plays an important role in facilitating antigen processing by macrophages. Glucocorticoids inhibit the synthesis and release of IL-1 by macrophages, thereby suppressing the activation of T cells. Glucocorticoids also inhibit IL-2 synthesis by activated T cells. Interleukin-2 plays a critical role in amplification of cell-mediated immunity. Additionally, glucocorticoids suppress the bactericidal and fungicidal actions of macrophages.

Septic shock. Earlier experimental models of septic shock in animals indicated that glucocorticoids can be of benefit but only if administered before or concurrently with endotoxin administration-that is, within the first 2 hours. In canine models severe mesenteric vasoconstriction within the first 15 minutes can lead to irreversible shock. Thus glucocorticoids provided no beneficial effects when administered 30 to 60 minutes after administration of the endotoxin. Rapidacting, water-soluble agents such as dexamethasone sodium phosphate (4 to 8 mg/kg intravenously), prednisolone sodium succinate or sodium phosphate (30 mg/kg intravenously), or methylprednisolone sodium succinate (30 mg/kg intravenously) have been recommended, at shock doses, which are 5 to 10 times the immunosuppressive dose. However, more recent data suggest that the use of glucocorticoids in patients with sepsis is controversial. Multiple meta-analyses of randomized human studies have demonstrated that high doses of glucocorticoids (e.g., methylprednisolone at 30 mg/kg) invariably do not prevent septic shock, reverse the shock state, or improve the 14-day mortality rate, despite theoretical and experimental animal evidence to the contrary. Indeed, mortality rates were greater in one study, presumably because of immunosuppression and secondary infection.³⁸¹ In contrast, stress-dose (or physiologic dose) glucocorticoids (e.g., hydrocortisone at 200 mg/day; approximately 3 mg/kg) intended to replace deficient corticosteroids (due to adrenal suppression) in patients with severe and refractory shock may be of benefit (see Chapter 17). Patients with persistent vasopressor-dependent shock should be targeted,³⁸¹ although controversies continue regarding this indication as well.³⁸⁰ In human patients use of glucocorticoids is controversial, with no improvement in survival in some studies.386

Hemorrhagic shock. The use of glucocorticoids for treatment of hemorrhagic shock is controversial. Some studies in dogs suggest that dexamethasone sodium phosphate (5 mg/ kg intravenously) may improve blood flow to the kidneys, lungs, and gastrointestinal tract. Other supportive measures, particularly aggressive fluid therapy, must also be instituted. Appropriate fluid replacement therapy will ensure adequate drug distribution to target tissues.

Oxygen radical scavengers. A neuroprotective role has been recognized for certain glucocorticoids and, most notably, methylprednisolone. Interest stemmed from the observation that the ability to inhibit CNS lipid peroxidation and influence other pathophysiologic processes strongly correlated with neurologic recovery. The neuroprotective effects have been separated from the glucocorticoid activity by the discovery of nonglucocorticoid steroids that are able to equal or surpass the antioxidant effects of methylprednisolone (see later discussion of lazaroids).

In a feline model of spinal injury, methylprednisolone (30 mg/kg) attenuates posttraumatic lipid peroxidation. In addition, perhaps because of the inhibitory effect on lipid peroxidation, methylprednisolone supports energy metabolism, reduces or prevents posttraumatic ischemia and neurofilament degradation, reduces intracellular calcium accumulation (resulting in the AA cascade), and inhibits vasoactive PGs (PGF₂ α and thromboxane). In addition, like other steroids, methylprednisolone may increase spinal neuronal excitability, which may also be important to neurophysiologic recovery. Several pertinent points must be appreciated regarding these effects of methylprednisolone on spinal cord injury. First, these effects occur only at a high concentration (i.e., that achieved with an intravenous dose of 30 mg/kg). Second, the effects are biphasic, with loss at 60 mg/kg. As with many protective mechanisms, the drug must be administered early in the pathophysiologic process because spinal uptake of methylprednisolone decreases rapidly with time after injury. Loss of effect may reflect a decrease in blood flow to damaged tissues or the irreversible nature of lipid peroxidase. Finally, the time course of neuroprotection of methylprednisolone follows the disappearance of the drug from plasma or tissue-that is, it lasts only 2 to 6 hours (the half-life of the drug in feline spinal tissue). Thus the drug must be administered frequently to preserve tissues and maximize the potential for recovery. The role of glucocorticoids in treatment of intervertebral disc disease is addressed in Chapter 27).

Lazaroids

After the unique protective effect of methylprednisolone among the glucocorticoids in damaged nerve tissue was recognized, attempts were made to refine the structure of the steroidal molecule such that the neuroprotective (anti lipid peroxidase) effects would be maintained but the glucocorticoid effects minimized.³⁹³ The result of these efforts was the synthesis of the 21-aminosteroids or lazaroids. Tirilazad mesylate is the prototypic drug (Figure 29-16). Lazaroids have been specifically designed to localize in cell membranes and inhibit (iron-mediated) lipid peroxidase. Although initial investigations were oriented toward acute trauma, because inhibition of lipid peroxidase may decrease neuronal degeneration, these drugs may also be useful for chronic neurodegenerative processes.

Tirilazad mesylate is a very lipophilic drug that preferentially distributes to the lipid components of cell membranes.

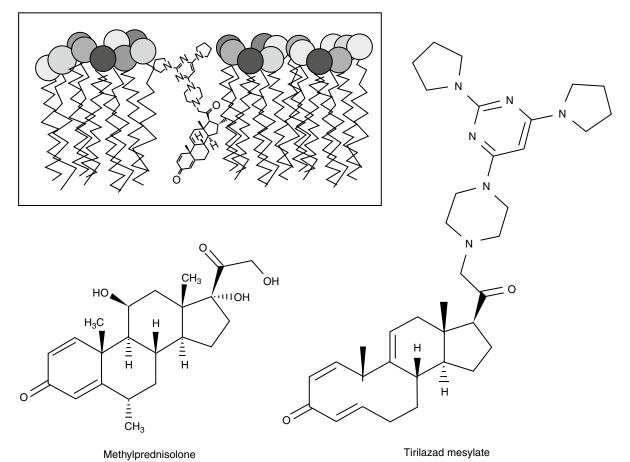

Figure 29-16 Tirilazad mesylate is an example of a lazaroid (a 21-aminosteroid). Compared with methylprednisolone *(left)*, a glucocortiocoid capable of scavenging oxygen radicals, the 21-aminosteroids are devoid of steroidal activity. Their ability to inhibit lipid peroxidation and provide a neuroprotective effect occur in part by insertion into the lipid bilayer of the cell membrane. Cell membrane fluidity is decreased, thus impairing the ability of oxygen radical formation to cascade across the lipid layer. Lipid peroxidation is thus minimized.

Because neuronal tissue is composed of a greater proportion of lipid components, these drugs preferentially accumulate in neuronal tissue. Its pharmacologic actions are complex and include a radical scavenging-antioxidant effect and a physiochemical interaction with the cell membrane such that the fluidity of the membrane is decreased (see Figure 29-16). Although action against iron-mediated lipid peroxidase was sought for these drugs, they will in fact inhibit lipid peroxidase in iron-free systems as well. Tirilazad has proved to be an effective inhibitor of lipid peroxidase in all in vitro models studied. It also acts to reduce hydroxyl radicals by either direct scavenging abilities or decreased lipid peroxidase. Stabilization of cell membranes is considered an important part of its protective action. The nitrogen component of the steroid is thought to interact with the phosphate of the "head" groups (hydrophilic portion) of the bilipid layer by way of ionic interactions. The steroidal component localizes in the lipophilic portion of the membrane, compressing the phospholipid groups. Restriction of the movement of the cell membrane reduces the potential for lipid peroxidase by restricting the movement of lipid peroxyl and alkoxyl radicals in the membrane.

Tirilazad also has a high affinity for vascular endotheliulm. It appears to be able to protect vascular endothelium from damage by reactive oxygen species, possibly by preserving endothelium-derived relaxing function. It also appears to protect the blood-brain barrier against traumatically or chemically induced permeability. Tirilazad may protect other endothelial cells during trauma or hypoxic damage, such as the hepatic endothelium during hemorrhagic shock.

Animal models used to study the effects (not safety) of tirilazad have been primarily rats and monkeys. A few studies have focused on dogs or cats. Models of CNS damage have included that induced by cardiac arrest, altered cerebral blood flow, and subarachnoid hemorrhage. The clinical pharmacology of tirilazad has been studied in humans. It appears to be a flow-limited hepatically cleared drug. In humans there is a discrepancy in the elimination half-life of approximately 4 hours in one report and, after steady state, 35 hours. The difference appears to be a longer terminal phase after multiple dosing compared with single dosing; it is likely that volume of distribution cannot be accurately assessed after single dosing. The disposition of tirilazad is linear and does not appear to change with plasma drug concentration. Safety studies in humans have revealed the drug to be safe. Pain occurs at the site of injection, but this has been overcome by dilution of the drug, a change in the site of injection, and frequent catheter changes. Tirilazad does not appear to adversely affect the heart, blood pressure, or hepatic or renal function. Tirilazad has no glucocorticoid activity and will not alter parameters indicative of glucocorticoids (i.e., glucose, hematologic indices, adrenocorticotropic hormone, or cortisol). Apparent indications for tirilazad in humans include acute head or spinal injury, subarachnoid hemorrhage, and ischemic stroke.

The lazaroids have also demonstrated efficacy in traumatic shock,³⁸⁷ hemorrhagic shock,³⁸⁸ and endotoxemia.^{389,390} Lazaroids decrease neutrophil accumulation, maintain arterial pressure, decrease myocardial injury, and increase survival. Lazaroids decrease formation of the eicosanoid mediators and production of TNF. When administered to dogs within 30 minutes of endotoxin infusion, lazaroids attenuated the effects of endotoxin.³⁹¹ Further studies are indicated before the use of lazaroids is confirmed. Currently, no lazaroid is approved for use in the United States.

Recombinant Human Activated Protein C

Activated protein C (APC) is an endogenous protein that simultaneously promotes fibrinolysis and inhibits thrombosis and inflammation, thus potentially modulating some of the negative sequelae of sepsis. In septic patients concentrations of protein C are decreased and conversion of protein C to activated protein C is inhibited. The role of protein C in septic shock led to the development and subsequent approval of a recombinant product, drotrecogin-activated, used in the treatment of human septic shock. In humans clinical trials largely support the safety and efficacy of the drotrecogin-alfa, activated, as indicated by decreased mortality rates.³⁸⁰ Its efficacy has been attributed to effects beyond those on the coagulation cascade, with antiapoptotic effects on endothelial cells suggested. The use of APC may be of most benefit in patients with a high risk of death but may be harmful in patients with a low risk of death.^{381,392} Consequently, the use of this product in small animals should be based on scientific studies that establish the optimal pharmacokinetic-pharmacodynamic relationship.

Inhibitors of Soluble Epoxide Hydrolase

The role of cytochrome P450 in the production of biologically active compounds, including the patient with septic shock, is largely overlooked. However, EETs or HETEs and EpOMEs are among the chemicals derived from the vascular endothelium that mediate vascular relaxation responses, as well as antiinflammatory effects in septic shock. Proposed mechanisms by which EETs modify the response of septic shock include inhibition of transcription factor nuclear factor-KB and IB kinase, thus preventing amplification resulting from macrophage production of proinflammatory proteins, such as TNF- α , IL-6, iNOS, and COX-2. Once formed, EETs and EpOMEs are further metabolized by soluble (in the cytoplasm) epoxide hydrolase (SEH). Persistence of these mediators by inhibition of SHE is being investigated as a therapeutic target in the patient in septic shock.²⁶¹ Drugs that target SHE not only facilitate EETs but also may facilitate the antiendotoxic effects of lipoxin.

Glucocorticoids and Mineralocorticoids

Dawn Merton Boothe and Katrina A. Mealey

Chapter Outline

PHYSIOLOGY: CONTROL OF ENDOGENOUS GLUCOCORTICOID SECRETION MECHANISM OF ACTION Mineralocorticoid and Glucocorticoid Receptors Nuclear and Non-nuclear Mechanisms of Action of Corticosteroids Glucocorticoid Resistance PHYSIOLOGIC EFFECTS Effects on Intermediary Metabolism: Carbohydrates, Proteins, and Lipids Water and Electrolyte Balance Hemolymphatic System Antiinflammatory and Immunosuppressive Effects Cardiovascular System Bone and Cartilage Skeletal Muscle Central Nervous System **Respiratory System** Alimentary Tract Reproduction STRUCTURE-ACTIVITY RELATIONSHIP CLINICAL PHARMACOLOGY Absorption Distribution, Metabolism, and Excretion DRUGS AND PREPARATIONS Hydrocortisone Prednisolone and Prednisone Methylprednisolone Dexamethasone Betamethasone "Soft" Glucocorticoids Tirilazad Mesylate Fludrocortisone Desoxycorticosterone Pivalate THERAPEUTICS

THERAPEUTIC INDICATIONS Dermatologic Otic Respiratory Musculoskeletal Central Nervous System Inflammatory Bowel and Liver Disease Gingivitis and Stomatitis Septic Shock and Functional Adrenocortical Deficiency Neoplasia Ophthalmic Hematopoietic Hypoadrenocorticism **ADVERSE EFFECTS** Central Nervous System Musculoskeletal Gastrointestinal and Liver Metabolic Hepatic Endocrine Renal Cardiovascular **Immune Function** Wound Healing **Immune Reactions** Respiratory Growth Retardation CONTRAINDICATIONS Infectious Disease Diabetes Mellitus **Renal Failure** Corneal Ulceration Pancreatitis Gastrointestinal Ulceration Pregnancy Epilepsy

Glucocorticoids (GLCs) are among the most frequently used and misused drugs in veterinary medicine. Optimal therapy with GLCs requires a thorough understanding of their actions on all body systems and knowledge of the pharmacodynamic and pharmacokinetic differences of the synthetic GLC derivatives. The physiologic and pharmacologic effects of GLCs, beyond suppression of the hypothalamicpituitary-adrenal axis, have not been extensively studied in the dog or cat; therefore much of the information presented represents data extrapolated from human patients or rodent studies. Whenever possible, information specific to the dog or cat has been included and is indicated as such.

PHYSIOLOGY: CONTROL OF ENDOGENOUS GLUCOCORTICOID SECRETION

The adrenal cortex comprises three zones, each of which synthesizes steroidal hormones. From superficial to deep, these include the zonas glomerulosa, the source of mineralocorticoids

(predominantly aldosterone but also corticosterone); reticularis, a source of (weak) androgens; and fasciculata, the source of GLCs (cortisol and cortisone). As with many hormones, the secretion of corticosteroids reflects a balance between positive and negative feedback pathways. Corticotropin-releasing hormone (previously corticotropin release factor, CRH) is secreted by the hypothalamus and travels through the hypophyseal portal system to the adenohypophysis, where it stimulates the synthesis and secretion of adrenocorticotropin (ACTH) from the basophilic cells of the adenohypophysis (Figure 30-1). In addition to its role in promoting ACTH secretion, CRF appears to be involved in the autonomic, immunologic, and behavioral response to stress independent of the hypothalamopituitary axis. Administration of CRF to dogs results in a decrease in gastric acid secretion by activation of the sympathetic nervous system, an immediate decrease in mean arterial blood pressure accompanied by reflex tachycardia, and a marked increase in plasma vasopressin concentrations.¹ These actions of CRF are independent of GLCs.

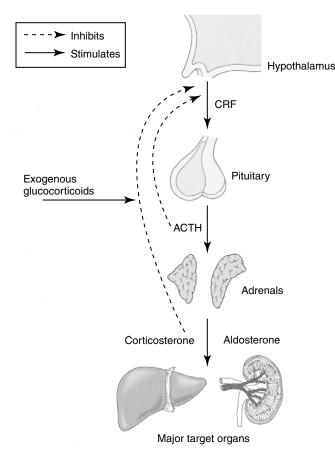

Figure 30-1 The relationship between the hypothalamus, pituitary, and adrenal glands. Release of corticotropin-releasing factor (CRF) is prevented by feedback inhibition of corticosteroids (exogenous or endogenous). Release of adrenocorticotropic hormone (ACTH) is subsequently inhibited, and further synthesis, primarily of glucocorticoids, is inhibited. The primary target organ of mineralocorticoids is the kidney; the liver and cardiovascular system are important targets of glucocorticoids.

In addition to CRF, ACTH also is stimulated by arginine vasopressor (AVP), which is a weak stimulator of ACTH but a strong stimulator of CRH and catecholamines; angiotensin II; serotonin; and vasoactive intestinal peptide. Other stimulators include the inflammatory cytokines interleukin (IL) -1, -2, and -6 and tumor necrosis factor- α (TNF- α).² Most stimulators of ACTH also stimulate CRH.² The primary short-term effects of ACTH are stimulation of the adrenal cortex synthesis and secretion of cortisol, corticosterone, aldosterone (the effect of ACTH on mineralocorticoid secretion is minimal), and weak androgenic substances. Long-term effects of ACTH increase the production of enzymes and cofactors necessary for cortisol production and cause an increase in adrenal receptors for low-density lipoprotein cholesterol.²

Cortisol and corticosterone concentrations in plasma subsequently influence CRF and ACTH secretion such that increased concentrations inhibit release of CRF and ACTH and reduced concentrations stimulate release of CRF and ACTH. Exogenous factors, such as trauma, heat, stress, surgery, and neural impulses, also mediate CRF and ACTH secretion. Exogenous corticosteroid administration can also suppress CRF and ACTH release. The degree of suppression depends on the particular drug used. For example, the synthetic drug dexamethasone is 50 to 100 times more potent in suppressing ACTH secretion than is the endogenous compound, cortisol.³ The diurnal variation in GLC secretion that occurs in humans has not been well documented in dogs or cats. Nonetheless, morning dosing (in dogs) is among the strategies used to minimize the risk of adrenocortical suppression that might result from exogenous glucocorticoid therapy. These approaches thus include: 1. Determining a minimum effective dose; 2. Alternate day dosing; 3. Use of a "short-acting" glucocorticoids whose effects are 24 hrs or shorter in duration; 4. Dosing in the morning (and potentially dosing at nights for cats); and 5. Tapering the dose over days to weeks as therapy is discontinued, thus facilitating readaptation of the adrenal gland to secretion.

MECHANISM OF ACTION

The myriad physiologic effects of GLCs result from interaction of the drugs with the glucocorticoid receptor (GR), one member of a nuclear hormone receptor superfamily that also includes receptors for thyroid hormone, mineralocorticoid, estrogen, and progesterone.⁴ Other activities may also reflect nonreceptor mechanisms.

Mineralocorticoid and Glucocorticoid Receptors

Two primary types of corticosteroid receptors exist. Type I, or mineralocorticoid receptors (MRs), bind both endogenous GLCs and aldosterone. Type II, or GRs, bind endogenous and exogenous GLCs but have a poor affinity for mineralocorticoids. The GRs and MRs are sufficiently similar that drugs may bind to both, causing similar responses. In human medicine, the cause and effect relationship between hypertension, heart failure, and MRs has led to a reassessment of the relationship between GLC and mineralocorticoid as well as androgen and progesterone receptors.⁵ The distinction

among the receptors, including the sequence of their evolution, becomes important when assessing the selectivity or lack thereof of therapeutic agents on each receptor type. In human medicine this is particularly germane to the impact of GLCs on the MRs and its implication in patients with cardiovascular disease.

Every cell appears to have GRs, although the liver is the primary target. The type and concentration of GRs varies between species and tissue. Type II receptors are more ubiquitous in the brain. The degree to which GLCs bind to each receptor type varies with the circulating concentration. At basal levels type I receptors are preferred, but as cortisol concentrations increase (e.g., during stress), type II receptors increasingly are activated.⁶

Within a given tissue, GR numbers appear to fluctuate with changing cell cycles and age and in response to a variety of endogenous or exogenous compounds. More than 15 endogenous regulators have been identified for GLC receptors.⁷ Response to GLCs reflects receptor density or GLC concentration, depending on the tissue. GR density is autoregulated; increased receptor density associated with hypoadrenocorticism can be reversed with GLC replacement.8 Likewise, chronic GLC therapy will result in downregulation of receptor density. However, autoregulation is tissue specific, and in some tissues the concentration of GLC is a more important determinant of response than is the number – or even type of receptors. For example, as noted, the MR acts similarly to the GR and is sufficiently similar in structure that responses to substrates are also likely to be similar.^{8,9} Any steroid with a ketone group at position 11 (Figure 30-2) will interact positively with either the MR or GR.² However, GLCs generally are present in concentrations that exceed those of mineralocorticoids by 1000-fold or more,² which suggests the potential for GLC response to predominate in any tissue exhibiting either GRs or MRs. The ability of receptors to respond to mineralocorticoids despite differences in concentration reflects a combination of conditions: (1) binding of glucorticoids by globulins, which effectively sequesters the hormone, precluding interaction with GRs or MRs; (2) activation of discrete sets of target genes, perhaps reflecting a difference in repression of transcriptional induction (e.g., aldosterone activates the expression of several genes, with that of Na+, K+-ATPase in the basolateral membranes of tubular cells being the best characterized); (3) restrictive expression of MRs only, with the principle sites occurring in the renal cortical distal tubules and collecting ducts, colon, salivary and sweat glands, and hippocampus⁸; (4) differing rates of GLC inactivation, which allows mineralocorticoids to predominate and stimulate response. For example, tissues differ in their expression of 11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD2), the enzyme that inactivates cortisol to corticosterone. Tissues with high concentrations of 11 beta-HSD2are those that typically respond to mineralocorticoids-kidney, colon, salivary gland—allowing mineralocorticoid effects to predominate.8,10 In the presence of 11 β -HSD2, GLC expression occurs only if present in concentrations several magnitudes higher than mineralocorticoids.

KEY POINT 30-1 Similarities in the mineralocorticoid and glucocorticoid receptors and steroid structures contribute to the shared action of drugs.

Certain disease conditions may reflect aberrations in methods allowing differential substrate response such as an absence of 11 β-HSD2 such that tissues respond to the inappropriate steroid.⁹ The importance of renal metabolism of cortisol is implied in the impact renal failure has on prolongation of plasma cortisol half-life in human patients; half-life increased 30% in one study.¹⁰ Impaired 11 β-HSD2 accompanying renal disease contributes to the pathophysiology of salt and water retention and hypertension in renal failure and therefore could contribute to selected consequences of renal disease (hypertension, sodium retention, hyperkalemia, and decreased glomerular filtration rate). Inhibition of 11β HSD2by selected compounds (licorice, selected angiotensin-converting enzyme inhibitors [ramipril]) contributes to pharmacologic or adverse events as well as drug interactions. Ramipril causes decreased ACTH-induced hypertension in the rat.¹⁰ Inhibition allows GLCs to excessively stimulate MRs such that hyperaldosteronism emerges. Such interactions also can be favorable:

Nuclear and Non-nuclear Mechanisms of Action of Corticosteroids

The molecular description of the GR as it relates to its mechanism of interaction has been described.¹¹⁻¹⁴ The GR consists of at least two isoforms.¹¹ The α isoform binds to GLCs, DNA, and transcription factors and thus modulates transcription activity. The α isoform may also act through nongenomic mechanisms. In contrast, although the β isoform binds to DNA, it does not bind other ligands, fails to activate transcription, and appears to be able to interfere with the activities of α isoforms.¹² Corticosteroid receptors are located in the cytoplasm of the target cell complexed with heat shock proteins (Hsp 70 and Hsp 90) that act as chaperones, proteins which in non-functional activities (e.g., folding, assembly) of macromolecules, and an immunophilin, an intracellular protein that binds other immunosuppressive compounds.9,11 The complexed receptor is inactive until bound to a steroid ligand.⁹ Steroids enter the cells by passive diffusion, although a rate-limited active transport mechanism may also exist (Figure 30-2) Once in the cell, the GLC binds to the receptor, causing the heat shock protein and other molecules to dissociate. Intracellular GLCs impart their effects in one of three ways: The steroid-receptor complex moves into the nucleus and (1) binds to specific DNA sequences causing the regulation of genes (for example, lipocortin or genes responsible for gluconeogenesis) (referred to as a "cis" or element, resulting in transactivation), (2) interacts with other transcription factors (e.g., AP-1, NF κ B), generally at lower concentrations, that prevent the transcription of targeted genes (e.g., TNFα, IL-1B, IL-4 and 5; referred to as a "trans element" resulting in transrepression); or (3) through non-genomic mechanisms involving membrane-associated GR and secondary messenger systems.^{2, 12a} Non-genomic responses are rapid in onset, and includes

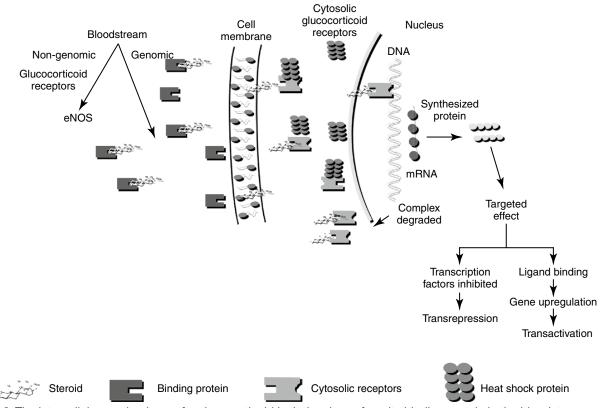

Figure 30-2 The intracellular mechanisms of a glucocorticoid include release from its binding protein in the bloodstream, passive diffusion of the drug through the cell membrane, movement through the cytosol in association with a receptor and chaperone heat shock protein, translocation to the nucleus, binding to DNA, transcription, either stimulation or inhibition of protein synthesis, and degradation of the protein–steroid complex.

vascular responses (eNOS activation), lymphocytolysis, and possibly, induction of inflammatory prostaglandins. "Permissive" effects of GLC may reflect non-genomic responses.

Because the effect of older, current and future GLC reflects the molecular relationship between drug and cellular macromolecules, a brief review or molecular interactions is warranted. Genomic effects of GLCs are initiated by translocation of the activated receptor-GLC complex to the nucleus (Figure 30-2). In the nucleus the complex binds to regulatory proteins of target genes. The short DNA sequences recognized by the activated GR are referred to as glucocorticoid responsive elements (GREs). It is through these GREs that specificity of GLC-modulated gene transcription is controlled.⁴ Transcription of the gene and subsequent formation of the targeted protein is either induced (transactivated) or inhibited (transrepressed). The receptor and GLC are eventually metabolized (the exact location or timing is not documented). The cellular half-life of the activated complex is about 10 hours.¹⁵ It is not known whether the rate of metabolism of the GLC-receptor complex is dependent on the specific GLC involved. Some of the proteins that are regulated by GLCs are listed in Table 30-1. The proteins encoded by these genes are responsible for some of the physiologic (pharmacologic) effects of GLCs.

KEY POINT 30-2 As with all steroids, corticosteroids cause their primary effects by inducing or inhibiting the synthesis of target proteins at the level of the gene.

Once activated, the activated ligand receptor influences gene expression by binding to specific GREs in the promoter regions of GLC-regulated genes. However, in addition to this classical transactivation mechanism, also referred to as positive GRE (pGRE), genes may also be negatively targeted, or transrepressed, through negative GRE (nGRE). The GR generally has a lower affinity for nGRE than pGRE. Transrepression involves protein-protein coupling to other transcription factors (e.g., nuclear factor kappa-B [NFKB], activator protein-1 [AP-1], STAT-5 (signal transducer and activator of transcription) or nuclear factor of activated T-cells [NFAT]) such that their activity is modulated. The importance of these different GR interactions results in differential physiologic (and pharmacologic) effects and ultimately provides a basis for directed drug therapy. The largely undesirable metabolic effects of long-term GLC therapy appear to be mediated by pGRE interaction (i.e., transactivation gene expression). In contrast, the desirable antiinflammatory effects appear to reflect modulation of transcription factors (i.e., transrepression through interaction with nGREs).^{16,17} Indeed, nGREs contribute to the regulation of the hypothalamicpituitary-adrenal axis (targeting pro-opiomelanocortin [POMC] and CRH), bone metabolism (through osteocalcin), skin function, inflammation (IL-1β), angiogenesis (proliferin), and lactation (prolactin).¹⁷ Trans (protein-coupling) effects, and repression in particular, appear to occur at concentrations lower than that necessary for cis (transactivation)

effects,¹⁸ providing another mechanism of directed therapy. "Designer" GLC might be developed such that potency for protein coupling (trans) repression is greater than DNA interaction, leading to cis or trans activation. Dexamethasone and prednisolone are examples of a "symmetric" GLC, characterized by equal binding affinity for both actions. Interestingly, medroxyprogesterone acetate exhibits a preponderance of transrepression activity rather than transactivation.¹⁶ Newer GLCs are likely to have a preponderance of activity for either activation or repression. The recognition of this dual mechanism of GLC action will also facilitate the development of GR antagonists, which might be useful for the treatment of Cushing's disease.¹⁶ Another term that has emerged is "Dissociated GLCs" which target GLC-dependent transactivation or alternatively act as inhibitors of NFkB-dependent transcription, thus retaining their in vivo antiinflammatory activity but avoiding their undesirable metabolic effects.¹⁹

KEY POINT 30-3 The desired inhibitory effects of glucocorticoids reflect indirect repression of transcription factors, whereas undesirable effects reflect direct interaction with DNA.

Differences in GR affinity for nGREs versus pGREs may also offer a mechanism for differential targeted drug response based on dose (or concentration). Treatment with low, rather than high, doses of GLCs appears to minimize undesirable side effects.²⁰ Using a retrospective analysis of published literature (meta analysis precluded by method variability) coupled with a prospective study, researchers found that most adverse effects to GLCs in humans were associated with high, rather than low, doses (7.5 mg prednisolone equivalent in humans [approximately 0.1 mg/kg]) of GLC (see the section on adverse events).

Glucocorticoid Resistance

Failure to respond to steroid therapy is observed in human patients being treated for a variety of diseases. Poor compliance and low bioavailability must be ruled out before other factors are considered. The documented phenomenon of GLC resistance (both familial and iatrogenic or drug induced forms have been reported in humans) may reflect, among other causes, reduced receptor numbers or affinity for GLC.²¹ Cellular response to GLCs has been directly correlated with receptor numbers. Reversible downregulation of receptor numbers and a subsequent decrease in biological effect are documented sequelae of GLC treatment.⁷ Such effects have been demonstrated on lymphocyte receptors.²² GLC failure in patients receiving longterm GLC therapy for treatment of host-versus-graft rejection has been attributed to downregulation of cytoplasmic GRs in T lymphocytes. GLC doses subsequently must be increased.²³ Pulsing of high doses of GLCs may overcome this relative resistance (see the section on therapeutic use).²⁴ The relative balance of the α and β isoforms of GR appear to influence cell sensitivity to GLCs; higher concentrations of β contribute to GLC resistance.12 Treatment of inflammatory bowel disease offers an example of potential mechanisms of GLC resistance. Some human patients with severe disease are nonresponsive to even high doses of GLCs. Lack of response has been associated with poor antiproliferative effects on blood T lymphocytes, in contrast to near-complete inhibition of responders. A similar relationship has been demonstrated for other chronic allergy-based diseases, such as asthma or rheumatoid arthritis, and renal allograft rejection. A relatively fast in vitro T lymphocyte proliferation assay has been useful in identifying nonresponders before treatment.²⁵ Several molecular mechanisms have been proposed to account for poor control of T cell proliferation by GLCs. These include overexpression of the multidrug resistance gene (MDR1 polymorphism), resulting in increased P-glycoprotein-mediated efflux of cytoplasmic (see relevant discussion in the section on neoplasia). This mechanism might be reversible by co-administration of cyclosporine, an inhibitor of P-glycoprotein. Other mechanisms include impaired GLC signaling by the GR and increased activation by epithelial cells of proinflammatory mediators that

directly inhibit GR transcription. This latter mechanism (postreceptor failure) is supported by the presence of clinical signs consistent with Cushing's disease in humans with poor inflammatory control.²⁵ Differences in activation patterns of NFκB have been associated with GLC resistance in human patients with chronic inflammatory bowel disease.¹⁹ Ultimately, differences in response at the molecular level may also be shown .

KEY POINT 30-4 Glucocorticoid resistance is a recognized contributor to therapeutic failure and reflects several potential mechanisms, some of which might be avoided with proper use.

PHYSIOLOGIC EFFECTS

Physiologic effects of GLCs required for the "normal" dayto-day function of the animal can be easily appreciated when GLCs are absent, as in the case of adrenocortical insufficiency (hypoadrenocorticism or Addison's disease), or present in excessive concentrations, as in hyperadrenocorticism. The primary role of aldosterone, the major mineralocorticoid, is regulation of sodium homeostasis. Interestingly, the effects of GLCs and mineralocorticoids can be directly antagonistic at some sites. For example, in some tissues aldosterone stimulates and GLCs inhibit sodium resorption.⁸ Likewise, cortisone can have different and opposing effects, depending on whether it interacts with MRs or GRs. Cortisone inhibits microglial proliferation through GRs but stimulates proliferation through MRs.²⁶ Dexamethasone also inhibits microglial cell proliferation at concentrations lower than those for cortisone.²⁶

Effects on Intermediary Metabolism: Carbohydrates, Proteins, and Lipids

The natural function of GLCs is to protect glucose-dependent cerebral functions by stimulating the formation of glucose by the liver, decreasing its peripheral utilization and promoting its storage as glycogen.²⁷ Teleologically, these effects protect glucose-dependent tissues, the brain and heart, from starvation.⁹ The hyperglycemic effect of GLCs, as seen in the stressed patient, is due to an increase in gluconeogenesis and insulin antagonism. Gluconeogenesis is the result of an increase in precursors necessary for gluconeogenesis as well as induction of hepatic enzymes that catalyze reactions of glucose synthesis. Increased breakdown of proteins, particularly skeletal muscle and collagen, provides gluconeogenic precursors (e.g., amino acids and glycerol). This effect is exhibited clinically as muscle wasting, delayed wound healing, and thinning of the skin. The anti-insulin effect of GLCs is a result of decreased peripheral tissue utilization of glucose and reduced affinity of cellular receptors for insulin. Utilization appears to be decreased by translocation of insulin receptors from the cell membrane to an intracellular location inaccessible by insulin.9

KEY POINT 30-5 The physiologic effects of glucocorticoids reflect their underlying physiologic intent: maintenance of the body, particularly during states of stress.

Metabolism of lipids is also affected by GLCs. Specifically, GLCs promote lipolysis, generating the free fatty acids that, along with amino acids, serve as substrates for hepatic glycogen synthesis and inhibit long-chain fatty acid synthesis. Effects of GLCs on lipid metabolism reflect, in part, a permissive effect of the steroids on other agents, including growth hormone and β -adrenergic receptors. One sequela of these effects is redistribution of body fat (such as is typified by Cushing's disease). Differences in adipocyte sensitivity to insulin and the facilitating effects of GLCs may explain the redistribution phenomenon.⁹

Water and Electrolyte Balance

Cortisol appears to be essential for the maintenance of renal blood flow and glomerular filtration rate. Volume repletion alone is not sufficient to return renal function to normal in states of hypoaldosteronism. GLCs also generally increase the filtration fraction; impact on renal vascular resistance is not clear, varying with the method studied.¹⁰ Aldosterone is the most potent natural corticosteroid that affects fluid and electrolyte balance. Mineralocorticoids act to enhance sodium reabsorption in exchange for potassium (from the distal renal tubules and collecting ducts) or hydrogen (the intercalated cells), resulting in a positive sodium balance, expansion of extracellular fluid volume, and an increase in glomerular filtration rate. Sodium reabsorption is enhanced by increasing the number of open Na⁺ and K⁺ pores; Na⁺, K⁺-ATPase activity at the basolateral membrane also is increased, causing sodium to be returned to the circulation. The ratio of exchange of these mono-charge cations may be greater than than 11:1.

KEY POINT 30-6 Actions of glucocorticoids will maintain blood glucose, blood pressure, cardiac output, and vascular volume. Accordingly, their absence can result in life-threatening cardiovascular collapse.

Effects of mineralocorticoids are not limited to renal tissues but also include the colon, ileum, ciliary apparatus, salivary, and (in human beings) sweat glands. GLCs influence water and electrolyte balance through mineralocorticoid actions. Differences in tissue response to various corticosteroids was addressed previously. Cortisol and the synthetic GLCs possess varying degrees of mineralocorticoid activity, but all have less than 1% of the mineralocorticoid activity of aldosterone. GLCs also impart a permissive effect on tubular mechanisms that maintain the glomerular filtration rate. GLCs have an inhibitory effect on antidiuretic hormone and may decrease permeability of the distal renal tubules to water through a direct action. The polyuria and polydipsia commonly observed in dogs (but not cats) receiving GLCs may result from a combination of mineralocorticoid and GLC effects.

Other reported renal actions of GLC include downregulation of sodium-phosphate co-transport and sulfate cotransport, upregulation on sodium-bicarbonate co-transport, modulation of the effects of sodium on amino acid transport, and other effects on acid-base balance.¹⁰ GLCs also influence several aspects of calcium movement. In the renal tubular cells, calcium excretion is increased, and in the small intestine its absorption is impaired. GLCs also increase parathormone secretion, which in turn increases osteoclast-mediated bone resorption. The net effect of GLCs on calcium homeostasis is a decrease in total body calcium stores.

Hemolymphatic System

GLCs tend to increase the red blood cell content of the blood by retarding erythrophagocytosis. Lymphopenia, eosinopenia, and monocytopenia caused by cellular redistribution and neutrophilia caused by increased release from bone marrow, demargination, and a reduction of their removal from the circulation are all associated with GLC administration.⁹ This blood cell profile represents the "stress leukogram" seen clinically in patients with increased concentrations of endogenous GLCs. The acute effects of GLCs on circulating lymphocytes are due to sequestration from the blood rather than lymphocytolysis, although cells of lymphocytic malignancies are destroyed by GLCs. In addition to reducing the number of circulating lymphocytes, GLCs also alter the responses of lymphocytes to mitogens and antigens. T lymphocytes are inhibited to a greater degree than B lymphocytes (see following discussion of immunomodulation). GLCs also induce lymphocyte apoptosis.²⁸ GLCs also have direct inhibitory effects on eosinophils, including eosinophil migration.²⁹ GLCs directly induce eosinophil and lymphocyte apoptosis.30

Antiinflammatory and Immunosuppressive Effects

GLCs are most frequently used in clinical medicine for their antiinflammatory and immunosuppressive actions (see Table 30-1).³¹ Because the antiinflammatory and immunosuppressive effects of GLCs reflect specific actions on white blood cells, these effects are inextricably linked. They generally occur only when the amounts of steroid are present in concentrations greater than those found in the normal physiologic state (i.e., pharmacologic concentrations). The effects of GLCs on leukocyte numbers were discussed earlier. GLCs also profoundly affect white blood cell function. Ultimately, both the humoral and cell-mediated arms of the immune response are affected. The antiinflammatory effects of GLCs reflect all three mechanisms of GLC action (genomic transcription and transactivation; nongenomic membrane receptor signaling).¹²

GLCs upregulate or downregulate as many as 2000 genes involved in the regulation of the immune response (Table 30-4).² GLCs inhibit early and late phases of the inflammation. Responses that are inhibited include edema formation, fibrin deposition, leukocyte migration, phagocytic activity, collagen deposition, and capillary and fibroblast proliferation. Many of these processes involve lymphokines and other soluble mediators of inflammation, and it is through these mediators that GLCs exert their antiinflammatory actions. GLCs induce annexin I (also known as lipocortin), which inhibits phospholipase 2, thus blocking the release of arachidonic acid and its subsequent conversion to eicosanoids (i.e., prostaglandins, thromboxanes, prostacyclins, and leukotrienes). (Figure 30-3). GLCs also preferentially inhibit transcription of cyclooxygenase-2 (COX-2), the inducible form of cyclooxygenase.^{12,32,33} Interestingly, recent evidence indicates that under some circumstances, GLCs may actually induce COX-2.34 The net effect of specificity to inhibit COX-2 may be inhibition of inflammatory prostaglandins without negatively affecting the protective effects of prostaglandins in other body systems (e.g., gastrointestinal, renal, hemostasis). GLCs induce the protein MAPK phosphatase 1, which through various actions inactivates a number of proteins important in the signaling of cytokines.¹² Through physical interaction, transcription of NFkB is inhibited by GLCs. Many of the antiinflammatory effects of GLCs occur rapidly, apparently independently of changes in gene expression (nongenomic). Examples include activation of endothelial nitric oxide synthetase,¹² offering an alternative mechanism of action of a new class of more selective antiinflammatory drugs.35

KEY POINT 30-7 Glucocorticoids inhibit essentially every phase of the inflammatory response, including the immune response and wound healing.

Among the sequelae of these mechanisms, GLCs inhibit release of TNF α and IL-2 from activated macrophages. TNF α induces cytotoxicity and can enhance neutrophil and eosinophil function.²⁷ The release of platelet-activating factor from leukocytes and mast cells is inhibited by GLCs. Plateletactivating factor induces vasodilation, platelet and leukocyte aggregation, smooth muscle contraction (especially in the bronchi), and increased vascular permeability.³⁶

The immunosuppressive actions of GLCs, like their antiinflammatory actions, involve disruption of intercellular communication of leukocytes through interference with lymphokine production, biological action, or both. GLCs inhibit the synthesis and release of IL-1 by macrophages, thereby suppressing the activation of T cells. GLCs also inhibit IL-2 synthesis by activated T cells. IL-2 plays a critical role in amplification of cell-mediated immunity. GLCs block the effects of the migration inhibitory factor- γ (causing macrophages to migrate away from the affected area) and interferon- γ (IFN- γ) on macrophages.²⁷ IFN-y, which is released from activated T cells, plays an important role in facilitating antigen processing by macrophages. Additionally, GLCs suppress the bactericidal and fungicidal actions of macrophages. GLCs also alter synthesis of and biologic response to collagenase, lipase, and plasminogen activator. The antiinflammatory effects of GLCs also may reflect inhibition of the inducible form of nitric oxide synthase (iNOS).³⁷ Synovial macrophage nitric oxide production and iNOS synthesis are inhibited by dexamethasone. The inhibitory effect appears to be mediated by lipocortin. The immunosuppressive actions of GLCs are more pronounced on the cellular arm than the humoral arm of the immune system (Figure 30-4). GLCs have minimal effects on plasma immunoglobulin concentrations but can modulate immunoglobulin function. For example, opsonization of bacteria is inhibited. Therapeutic doses of GLCs do not significantly decrease an animal's antibody response to antigenic challenge (e.g., vaccinations). The immunosuppressive effects

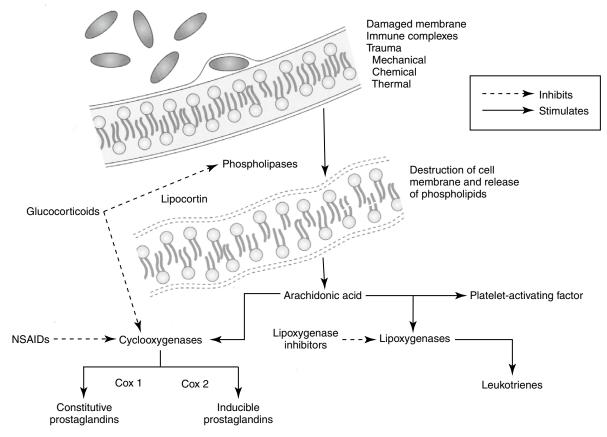

Figure 30-3 Site of glucocorticoid action in the arachidonic acid cascade. Glucocorticoids inhibit phospholipase and its subsequent degradation of cell membrane phospholipids to mediators of inflammation (platelet-activating factor, leukotrienes, and prostaglandins). Lipocortin is the effector protein whose synthesis is stimulated by glucocorticoids. In addition, glucocorticoids selectively inhibit cyclooxygenase-2. *NSAIDs*, Nonsteroidal antiinflammatory drugs.

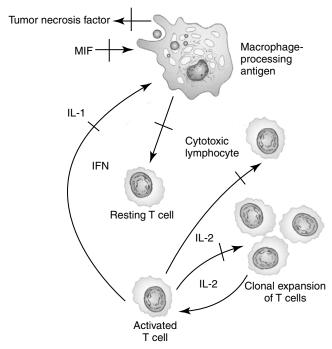

Figure 30-4 Glucocorticoids exert inhibitory effects at several sites in the cell-mediated response. Both macrophages and T cells are targeted. *IFN*, interferon; *IL*, interleukin; *MIF*, migration inhibitory factor.

of GLCs may also reflect actions on the hypothalamic-pituitary-adrenal axis. Multiple cytokines appear to regulate this axis. Specifically, IL-1 appears to stimulate the release of CRH and directly increase the release of ACTH, and it may cause the adrenals to release GLCs. These interactions appear to be important to modulation of stress and thus maintenance of homeostasis.⁹

Cardiovascular System

Corticosteroids have two major effects on the cardiovascular system. Mineralocorticoids and, to a lesser extent, GLCs affect the maintenance of extracellular fluid volume, as described previously. Interestingly, mineralocorticoids also appear to have direct actions on cardiovascular tissues; increased cardiac fibrosis has been induced experimentally in rats by administration of excessive mineralocorticoids, suggesting an indication for spironolactone as a diuretic in congestive heart failure associated with myocardial disease.9 In addition, corticosteroids (predominantly GLCs) enhance vascular reactivity to other vasoactive substances (e.g., norepinephrine, angiotensin II).9 Mechanisms appear to include increased receptor numbers in the vascular wall or other tissues. Other proposed mechanisms of GLC-induced hypertension include reduced activity of depressor systems (e.g., kallikrein-kinin, prostaglandins, and nitric oxide) and increased responsiveness to angiotensin II and norepinephrine.³⁸ In humans, Cushing's syndrome or prolonged administration of synthetic GLCs is associated with hypertension characterized by sodium chloride retention and volume expansion. However, hypertension may be independent of these effects; rather, downregulation of nitric oxide synthetase may be a more plausible explanation.³⁹ In contrast, in patients with insufficient concentrations of GLCs, negative sequelae include increased capillary permeability, decreased cardiac output, and inadequate vasomotor response of the smaller blood vessels to catecholamines. In humans, glucocorticoids are associated with worsening of cardiovascular disease. Hypertension appears to reflect increased glucocorticoid-mediated peripheral vascular resistance rather than aldosterone-mediated rather than sodium retention. The latter mechanism, along with myocardial remodeling, has been associated with worsening congestive heart failure.^{39b}

Bone and Cartilage

GLCs antagonize the effects of vitamin D₃, accelerate bone resorption, and decrease bone formation (through direct action on osteoblasts), resulting in osteoporosis. This phenomenon is well documented in human patients after chronic GLC therapy, but to the authors' knowledge it has not been observed in animals.⁴⁰ At physiologic doses, glucocorticoids stimulate collagen. At supraphysiologic doses GLCs inhibit collagen synthesis by fibroblasts; depress chondrocyte metabolism; and decrease the proteoglycan content of cartilage, resulting in morphologic changes in articular cartilage.^{41,42}

Skeletal Muscle

The permissive effects of GLCs include their influence on the ability of skeletal muscle to function normally. Too little will result in muscle wasting (generally resulting from hypokalemia). Likewise, and paradoxically, too much also will result in muscle wasting. Increased use of amino acids from muscle proteins is likely to contribute to this effect. Although the exact mechanisms of muscle wasting are unknown, the term *steroid myopathy* has been coined to reflect this condition in human patients and is used to refer to similar manifestations in small animals with hyperadrenocorticism.⁹

Central Nervous System

In the central nervous system (CNS), the highest concentration of MRs is in the limbic system, whereas GRs are more ubiquitous in the brain.⁶ Indirectly, GLCs maintain adequate plasma concentrations of glucose for cerebral functions, maintain cerebral blood flow, and influence electrolyte balance in the CNS. GLCs decrease formation of cerebrospinal fluid, which results in a reduction of intracranial pressure. In human beings GLCs are believed to influence mood (e.g., producing euphoria), behavior, and brain excitability.⁹ The euphoric effect commonly recognized in dogs also is likely to reflect differences in GRs. Steroids, including GLCs, also appear to regulate neuronal excitation, with differential effects occurring for some drugs. For example, dexamethasone inhibits microglial cell proliferation; cortisone also will inhibit proliferation at higher doses through GRs, but stimulate proliferation through MRs.²⁶ GLCs appear to have a protective effect in the CNS through induction of glutamine synthetase in both the CNS and peripheral nervous system; the enzyme adds an amine to and thus removes glutamate.⁴³ Increased glutamate has been associated with CNS pathology, although the relationship between the two remains controversial.^{44,45} However, efficacy reflects regulation through transcription, which takes at least 24 hours. Glutamine has several roles in the CNS; in the presence of hyperammonia (e.g., liver disease) increases formation of glutamine in brain cells and the potenetial for cerebral edema.^{45b} The use of glucocorticoids for treatment of cerebral edema might be avoided in situations in which increased glutamine increases the risk of cerebral edema.

Interestingly, GLC concentrations appear to be directly related to the severity of memory impairment in animals, including humans.⁶ Learning is impaired in animals exposed to prolonged reductions in circulating concentrations of GLCs; conversely, memory also appears to be impaired if GLC concentrations are too high.

Respiratory System

GLCs are reported to have "permissive" effects (increased receptor number or affinity have been proposed) on β_2 -receptors, promoting bronchodilation.⁴⁶ Other mechanisms are likely to evolve as non-genomic effects are understood. The effects of GLCs on leukotrienes, platelet-activating factor, and other mediators important in the pathogenesis of respiratory inflammatory diseases were discussed earlier and also are addressed in Chapters 20 and 29.

Alimentary Tract

GLCs decrease the absorption of calcium and iron from the gastrointestinal tract and increase the absorption of fats. Secretion of gastric acid, pepsin, and trypsin are increased by GLCs. Gastric mucosal cell growth and renewal are reduced by GLCs, and mucus production is decreased, resulting in compromise of the protective barrier of the gastric mucosa. Collectively, these effects contribute to increased susceptibility to gastric ulceration. A retrospective study in humans found that 5% developed gastric mucosal lesions while receiving GLCs, particularly patients with rheumatoid arthritis and collagenosis.⁴⁷ It is not clear whether the effects of GLCs on the gastric mucosa occur as a result of impaired mucosal prostaglandin synthesis, although failure of misoprostol (prostaglandin E) to protect against GLC-induced ulceration indicates that they do not. Indeed, some studies have shown that GLCs provide a gastroprotective effect during stress-induced ulceration.48 Deposition of glycogen in the liver, resulting in hepatomegaly in animals chronically treated with GLCs, is a consequence of increased glycogen synthesis, as described previously. Excessive cortisol levels can induce pancreatic ductule hyperplasia.

Reproduction

GLCs can induce parturition during the latter stages of pregnancy in ruminants and horses, but their effect in dogs and cats has not been determined. GLC administration in pregnant dogs has been associated with cleft palate and abortion. GLCs have been shown to inhibit cell division, DNA synthesis, or both in the developing liver, lung, brain, and thymocytes.

STRUCTURE-ACTIVITY RELATIONSHIP

There are close to 50 generic corticosteroid products approved for human use and several approved for use in small animals. These drugs differ primarily in their duration of action, mineralocorticoid activity, and antiinflammatory potency (Table 30-2). As the antiinflammatory potency of a particular agent increases, its biological half-life and duration of action also tend to increase. Antiinflammatory properties also parallel the effects on metabolism, that is, carbohydrate and protein metabolism, but mineralocorticoid effects can be altered independently by changing the molecular structure of the steroid (Figure 30-5). The 4,5 double bond and the 3-ketone are necessary for mineralocorticoid and GLC effects. Synthetic modifications of cortisol increase the antiinflammatory activity, decrease protein binding, and decrease hepatic metabolism, thus prolonging activity. First-generation GLCs formed with the addition of a 1,2 double bond increased the ratio of GLC to mineralocorticoid effects (prednisolone, prednisone, and methylprednisone) and duration of action. The second-generation steroids were fluorinated at the C-9 position, increasing potency. Methylation at the C-16 position eliminates mineralocorticoid activity (dexamethasone, betamethasone, and triamcinolone).

KEY POINT 30-8 In general, as exogenous glucocorticoid effects become more potent, mineralocorticoid effects become less potent.

The effects of GLCs are generally recognized to be dose dependent. Indeed, GLCs can be classified on the basis of their potency, generally relative to hydrocortisone. For example, dexamethasone is 30 times and prednisolone 4 times as potent as hydrocortisone in impairing glucose metabolism (Table 30-2).²⁰ Daily doses of glucocorticoids used therapeutically have been variably referred to as physiologic, which generally reflects 0.1 to 0.25 mg/kg predniosolone or equivalent, and a pharmacologic or supraphysiologic, ranging, for prednisolone, 0.8 mg/kg IV, to 1 to 2 mg/kg/day, and a high dose of approximately 10 mg/kg orally (or 4 to 60 mg/m²/day). Some references refer to very high supraphysiologic doses (in dogs: hydrocortisone at 2-4 mg/kg, IV every 6 to 8 hrs, 4 to 20 mg/kg prednisolone IV every 2 to 6 hrs, 0.5 to 2.0 mg/kg dexamethasone, or 30 to 100 mg/kg methylprednisolone), which also might be referred to as a "shock" dose.

CLINICAL PHARMACOLOGY

Absorption

Several products are well absorbed orally. Differences between oral absorption occur, for example between prednisone and prednisolone in both the dog and cat (see below). For intramuscular or subcutaneous administration, the duration and onset of action of a particular GLC can be altered by the addition of an ester, usually bound to C-21. The GLC esters must be hydrolyzed - often by esterases located at the site of administration - to release the active, free form of the drug. However, the sodium phosphate and sodium succinate esters are water soluble, can be administered intravenously, and are rapidly hydrolyzed. These characteristics make them ideal for treatment of acute conditions. The acetate, acetonide, valerate, and dipropionate esters are water insoluble and release of the active steroid is very slow, providing GLC activity for days to weeks (i.e., repositol, or depot, products). The major advantage of these esters is convenience of administration. Administration at 2- to 6-week intervals, depending on the preparation used and disease being treated, has been recommended.

Glucocorticoids	Glucocorticoid Potency*	Mineralocorticoid Effect	Equivalent Dose	Duration of Effect on HPA
Cortisol	1	1	20	12 (S)
Cortisone	0.8	0.8	25	12 (S)
Hydrocortisone	1	0.8	20	12 (S)
Prednisone-Prednisolone	3.5-4	0.8	6	12-36 (I)
Methylprednisolone	5	0.5	4	12-36 (I)
Triamcinolone	5	0	4	12-36 (I)
Betamethasone	25	0	0.8	>48 (L)
Dexamethasone	30	0	0.7	>48 (L)
Mineralocorticoids		Mineralocorticoid Potency		
Fludrocortisone	10	125-200		12-36 (I)
Deoxycorticosterone	0	20		
Aldosterone	0	200-1000		

HPA, Hypothalamic-pituitary-adrenal axis, I = intermediate, L = long acting, S = short

*Both glucocorticoid and antiinflammatory potency.

Disadvantages include unpredictability of blood concentrations, chronic suppression of the hypothalamic-pituitaryadrenal axis (up to 12 weeks or more after administration of a single dose), possible induction of steroid resistance (mediated by receptor downregulation), and the fact that the drug cannot be withdrawn should adverse reactions develop. For these reasons the authors recommend the use of short- to intermediate-acting preparations administered daily or on alternate days over repositol steroid preparations.

KEY POINT 30-9 The slow-release salts of glucocorticoids preclude advantages of alternate-day dosing that occur with administration of short- or intermediate-acting base drugs.

There are many forms of GLCs available for topical use, including extensions of the skin such as the external ear canal and anal sacs. Once absorbed through the skin, topical corticosteroids are handled by the body in the same capacity as systemically administered GLCs. The extent of percutaneous absorption of topical GLCs depends on factors such as the vehicle, the ester form of the steroid (greater lipid solubility enhances percutaneous absorption), duration of exposure, surface area, and the integrity of the epidermal barrier. Ointment bases are occlusive and are therefore more likely to increase percutaneous absorption of the same GLC in a cream base. Highly potent preparations in any form should not be used on abraded skin.

GLCs are absorbed and can achieve physiologic and possibly pharmacologic concentrations after local administration. This includes the skin, as previously noted, synovial spaces, conjunctival sac, and the respiratory tract.⁹ Suppression of the hypothalamic–pituitary–adrenal axis has been documented after ocular,⁵⁰ otic,⁵¹ and topical⁵² administration for several weeks. The impact of dexamethasone and betamethasone administered as a topical commercial otic preparation on

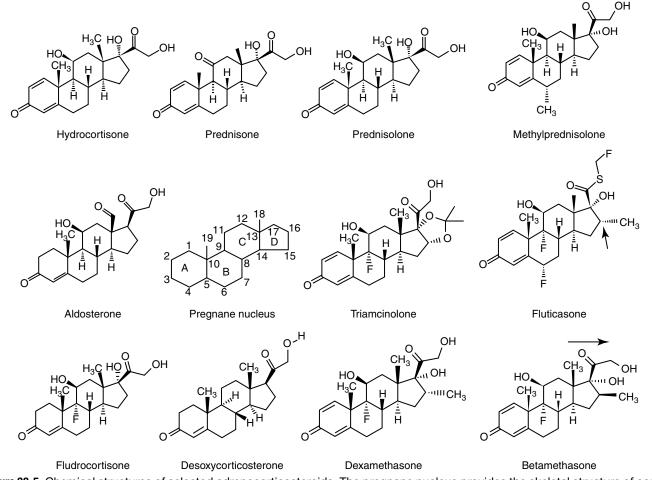

Figure 30-5 Chemical structures of selected adrenocorticosteroids. The pregnane nucleus provides the skeletal structure of corticosteroids. Corticosteroid activity depends on the double bond at position 4,5 and the keto group in the 3 position. Compounds with a double bond at position 1,2 have increased glucocorticoid activity (e.g., prednisone versus hydrocortisone) as well as a longer duration of action. Prednisolone differs from the prodrug prednisone only by the presence of a hydroxyl rather than a ketone group on the C ring. A methyl group at the C-16 position (*arrow*) eradicates mineralocorticoid activity (e.g., dexamethasone). Fluorination at the C-9 position enhances corticosteroid potency. The difference between betamethasone and dexamethasone is the orientation of the methyl group at position 16. The addition of acetate rather than succinate esters (*not shown*) to the various compounds also prolongs duration of action.

adrenal function was studied in normal dogs (with normal ears). Drugs were administered twice daily for 2 weeks according to the package insert: dexamethasone at 10 drops (0.223 mg) and betamethasone at 4 drops (0.1193) per ear. For the betamethasone-treated group (n = 7), ACTH response tests were normal at the end of the treatment period, which was in contrast to the dexamethasone-treated group, for which the adrenal gland was suppressed in 71% (five of seven) of animals. Response normalized in 1 to 2 weeks for all animals. No animal exhibited signs of hyperadrenocorticism.53 Ginel and coworkers⁵⁴ prospectively examined the effect of 2 weeks of topical betamethasone administration (4 to 8 drops, depending on body weight, of 0.88 mg betamethasone/mL, Otomax) compared with placebo using a randomized crossover design with a 4-week washout period. Although adrenal gland suppression did not occur, serum alkaline phosphatase increased (but remained within normal limits) and response to intradermal testing was muted by day 14 of treatment.

Using a prospective parallel approach, Aniya and Griffin⁵⁵ recently compared the effect of vehicle and concentration of dexamethasone applied topically in the normal (not inflamed) ear of dogs (n = 21). Dexamethasone was applied as either 0.01% or 0.1% in saline (n = 7 each) and 0.1% in the commercially available product (Tresaderm; n = 7), for which propylene glycol is the carrier. Animals were treated for 2 weeks with 10 drops in each ear twice daily, resulting in a dose of approximately 0.89 mg dexamethasone for the 0.1% product (0.07 to 0.25 mg/kg). On the basis of ACTH stimulation, four of seven dogs in each 0.1% treatment group, but no dogs in the 0.01% treatment group, experienced adrenal gland suppression. Further, serum alkaline phosphatase was increased in one of seven dogs in the 0.1% propylene glycol treatment group. Finally, Reeder and coworkers⁵⁶ compared four GLC-containing otic preparations in dogs with otitis externa using a randomized, double-blinded parallel design. Drugs studied included 0.007 to 0.02 mg/kg once daily of mometasone (Mometamax; n = 9), 0.002 to 0.03 mg/kg twice daily of triamcinolone (Panalog; n = 12), 0.004 to 0.024 mg/ kg twice daily of dexame has one (Tresaderm; n = 8), and 0.006 to 0.03 mg/kg twice daily of betamethasone (DVMax; n = 11). Dogs were treated for 7 days. Mometasone was described to have 1.5 times the potency of fluticasone and 22 times that of dexamethasone.⁵⁶ Plasma cortisol was suppressed at 7 days in 0%, 9%, 17%, and 50% of the animals receiving Mometamax, betamethasone, triamcinolone, and dexamethasone, respectively.

KEY POINT 30-10 With few exceptions, it should be assumed that topical administration of glucocorticoids will result in drug absorption sufficient to affect the hypothalamic–pituitary–adrenal axis.

Selected steroids have been studied after transdermal administration in cats. Using a randomized crossover design, Willis-Goulet and coworkers⁵⁷ measured dexamethasone in the serum of cats (n = 6) after single-dose oral or transdermal administration of 0.05 mg/kg. Although drug was detected

after oral administration (peak 30 µg/mL), drug was not detected after transdermal administration. A similar finding was reported by other investigators.⁵⁹ Oral absorption of GLCs may be affected by P-glycoprotein, depending on the specific drug.⁵⁸ Cortisol, aldosterone, and dexamethasone are demonstrated substrates. Even in dogs, oral absorption of prednisone may not result in prednisolone concentrations comparable to that achieved with oral prednisolone.

Distribution, Metabolism, and Excretion

In humans (and presumably many animals), endogenous (and exogenous) cortisol is bound to corticosteroid-binding globulin (transcortin). The two main binding proteins are cortisolbinding globulin and albumin.²

Transcortin is an α -globulin secreted by the liver. Whereas it has a high affinity for steroids, it has a relatively low binding capacity. Albumin, which has a low affinity but large binding capacity, also binds GLCs. Corticosteroids compete with one another (endogenous and exogenous) for binding sites and at high concentrations will displace one another. Steroidal hormones tend to be eliminated by oxidation or reduction followed by conjugation (generally glucuronide or sulfate) and excretion (principally renal). Metabolism occurs at both hepatic and extrahepatic (including the kidney) sites. Prednisone is the prodrug form of prednisolone; it is assumed, but not proven, that no barrier exists to formation of the latter Cortisol is metabolized by the liver by phase I and II enzymes. Metabolism to inactive corticosterone is mediated by 11 beta-hydroxysteroid dehydrogenase, particularly in the kidney.² Renal expression of this enzyme is one means whereby aldosterone response predominates; elimination of cortisol in human patients with renal disease may be prolonged as much as 30%.60 Cortisol is metabolized by the liver by phase I and II enzymes and in the kidney, where it is converted to the inactive metabolite cortisone by 11 beta-hydroxysteroid dehydrogenanse.²

Biliary and fecal elimination of corticosteroids do not appear to be that significant.⁹

DRUGS AND PREPARATIONS

Knowledge of a few commercial preparations is sufficient for most clinical purposes (Tables 30-3 and 30-4). Selection is most commonly based on balancing the need for efficacy with the risk of adverse effects. Some distinct characteristics of selected steroids are presented in the following sections.

Hydrocortisone

Hydrocortisone is identical to cortisol, the most important endogenous GLC for most species. Extrahepatic elimination of hydrocortisone contributes substantially to clearance in the dog. Elimination is flow limited, with clearance being greatest in organs with greatest blood flow.⁶¹ Elimination of hydrocortisone from the plasma is biphasic in dogs, with an elimination half-life of the terminal phase of 50 minutes. The volume of distribution in dogs is greater than 1 L/kg. Because of its short duration of action (<12 hours) and low potency,

	Preparations	Intravenous Popid	Intralesional Slow		Trade Name
Base	Oral	Intravenous Rapid IM, SC Absorption	Intralesional Slow IM, SC Absorption	Topical	Products*
Beclomethasone				Dipropionate, inhalant (1)	(1) Beclovent, Vanceril
Betamethasone	Free base (2)	Na phosphate (31V)	Acetate (32V); Diproprionate (V)	Free base, benzoate, diproprianate (3); Valerate: otic (33V), ointment (34V), Topical Spray (35V)	 (2) Celestone; (3) Diprolene; (30V, 31V: Betavet); (32V) Gentocin; (33V): Topagen; (34V) Gentocin, Otomax
Budesonide	Free base (4)		Diacetate	Free base: Inhalant (5), also with formeterol and fumerate (6); Nasal Spray (7)	(4) Entocort, (5) Pul- micort (6), Symbi- cort (7)Rhinocort
Desoxycortico- sterone			Pivalate (35V)		(35V) Percorten
Dexamethasone	Free base (36V)	Na phosphate (37V)	Acetate	Free base: ophthalmic (8), otic (38V)	 (8) Maxidex; (36V) Azium, Pet-Der III; (37V) Dex-A-Vet, Dexium SP; (38V) Tresaderm
Fludrocortisone	Acetate (9)				(9) Florinef
Fluticasone				Fumorate: nasal spray (10); fumarate: inhalant (11), also with salme- terol (12) Proprionate spray (13), cream	(10) Veramyst (11) Flovent HFA; (12) Advair, (13) Flonase
Hydrocortisone	Free Base, Acetate (14), cypionate	Na succinate (19)	Acetate	Free base: ointment (with multiple drugs), cream (15), lotion, spray (39V, with oxytetracycline); Acetate: rectal spray (16), Ointment with antibiotics (40V); Valer- ate: cream (17) Otic suspension; Butyrate: cream (18)	 (14) Cortef; (15) Ala-cort, Synacort; (16) Cortifoam; (17) Locoid; (18) Westcort; (19) Solu-Cortef; (39V) Liqua-Cortril; (40V) Neo-Cortef, Amphoderm, Corticosporin
Methylpredniso- lone	Free base (20), (41V), with aspi- rin, methylpred- nisolone (42V)	Na succinate (21)	Acetate (22), (43V)	Acetate	(20) Medrol; (21) Solu-Medrol; (22) Depo-Medrol; (41V) Medrol, (42V) Cortaba; (43V) Depo-Medrol
Prednisolone	Free base; Acetate (23), (44V) and with trimeprazine (45V); sodium phosphate (24)	Sodium phosphate (46V), sodium succinate (47V)	Acetate (48V), tebutate, Sodium phosphate, Acetate	Free base; Acetate: Oph- thalmic ointment (25) and with sulfacetamide (26); with antibiotics (49V) and ophthalmic solution (50V); Sodium phosphate: ophthalmic; Sodium succinate	 (23) Flo-Pred; (24) Orapred; (25) Pred Mild, Pred Forte; with sulfacetamide (26); (44V) Delta Albaplex, Predni- sTab; (45V)Temaril P; (46V) Prednis-A- Vet; (47V) Solu- Delta-Cortef; (48V) Meticortelone; (49V) Optisone,

	Panosteitis, hypertrophic osteopathy	0.5 mg/kg (D)	РО	12-24
	Plasmacytic-lymphocytic enteritis	1-2 mg/kg	РО	12, then taper dose weekly
	Pulmonary eosinophilic infil- trates	0.5-1 mg/kg	РО	24

Table 30-4 Dose					
Drug	Indication	Dose	Route	Interval (hr)	
Prednisone/ Prednisone (9, 11)	Replacement therapy (hypoad- renocorticism) acute	Initial dose: 4-20 mg/kg	IV (over 2-4 min)	Once	
	Replacement therapy (hypoad- renocorticism) acute	Followed by 0.2-0.4 mg/kg	РО	24	
	Shock	15-30 mg/kg (D)	IV	Repeat in 1, 3, 6, or 10	
	Sterile pyogranulomas	2-4 mg/kg (D)	PO	24	
	Systemic lupus erythematosus	1.5-2 mg/kg	РО	12-24, then taper to <1 mg/kg every 48	
	Urethritis, persistent hematuria	2.5-5 mg/cat	PO	24-48	
Prednisolone acetate	Hypoadrenocorticism	0.1-0.2 mg/kg	IM	12	
Prednisolone sodium phosphate (12)	Shock	11 mg/kg	IV	Repeat in 4-6	
Prednisolone sodium succinate (13)	Chronic allergic diseases (asthma, atopy, IBD)	2-4 mg/kg (D)	IV, IM	Repeat in 4-6	
		1-3 mg/kg (C)	IV, IM	Repeat in 4-6	
	CNS trauma	Initial dose: 15-30 mg/kg	IV	Once	
		Maintenance dose: 1-2 mg/kg	IV	12	
	Hypoglycemia	1-2 mg/kg	IV	Repeat in 4-6	
	Shock	11-30 mg/kg (D)	IV	Repeat in 4-6	
Triamcinolone (3)	Antiinflammatory	0.25-2 mg (D)	РО	24	
		0.25-0.5 mg/cat	PO	24×7 days	
		0.11-0.22 mg/kg	IM, PO, SC	24-48	
	Esophogeal dilation to prevent restricture	1-2 mg	In the esophageal submucosa	Infiltrate at 4 circumferential points	
	Feline plasmacytic pharyngitis, pododermatitis	2-4 mg/cat	РО	24-48	
	Feline polymyopathy	0.5-1 mg/kg	PO	24	
Triamcinolone acetonide (3)	Glucocorticoid effects	0.1-0.2 mg/kg	IM, SC	24	
	Anticancer	1.2-1.8 mg or 1 mg for every diameter of tumor	Intralesional	Every 2 weeks	
Triamcinolone ophthal- mic solution	Pannus, eosinophilic kerati- tism, episcleritis	4-8 mg ophthalmic solution (D)	Subconjunctivally	Once; follow with topical therapy	
		4 mg ophthalmic solution (C)	Subconjunctivally	Once; follow with topical therapy	

MDI, Metered dose inhalant; D, dog; IM, intramuscular; PO, by mouth; IV, intravenous; CNS, central nervous system; SC, subcutaneous; C, cat; CRI, constant-rate infusion; IBD, inflammatory bowel disease.

1 Potency facilitates topical efficacy.

3 Long-acting and thus not indicated for alternate-day use.

4 Increased risk of gastrointestinal toxicity may occur with oral use.
5 Rapid onset, short-acting, low potency; activity requires conversion to hydrocortisone.

6 Propylene glycol vehicle of intravenous solution may cause cardiac arrhythmias and sudden death with rapid administration.

7 Rapid onset reflects enhanced cell penetration.

8 Low potency not recommended for alternate-day use.

9 Acceptable for alternate-day use.

10 Choice for CNS damage.

11 Glucocorticoids generally are dosed to remission, then tapered to a minimum effective dose for maintenance. Doses should be tapered as drugs are discontinued. Prednisolone is generally preferred to prednisone in cats.

12 Efficacy in shock requires early and aggressive intervention.

13 50 mg/mL solution for IM injection is irritating.

² Decreasing dose: every 5×5 days, every 6×4 days, every 8×3 days, every 12×2 days, then every 24×1 day.

hydrocortisone is not frequently used for systemic therapy. Hydrocortisone is available in creams and ointments for topical use.

Prednisolone and Prednisone

Prednisone is rapidly metabolized by the liver to prednisolone (C-11 ketol reduction). Liver disease probably has minimal effect on activation. Prednisone elimination in dogs is biphasic, with apparent half-lives of 15 and 82 minutes for each phase after intravenous administration.⁶² However, prednisolone has an intermediate duration of action (12 to 36 hours) and is therefore considered appropriate for alternate-day administration.

Prednisone and prednisolone generally are considered equivalent in terms of therapeutic dosing in both dogs and cats. However, the two are not necessarily equivalent, as has been demonstrated in dogs and cats. Colburn and coworkers⁶³ demonstrated in Beagles (n = 16) that relative bioavailability is greater for prednisolone. After 5 mg orally of either drug, the C_{max} was twice as high and the area under the curve 40% higher for prednisolone compared with prednisone. All dogs received either 5 mg prednisolone or prednisone orally using a randomized crossover design. Both steroids were measured with each study. The pertinent pharmacokinetic parameters differed between the two drugs and were as follows: AUC (area under the curve; ng*mL/hr), C_{max} , (ng/mL), T_{max} (hour), and elimination half-life (hour). After administration of 5 mg prednisolone, the data for prednisolone was 986, 273, 0.9, and 1.8; and for prednisone, 855, 205, 1.3, and 1.6. After oral administration of 5 mg prednisone, the numbers were for prednisolone: 638, 111, 2, and 2.2; and for prednisone: 694, 132, 1.2, and 2.3. These data suggest rapid interconversion between both steroids, regardless of which is administered, in the dog but also about a 65% relative bioavailability for prednisolone (or prednisone) when prednisone is administered compared to prednisolone. Prednisolone also has been studied after IV administration but only in a single Beagle.^{63a} The dog was dosed at 1.8 and 3.6 mg/kg. Clearance was 34 ml*kg/min and volume of distribution was 0.7 L/kg. Elimination half-live was 0.3 hour. The oral bioavailability of prednisolone solution or tablet approximated 50% but this was increased to essentially 100% when administered as a slurry. This study, although in one dog, supports a dose-dependent disposition of prednisolone.

That the two are not equivalent in cats was demonstrated by Graham-Mize and Rosser.⁵⁹ Disposition of prednisolone in cats after oral administration was as follows: area under the curve 3230.55 ng/mL/hr and C_{max} 1400.81 ng/mL, with a halflife for excretion of 1 hour. This compares to an area under the curve of 672.63 ng/mL/hr and C_{max} of 122.18 ng/mL after oral administration of prednisone. The half-life of prednisone was longer at 2.46 hours. According to these data, the dose of prednisone must be at threefold to fivefold higher than that of prednisolone to achieve equivalent activity. Boothe has studied the efficacy of drug delivery of prednisone and prednisolone after multiple (3 weeks) transdermal administration. Cats were studied using a random crossover design. Cats received prednisone and prednisolone (2 mg/kg) either orally or transdermally twice daily. At the end of each 3-week dosing period, and a 1-week washout, cats were rotated to the next randomly assigned treatment. Two-hour peak and 12-hour trough serum samples were assayed for the presence of prednisone and prednisolone. After 3 weeks of dosing (n = 6), neither prednisone nor prednisolone concentrations were detectable after oral or gel administration of prednisone. Prednisolone was not detectable after gel administration of prednisolone, but prednisolone reached therapeutic concentrations after oral administration of prednisolone. The use of prednisolone rather than prednisone might be more prudent for both species. Liver disease does not appear to impact conversion of prednisone to prednisolone as was demonstrated in human patients with chronic active liver disease (n = 10) compared to healthy volunteers (n = 7).^{63b}

Methylprednisolone

Methylprednisolone possesses lipid antioxidant activity that has been shown to be beneficial in the treatment of experimental spinal cord trauma in cats and experimentally induced Escherichia coli bacteremia.^{65,66} In contrast, methylprednisolone did not appear clinically beneficial in a canine model of spinal trauma, although the model may have caused insufficient damage for effective evaluation.⁶⁷ Although some other GLCs (dexamethasone, prednisolone) are efficacious as lipid antioxidants, methylprednisolone is the most potent. Methylprednisolone has an intermediate duration of action (12 to 36 hours) and is also a good candidate for alternate-day administration. The disposition of methylprednisolone succinate was described in normal dogs and then again after induction of hemorrhagic shock (n = 5).⁶⁸ The drug is characterized by a clearance of 1.6 ± 0.5 L*kg/hr and half-life 15.3 ± 3.8 minutes. During states of hemorrhagic shock, the clearance is reduced to 0.5 \pm 0.2 L*kg/hr and half-life was prolonged to 41 \pm 23 minutes.

Dexamethasone

Dexamethasone is a highly potent GLC, but it has virtually no mineralocorticoid activity. It possesses some lipid antioxidant activity. The disposition of dexamethasone in dogs exhibits dose dependency. Greco and coworkers⁶⁹ studied the disposition of dexamethasone after a low (0.01 mg/kg) and high (0.1 mg/kg) dose using a randomized crossover disease. The relevant pharmacokinetic parameters at each dose were A and B, (the Y intercept extrapolated from the initial and terminal components of the plasma drug concentration versus time curve, respectively; ng/mL), elimination half-life (hour), mean residence time (hour), and volume of distribution (L/kg). At 0.01 mg/kg, the data were: 22 \pm 13.5, 5.3 \pm 4.11, 192, 174 \pm 42, and 1.9 ± 1.2 . At 0.1 mg/kg, the data were 118 ± 74, 9.0 \pm 5.7, 412, 324, and 6.41 \pm 2. In addition to dose-dependent differences in clearance, the authors suggested that saturation of plasma protein-binding sites at the higher dose might explain the marked increase in volume of distribution. Elimination half-life is longer at a higher (0.1 mg/kg) compared with lower (0.01 mg/kg) dose, despite an increase in clearance; the differences presumably reflects the increase in the volume of distribution of dexamethasone at the higher dose.⁶⁹ The disposition of dexamethasone did not differ in the presence of simultaneous administration of ACTH (0.5 U/kg intravenously), although the power of the study was not addressed. The prolonged duration of action (biological half-life approximately 48 hours) of dexamethasone makes it inappropriate for alternate-day administration.

Betamethasone

Betamethasone is a very potent GLC that varies from dexamethasone only in the orientation of a side chain. Thus, like dexamethasone, it has virtually no mineralocorticoid activity. It has a long duration of action (biological half-life approximately 48 hours) and is therefore not appropriate for alternateday administration.

"Soft" Glucocorticoids

Among the mechanisms whereby undesirable side effects of GLCs can be minimized is topical administration of drugs that are potent for GRs but also rapidly metabolized should the drug be absorbed into systemic circulation via the oral route. These efforts generally reflect manipulation of chemical groups on the D ring of the GLC. Examples include beclomethasone, budesonide, and fluticasone propionate, steroids designed specifically for use in inhalant metered doses. Their potency when inhaled varies in clinical trials, with fluticasone propionate being most potent and budesonide and beclomethasone dipropionate approximately equipotent. Time of onset in humans to budesonide is approximately 10 hours based on evidence of clinical improvement at that time. Improvement can be expected over the next 1 to 2 days, with maximum effects potentially not being evident until 2 weeks after therapy has begun.

KEY POINT 30-11 The use of topical "soft" glucocorticoids for treatment of asthma or inflammatory bowel disease may reduce side effects in humans but not necessarily in dogs or cats.

Budesonide is rapidly metabolized in the liver by CYP3A4, with affinity of metabolites of the GCR being less than 1% of the parent. Essentially 100% of topically (inhalant) administered drug in humans appears as metabolites in the urine, indicating that systemic absorption of the drug does occur.⁷⁰ Indeed, inhaled drug is generally considered to be absorbed, and as much as 25% of the inhaled dose in humans circumvents hepatic metabolism before entering systemic circulation. Because the potency that characterizes enhanced topical activity can similarly lead to peripheral effects, further development has focused on minimizing peripheral effects of topically administered GLCs that avoided hepatic metabolism.¹⁸ Budesonide represented one of the first successful products of those efforts, with local receptor binding of the drug being greater than peripheral binding. Intracellular fatty acid esterification inactivates the drug. As such, esterification serves as a storage site, with esterified drug being rereleased as the concentration of free drug declines with clearance. The ability to esterify varies among tissues, with pulmonary tissue apparently having a much higher capacity compared with other tissues, leading to greater storage in airways than in peripheral tissues.

Topical GLCs combine enhanced efficacy with some reduction in systemic exposure. Because lipophilicity increases transcutaneous movement, GLC esters are the most effective choices in human medicine for treatment of atopic dermatitis and other inflammatory skin diseases. The 17-esters, in particular, are characterized by high activity, presumably because of tighter GR binding (i.e., increased potency). However, greater potency may lead to irreversible skin atrophy. This contrasts with 21-esters, whose lower potency may decrease the risk. Combination 17, 21-double esters such as prednicarbate, a prednisolone double ester, offers the advantages and minimizes the disadvantages of both ester types and therefore is characterized by an improved benefit–risk ratio.⁷¹

The side effects of GLCs might be reduced but probably will not be eliminated by topical therapy. Drugs that impaired CYP3A4 may increase the plasma drug concentration of budesonide over sevenfold. Even by itself, budesonide appears to suppress the hypothalamic-adrenal-pituitary axis in dogs based on a clinical trial in dogs (n = 6) with inflammatory bowel disease. Endogenous ACTH and baseline and post-ACTH-stimulated cortisol were decreased after treatment with budesonide (30 days at 3 mg/m^2) compared with baseline.⁷² Although no differences were described in serum alkaline phosphatase activity, urine specific gravity or the incidence of side effects typical of GLCs (polyphagia, polyuria), the power to detect these indicators of hyperadrenocorticism was not described. Anecdotally, dogs receiving budesonide for prolonged periods to treat inflammatory bowel disease do develop clinical signs associated with iatrogenic hyperadrenocorticism.

Tirilazad Mesylate

Tirilazad mesylate is a novel, non-GLC, 21-aminosteroid (lazaroid) that possesses potent antioxidant activity (i.e., it protects against oxygen-derived free radicals). Unlike the GLCs, this agent does not inhibit phospholipase A_2 , but it does inhibit lipid peroxidation-induced arachidonic acid release.⁷³ The mechanism appears to reflect, in part, insertion into the cell membrane. These products are discussed in depth in Chapter 29.

Fludrocortisone

Fludrocortisone is a synthetic steroid hormone with mineralocorticoid activity. In humans, although it has tenfold activity at the GR compared with cortisone, it has no appreciable GLC effect at standard human doses. Its mineralocorticoid activity is 125-fold greater than cortisol and is used for mineralocorticoid replacement therapy.⁹ Fludrocortisone acetate is administered orally at 24- to 48-hour intervals for treatment of hypoadrenocorticism.

Desoxycorticosterone Pivalate

Desoxycorticosterone pivalate (DOCP) is an ester salt of a synthetic steroid hormone with mineralocorticoid (no GLC) activity. This form of desoxycorticosterone has a 20- to 30-day duration of action after intramuscular injection. Addisonian

patients who have failed to completely respond to fludrocortisone may respond to therapy with DOCP.

THERAPEUTICS

Unless GLCs are being administered for replacement therapy in a deficiency state (i.e., hypoadrenocorticism), GLC therapy is not directed at the inciting agent. GLC therapy is intended to reduce the physiologic processes that are activated in response to the disease. Despite the adverse events associated with their use, GLCs continue to be heavily used in veterinary medicine, potentially at doses that exceed those recommended. Indeed, in human medicine the use of GLCs clearly exceeds that recommended in textbooks and review papers.²⁰ The advantages of low versus high doses have been previously discussed and are addressed again in the section on adverse reactions. In general, an antiinflammatory dose is considered to be 10 times the physiologic dose, and immunosuppressive doses are twice the antiinflammatory dose. Shock doses of GLCs have been reported at 5 to 10 times the immunosuppressive dose; however, the disadvantages of this high dose and the advantages of low-dose therapy in shock patients are discussed later. When treating a patient for an immediately life-threatening condition such as immune-mediated hemolytic anemia, the clinician should institute aggressive therapy, with a minimum effective dose determined after response has been achieved. Because high doses of GLCs are often required to adequately treat immune-mediated diseases, adverse effects are likely to occur and should be anticipated. Tapering of doses not only helps prevent side effects associated with long-term therapy but may also prevent the antibody rebound that has been associated with abrupt withdrawal of GLCs in human patients treated for prevention of graft-versus-host transplant rejection. Dose reduction in patients with autoimmune diseases should be conducted gradually. The reduced dose should be continued for at least 2 weeks before the next attempted dose reduction, and the actual dose should be decreased by no more than half. It is essential to assess the patient's status frequently for recurrence of clinical signs. Concurrent administration of additional immunosuppressive (azathioprine, cyclophosphamide) or antiinflammatory drugs other than NSAIDs (antihistamines, omega fatty acids) may allow the GLC dose to be decreased (dose-sparing effect; see Chapters 29 and 31).⁷⁴ High-dose pulse therapy has been reported in human patients with acute relapse of chronic graft-versus-host disease. In an open-design study, patients receiving no immunosuppressive therapy or patients that failed (a median of two failures) current therapy (mean prednisolone dose of 0.2 mg/kg per day, range of 0 to 2.5 mg/kg per day) were treated with methylprednisolone at 10 mg/kg intravenously or orally for 4 days. The rationale behind the high dose is based on the lympholytic properties of this dose, thus causing destruction of lymphocytes that otherwise would cause irreversible organ damage. The high dose is assumed to target the (nongenomic) metabolic processes necessary for sustained activity of lymphocytes, as opposed to the low (genomic) doses that target lymphocyte replication. Additionally, the high dose is

considered to overcome GR saturation associated with GLC therapy, causing significant GLC downregulation. Induction of T lymphocyte apoptosis may also occur. Standard infection prophylactic therapy also was begun on day 1, consisting of fluconazole, levofloxacin, and valacyclovir (days 1 to 7) and a sulfadiazine-trimethoprim combination (continued until evidence of immunosuppression resolved). On day 5 a new immunosuppressive therapy (which varied with the hospital) was started using standard doses of standard immunosuppressive drugs. With use of this protocol, 75% of patients responded (48% classified as major response, indicating resolution of unequivocal improvement). During a 2-year follow-up, patients tolerated the therapy well, with no major life-threatening effects occurring in the first three months after treatment. However, three patients developed infections after completion of the therapy, suggesting profound immunosuppression. Yet the median time to progression of disease was 2 years after treatment, leading the authors to conclude that high-dose pulse steroid therapy is an effective and well-tolerated treatment for progressive graft-versus-host disease.²⁴ The author (Boothe) has used this approach in a single case of lymphosarcoma in a dog whose sole treatment was GLC therapy. After the first relapse at 5 weeks, a high dose of dexamethasone (1 mg/kg intravenously) was followed by a second remission, with relapse occurring 3 weeks later. Should this approach be considered as a "rescue" scenario, antimicrobial (and possibly antifungal) treatment might be anticipated along with prophylactic antiulcer therapy.

Long-term use should strive to identify the smallest dose of GLC that will achieve the desired effect, particularly for relatively benign, chronic inflammatory conditions such as atopy or flea allergy dermatitis. Optimum doses (initial and maintenance) for the variety of syndromes responsive to GLCs are largely based on trial and error, with intermittent reevaluation. Eventually, anti-inflammatory GLCs with minimal metabolic effects will be associated with a lower risk. An every-other-day dosage regimen with a short- or intermediate-acting agent can achieve therapeutic effects without untoward effects in many patients. Agents that are ideal for alternate-day administration include prednisone, prednisolone, and methylprednisolone. The duration of action of hydrocortisone and cortisone may be too short for effective alternate-day therapy. Although triamcinolone's duration of action is similar to those of prednisolone and methylprednisolone, its ability to suppress the hypothalamic-pituitary-adrenal axis is more typical of the long-acting agents such as dexamethasone and betamethasone. Side effects can occur if withdrawal of a GLC occurs too rapidly. In human patients receiving GLCs, the most frequent problem encountered with rapid withdrawals is recrudescence of the underlying condition for which the GLC was indicated.9 The most severe but rare complication, however, is acute adrenal insufficiency. Because of variability in GLC impact on the hypothalamic-pituitary-adrenal axis and variability within and between animals, predicting which animal is likely to develop insufficiency is difficult. In general, iatrogenic Addison's disease is not common, but even this risk can be minimized by gradual withdrawal of the GLC. In human patients those who receive supraphysiologic doses for 2 weeks within the preceding year are considered to have some level of hypothalamic–pituitary–adrenal suppression.⁹

THERAPEUTIC INDICATIONS*

Dermatologic

GLCs are the cornerstone of therapy of many of the autoimmune diseases affecting the skin, including the pemphigus complex, systemic lupus erythematosus, and discoid lupus erythematosus. Optimal therapy for each of these diseases varies, insofar as some may respond to GLCs alone and some may require a combination of GLCs and alternate immunosuppressive drugs such as azathioprine or cyclophosphamide.

The long-term management of canine atopy (allergic inhalant dermatitis) frequently requires the use of GLCs. If at all possible, hyposensitization and avoidance therapy should be attempted before medical management. Although GLCs are the most effective antiinflammatory-antipruritic medication currently available for the atopic patient, alternate forms of therapy, as previously noted (e.g., antihistamines, misoprostol, omega fatty acids, and combinations thereof), should be attempted before sentencing a patient to chronic GLC therapy. Initial treatment with prednisolone at an antiinflammatory induction dose of 0.5 to 1 mg/kg per day is recommended. After resolution of clinical signs, the therapy should be switched to an alternate-day regimen. An effective alternate-day dose can be achieved by taking the lowest effective daily dose and increasing it by 50%.75 Some dogs may require medication every 3 to 4 days. The use of injectable repositol forms of GLCs is not recommended for treatment of canine atopy.

Atopy is also believed to exist in the cat. There is little information regarding the efficacy of antihistamines and fatty acid supplements as antipruritics in the cat. GLCs are the therapy of choice for treatment of atopic pruritis in the cat.⁷⁶ As with dogs, short-acting to intermediate-acting compounds (prednisolone 1 to 2 mg/kg per day) are recommended, and alternate-day therapy should be the goal.

Otic

Otitis externa, often occurring as a component of atopy, is frequently responsive to topical GLC therapy (see Chapters 8 and 9 for discussion of antimicrobial drugs). Products usually contain an antibiotic and antifungal in addition to the GLC, and these agents can help resolve secondary infections. It is important to note that topically administered GLCs can be absorbed systemically.⁵¹ Efforts to remove or resolve the inciting factors should be made in cases of chronic otitis externa. More severe otitis externa, such as idiopathic hyperplastic otitis externa of Cocker Spaniels, may require systemic GLC treatment (prednisolone at 0.5 to 1 mg/kg per day).⁷⁷ Follow-up examinations, usually at 2-week intervals, should include otoscopic and cytologic examinations to identify potential complications (otitis media, secondary yeast or bacterial infection, parasites, and so forth). It should be stressed that GLC therapy is *not* a substitute for thorough cleaning and drying of the ear.

Respiratory

GLCs have a pivotal role in the treatment of selected respiratory conditions (see Chapter 20). Their efficacy as bronchodilators (through their permissive effects on β_2 -receptors) and as antiinflammatory agents has been well documented in patients with asthma. Among clinically used antiinflammatory drugs, GLCs alone inhibit prostaglandins, leukotrienes, and plateletactivating factor. Their effects on macrophage processing are well documented. These mediators have important roles in the pathophysiology of chronic bronchial disease. In human patients inhaled GLCs (beclomethasone, triamcinolone) tend to be first-line drugs. In cats suffering from bronchial asthma, GLCs are administered acutely and are the cornerstone of long-term therapy. Preference for the particular drug varies among clinicians. In patients suffering from status asthmaticus, water-soluble preparations of prednisolone tend to be used for their rapid effects, whereas dexamethasone may be preferred because it is more potent and provides a more prolonged effect. A combination of both products might be considered for immediate effects, followed by the more prolonged effects. Long-term therapy generally consists of oral forms of prednisolone, although some clinicians may prefer triamcinolone because of its enhanced potency. Alternate-day therapy may, however, be of no benefit for this intermediate- to longacting GLC. As with other conditions requiring prolonged therapy, a higher dose is administered initially, with tapering of the dose to a minimal acceptable level. Lifelong therapy may be necessary for some cats. The use of repositol steroid preparations is controversial. Although they are convenient, the lack of predictability regarding retreatment may preclude their effective use. In cases of relapse, intravenous administration of dexamethasone or nebulized steroid therapy may be of benefit. Greater discretion is indicated for long-term use of GLCs in chronic respiratory diseases in dogs. Noninfectious diseases associated with eosinophilic or macrophage infiltrates are indications for GLC therapy, usually in conjunction with bronchodilator therapy. Short-acting GLCs can be used on a short-term basis (<48 hours) to break a cough cycle in patients with upper respiratory syndromes associated with inflammation (i.e., tracheobronchitis).

The design of topically administered inhalant GLCs and their use is also discussed with regard to "soft steroids" and adverse events, as well as in Chapter 20.

Musculoskeletal

Understanding the implications of GLC use for the treatment of osteoarthritis requires appreciation of the pathophysiology of osteoarthritis and the effects of GLCs on normal joint

^{*}Among the difficulties in identifying a scientific basis for the recommended use of glucocorticoids in dogs or cats is the limited number of clinical trials. Further, many of the clinical trials base response on prednisone, rather than prednisolone. Caution is recommended in overinterpreting studies that fail to detect a response to prednisone (rather than prednisolone) because of evidence of poorer absorption of the former compared to the latter in both dogs and cats.^{59, 63}

physiology. GLCs have variable and opposite effects on joint physiology, depending on the dose used.⁷⁸ Low concentrations appear to be chondroprotective, whereas higher concentrations are chondrodestructive.

The term *steroid arthropathy* was coined to refer to the destructive condition that occurs in joints after multiple intraarticular injections of GLCs in human patients.⁷⁸ In animal models (including dogs), the detrimental effects of GLCs can occur after administration of a single intraarticular injection or multiple systemic doses. In addition to the destruction induced by GLCs on cartilage, indirect damage may occur because of failure to rest an injured joint. Finally, GLCs negatively affect subchondral bone by inhibiting osteoblastic activity.

Despite the obvious role GLCs have in preventing cartilage catabolism and controlling inflammation, their use for the treatment of osteoarthritis is controversial. Although short-term use is generally accepted for acute conditions or trauma, long-term use is less acceptable. Much of the controversy might be resolved if a physiologic dose could be defined. In a canine model of osteoarthritis, an oral dose of 0.2 to 0.25 mg/kg per day of prednisone or an intraarticular dose of 5 mg per month of triamcinolone hexacetonide significantly reduced the incidence and severity of cartilage lesions and osteophyte formation⁷⁹ The advantages of intraarticular administration include minimization (but not total elimination) of systemic effects. Disadvantages include the potential need for chemical restraint and the risk of sepsis.

Newer GLCs characterized by increased antiinflammatory potency yet decreased negative effects on cartilage may resolve the controversy regarding the use of GLCs in the treatment of osteoarthritis. Until these drugs are available or a physiologic dose has been established, the authors recommend reservation of GLCs in the treatment of osteoarthritis to animals that have failed to respond to chondroprotective agents or nonsteroidal antiinflammatory agents that are chondroprotective. Concurrent use of GLCs and nonsteroidal antiinflammatory agents enhances the risk for gastrointestinal ulceration and is not recommended. Finally, if GLCs are used, low doses (as noted previously) should be administered, and the simultaneous use of disease-modifying chondroprotective agents should be considered.

In humans suffering from osteoarthritis, intraarticular treatment with triamcinolone, methylprednisolone, and prednisolone are used to treat symptoms associated with osteoarthritis. Contraindications for such use include evidence of infection (e.g., bacteremia, adjacent osteomyelitis, or overlying skin) and joint prostheses. In humans corticosteroid injections are considered relatively safe, with long-term concerns focusing on the risk of long-term joint damage or infection.⁸⁰ The use of GLCs for treatment of osteoarthritis reduces the number of GRs in treated patients, leading to a decrease in responsiveness. Subsequent activation of metalloproteinases may contribute to joint degeneration, although long-term (>1 year) therapy was associated with a trend toward improvement in humans with osteoarthritis of the knee. However, because the long-term effects of GLC therapy are not clear, their use is generally limited to patients who have not responded to other therapies.

Central Nervous System

GLCs are used for treatment of both brain and spinal cord disease. Their beneficial effects include protection from free radicals, reduction in intracranial pressure (decreased production of cerebrospinal fluid), and maintenance of normal microvasculature integrity. GLCs appear to be beneficial in reducing or preventing cerebral edema associated with neoplasia; however, cerebral edema caused by trauma is thought to be less responsive to GLC therapy.

There is increasing evidence that lipid peroxidation and resultant formation of oxygen-derived free radicals play an important role in tissue damage subsequent to brain or spinal cord trauma. Several GLCs, including methylprednisolone (most potent), dexamethasone, and prednisolone, are capable of inhibiting lipid peroxidation.73 Their ability to inhibit phospholipase A2 may also protect injured nervous tissue. For treatment of acute CNS injury, the water-soluble salts should be used. Recommended dosage regimens for these agents in the treatment of CNS injury in dogs and cats are methylprednisolone sodium succinate 30 mg/kg intravenously, followed by 15 mg/kg 2 and 6 hours later, and then 2.5 mg/kg per hour for the first 48 hours; prednisolone sodium succinate 60 mg/kg intravenously, followed by 30 mg/kg 2 and 6 hours later, and then 5 mg/kg per hour for the first 48 hours; and dexamethasone sodium phosphate 4 mg/kg intravenously every 6 hours for the first 48 hours.73 In studies involving cats with spinal cord injury, methylprednisolone sodium succinate-treated cats had significantly improved neurologic outcome, whereas the neurologic outcome of cats treated with dexamethasone was not significantly different than that of cats receiving placebo.^{81,82}

Noninfectious, or so-called steroid-responsive, meningitis and granulomatous meningoencephalitis are diseases that frequently respond dramatically to GLC therapy. Prednisolone at a dose of 2 to 4 mg/kg per day has been recommended. The use of glucocorticoids for treatment of intervertebral disk disease is addressed in Chapter 28.

Inflammatory Bowel and Liver Disease

Inflammatory bowel disease in cats (especially those with lymphocytic–plasmacytic infiltrates) is frequently responsive to prednisolone at 2.2 mg/kg per day⁸³ (see Chapter 19). For more severe cases, dexamethasone at 0.22 mg/kg per day plus metronidazole may be effective. In either case, the initial dose should be maintained for 2 weeks beyond the time that the cat's clinical signs begin to resolve. Cats that respond immediately should receive the initial dose for at least 4 weeks before dose reduction is attempted.

Inflammatory bowel disease in dogs may be less responsive to GLC therapy than is the case in cats (canine patients with eosinophilic infiltrates are an exception). Initial treatment of lymphocytic–plasmacytic enteritis and colitis is with 2.2 mg/ kg of prednisolone per day. Frequently, additional therapy is necessary (metronidazole, azathioprine). In all cases dietary modification should accompany pharmacologic therapy. Alimentary lymphosarcoma should be ruled out before steroid therapy is initiated (especially in cats). The use of GLC for treatment of inflammatory bowel disease is also discussed in Chapter 19.

Corticosteroid therapy for liver disease remains somewhat controversial. Clinical studies in human medicine have shown that steroid therapy in chronic active hepatitis improves survival rates. Nonsuppurative cholangitis-cholangiohepatitis may respond to immunosuppressive GLC therapy.

Gingivitis and Stomatitis

The eosinophilic granuloma complex in cats is usually responsive to high-dose GLC therapy such as methylprednisolone acetate 20 mg intramuscularly every 2 to 3 weeks for three treatments. Lymphocytic–plasmacytic gingivitis and stomatitis in cats may respond to GLC therapy (prednisone 2 to 4 mg/ kg orally every 24 hours).

Septic Shock and Functional Adrenocortical Deficiency

The antibacterial treatment of septic shock is addressed in Chapter 8, and the antiinflammatory component also is addressed in Chapter 29. A number of bacterial and viral infections activate the HPAA such that GLC release increases. The mechanism probably reflects cytokines or other inflammatory mediators.⁴ It is likely that activation reflects both a direct effect on the adrenal glands or the hypothalamus or pituitary. Other proteins (e.g., Staphylococus, Clostridium, Mycoplasma) can also stimulated the response. A number of viruses have similar capability. However, although both bacterial and viral infections affect the hypothalamic-pituitaryadrenal axis such that GLC release is increased, other factors in the infected patient, such as pain, psychological stress, and the debilitating effects of infection, likewise activate the hypothalamic-pituitary-adrenal axis⁴ and will modulate response to infection.

The use of GLCs in septic shock has been controversial, although their potential benefits were recognized as early as 1951^{84,85} (see Chapter 29). Evidence varies with experimental versus clinical studies. Earlier experimental models of septic shock showed GLCs to be beneficial if administered before or concurrently with endotoxin administration (i.e., within the first 2 hours). In canine models, severe mesenteric vasoconstriction within the first 15 minutes can lead to irreversible shock. Thus GLCs are unlikely to provide beneficial effects if they are administered 30 to 60 minutes after administration of the endotoxin.⁸⁶ One of the differences between results of experimental versus clinical (spontaneous) models of septic shock may be the choice of outcome measures. Survival rates in experimental models are often based on short-term analysis (i.e., survival for several hours). In addition, the likelihood of knowing the time of onset of endotoxemia or sepsis in a clinical setting is extremely low.

The use of GLCs in human patients suffering from sepsis and septic shock was addressed in a large meta-analysis of human clinical trials.⁸⁴ In this study 10 of 49 published reports investigating the effects of corticosteroids in human patients experiencing septic shock were considered to be superior on the basis of scientific design (e.g., controlled study, blinding techniques). Even within these 10 studies, however, differences in experimental design, definition of septic shock, drugs, dosing regimens, timing of steroid administration, and other design considerations limited the number of conclusions that could be made. Mortality rates often were the basis of analysis; however, mortality was not determined at the same time in all 10 studies. Of the 10 studies examined, only one study offered a significant positive effect for patients receiving GLCs. Most studies show a beneficial effect of steroids during the first few hours after the initiation of shock. Patients with sepsis associated with gramnegative infections demonstrated a slightly better outcome. The most common or severe side effects after steroid treatment was gastrointestinal bleeding (reported in five studies), generally associated with administration for 6 or more days or months. Superinfection (secondary infection) was reported in 7 of the 10 studies. The authors made the following conclusions: (1) The broad use of corticosteroids in patients with sepsis or septic shock is not beneficial, and the authors went so far as to suggest that a new trial would not be indicated. (2) Short-term, highdose treatment did not increase the risk of complications. (3) Very early initiation (or prophylactic use) of steroid therapy in gram-negative infections might reduce the generalized inflammatory response to infection.⁸⁴ The results of this and other studies led to a decline in the use of GLCs in septic shock in the early 1990s, only to be followed by a re-examination of the question in the late '90s and early 2000s. Renewed interest reflected the recent recognition that sepsis and septic shock are aggravated by transient adrenal failure and negative cardiovascular sequelae associated with adrenal insufficiency.² Mortality rates are increased in acutely septic patients in which corticotropin stimulation is attenuated.⁸⁷ In humans bilateral adrenal hemorrhage or necrosis is present in as many as 30% of patients dying as a result of septic shock, and peripheral ACTH resistance has been described in close to 20% of humans with septic shock. Predisposition to acute renal failure in septic shock may be facilitated by underlying pituitary or adrenal pathology, or cotreatment of drugs that impair cortisol synthesis (e.g., ketoconazole) or increase cortisol metabolism (e.g., phenobarbital).²

In contrast to early studies that focused on high doses of GLCs for treatment of septic shock, the realization of the potential role of adrenal insufficiency led to a physiologic approach to adrenal hormone replacement. A recent metaanalysis⁸⁸ concluded that the dose of GLC used in the patient experiencing septic shock affected risks associated with increased mortality. Whereas clinical trials reported before 1989 (n = 8) found decreased survival in patients treated with GLCs, analysis studies after 1997 (n = 5) consistently found beneficial effects on survival if physiologic doses were used, even if longer than 6 days. The mean total hydrocortisone equivalent reported in the later trials was 1209 mg, or 300 mg per day (approximately 4 mg/kg/day), compared with a mean total dose of 20 times that amount in the earlier studies. The impact of secondary bacterial infections was considered a contributing factor to increased mortality rates in trials before 1989. Although the incidence of secondary bacterial

infections did not differ between the two time periods, the time to resolution of the secondary infection was shorter after 1997, presumably because of less immunosuppression and fewer deaths associated with secondary infection. The authors concluded that whereas short courses of high-dose GLCs decreased sepsis survival, a 5- to 7-day course of physiologic hydrocortisone doses, with subsequent tapering of doses, increased survival. The impact of physiologic GLCs appears to reflect reversal of vasopressor-dependent septic shock, including improved response to vasoactive drugs.⁸⁸ Other investigators have described decreased body temperature and heart rate when subjects are treated with low-dose GLCs. Improved survival rates in septic human patients treated with low-dose GLC therapy have led to the development of criteria intended to aid in the recognition of adrenal failure so that low-dose GLC therapy might be initiated. Basal cortisol concentration below 15 µg/dL are considered indicative of adrenal insufficiency in humans; for dogs, concentrations are $< 2 \mu g/dL$ pre and post ACTH response (see also Chapter 21).² Treatment for adrenal failure in humans focuses on replacement therapy with hydrocortisone (200 to 300 mg/kg per day [for a 70-kg patient]) combined with fludrocortisone (50 µg per day) for up to 7 days.

Septic shock is not the only acute illness for which functional ACTH deficiency may occur. Deficiency associated with acute illnesses in humans has been reviewed.⁸⁹ Acute situations such as severe infection, trauma, burns, and surgery may cause up to a sixfold increase in cortisol secretion, with the increase proportional to the illness. Secretion may be impaired, however, for a variety of reasons, including preexisting disease affecting the hypothalamic-pituitary-adrenal axis, drug-impaired synthesis (e.g., imidazole antifungals, etomidate), adrenal necrosis, or hemorrhage as might accompany coagulopathies, or iatrogenic suppression such as that which may occur with exogenous GLC therapy. Cytokines associated with systemic inflammation may cause tissue GLC resistance; indeed, human patients with the most severe illness may have the highest cortisol concentrations, making "spot checks" of cortisol less helpful in the diagnosis of these patients.⁸⁹ The deficiency is generally transient but is difficult to diagnosis. In humans, hyponatremia, hyperkalemia, hypoglycemia, and eosinophilia may be present. A corticotropin stimulation test might be used to detect an incremental response. Deficiency, once diagnosed, is treated in humans differentially, depending on the severity of illness. No treatment is indicated for mild illness. A moderate illness or condition may be treated with approximately 0.2 mg/kg per day, with discontinuation (or return to predeficiency doses in those patients receiving GLCs) within 24 hours of resolution. Severe illness or major surgery is treated with approximately 0.7 mg/kg cortisone every 6 hours; on resolution, the dose is tapered 50% every day. Septic shock is treated similarly with the addition of 0.7 µg/mL of fludrocortisone daily; treatment continues for 7 days.89

The final word on the role of GLCs in critical patients has yet to be determined. A meta-analysis of controlled clinical trials (n = 5) evaluating the efficacy of GLC therapy in patients experiencing septic shock. The analysis found that a short course of high-dose hydrocortisone decreased survival rates, whereas a longer course (5 to 7 days) of low-dose hydrocortisone increased survival rates.88 However, a recent multicenter clinical trial in humans (n = 251) with persistent hypotension despite fluid and resuscitation therapy found no significant response to corticotropin in patients that received low-dose hydrocortisone (approximately 0.72 mg/kg; n = 251) compared with saline placebo (n = 248) every 6 hours. Although time to reversal of shock was shorter in the treatment group, no difference in mortality rates was detected between groups or between responders and nonresponders within each treatment group.90 Factors that may have led to the lack of difference, as opposed to other studies that have reported treatment success, included lack of fludrocortisone treatment, patients that were less severely ill compared with those in other studies, and continued therapy for up to 11 days (as opposed to 7 or fewer days for other studies). The authors concluded that corticotropin response does not seem to be a viable test for predicting the need for steroid therapy. Interestingly, perioperative glucocorticoid supplementation in the surgical patient has been a point of controversy for more than half a century.^{90a} The rationale is based on the recognition of surgery-associated adrenal insufficiency. The need for use and guidelines for administration were reviewed by Salem and coworkers in 1994. In 2008, Jung and Inder revisited the issue, recognizing that no consensus exist regarding dosing regimens or duration. However, high doses (>200 mg hydrocortisone equivalent, or approximately 2.75 mg/kg a day) beyond 2 to 3 days clearly are to be avoided in the uncomplicated case.90b

Neoplasia

Prednisolone is often included in combination chemotherapy protocols for treatment of lymphoma and multiple myeloma for their cytotoxic actions. The impact of GLC treatment alone in patients with GLC-responsive cancer, before implementation of combination chemotherapy, is controversial. In general, use of GLCs before chemotherapy is generally discouraged because of the clinical perception that such use is associated with a decreased duration of survival, which presumably reflects rapidly developing resistance to GLCs. Indeed, Price and coworkers91 demonstrated a significant decrease in the median duration of remission in dogs receiving GLCs before chemotherapy (134 days) compared with that of dogs not receiving GLCs (267 days). Proposed mechanisms whereby this might occur include the advent of multidrug resistance (e.g., by way of P-glycoprotein or related proteins) or a decrease in GLCs receptors. The use of GLCs as a single agent for treatment of lymphoma theoretically may rapidly induce multidrug resistance in neoplastic cells, causing the cell to be less responsive to not only GLCs but also other anticancer drugs, such as doxorubicin and vincristine. However, an in vitro study using canine cancer cells demonstrated dexamethasone resistance to cisplatin and methotrexate, but the resistance did not appear to reflect the multidrug resistant genes studied.92 Because of the controversy surrounding single-agent chemotherapy of lymphoma with prednisolone, this approach is generally not recommended except under certain circumstances, such as in the presence of life-threatening or organ (kidney) hypercalcemia.

The impact of GLCs on drug-receptor interaction may be a more likely cause for the development of resistance. Failure has been correlated to receptor density, with cells (e.g., T lymphocytes) characterized by low density being less responsive to chemotherapeutic drugs in general.

GLCs are often used in patients with mast cell tumors to decrease the inflammatory response associated with mast cell degranulation. Additionally, GLCs may induce a partial or complete remission in some canine patients with mast cell tumors.⁹³

Ophthalmic

Topical GLC therapy is efficacious for treatment of noninfectious conjunctival, scleral, corneal, and anterior uveal inflammatory diseases.⁹⁴ Before topical corticosteroid use, however, the corneal epithelium should be examined (using fluorescein dye) for signs of ulceration. The effects of glucocorticoids on corneal epithelial cells is biphasic, stimulating growth at low (physiologic) concentrations and inhibiting it at higher concentrations (supraphysiologic or pharmacologic).^{94a} The presence of corneal ulceration precludes the use of topical corticosteroids. Prednisolone acetate penetrates the intact corneal epithelium and is therefore effective for treatment of intraocular inflammation.⁹⁴ Systemic absorption of topical ophthalmic corticosteroids has been documented in dogs. Systemic GLC therapy is necessary for treatment of noninfectious posterior segment inflammatory conditions.

Hematopoietic

GLCs are the mainstay, first-line therapy for both immunemediated hemolytic anemia and thrombocytopenia. Some anecdotal evidence suggests that initial treatment with dexamethasone may be superior to prednisone therapy, but no controlled studies have substantiated this claim. This may, reflect, however, poor bioavailability of prednisone. Prednisone (2 to 4 mg/kg per day) or dexamethasone (0.3 to 0.6 mg/kg per day) therapy should be continued until erythrocyte or platelet numbers steadily increase. Subsequently, the dose should be slowly (over 3 to 6 months) tapered. Addition of GLCs is also beneficial for treatment of immune-mediated neutropenia and for treatment and prevention of transfusion reactions.

Hypoadrenocorticism

Replacement corticosteroid therapy for treatment of hypoadrenocorticism is discussed in Chapter 21. An Addisonian crisis requires treatment with rapid-acting GLCs and mineralocorticoids. Not all synthetic GLCs are effective for replacement of mineralocorticoid deficiency. Dexamethasone, methylprednisolone, triamcinolone, and betamethasone are virtually devoid of mineralocorticoid activity. For treatment of acute hypoadrenocorticism, if a mineralocorticoid such as fludrocortisone (Florinef) or DOCP is unavailable, prednisolone or cortisone may provide adequate mineralocorticoid activity.

ADVERSE EFFECTS

Adverse reactions resulting from GLC therapy can occur through either cessation of therapy or prolonged use. Acute adrenal insufficiency results from rapid withdrawal of GLCs after prolonged treatment (see earlier discussion of clinical use). Termination of GLC therapy in a chronically treated patient should be performed gradually over several months. Complete recovery of the hypothalamic–pituitary–adrenal axis may require 9 months. During this time, patients may need supplemental GLCs during "stressful" situations (e.g., surgery).

Complications of GLCs related to prolonged therapy are described later. In general, dogs are more susceptible to these complications than are cats. The incidence of adverse effects resulting from GLC administration is frequently related to the dose and duration of treatment. Alternate-day therapy with short-acting preparations can significantly reduce the incidence of adverse reactions.

The avoidance of GLC side effects is a focus of intense research in human medicine. The critical role that GLCs play in human asthma has directed much research in the design and development of the ideal GLC: one that combines marked efficacy and long-term safety, a convenient delivery device, and a reasonable price. Among the current methods by which risks are reduced is the design of drugs that target transrepression and through manipulation of the pharmacokinetic properties of GLC. This includes the administration of "soft" GLCs (previously discussed).¹⁸ Another mechanism by which systemic effects of GLC might be reduced is activation of a prodrug at the site of action. For example, ciclesonide is a novel, inhaled corticosteroid approved or treatment of asthma. The drug is activated in the lungs to the potent drug desisobutyrylciclesonide (des-CIC) in the lungs. The metabolite exhibits 100-fold affinity for GR in the lungs compared with the parent compound, and thus is comparable to fluticasone in potency. Further, the drug is characterized by low bioavailability, in part because of its high first-pass metabolism.95

The use of low rather than high doses may prevent some undesirable side effects, although the impact varies with the adverse event in human medicine.²⁰ Osteoporosis persists, whereas osteonecrosis might be reduced. Myopathy is rare with low doses, whereas endocrinopathies, including glucose intolerance, fat redistribution, and weight gain, remain present with low doses; however, diabetes mellitus rarely occurs with low doses. Cardiovascular adverse events (e.g., atherosclerosis, sodium and water retention) tend to be minimized at low doses, whereas dermatologic events consistent with iatrogenic Cushing's syndrome persist, albeit at a lower level. Psychologic disturbances, including steroid psychosis, are largely absent at low doses. Ophthalmic events such as glaucoma and cataracts are largely reduced with low doses, as are gastrointestinal events, including gastroduodenal ulceration (generally associated with concomitant use of nonsteroidal antiinflammatory drugs) and pancreatitis. Immunosuppression resulting in increased susceptibility to infectious disease also is largely reduced but still remains for some pathogens

(e.g., *Pneumocystis carinii*) at low doses. The impact of dose dependency on the use of GLCs for treatment of septic shock was previously discussed.

Steffan and coworkers⁹⁶ compared adverse events associated with cyclosporine A (n = 119; 5 mg/kg per day induction followed by tapering doses) versus methylprednisolone (n = 59; 0.5 to 1 mg/kg per day for 1 week, then every other)day for 3 weeks, then tapered) in dogs with atopic dermatitis. The incidence of adverse events was similar between groups. The incidence of vomiting was significantly less in the methylprednisolone-treated group compared with the cyclosporine A-treated group (vomiting, 37% versus 5%). Whereas infections occurred with similar frequency in the two treatment groups, they were more likely to be classified as severe or very severe in the methylprednisolone-treated group, leading to more dropouts. Polyuria and polydipsia were more common in the methylprednisolone-treated group (25%) versus the cyclosporine A-treated group (4.3%); increased appetite and weight gain were also greater in the methylprednisolonetreated group (12% versus 3%). Serum chemistries indicative of renal function did not change from baseline levels. Potassium decreased approximately 0.7 mg/dL (and increased in the cyclosporine A-treated group) but was within normal values.

Levine and coworkers⁹⁷ retrospectively compared the adverse events associated with dexamethasone (n = 49) compared with no treatment (n = 80) and other GLC therapy (primarily methylprednisolone sodium succinate) for treatment of acute thoracolumbar intervertebral disk herniation in dogs. The mean dose was 2.25 mg \pm 4.28 m/kg (range 1 to 30 mg/kg). Adversities that were greater in the dexamethasone-treated group included vomiting, diarrhea, and anemia. Urinary tract infections also were more frequent in the dexamethasone-treated patients, although not all patients were tested for infection.

Central Nervous System

GLCs act as centrally active appetite stimulants to induce polyphagia in dogs and, to a lesser degree, in cats. This may contribute to the development of obesity in some patients, but it also may stimulate the appetite of an anorexic patient. Changes in mood or behavior have been noted in human patients treated with GLCs. Although these are more difficult to document in veterinary patients, most clinicians have noted positive attitude changes in patients being treated with GLCs.

Musculoskeletal

Muscle weakness and muscle atrophy are commonly observed in dogs with hyperadrenocorticism and dogs receiving large doses of GLCs (see previous discussion). These effects in part reflect muscle wasting that may result from the catabolic gluconeogenic effects of GLCs.

GLCs are associated with osteoporosis and vertebral compression in 30% to 50% of human patients receiving the drugs chronically. Mechanisms include direct inhibition of osteoblasts (decreased bone formation); inhibition of calcium absorption from the intestines; increased parathormone secretion, which in turn increases osteoclast-mediated bone resorption; and increased calcium excretion.⁹ Osteoporosis is not a clinically recognized entity in small animals receiving GLCs, in part because of differences in body posture as well as duration of therapy. Prudence is indicated, however, when GLCs are used in the face of conditions that facilitate or are facilitated by the negative sequelae of GLCs on bone formation. Aseptic necrosis has been reported in human patients after a short course of high doses of GLCs.⁹

Gastrointestinal and Liver

The likelihood of GLCs causing gastrointestinal ulceration is controversial. In general, patients that develop ulceration are predisposed to ulceration because of stress or are receiving other drugs that contribute to gastrointestinal damage, most notably nonsteroidal antiinflammatory drugs. In stressed animals peripheral effects of centrally or peripherally mediated norepinephrine may be important to the manifestation of gastrointestinal ulceration mediated by GLCs.98 Colonic perforation in dogs with spinal cord injuries has been associated with the use of dexamethasone, perhaps in part because of modulation of local blood flow. Pancreatitis has been associated with the use of GLCs alone and in combination with azathioprine. GLCs can induce hepatocellular swelling as a result of fat, perivascular glycogen, or water accumulation. Centrilobular vacuolization is common, and focal necrosis occasionally occurs. Clinically, these changes are seen as hepatomegaly and elevated liver enzyme activity. In dogs induction of a steroid-induced alkaline phosphatase isoenzyme occurs in patients receiving GLCs. The effects of GLCs on the liver are slowly reversible, persisting 1 to 1.5 months after therapy is discontinued.

Metabolic

Glucose intolerance, insulin resistance, overt diabetes mellitus, and hyperlipidemia can be induced in canine patients receiving GLC therapy.

Hepatic

GLCs consistently cause diffuse to centrilobular vacuolization and perivascular glycogen accumulation in hepatocytes.^{99,100} Focal necrosis has been occasionally described in clinical cases. Similar lesions result with hyperadrenocorticism. In addition to serum biochemical changes consistent with liver disease, GLCs also cause elevations in a steroid-specific alkaline phosphatase isoenzyme, which can be discerned with the levamisole test. This increase (induction) is not considered indicative of liver disease if other indicators of liver disease are absent. The pathologic changes associated with GLCs are slowly reversible over 1 to 1.5 months after discontinuation of therapy.

Endocrine

Exogenous administration of GLCs suppresses the hypothalamic-pituitary-adrenal axis through feedback inhibition on the anterior pituitary and the hypothalamus. Chronic suppression of the axis can result in iatrogenic hypoadrenocorticism on discontinuation of exogenous GLCs. GLCs cause a decrease in plasma concentrations of total triiodothyronine, thyroxine, and thyroid-stimulating hormone, with a normal free triiodothyronine and thyroxine concentration.¹⁰¹ Therefore, when assessing thyroid function in animals receiving GLCs, the clinician should keep in mind their influence on total thyroid hormone concentrations. GLC administration does not result in clinical hypothyroidism because the free hormone concentration is minimally affected. GLCs increase parathormone secretion.

Renal

Polyuria and polydipsia are classically associated with excessive GLC (either endogenous or exogenous). Several factors probably contribute to this effect, including increased glomerular filtration rate resulting from increased vascular volume, increased renal calcium excretion, inhibitory actions on antidiuretic hormone, and direct actions decreasing permeability of the distal tubule. Glucocorticoids may increase the risk of azotemia in patients with renal disease because of their catabolic effects, particularly in the presence of metabolic acidosis.

Cardiovascular

Many human patients receiving GLCs develop hypertension as a result of sodium retention. Hypertension occurs in dogs with hyperadrenocorticism and presumably could also occur in veterinary patients receiving exogenous GLCs. Postulated mechanisms for hypertension in canine hyperadrenocorticism include increased activation of angiotensin I, increased vascular responsiveness to catecholamines, and reduction of vasodilator prostaglandins.

Immune Function

Although the intent of GLC therapy generally reflects suppression of some facet of immune function, such use generally is associated with an increased risk of bacterial, viral, and fungal infection, although this effect is dose dependent, as was previously discussed with regard to treatment of septic shock. It is generally recognized that a single dose of a short- to intermediate-acting GLC is unlikely to significantly suppress immune function, but caution with this approach is prudent, particularly for infectious diseases. Chronic administration of GLCs can result in recurrent cystitis, septicemia, and endocarditis. Causes for these effects are multiple, including immune suppression and, potentially, upregulation of P-glycoprotein (see the discussion of neoplasia). Ihrke and coworkers¹⁰² demonstrated as early as 1985 that close to 40% of dogs receiving immunosuppressive GLC therapy (mean of 0.8 mg/kg) also had a urinary tract infection. In a study of close to 200 dogs with pruritic skin disease, those receiving GLCs (either prednisone [70%] or methylprednisolone [30%]) for longer than 6 months had a higher incidence of urinary tract infections compared with dogs that did not receive GLCs.¹⁰³ Doses ranged from 0.12 to 1 mg/kg, with a mean of 0.28 \pm 0.14, generally administered every 48 hours. The overall incidence was lower than that of the earlier study, at 12% for treated dogs compared with 0% for untreated dogs, when based on the first urine sample collected for each dog. However, the number increased to 23% when subsequent samples were included in the analysis, indicating the need for repetitive culturing in animals receiving GLCs. This study provided evidence that clinicians should perform routine cultures for patients with hyperadrenocorticism rather than rely on clinical signs or urinalysis. No dog with bacteriuria manifested clinical signs of urinary tract infection. Whereas the presence of bacteriuria and pyuria consistently indicated the presence of a urinary tract infection, the absence of bacteruria did not rule out urinary tract infection: Bacteriuria was not detected in 24% of urine samples that subsequently yielded bacterial growth. Female, but not male, dogs receiving GLCs were predisposed to infection, although this finding may have been biased by the limited number of male dogs treated with GLCs. Although E. coli was the most common organism isolated (14 of 34), a total of 10 different organisms were isolated. This study might be interpreted as justification of the routine use of antimicrobials. However, only 6 of 52 urine samples collected in patients receiving antibiotics were positive on culture. Particularly problematic was the fact that isolates cultured in dogs receiving cephalexin were resistant to the drug. Indeed, 51% of all isolates were resistant to cephalexin (a pattern typical of E. coli in general) and 22% were resistant to enrofloxacin, emphasizing the need for selection of an antimicrobial on the basis of susceptibility testing (see Chapter 8). Presumably, achieving bactericidal concentrations of a drug at the site of the urinary tract infection is paramount, should the decision be made to treat the infection. Dogs with intervertebral disk disease have an increased risk of UTI when treated with glucocorticoids (see Chapter 27).

Wound Healing

The impact of glucocorticoids on wound healing has been generally recognized for decades.^{103a} The impact of exogenous glucocorticoids largely reflects their antiinflammatory effects and down regulation of pro-inflammatory cytokines (as reviewed by Grose et al, 2002).^{103a} However, these effects occur at supraphysiologic (i.e., pharmacologic) doses. The effects of endogenous glucocorticoids (physiologic concentrations) also appear to be suppressive, but these latter effects may actually be beneficial in the control of late would healing.^{103a}

Immune Reactions

Paradoxically, despite their immunomodulatory effects, GLCs have been associated with allergic reactions in humans, albeit rarely. Types I, III, and IV reactions have been reported, with reactions more common in patients treated chronically (e.g., asthmatics, transplant recipients) and patients receiving either hydrocortisone or methylprednisolone intravenously.^{49,104} In addition to the active ingredient, reaction to (sulfate) excipients or to succinate salts has also been suspected. Vasculitis reactions have been reported after oral administration of either prednisone or prednisolone. Nakamura and coworkers¹⁰⁵ reported anaphylaxis that occurred after intravenous administration of succinate-containing GLCs (hydrocortisone or methylprednisolone) in severely atopic asthmatic humans. In this retrospective study, phosphate-containing drugs appeared to be safe. The authors recommended slow intravenous drip

administration in patients with severe allergic disease who have been previously exposed to GLCs. Erdmann and coworkers¹⁰⁶ reported an anaphylactic reaction in an atopic person receiving oral prednisone; skin testing revealed reaction to prednisolone, prednisolone hydrogen succinate, prednisone, and betamethasone but not methylprednisolone or dexamethasone. Accordingly, anaphylaxis should be suspected with any GLC if clinical signs are supportive. Allergic reactions may not be limited to type 1. Finally, reactions may not be limited to active drug but may involve vehicles or salt forms. One case of anaphylaxis has been reported in a dog receiving dexamethasone.¹⁰⁷ The dog had been previously treated with dexamethasone in propylene glycol as well as oral prednisone therapy for immune-mediated hemolytic anemia. The vehicle contained methylparaben and propylparaben as well as benzyl alcohol. No occurrences of anaphylaxis or anaphylactoid reactions were cited in a review of adversities associated with dexamethasone treatment in dogs with thoracolumbar disease (n = 161).⁹⁷ In a review of the literature, Schaer and coworkers¹⁰⁷ noted that anaphylactoid reactions also have been reported.

Respiratory

Pulmonary thromboembolism is a potential complication of hyperadrenocorticism and presumably also can occur with excessive exogenous GLC. The exact pathophysiologic mechanism is unknown but may be a result of obesity, hypertension, increased hematocrit level, or hypercoagulability. In addition, because of the myopathic effect of GLCs, muscles of respiratory function may be weakened in animals receiving high doses of GLCs.⁹

Growth Retardation

The administration of small doses of GLCs to children has been associated with retardation of growth. The mechanism may reflect changes in collagen synthesis but is likely to be much more complex. Prepartum exposure to GLCs can predispose experimental animals to malformations (e.g., cleft palate).

CONTRAINDICATIONS

GLCs produce profound actions on virtually all systems of the body. Many of these effects can be tolerated by a healthy animal, but in certain disease states the use of GLCs may be deleterious. Diseases and conditions that the authors consider to be major, moderate, and minor contraindications to GLC therapy are mentioned in the subsequent sections.

Infectious Disease

Infectious diseases are a major contraindication. GLCs can exacerbate viral, bacterial, and fungal infections because of their immunosuppressive properties (although a single antiinflammatory dose of a short-acting agent is unlikely to be harmful).

Diabetes Mellitus

Diabetes mellitus is a major contraindication. GLC-mediated gluconeogenesis and general anti-insulin effects make regulating diabetic patients difficult.

Renal Failure

Renal failure is a moderate contraindication. Increased protein catabolism induced by GLCs results in increased quantities of nitrogenous waste products to be excreted. Additionally, patients with renal failure are already immunocompromised. Further immunosuppression would greatly increase their risk of developing pyelonephritis.

Corneal Ulceration

Corneal ulceration is a major contraindication. Topically administered GLCs delay healing of the cornea and may lead to corneal perforation.

Pancreatitis

Pancreatitis is a moderate contraindication. GLCs are believed to aggravate pancreatitis by increasing fatty acid circulation.

Gastrointestinal Ulceration

Gastrointestinal ulceration is a moderate contraindication. GLCs promote progression of ulcerative disease by delaying healing, increasing acid and pepsin secretion, and reducing the rate of mucosal cell proliferation in the gastrointestinal tract. Patients with eosinophilic enteritis, lymphocytic–plasmacytic enteritis, and certain ulcerative and granulomatous enteritides are potential exceptions. Colonic ulceration is a significant risk in animals with spinal trauma that are receiving dexamethasone. Concurrent administration of a nonsteroidal antiinflammatory drug greatly increases the likelihood of gastrointestinal ulceration and is *not* recommended. Misoprostol, a prostaglandin E_2 analog, may provide protection against GLC-induced gastric ulceration.

Pregnancy

Pregnancy is a moderate contraindication. GLC administration has been associated with abortion and cleft palate in the dog. Additionally, GLC administration to a bitch within 24 hours of parturition reduces neonatal intestinal permeability of immunoglobulins, thereby reducing colostrum absorption.¹⁰⁸

Epilepsy

Epilepsy is a moderate contraindication. Endogenous GLCs suppress neuronal excitability, perhaps by potentiating the inhibitory effects of the neurotransmitter γ -aminobutyric acid. Chronic GLC use has been reported to be associated with lowering the seizure threshold. The mechanism for this possible effect is not clear. Exogenous GLCs may; however, downregulate steroid receptors, resulting in increased neuronal excitability.

THE IMMUNE RESPONSE

Immunomodulators, or biological response modifiers, are agents or drugs that act to regulate or modify the host's immune response to a microbe, neoplasm, or inflammatory response. It is beyond the scope of this chapter to provide a comprehensive review of the immune system. The following is a general review only. Cytokine biology can also be reviewed elsewhere,^{1,2} as can interferon (IFN) biology.³

Immune Defenses

Immune defenses are composed of the innate and adaptive systems. The innate systems are nonspecific in their response and are best exemplified by barriers provided by the integument; the gastrointestinal environment (acid pH, mucosal and epithelial barriers, microbiota); the mucociliary tract of the respiratory system; and the intimate vasculature of

selected organs such as the placenta, brain, and prostate. Other nonspecific defense mechanisms are exemplified fever and the antimicrobial actions of many secretions. White blood cells also represent innate immunity. These include neutrophils, eosinophils, basophils, macrophages, and dendritic cells, and unconventional T-cell subsets bearing T-cell receptors (TCR), natural killer (NK; CD1d) cells and gamma/ delta ($\gamma\delta$) T-cells. Natural killer (NK) cells are innate (non conventional) cytotoxic T cells that work in concert with the adaptive arm of immunity, targeting compromised host cells such as tumor or virally infected cells. Released in the vicinity of a cell slated for destruction, it is stimulated by macrophage cytokines. They recognize targeted cells which containing abnormally low concentrations of major histocompatibility complex [MHC] class I antigen ("missing self"). Materials that induce apoptosis enter the target cell through the pores, thus avoiding cellular lysis, which is of benefit in the presence of virally-infected cells that might release viral materials causing host re-infection. NK cells exhibiting the FrC receptor interact with the humoral arm of adaptive immunity, causing antibody-dependent cell cytotoxicity. Gamma-delta

^{*}The author and publisher wish to acknowledge the original contributions of S. Kruth for the Regressin-V and Acemannan sections of this chapter.

T cells contain characteristics of both the innate and adaptive systems.

The adaptive immune system provides the host an ability to recognize and, with subsequent presentation, remember specific pathogens (B and T memory cells), and increasingly stronger responses each time the pathogen is presented. These capabilities reflect both hypermutability and irreversible genetic recombination in cells that are carried forward in subsequent progeny. The system is composed of two major arms, cell-mediated immunity and humoral immunity, each accompanied by a variable number of cells and their chemical mediators. Some of the nonspecific components are also part of the innate immune system, including phagocytic circulating leukocytes and tissue macrophages, and secretions or body fluids such as IFN, complement, and leukocyte substances such as lysozyme. The adaptive arm of the immune system provides the primary targets of pharmacologic manipulation. The adaptive response recognizes both non-self and missing-self antigens. As such, MHC plays a major role in the adaptive arm of the immune system. This large gene complex encodes proteins unique to the individual. Expression on the cell surface allows recognition of self by relevant cell types. At least two subgroups of MHC are important in adaptive immunity. All cells, save non-nucleated cells, generally express MHC class I peptides on the cell surface. They are derived from the cytosol and contain other cytosolic proteins. Abnormalities in MHC class I expression that initiate an adaptive response generally result in interactions exclusively with CD8+ cells, inducing apoptosis. The MHC class II complexes are located on antigenpresenting cells, including dendritic, macrophage, activated T cells, and B cells. These peptides generally are associated with presentation of extracellular pathogens, and presentation that results in an adaptive response generally reflects interactions only with CD4+ cells (T helper or T_h cells).

KEY POINT 31-1 The primary targets of pharmacologic manipulation of the immune system are the adaptive arms of the immune system.

Both cell-mediated and humoral immune mechanisms are characterized by specificity toward antigenic epitopes expressed as molecular components of infectious organisms, foreign (transplanted) cells, or transformed (malignant) cells. Cytokines, including soluble growth and activation factors (Table 31-1), are a vital component of the adaptive response and are released and subsequently mediate the response of the various cell populations involved in both cell-mediated and humoral immunity.⁴ In addition to cytokines, a number of other molecules (e.g., adhesion or accessory molecules) are necessary as "second signals" for antigen processing, recognition, or response.⁴

Effectors

The following is a brief synopsis of the events following infection to implementation of the immune response (Figure 31-1). The antigen is exposed to an antigen-processing or presenting cell (APC), which includes dendritic cells (the principle APC), macrophages, and activated B cells.⁴ The antigen is identified by the APC as foreign and is subsequently phagocytized by the APC. The APC "processes" the antigen and "exhibits" it on the cell surface in a groove made by the MHC molecule. Peptides derived from endogenous cytosolic proteins synthesized within the cell complex (including those synthesized in response to viral stimuli) are expressed with class II MHC molecules on the cell surface, whereas exogenous intracellular proteins are expressed bound to a class I MHC groove for presentation.⁴

A single APC surface may have tens of thousands of MHC molecules, each containing a different peptide; a single animal may have more than 108 APCs. The APC migrates to the T cell area of a lymph node and presents the antigen to naïve CD4 T cells. If the APC comes into contact with a CD4 T cell with a TCR that recognizes the antigen associated with the MHC, it becomes activated. The release of adhesion molecules causes the two cells to stick together, which facilitates interaction between the APC and the CD4. Cytokines move between the two cells, and production of interleukin-1 (IL-1) by the APC and interleukin-2 (IL-2) from the activated CD4 cell itself amplifies the sequelae of CD4 activation. The activated CD4 cell differentiates, proliferates, and produces a number of cytokines (see Table 31-1), which results in recruitment of other leukocytes, initiation of B cell production of immunoglobulins (Igs), and formation of other T cell colonies, including "memory" cells (see Figure 31-1).^{4,5}

Cellular Components

Efficient pathogen elimination depends on the adaptive immune response. Two classes of lymphocytes are responsible for adaptive immunity (see Figure 31-1). B lymphocytes must be programmed to respond to antigen exposure and, after activation to plasma cells, are responsible for the production of specific Igs (humoral response). T lymphocytes provide the primary regulation of the immune response. T cell activity begins with specific antigen recognition by a receptor on the surface of the cell.⁴ T cells are further subdivided into several populations of cells depending on their role in immunoregulation (see Figure 31-1). Helper cell (CD4 T cells; T_h cells) receptors recognize and bind to the peptide-MHC class II complex of APC cells. In response to IL-1, CD4 cells consequently proliferate and become primed as either T_h1 or T_h2 CD4 cells, which modulate further responses in both the cell-mediated and humoral arms (see Figure 31-1). Migration of activated lymphocytes from lymph nodes to tissues is facilitated by adhesion molecules expressed by endothelial cells in tissues. Whether a T cell becomes T_h1 or T_h2 reflects the stimulating cytokine: IL-12 activates signal transducer and activator of transcription 4 (STAT-4), which regulates T_h1 differentiation, whereas IL-4 activates STAT-6 and Th2 differentiation.5

KEY POINT 31-2 T lymphocytes provide the primary regulation of the immune response, whereas B lymphocytes must be programmed to respond to antigen exposure.

Table 31-1	Immune Modu	latory Functions of Cytokines					
Chemokine	Produced by	Target Cells	Effect				
GM-CSF	Macrophages	Myeloid stem cells	Differentiation to granulocytes and monocytes				
IFN-alpha	Leukocytes	Normal cells	Antiviral, MHC I expression				
IFN-β	Fibroblasts	Multiple	Antiviral, MHC I expression				
IFN-γ	T _h 1	Multiple	Antiviral, MHC I expression				
·	Tc	Macrophages	MHC expression, elimination of pathogen; possible				
			T _h 2 antiproliferation				
	NK	T _h 2	Antiproliferation				
		Activated B cells	Switch to IgG2a				
IL-1	Monocytes	T _h	Activation; fever (endogenous pyrogen)				
Aβ precursors)	T 	B cells	Maturation, expansion				
	B cells	NK cells	Activation				
IL-2	T _h 1	Activated T, B, NK cells	Induce proliferation, activation				
IL-3	T _h 1	Stem	Suppress IL-1 production				
	NK	Mast cells	Proliferation, degranulation				
		B (antigen primed)	Activation, differentiation, IgG and IgE synthesis				
IL-4^*	T _h 2	B (activated)	Proliferation				
		Macrophages	Class switching (MHC class II)				
		T cells	Proliferation				
IL-5	T _h 2, most cells	Activated B cells	Differentiation, IgA synthesis				
		Eosinophils	Colony-stimulating factor				
IL-6	T _h 2	Proliferating B cells	Differentiation to plasma cells				
	Monocytes	Plasma cells	Antibody secretion				
	Macrophages	Myeloid stem cells	Differentiation				
	Stromal cells	Myeloid stem cells	Differentiation				
		Various	Acute phase response				
IL-7	Marrow stroma	Stem cells	Differentiation into T, B progenitor				
	Thymus stroma						
IL-8	Connective tissue	T	Chemoattractant				
	Macrophage	PMN					
IL-9*	T cells	Hemopoietic cells	Cell proliferation, apoptosis				
IL-10 [*]	T _h 2	Macrophages (lymphocytes)	Suppress IL-1 production, suppress TNF-a				
		B cells	Survival, activation, antibody production				
IL-12	Macrophages	Activated Tc	Differentiation to Tc; production of TNF- α , IFN- γ				
	B cells	T _h 1	Proliferation				
IL-13*	Overlap with IL-4						
MIP1-alpha	Macrophages	Monocytes, T cells	Chemoattractant				
MIP1β	Lymphocytes	T cells, monocytes, macrophages	Chemoattractant				
TGF-β [*]	T cells, monocytes	Macrophages, monocytes, activated B cells	Differentiation to granulocytes and monocytes				
TNF-alpha	Macrophages, NK	Tumor cells	Cytotoxic				
TNF-β	T _h 1, B	Tumor cells	Cytotoxic				
C3a, C5a	11 ⁻ , -	Mast cells	Chemoattractant				

GM-CSF, Granulocyte-macrophage colony stimulating factor; *IFN*, interferon; *MHC*, major histocompatibility complex; *T_h1*, *2*, helper T cells (CD4); *Ig*, immunoglobulin; *NK*, natural killer cells (a subset of cytotoxic T cells); *PMN*, polymorphonuclear leukocytes; *TNF*, tumor necrosis factor; *Tc*, killer T cells, cytotoxic (CD8); *MIP*, macrophage inflammatory factor; *TGF*, transforming growth factor; *C*, complement.

*Antiinflammatory signals included in actions

The T_h1 subsets of CD4 produce primarily proinflammatory cytokines such as IFN- γ (IFN- γ) and tumor necrosis factor-alpha (TNF- α) (cachexin; see Figure 31-1). As such, T_h1 cells regulate signals that promote cell-mediated immunity and control intracellular pathogens. T_h1 response is paramount to successful resistance to most microbial pathogens, including bacteria, intracellular protozoa, and fungal organisms. Additionally, T_h1 cells mediate organ-specific autoimmunity and as such are crucial to the pathogenesis of autoimmune diseases. The cell-mediated response occurs when activated CD4 (T_h1) cells attract other cells (polymorphonuclear leukocytes, eosinophils, and monocytes) to support cellular killing; the result is referred to as *delayed hypersensitivity*. Activated CD4 cells also yield, in response to IL-2, helper T cells that contain the glycoprotein CD8 and are responsible for the T cell-mediated cytotoxic response. Receptors of the CD8 T cells recognize

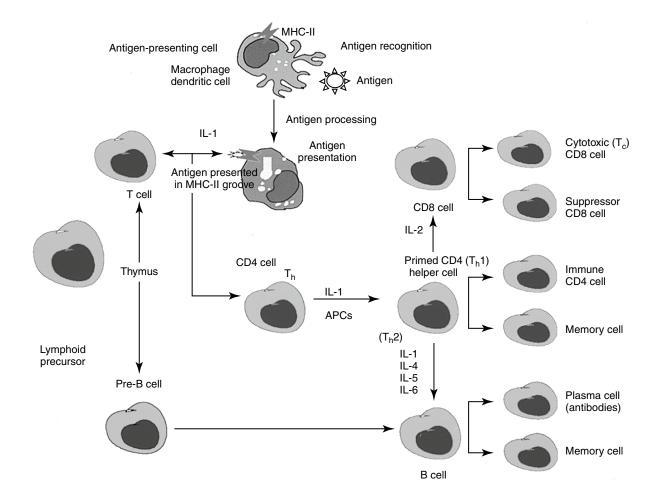

Figure 31-1 Overview of the immune response to antigen presentation. The antigen is presented to an antigen-presenting cell (APC), which processes the antigen and expresses its peptides in a groove located on the major histocompatibility complex (MHC) molecule. When presented to naïve CD4 T cells with appropriate receptors, the helper cell becomes primed to form CD8 cells, capable of directly killing cells presently containing the antigen; T_h1 cells, which result in the formation of memory T cells and T cells that attract other leukocytes (type IV hypersensitivity); or T_h2 cells, which stimulate B cell production of antibodies. A number of interleukins signal the activities; adhesion molecules (not shown) facilitate communication between cells as well as movement from lymph nodes through vascular endothelial cells into tissues. *IL*, Interleukin; T_h , T helper cell.

peptide-MHC class I complexes (generally associated with endogenous peptides present on all nucleated cells) on APCs. Recognition of the CD8 receptor and subsequent interaction with CD4 cells result in the generation of cytolytic (CTL) or cytotoxic T cells (T_C; killer T cells). Cytotoxic T cells are capable of directly (without further interaction with CD4 cells) causing lysis of cells expressing the targeted specific peptide-MHC complex.⁴ This includes normal but otherwise damaged (include virally infected or cells damaged by TNF-B or lymphotoxin) cells. CD8 cells release several different cytotoxins which cause pores in the target cell membrane. Cytotoxic T cells also undergo clonal expansion, resulting in prepared effector cells. In contrast to T_h1 cells, T_h2 cells secrete antiinflammatory cytokines (IL-4, IL-9, IL-10, IL-13) (in additional to pro-inflammatory cytokines) and support the humoral immune response, including host defense against intestinal helminths. Because of their antiinflammatory effects, Th2 cytokines can decrease autoimmune diseases associated with cell-mediated immunity; however, an imbalance toward T_h2 cells have been implicated in the pathogenesis of asthma and allergy (see below).⁵ Dysregulation of the influence of STAT-4 and STAT-6—which have contrary effects—has been associated with immune-mediated diseases. For example, each STAT is reported to be involved in systemic lupus erythematosus: STAT-6 contributes to the development of glomerulosclerosis and antibody production, which is exacerbated in the absence of STAT-4.⁵

In contrast to immune-mediated diseases, in which T_h1 cells play key roles, key effector cells in all chronic allergic diseases include eosinophils, basophils, and T_h2 cells.⁶ Their involvement occurs through release of preformed, or formed in situ, granule proteins and cytokines.⁷ A focus on eosinophil regulation may offer targeted therapy for chronic allergic diseases. Cysteinyl leukotrienes appear to have an important role in the regulation.⁷ Eosinophils are generated from CD34+ progenitors in the bone marrow upon stimulation by cytokines such as IL- 5. A single dose of IL-5 antibody

profoundly inhibited circulating eosinophils and allergeninduced sputum eosinophils but not airway hyperreactivity in humans. In a follow-up study, eosinophil numbers in blood and bronchoalveolar lavage were reduced 80% or more after 3 months of anti-IL-5 therapy numbers in bone marrow and bronchial biopsies were reduced 50% to 60%. This suggests that IL-5 antibody therapy effectively reduces circulating and airway luminal eosinophils, but less so bone marrow and lung parenchymal eosinophils.8 Cys-leukotrienes (LTs) may also play a role in eosinophil regulation.Circulating eosinophil counts in humans decrease by almost 20% after treatment with cyst-LT-receptor antagonists. These effects may reflect actions at the level of the bone marrow. Eosinophil-basophil colony-forming units increase in number, adhesion, and function, including production of IL-4 when exposed in vitro in the presence of LTD4. These responses are blocked by the presence of cysLT1 antagonists.

Activation of the humoral system occurs when naïve B lymphocytes with appropriate receptors (Igs) recognize an epitope in the intact foreign antigen. The antigen binds to the Ig, is ingested, and is processed such that it is expressed on the surface of the B cell in association with the same MHC (class I or II) that presented the antigen initially.⁴ Binding of the Ig receptor with the peptide and subsequent interaction with a CD4 cell that recognizes the antigen in its MHC complex stimulates proliferation of B cells, their differentiation into plasma cells, and the secretion of antibodies able to bind the epitope. Ig production is stimulated by IL-1, IL-4, IL-5, and IL-6 in B lymphocytes. The complete sequence occurs over 8 to 14 days and results in an anamnestic, or secondary, response. Generation of "memory" B and T cells provides a long-term mechanism for a rapid immune response on reexposure to the epitope (antigen).⁴

KEY POINT 31-3 The T_h1 subsets of CD4 produce primarily proinflammatory cytokines such as interferon- γ (IFN- γ) and tumor necrosis factor-alpha (TNF- α).

KEY POINT 31-4 In contrast to T_h1 cells, T_h2 cells secrete antiinflammatory cytokines and support the humoral immune response, including host defense against intestinal helminths.

Soluble Components

Soluble components of the immune response include the cytokines previously described, Igs described later, and the complement cascade.

Cytokines

More than 13 chemokine receptors are associated with rheumatoid arthritis, and at least 16 chemokines interact with these receptors.⁹ Both constitutive (responsible for physiologic trafficking and homing of the adaptive immune response) and inducible (responsible for effector white blood cell recruitment, including lymphocytes) responses are involved. A number of the chemicals also are responsible for angiogenesis. The inappropriate production of chemokines is associated with formation of an ectopic germinal center, which contributes to an uncontrolled immune response. Consequently, drugs directed toward chemokine receptors offer a therapeutic approach to control.

TNFα induces a broad spectrum of activity. Cytotoxicity of multiple cell types, including tumors, reflects both apoptosis and necrosis. A large number of proteins are targeted, along with other central mediators of the inflammatory process and immune activation. Examples include nuclear factors (e.g., NFKB), nitric oxide synthetase (NOS), cell-surface molecules, MHC classes I and II, and secreted proteins such as IL (e.g., -l, -6, -8), IFN, granulocyte-macrophage colonystimulating factor, platelet-derived growth factor, urokinase plasminogen activator, and TNF- α itself. When administered exogenously, high concentrations of TNFa causes a toxic syndrome similar to septic shock. Bacterial lipopolysaccharide is the most potent stimulator of macrophage TNF α production. TNF α appears to mediate ischemiareperfusion injury after transplantation of the liver, kidney, intestine, heart, lung, and pancreas and is a marker cytokine during organ rejection. Inhibitors have proved useful in human medicine for treatment of a number of autoimmune diseases, including Crohn's disease, rheumatoid arthritis, psoriasis, and ankylosing spondylitis. Indications included corticosteroid-resistant graft-versus-host disease after bone marrow transplantation.¹⁰

KEY POINT 31-5 TNF α plays a pervasive role in the inflammatory response, interacting with a number of other cytokines and other mediators and has been identified as a major role player in the "cytokine storm" associated with some syndromes.

Not surprisingly, the pervasive role of TNF α has led to the development of drugs that inhibit its actions. Included are glucocorticoids, pentoxifylline, and monoclonal immunoglobulin G (IgG) antibodies (e.g, infliximab, etanercept and the "humanized" adalimumab) etanercept, a humanized soluble TNF α receptor (TNFR) construct, and onercept, a TNF α -binding protein.¹⁰ A variety of other drugs targeting TNF α or its receptors are currently under investigation, as well as metalloproteinase inhibitors such as TNF α -converting enzyme (TACE). The use of these drugs, not surprisingly, is associated with a number of side effects. These include immunosuppresion, acute infusion reactions, delayed-type hypersensitivity reactions, autoimmune diseases, cardiovascular and neurologic adverse events, malignancies and lymphomas, and infectious complications.

Complement

The complement cascade is a major effector mechanism of the immune response. The cascade results in highly amplified events that interact with other physiologic cascades, including the coagulation pathway, kinin formation, and fibrinolysis.¹¹ Consequences of complement activation include opsonization, the release of biologically vasoactive peptides, and cellular lysis. Cell-mediated cytotoxicity is implemented by cytotoxic T lymphocytes, NK cells and antibody-dependent cell-mediated cytotoxicity (ADCC), mediated by a variety of cells that express surface Fc receptors. Effector cells of ADCC include monocytes, neutrophils, eosinophils, selected cytotoxic T cells, and NK cells.

Immunoglobulins

Five classes of Igs are recognized in animals. IgM is the largest, forming up to 15% of the total Ig present. IgM exists as a monomer or a large polymeric form. IgM is responsible for the primary Ig response; in animals, for some infections, it is the only defense.¹¹ The availability of five binding sites renders IgM efficient at antigen binding and agglutination, virus neutralization, and opsonization. IgM also is a potent activator of complement. Because it is such a large molecule, unless vascular permeability is altered, most IgM stays in circulation.

IgG (with multiple subclasses) makes up the majority of total Ig. It is the most soluble of the Igs and thus is able to reach extravascular spaces. Its primary biological functions are to facilitate the removal of microorganisms; neutralize toxins; and bind to microorganisms or infected cells, initiating effector mechanisms. IgG activates complement or initiates Fc-bearing effector cells (ADCC) and promotes removal of Ig-coated cells by ADCC.

IgE has a major role in the response to parasites and in the pathogenesis of allergic diseases in part because of its unique ability to bind by way of the Fc portion of the IgE molecule to specific receptors on mast cells and basophils. Cross-linkage of two IgE molecules results in calcium-mediated mast cell degranulation and the release of a number of preformed (e.g., histamine and serotonin) and synthesized (e.g., metabolites of arachidonic acid) mediators.

IgA is produced in submucosal lymphoid tissues and regional lymph nodes. After secretion outside of the cell, it travels to epithelial cells, where the secretory component of the IgA acts as a receptor, binding to IgA and stimulating its endocytosis. The two components are eventually exocytosed and attach to the mucosal surface, where they provide a protective component, neutralize toxins, adhere to bacteria and viruses, and interact with parasites.¹¹

Each Ig molecule monomer comprises two heavy chains and two light chains attached by covalent bonds. The number of bonds varies with the Ig; the number of dimers varies with the class. A number of fragments (generated by enzymatic cleavage) can be described, including Fab, the antigen-combining fragment, and Fc, the crystallizable fragment, which binds to Fc receptors found on cells of the innatue immune system (e.g., NK cells, macrophages, neutrophils and mast cells).¹¹

Mucosal Immunity

The common mucosal immune system (CIMS) has evolved as a system separate from the general systemic immune system. It includes the mucosa-associated lymphoid tissue (MALT), a complex network of tissues, lymphoid- and mucous membrane-associated cells and their effector molecules. Components include gut-associated lymphoid tissue (GALT) or nasal-associated lymphoid tissue (NALT), the mucosa of the genitourinary tract, the mammary and salivary glands, and draining lymph nodes. MALT differs from systemic lymphoid tissues in its characteristic lymphoid architecture, an epithelium that is unique in its uptake of antigen, and unique APCs (e.g., dendritic cells). Most notable among the differences is the predominance of IgA and the return of immune effector cells to either the originating mucosal sites or distant mucosal sites. Innate components of the CIMS include epithelial cells and antimicrobial peptides (AMP; see later discussion), the latter being exemplified by defensins; lactoferrin; lysozyme; the lactoperoxidase, secretory phospholipase A2, and cathelin-associated peptides. Adaptive components include IgA antibody and CD4+ T cell responses, and mechanisms that impart mucosal (oral) tolerance.

Effective mucosal immunity depends on induction of effective mucosal immune responses. Oral tolerance refers to the prevention of unwanted immune reactions to food or environmental antigens; such tolerance also can be induced nasally. Integral to mucosal tolerance are Toll-like receptors (TRC). Key molecules of the innate immune system, these receptors recognize conserved microbial molecules, alerting the system to their presence when physical barriers are breeched. The term "toll" refers to effect that toll gene mutations have on the physical appearance of Drisophila flies (making them appear "toll", the German translation meaning "wild"). Toll receptors are a type of pattern recognition receptor, able to distinguish host from microbial pathogen associated molecular patterns (PAMPS).

Induction of nasal mucosal tolerance can be manipulated, leading to mucosally induced immune therapy against selected infectious diseases (e.g, in Escherichia coli in human medicine). Mucosal tolerance has the advantage of inducing local and thus targeted Th1- or Th2- type immune responses, thus avoiding the negative sequelae of systemic cytokine injection. Mucosal adjuvants co-administered with antigens include cytokines (e.g., IL-1 and IL-12), or chemokines which promote specific CD4+ T helper cell cytokine responses (e.g., RANTES, lymphotactin, macrophage inhibitory protein-1 [MIP-1]). Therapeutic modulation of mucosal immunity generally targets unique T_h cells and cytokine responses. For example, inflammatory bowel diseases (IBDs) appear to reflect failure of oral tolerance to luminal antigens, resulting in an imbalance of regulatory cytokines involving both T_h1 and T_h2 cell-mediated inflammation.¹² Differences exist between orally and nasally induced immune responses. For example, aging more negatively influences GALT compared to NALT immunity. Nasal vaccines are more effective than oral vaccines in the promotion of protective immunity in the genitourinary tract. That these differences exist suggests that pharmacologic therapies might also be manipulated to locally target systemic effects or to limit therapy to local effects only, thus increasing benefits versus risks of treatment and that these therapies are likely to differentials, affect the different CIMS.

Antimicrobial and Host Defense Peptides

Antimicrobial peptides (AMPs, also called host defense peptides;) are evolutionarily ancient yet essential small cationic molecules found in animals, plants, and bacteria. Because they exhibit antimicrobial activity against a wide range of bacteria, fungi, and viruses, they are considered part of mucosal immunity. AMPs primarily act as cations, interacting with the anionic structure of and thus disrupting microbial membranes.¹³ Phosphatidylcholine in eukaryotic cell membranes is thought to be more positive compared to that in prokaryotic membranes, thus decreasing attraction to (or repelling) positively charged AMPs. However, in addition to antimicrobial actions, AMPs also serve as multifunctional mediators of immunity, inflammation, and wound repair. The importance of AMP or HDP in veterinary medicine has been reviewed by Linde and coworkers.¹⁴

KEY POINT 31-6 Antimicrobial peptides are an ancient evolutionary arm of the mucosal immune system that act to disrupt microbial membranes.

Three major classes of antimicrobial molecules have been described: defensins, cathelicidins, and the four-disulfide core proteins, secretory leukocyte proteinase inhibitor (SLPI) and elafin. Cathelicidins are produced and stored inactive yet capable of exhibiting broad-spectrum killing activity. The number of cathelicidins among species ranges from multiple (pigs and cows) to one (humans and mice). The SLPI and elafin exhibit antimicrobial activity toward a number of bacteria (e.g., E. coli, Pseudomonas aeruginosa, Staphylococcus aureus, Staphylococcus epidermis, and group A Streptococcus); fungi (e.g., Aspergillus fumigatus and Candida albicans); and selected viruses (e.g., human immunodeficiency virus). In addition to their antimicrobial properties, SLPI and elafin are potent antiproteases, neutralizing potentially harmful proteases (e.g, human neutrophil elastase) and inhibiting proinflammatory microbial products (e.g., lipopolysaccharide). Many are chemotactic for white blood cells, including T lymphocytes. Other activities include, but are not limited to stimulation of angiogenesis or inhibition of signals which activate B cells (e.g., NFKB).

The AMPs are extensively integrated into other defense systems. They are stimulated by a number of signals (e.g, macrophage cytokines such as IL- β and TNF- α). In contrast, microbes may protect themselves by downregulating AMP expression. Microorganisms have other protective mechanisms, including changes in cell wall or membrane composition, secretion of factors that block AMP action, or manipulation of host cells such that AMP activity is decreased.

It is likely that the ability of AMP to modulate inflammation, immunity, and tissue repair processes contributes to a central role in numerous essential host defenses. Pharmacologic modulation of AMP is a focus of investigation for a treatment and prevention measures for a variety of disease, including as adjuvants for tumor or infectious vaccines.

Hypersensitivity Reactions and Cytokine Storm

An imbalance in the activities of CD4 T_h1 and T_h2 subsets may be responsible for the onset or exacerbation of immunemediated diseases. Increased concentrations of T_h1 (and decreased T_h2) are associated with response to viral and fungal infections, whereas increased concentrations of T_h2 (and decreased T_h1) are associated with increased production of IgE and IgA antibodies. Autoimmune diseases are associated with a predominance (reflecting an imbalance) of T_h1 . Imbalances also have been associated with resistance to infectious disease and malignancy.¹⁵ In contrast, allergic inflammatory diseases (eg., atopy, inflammatory bowel disease, asthma) may reflect an imbalance that favors T_h2 .

KEY POINT 31-7 An imbalance in the activities of CD4 T_h1 and T_h2 subsets may be responsible for the onset or exacerbation of immune-mediated diseases.

Multiple novel mechanisms have been identified for their underlying role in the pathogenesis of immune-mediated diseases. Most, if not all, involve transcription factors, each providing potential current of future opportunities for manipulation. Among the prominent immune-mediated diseases being intensely studied in an attempt to understand the molecular mechanisms of immune mediated diseases are diabetes type 1, rheumatoid arthritis, multiple sclerosis, IBDs, psoriasis, and systemic lupus erythematosus (SLE).¹⁶

Four types of reactions result from activation of immunologic pathways. Type I hypersensitivity results from antigen-IgE interaction (Figure 31-2). IgE that has previously interacted with the antigen binds to the surface of a basophil or mast cell. Subsequent interaction with the same antigen causes mast cell degranulation and the release of a number of mediators associated with immediate hypersensitivity. Mediator release can be instantaneous (e.g., anaphylaxis); delayed for 2 to 4 hours; or biphasic, with both an immediate and a delayed reaction. Systemic release of mediator results in systemic anaphylaxis; localized mediator release limits reaction to the site of release (eg, swelling, redness, pain). Atopy is an inherited predisposition to develop IgE antibodies to environmental antigens and is characterized by constant high levels of IgE. An anaphylactoid reaction may be similar to anaphylaxis in presentation but reflects nonimmune-mediated mast cell degranulation (e.g., cationic drug-induced) (see Chapter 4).

Type II hypersensitivity occurs when ADCC occurs after antibody binds to a cell or to an exogenous antigen associated with a cell surface or a basement membrane. Complement may be activated and contribute to the damage. Examples of type II hypersensitivity include drug hypersensitivities, autoimmune hemolytic anemia, immune-mediated thrombocytopenia, immune-mediated endocrinopathies, and immune-mediated dermatologic disorders such as bullous pemphigus.¹¹

Type III hypersensitivity results from the formation of antigen–antibody or immune complexes that either circulate or are deposited as microprecipitates in vascular beds or

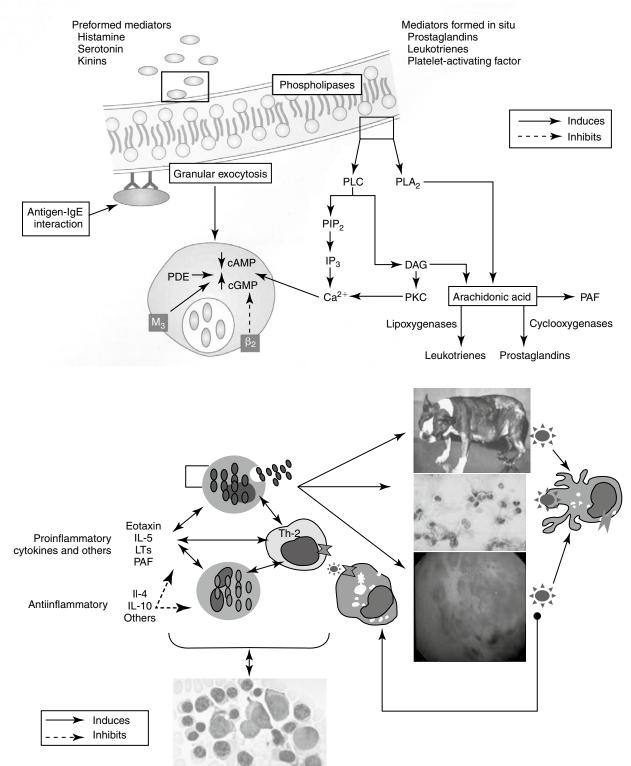

Figure 31-2 The shared pathophysiology of chronic allergic inflammatory disease begins with antigen processing at the tissue (e.g., skin, airways, gastrointestinal tract). Presentation and subsequent $T_h 2$ helper cell acitivity results in signaling to basophils and eosinophils. Their release of inflammatory mediators at the site may perpetuate the response by increasing tissue permeability, allowing access of the antigen to deeper tissues. The chemotactant cytokine eotaxin and its interaction with interleukin-5 plays a major role in stimulating local responses as well as bone marrow production of eosinophils; leukotrienes may serve as signals for these interactions. Ultimately, cells released from the bone marrow perpetuate the response at the tissue. Accordingly, therapy might target not only the affected tissue (including adjuvant therapy) but also the bone marrow itself. *Inset:* Diagrammatic representation of a type I hypersensitivity reaction involving antigen bound to immunoglobulin E and calcium-mediated degranulation. Degranulation results in the release of both preformed mediators and mediators formed in situ (e.g., from arachidonic acid). Stimulation of muscarinic (M₃) receptors supports exocytosis, which is inhibited by stimulation of beta₂-adrenergic receptors. *cAMP*, Cyclic adenosine monophosphate; *CGMP*, cyclic guanosine monophosphate; *DAG*, diacylglycerol; *IP₃*, inositol triphosphate; *PAF*, platelet-aggregating factor; *PDE*, phosphodiesterase; *PIP₂*, phosphatidylinositol; *PKC*, protein kinase C; *PLA₂*, phospholipase A₂; *PLC*, phospholipase C.

basement membranes. The Arthus reaction occurs 2 to 4 hours after IgG interacts with an antigen in the vessel wall. Serum sickness occurs when circulating immune complexes develop as a result of intravascular injection of the antigen. Microprecipitates in circulation deposit in basement membranes and the vascular endothelium, resulting in immune complex diseases. The risk of serum sickness increases with the persistence of antigen. The size of the immune complex also determines the degree of damage because larger complexes are more likely to deposit and initiate inflammation. Complement both contributes to and protects against damage caused by immune complex disease.¹¹

Type IV hypersensitivity involves sensitized T cells that initiate a cell-mediated reaction on interaction with the appropriate class II MHC antigen. Lymphocyte and macrophage influx to the site occurs over a 24- to 72-hour period. Allergic contact dermatitis is an example of a type IV hypersensitivity.¹¹

The term cytokine storm, or hypercytokinemia, has been used to describe the inappropriate systemic reaction resulting from the release of cytokines (more than 150) from a healthy and reactive immune system. Its importance emerged in response to the impact that swine flu to have in some, but not all afflicted human patients.¹⁷ The immune system appears to lose the control normally provided through a system of checks and balances involving both inflammatory signals (e.g., TNF α , IL-1, and IL-6) and antiinflammatory signals (e.g., IL-10), as well as coagulation factors, and oxygen free radicals. The impact of these signals on body tissues and organs can be profound and is exemplified by acute respiratory distress syndrome (particularly that associated with influenza or flu), sepsis, and systemic inflammatory response syndrome. Inhibiting T cell response has been proposed as a potential mechanism of treatment or prevention. Drugs that alter production or the impact of TNF α are among those studied for possible efficacy.

Regulation of the Immune Response Transcription Factors

Regulation of the immune response reflects a balance of the integrated actions of proinflammatory and antiinflammatory cytokines that act to trigger signaling pathways. The pathways, in turn, modulate gene expression program in the cells. Transcription factors targeted by cytokines include NF κ B (proinflammatory),¹⁸ activator protein 1 (AP-1), SMAD proteins (responsible for transfer of extracellular signals from transforming growth factor to intracelluar nuclear TGF- β gene transcription), glucocorticoid receptors (antiinflammatory)^{19, 20} (see Chapter 30), and members of the STAT protein family (proinflammatory and antiinflammatory).⁵

NF κ B is a transcription factor that, upon induction by a number of inflammatory agents, participates in the expression of a large number of target genes, many of which regulate both innate and adaptive immunity. Because a number of the target genes activate NF κ B, signal amplification may occur at very low concentrations of the inciting antigen, causing profound effects. Regulatory failure has been associated with a number of autoimmune diseases, including IBDs such as Crohn's disease and ulcerative colitis.¹⁸ NF κ B appears to play a key

role in rheumatoid arthritis in humans. Metalloproteinase-1 (MMP-1) and TNF- α are among the molecules it regulates.¹⁶ The NFkB system is vital to survival, but regulatory activity is very complex, and undirected inhibition may result in undesirable immune suppression. For example, pharmacologic interference with a potentially therapeutic aspect (e.g., inactivation in enterocytes such that a systemic inflammatory response is avoided) often is accompanied by potentially lethal parallel effects (e.g., severe apoptotic damage to the reperfused intestinal mucosa). Pharmacologic manipulation is most likely to succeed only when tissue- or organ-targeted inhibition is possible. Another major role player is activator protein 1 (AP-1), a transcription factor with major proinflammatory effects. It regulates gene expression stimulated by cytokines, growth factors, stress, and bacterial and viral infections, thus controls diverse cellular processes such as differentiation, proliferation, and apoptosis.

KEY POINT 31-8 Nuclear factor kappa B (NF κ B), a transcription factor induced by a number of inflammatory signals, is involved in the expression of genes that regulate both innate and adaptive immunity.

Patients with glucocorticoid-sensitive versus glucocorticoid-resistant chronic inflammatory disease exhibit different cellular activation of NF κ B, and AP-1 and upstream kinases; activation occurs in macrophages of the lamina propria in steroid-responsive patients but predominantly in epithelial cells of steroid resistant patients. Thus directed therapy for steroidresistant patients might focus on inhibition of NF κ B activation in epithelial cells.¹⁸

The Janus kinase (JAK)-STAT pathway is a major signaling pathway by which cytokine signals lead to the expression of genes that regulate immune cell proliferation and differentiation. The JAK-STAT signaling pathway is activated in response to cytokines (e.g., ILs and IFNs) as well as certain peptide hormones. The binding of the signaling molecules to the receptors causes activation (phosphorylation) of JAKs (e.g., JAK-1 through -3), which provide docking sites on the JAK protein for STAT proteins. The STAT proteins are then activated (phosphorylation) and translocated to the nucleus, where they bind to their response elements in the promoter of target genes. Transactivation cannot occur without coactivation by proteins such as acetyl transferase binding protein (e.g., CREB, a cyclic adenosine monophosphate [cAMP]responsive element binding protein that increases MMP production in the synoviocytes of patients with rheumatoid arthritis).16

Cytokines that promote immune and inflammatory responses (e.g., IL-6, IFN- γ , IL-12, and IL-18) as well as those that suppress the immune response (e.g., IL-4, IL-10, IL-13) mediate cellular responses through the JAK–STAT signaling pathway. Up to seven STAT (including STAT-1 through -4, 5a and 5b, and STAT-6) proteins have been identified in mammals, each with a specific function in the immune response that modulates either proinflammatory or antiinflammatory responses. For example, STAT-3, originally discovered as an

acute-phase response factor activated by IL-6, is also activated by many other cytokines and appears to be a constitutive protein that influences chronic inflammation. However, its embryonic deletion is lethal.⁵

Immunomodulatory Effects of Opioids

The potential of opioids to influence the immune system was first recognized close to 100 years ago when the effects of opium on phagocytic function were observed.²¹ Heroin addicts are more susceptible to infection. Rodent studies indicate increased mortality and morbidity rates when opioid-treated animals are exposed to infectious agents. The presence of opioid receptors on cells of the immune system has been recognized since the late 1970s.^{21,22} Although further studies are needed to fully elucidate the effect of opioids on immune function, thus far both the cellular and humoral immune reactions are believed to be affected.

Effects of opioids on the immune system are variable but are directed centrally, rather than peripherally, and involve primarily, but not exclusively, supraspinal mu receptors. Effects (inhibitory versus stimulatory) are dose dependent but occur at clinically relevant doses in animal models. Multiple central opioid receptors and endogenous opioids appear to be involved in complex immune responses. NK cytolytic activity and mitogen-stimulated T-cell proliferation are reduced by centrally administered morphine by way of mu receptors, whereas antibody production is both increased and decreased by met-enkephalin, which probably reflects interaction with multiple receptors. Effects can occur with single or multiple administration of exogenous opioids. Both the neuroendocrine system and the autonomic nervous system may serve as the efferent mechanisms mediating central opioid modulation of the immune system.²¹ Tolerance appears to develop to some of the immunomodulatory effects, but this remains controversial. The clinical implications regarding the role of opioids in modulating the immune response are not clear.

Immunomodulatory Effects of Vitamin D

Increasingly, vitamin D (1,25, dihydroxyvitamin D_3) is recognized to have a noncalcemic role. Among the proposed activities is support of the immune system, particularly T cellmediated immunity.²³ Both T lymphocytes and macrophages are characterized by a high density of vitamin D receptors, particularly in immature immune cells and mature CD8 cells. Vitamin D compounds have been demonstrated in animal models to selectively immunosuppress, effectively preventing or modulating autoimmune diseases, including systemic lupus erythematosus, encephalomyelitis, rheumatoid arthritis, and IBD. Suppression or prevention of transplant rejection has been demonstrated in animal models. Mechanisms may include stimulation of the antiinflammatory mediators transforming growth factor beta 1 (TGF- β 1) and IL-4. These effects appear to occur without negatively affecting normal immune defense mechanisms. Therapeutic use may be limited by the advent of hypercalcemia, leading to investigations of noncalcemic analogs; indeed, some suggestion exists that hypercalcemia may be required for immunosuppression.

CLASSIFICATION OF IMMUNOMODULATORY DRUGS

Immunomodulators often are classified according to their source: microbial, animal, or synthetic. Immunomodulators can also be classified by either an inhibitory or a stimulatory effect on the immune system. Prohost agents augment the cellular immune response either by facilitating a normal response in the face of immunosuppression (immunorestoratives) or by stimulating the immune response (immunostimulants). Immunostimulants can be used either before antigenic challenge to protect immunocompromised patients at risk or after exposure to potentially virulent agents has occurred. Immunosuppressant agents are used to manage hypersensitivity reactions, including autoimmune diseases, and as anticancer drugs. Many immunomodulatory drugs are target specific in their effects. However, many also have nonspecific effects that affect several to many arms of the immune response. Immunostimulants may in fact inhibit components of the immune response in some instances. Care should be taken when selecting an immunomodualtory drug, particularly if all the effects of the drug are not known or anticipated. For example, selective depression of some virally induced immune reactions is beneficial if the host's immune response to the infecting virus threatens the host's survival. Drugs that inhibit B lymphocyte activity (e.g., cyclophosphamide) often lower the mortality risk associated with some human influenza viruses and presumably should prove beneficial in the treatment of feline viral diseases associated with poorly controlled Ig production (i.e., feline infectious peritonitis).

The major indications for pharmacologic modulation of the immune system in animals are treatment of autoimmune diseases; prevention or treatment of infections, particularly in immunocompromised hosts; and prevention and therapy of malignancies. A less common but increasingly growing use of immunomodulators in small animals is treatment of graftversus-host reactions after organ transplantation.

IMMUNOMODULATION IN VIRAL AND NEOPLASTIC DISEASES

Biologica l response modifiers are discussed in Chapter 32. Their primary indications are for treatment of viral or neoplastic disease or (generally their antagonism) for treatment of immune-mediated disease.

Viral Diseases

Biological response modifiers potentially offer a logical and unique approach to the treatment of viral diseases because (1) viruses are capable of immunosuppression and (2) the immune response is an important determinant in the host's ability to overcome viral infection.^{24,25} Resistance against and recovery from viral infections in mammals depend on three components of the immune system. The mononuclear phagocytic (reticuloendothelial) system represents the first barrier to viral infections, but it is nonspecific and not always efficient. Sensitized T lymphocytes provide specific cell-mediated immunity, which is followed later by humoral events, either narrowly specific (antibodies) or nonspecific (IFN). Multiple interactions occur among these systems. Unfortunately, several systems also contribute to the pathogenesis of viral disease. Viruses may cause immunosuppression by several mechanisms: They may directly injure or impair all classes of lymphocytes; cause the production of soluble immunosuppressing chemicals (e.g., IFN, p15[E] of feline leukemia virus [FeLV]) damage all three cell systems by infection, or cause an imbalance in immunoregulation, thus leading to overactivity of suppressor T cells.

Neoplastic Diseases

Many tumors have surface antigens toward which specific antibodies can be directed. Biological response modifiers can alter response to tumor antigen at one or several of these points, depending on the drug. Some biological response modifiers augment or restore normal host effector mechanisms by acting as either a mediator or an effector of the antitumor response. Transformation of tumor cells may be decreased or maturation of tumor cells may be increased by biological response modifiers. Host tolerance of damage caused by cytotoxic chemotherapeutic drugs also may be increased by biological response modifiers. Finally, biological response modifiers have been used to alter patient response to FeLV viremia and thus the subsequent associated neoplasms.^{26,27}

IMMUNOMODIFYING DRUGS

The sequelae of immunomodulation are not always beneficial; alteration of the immune response can impair many aspects of the host's normal defense system. The use of immunomodulators remains in its early stages despite advances; this remains particularly true for veterinary medical applications. Because of the many facets of the immune system susceptible to regulation, the dose, timing, and route of administration of these drugs are important if undesired effects are to be avoided (Table 31-2). In addition, host effects such as age and nutritional status and the nature of the disease may be important determinants in the patient's response to these drugs.

Marked advances have been made in the use of drugs that target the adaptive immune response. For the purposes of this text, drugs used to modify the immune response will include drugs whose actions are relatively nonspecific in their immunomoldulatory effect and those products of biological (animal) origin that target specific mediators of the immune response or their receptors, the latter is the focus of Chapter 32.

The role of P-glycoprotein in drug-induced immunomodulation is an emerging area of interest.²⁸ The protein is expressed on peripheral blood mononuclear cells. It influences the secretion of cytokines secreted from antigen-presenting cells and selected T cells, and it has been shown to influence lymphocyte survival and antigen-presenting cell differentiation. These actions appear to contribute to the immunomodulatory actions of selected drugs capable of inhibiting P-glycoprotein (e.g., verapamil, progesterone, tamoxifen) and may account for the therapeutic immunomodulatory functions of these drugs. Eventually, these effects might be redirected for therapeutic benefit in allograft rejection and cell-mediated autoimmune disorders.

Immunosuppressant Drugs

Four major classes of immunosuppressive drugs are described in human medicine: glucocorticoids (discussed in Chapter 30), calcineurin inhibitors, antiproliferative–antimetabolic drugs, and biological agents.⁴ The latter includes biological response modifiers (Chapter 32).

Several principles should guide use of immunosuppressant drugs.⁴ First, suppression of the primary immune response is more easily accomplished than is suppression of the secondary (amnestic) response. Second, successful inhibition or suppression is easier if therapy begins before exposure to the inciting immunogen (antigen). Third, immunosuppressive drugs do not cause the same effect on all aspects of the immune system. Often, opposite effects are concentration dependent. Thus failure to achieve the desired response should not necessarily lead to an increase in dose. Finally, patients often require lifelong therapy, which increases the risk of adverse effects.

Two major limitations characterize immunosuppressive therapy. Patients receiving immunosuppressive therapy are predisposed to infections of any type. In addition, the risk of lymphomas and related malignancies is increased. This latter risk is more problematic in human patients because, in part, of their longer life span, but has proven a risk in dogs or cats receiving cyclosporine. Events that immunosuppressive drugs tend to target include antigen recognition, stimulation of IL-1, synthesis and release of IL-2 or other cytokines, and lymphocyte proliferation and differentiation.⁴ Secondary signal molecules are also becoming increasingly important as targets of immunosuppressive therapy.

Immunosuppressive drugs are used to treat immunemediated disease, which in this chapter include autoimmune diseases (e.g., immune-mediated anemias or thrombocytopenias) as well as chronic allergic inflammatory diseases (e.g., atopic dermatitis and asthma, IBD). A third, less common indication in veterinary medicine is prevention of organ rejection in renal transplant patients. Autoimmune diseases are characterized by sensitization to endogenous proteins that are perceived to be foreign. Both cell-mediated and humoral responses can be directed toward the protein. Many immune-mediated disorders afflicting dogs and cats respond sufficiently well to glucocorticoids (discussed in Chapter 30) and, when necessary (in severe cases), cytotoxic drugs. These include immune-mediated autoimmune hemolytic anemia or thrombocytopenia, acute glomerulopathies, and many dermatologic disorders with an immune-mediated basis. However, the approval of cyclosporine (CsA) for chronic allergic dermatitis has increased its use for autoimmune diseases, providing an alternative to cytotoxic drugs as a second tier.

Calcineurin Inhibitors

Calcineurin is a protein phosphatase that dephosphorylates and thus activates the transcription factor nuclear factor of activated T cell (NFATc). Upon activation, NFATc translocates to the nucleus and upregulates IL-2 expression of regulatory proteins.

Drug	Dose	Route	Interval		
Acemannan	2 mg	Intratumorally	Weekly for 6 weeks		
	1 mg/kg	Intraperitoneally	Weekly for 6 weeks		
Aurothioglucose					
Test dose	1 mg < than 10 kg, 5 mg ≥ 10 kg	IM Twice, 1 week apart			
	1 mg/kg (D)	IM	Weekly until remission; then alternate weeks		
With prednisolone	1 to 2 mg/kg	PO	12 to 48 hr

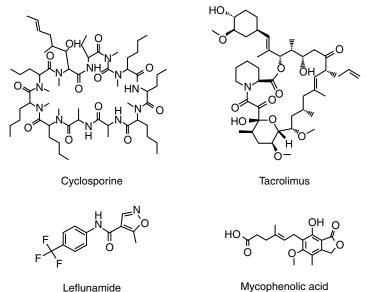

Figure 31-3 The chemical structure of selected immunomodulating drugs.

Cyclosporine A

Chemistry–Structure Relationship

Cyclosporin A (CsA), now known as *cyclosporine*, is the most important immunosuppressive drug for human transplantation and the treatment of selective autoimmune disorders.^{4,30} CsA is one of nine cyclosporins (A through I), each a cyclic peptide drug (Figure 31-3) isolated from the fungi *Cylindrocarpon lucidum* and *Trichoderma polysporum*. An M designation, when present, indicates a metabolite. The drug is both very lipophilic (hydrophobic) and must be solubilized before administration.⁴ The oral preparation is a soft gelatin capsule (Sandimmune) or a (newer) microemulsion formulation (Neoral). The intravenous preparation is an ethanol– polyoxyethylated castor oil mixture. Historically, CsA has been formulated in peanut oil (for treatment of ophthalmic ocular disorders in dogs); however, an approved product formulated for topical use is now available.

Mechanism of Action

CsA is a unique immunosuppressant in that it specifically inhibits T_h cells (both T_h1 and T_h2) early in their immune response to antigenic and regulatory stimuli⁴ without affecting suppressor cells. Suppression occurs as CsA binds to cyclophilin, a cytoplasmic receptor protein, forming a heterodimeric complex. This complex then binds to calcineurin. Binding of calcineurin inhibits calcium-stimulated phosphatase that dephosphorylates the regulatory protein. As such, CsA prevents transcription of T cell genes enhanced in response to T cell activation. Transcription mediated by IL-2, certain proto-oncogenes, and selected cytokine receptors are particularly affected.⁴ IL-2 production (and thus T cell proliferation and antigen-specific cytotoxic T lymphocyte generation) also is attenuated because the expression of TGF- β , a potent inhibitor of IL-2, is increased.⁴ B cells are not affected. The drug is most effective when administered before T cell proliferation has occurred. In addition to these immunomodulatory effects,

CsA also affects other inflammatory cells. CsA inhibits skin mast cell numbers, survival, and response (secretory and histamine release) as well as secretion of IL-3, IL-4, IL-5, IL-8, and TNF α . Similarly, eosinophile response (release of granules and cytokines) and recruitment to allergic sites is impaired. CsA prevents TNF α -mediated late phase reactions, thus inhibiting IgE and mast cell-dependent cellular infiltration in the skin and bronchial mucosa. However, CsA does not inhibit IgA secretion or IgG and IgM formation in dogs and has no apparent effect on serum allergen-specific IgE levels, intradermal tests, or vaccination.

KEY POINT 31-9 Cyclosporine A specifically inhibitits T helper cells; however, little information is available regarding its impact on immune response in dogs or cats.

Surprisingly little information is available regarding immunomodulatory effects of CsA in dogs or cats. Using dermal microdialysis, Brazis and coworkers³¹ demonstrated that CsA at 5 mg/kg per day for 15 and 30 days decreased histamine, but not prostaglandin D₂, release in sensitized Beagles challenged with *Ascaris suum*.

Preparations

CsA is available in a variety of preparations, two of which are approved in the United States for use in animals. CsA was first formulated for oral use in humans as vegetable oil. Oral absorption in this preparation depends on emulsification by bile acids. Poor oral bioavailability led to the formulation of a microemulsion preparation (modified CsA, ME), which, on contact with gastrointestinal fluids, disperses into a homogeneous monophasic microemulsion that mimics the mixed micellar phase of the standard formulation. In dogs the ME formulation offers a 35% bioavailability (Novartis Animal Health data on file).

Atopica is the veterinary-approved microemulstion preparation of CsA intended for systemic use in both capsules and solutions. A 0.2% ophthalmic ointment (Optimmune) is also available. A number of human-approved drugs are available, including an injectable solution, an oral solution (100 mg/mL), an ophthalmic emulsion (0.05%), and a variety of capsule sizes for the standard and the microemulsion-modified preparation. Included are a number of generic-modified CsA products. However, the therapeutic equivalence that has been established for these products in humans should not be assumed to be therapeutically equivalent to Atopica in animals. Indeed, one preparation made by IVAX Pharmaceuticals and sold by selected chain pharmacies appears to result in much higher concentrations in dogs compared with other preparations on the basis of samples submitted through the author's laboratory. Monitoring should be the basis for assessing the appropriate dose-concentration relationship for oral human CsA products used in dogs or cats; owners might need to be aware if and when a pharmacy switches from one human generic to another such that prophylactic monitoring might be implemented.

Clinical Pharmacology

The pharmacokinetic behavior of CsA is complex, resulting in marked variability in the relationship between dose and blood concentrations.³² Variability reflects not only differences in both hepatic and intestinal metabolism (by CYP3A4) but also differences in P-glycoprotein among various tissues.³² The disposition of CsA has been well reviewed in the dog.33 Absorption after oral administration is slow and incomplete. The complex lipid nature of CsA complicates absorption by being dependent on bile acids, which generate a microemulsion. In humans oral bioavailability of the capsule ranges from 20% to 50% but is improved by 10% to 20% in the microemulsion form which is not dependent on bile acids.^{4,34} Peak concentrations occur 1 to 4 hours after oral administration in human beings. When the capsule-but not the microemulsion-is administered with a fatty meal, absorption is slowed. Studies suggest that decreased bioavailability of CsA after oral administration may reflect activity of drug-metabolizing enzymes of the intestinal epithelium³⁵ or P-glycoprotein-mediated drug efflux.

KEY POINT 31-10 The kinetics of cyclosporine A are complicated by its large, liphophilic molecular structure.

The oral bioavailability of microemulsion in dogs is 35% compared with the 20% of the oral preparation.³³ Bioavailability of orally administered CsA is approximately 25% to 30% after multiple oral administration in cats (n = 6). Food may impair the absorption of CsA; peak concentrations in fasted dogs were 20% higher than in nonfasted dogs in one study, although time to peak (approximately 1.5 hours) was the same.³³ The drug is not predictably absorbed topically after transdermal administration (unpublished data, Boothe 2007). CsA is widely distributed, characterized by a large volume of distribution (13 L/kg in humans). The drug accumulates in erythrocytes (accounting for 50% or more of the drug in humans), and leukocytes (accounting for 10% to 20% of circulating drug in humans).⁴

Consequently, monitoring of whole blood rather than plasma or serum is recommended. Remaining circulating drug is bound to plasma lipoproteins. Further, concentrations in skin are up to tenfold higher than in blood, although this is based on homogenate data (as reviewed by Guaguère and coworkers³³). In contrast, largely because of the influence of adenosine triphosphate–binding transporters P-glycoproteins, especially the ABCB1 cassette (P-glycoprotein, MDR1 gene product), little CsA crosses the blood–brain barrier.

KEY POINT 31-11 In addition to its chemistry, the oral absorption of cyclosporine A is affected by a number of factors, resulting in marked variability. Differences in absorption of human generic or compounded preparations should be anticipated.

CsA is metabolized to a large number of metabolites predominantly by the liver, although sufficient metabolism occurs by intestinal enterocytes that oral bioavailability is affected. Microflorae also may contribute to metabolism.37 CYP3A4 (commonly associated with P-glycoprotein or other efflux pumps) plays a major role in metabolism; many of the drug interactions involving CsA also involve CYP3A4 or associated glycoprotein. More than 25 to 30 metabolites have been documented in humans and dogs.^{32,38,39} Metabolism is targeted primarily toward the side chains rather than the ring structure and reflects hydroxylation, demethylation, sulfation, and cyclization. The major hydroxylated metabolites (AM1 and AM9) are further metabolized, contributing to the complex metabolic profile. Both AM1 and AM9 may contribute 10 to 20% of CsA activity, with AM1 contributing 27% of trough activity.⁴⁰ In humans AM1 accumulates with chronic dosing and ultimately may surpass CsA, and monitoring assays might ideally detect the active compounds.³⁹ They are detected to variable degrees by selected immunoassays based on a monoclonal antibody (e.g., Abbott TdX, Architect systems, Seimens Dimension).41,42 Selected laboratories may also offer a high-performance liquid chromatography (HPLC)-based system that, may or may not (generally not) quantitate the metabolites.³⁹ Ultimately metabolism continues until the drug is totally inactivate the drug, although this has not been proved conclusively.4 Metabolites are excreted in bile and feces, with less than 2% of unchanged drug eliminated in the kidneys of dogs. CYP3A4 is largely responsible for metabolism.

The half-life of CsA in dogs is quite variable, depending on the investigator and assay. In blood the half-life ranges from a low of 5 hours (HPLC) to a high of 18 hours (using fluorescent polarized immunoassay [FPIA]); 29 hours was reported for serum.⁴³ That reported for Atopica, the product approved for use in dogs, is 4.5 hours, a length more consistent with that measured in the author's therapeutic drug monitoring laboratory using FPIA. In a manufacturer-sponsored affinity colonymediated immunoassay (ACMIA) study, Steffan and coworkers⁴⁴ reported the disposition of CsA (5 mg/kg) after single-dose oral administration of either capsules or solution in fasting or fed conditions using a randomized crossover design with a 1-week washout between studies (Table 31-3); food decreased peak concentrations and area under the curve by 22%.

In cats elimination half-life of CsA is 8 hours, which was similar to that after intravenous administration. Liver disease will decrease clearance of CsA substantially. However, for the nonmicroemulsion form, decreased oral absorption in the face of decreased bile may balance decreased clearance. Monitoring is recommended in the presence of hepatic or gastrointestinal disease.

Mehl and coworkers⁴⁵ reported the disposition of CsA in cats (n = 6 male) after single-dose intravenous (1 mg/kg) and multiple-dose (14 days; 3 mg/kg twice daily) as Neoral (see Table 31-3). Variability in plasma drug concentrations among cats and across time underlines the importance of monitoring if treating life-threatening conditions. After multiple-day (7 to 14 days) oral administration (3 mg/kg), mean (peak) plasma concentrations at 2 hours were 740 ± 326 (7 days) and 655 ± 285 ng/mL (14 days), whereas trough concentrations were 332 ± 237 and 301.5 ± 250 ng/mL, respectively. Oral bioavailability was only 25% to 29%.

Because cats may find the oral preparation unpalatable, the oral solution can be given diluted in olive oil. The intravenous preparation (4 to 6 mg/kg as a 4-hour intravenous infusion) can be given to animals for which oral administration is not possible.⁴⁶ Ocular administration might serve as an alternative route for systemic delivery of CsA in cats.⁴⁷ After ocular administration of either an oral preparation or an ocular preparation of CsA in olive oil, (5 mg/kg in each eye as a 10% solution) peak concentrations of 450 to 1033 ng/mL (oral preparation) and 288 to 648 ng/mL (ocular) were achieved, with an absorption lag time ranging from 0 to 1.34 hours for the oral solution and 0.27 to 1.2 hours for ocular preparation. The elimination half-life ranged from 2.41 to 10.04 hours (oral), and 3.09 to 15.75 hours (ocular), respectively. Blood concentrations were sufficient to inhibit lymphocyte activity as measured in vitro, leading the authors to conclude that ocular administration of CsA in an olive oil vehicle might be a reasonable alternative to oral, or even intravenous, administration in cats intolerant to the latter.

Drug Interactions

Novartis⁴⁸ provides a transplant drug interactions monograph that cites more than 600 references and delineates cyclosporine interactions involving more than 300 drugs. The list of drugs that might interact with CsA is extensive. The manual is available on the Novartis website at no charge and should be consulted when treating patients receiving additional drugs. Selected interactions can be found in Table 31-4. This review will focus on some of the more common interactions, including those used intentionally.

KEY POINT 31-12 Cyclosporine A is involved with a large number of drug interactions that might cause higher or lower than anticipated plasma drug concentrations.

The enzyme that metabolizes CsA (CYP3A4) is responsible (in humans) for approximately 30% of all drug metabolism; many of CsA drug interactions occur with this enzyme. Further, CsA is a target of P-glycoprotein, another site characterized by a substantial number of CsA-drug interactions.^{4,49} The risk of drug interactions is another indication of the need for therapeutic drug monitoring as a guide to proper dosing regimens. CsA elimination is accelerated, probably in part because of the induction of drug-metabolizing enzymes, by phenytoin, phenobarbital, rifampin, and sulfamethoxazole–trimethoprim combinations, and others. Dexamethasone also is an inducer of CsA.³² Its elimination is decreased by amphotericin B, erythromycin, and ketoconazole.⁴ CsA also appears to alter the oral absorption of other drugs.³⁵ CsA use with other immunosuppressive drugs may benefit from these interactions, including glucocorticoids.⁴

The inhibitory effect of ketoconazole on intestinal epithelial and hepatic drug metabolism and on P-glycoprotein efflux may be of therapeutic benefit in patients receiving CsA by decreasing hepatic clearance and increasing oral bioavailability.35,50-53 Ketoconazole may also decrease the lipoprotein that binds CsA, resulting in higher concentrations of free CsA.⁵¹ Studies with ketoconazole in humans found the dose of CsA to be reduced by approximately 70% to 85%.54 The use of ketoconazole in conjunction with CsA as a means of decreasing drug cost has been well accepted in human transplant patients.⁵¹ The two drugs have been used safely for up to 47 months in one study reducing the CsA dose as much as 88%.⁵¹ Although the effects emerge rapidly, with 62% of the effect is apparent by day 7, the maximum inhibitory effect may not be present for 12 months. This has implications regarding monitoring and supports the need for collection of peak and trough samples such that the impact of ketoconazole on drug elimination halflife might be determined.

The effect of combining ketoconazole with CsA has been studied in dogs.⁵⁵ Ketoconazole was studied at doses ranging from 1.25 to 20 mg/kg per day, with the magnitude of inhibition increasing with the dose of ketoconazole above but not below 2.5 mg/kg.55 Clearance was reduced by 85% at 10 mg/ kg per day. Differences in clearance did not result in significant differences in oral bioavailability. In their review, McNaulty and Lensmeyer⁵⁶ indicated that in dogs, CsA half-life will increase over twofold and decrease the concentration of active metabolites in response to 2.5 to 10 mg/kg ketoconazole. Up to 75% of the CsA dose could be reduced experimentally in Beagles concurrently receiving a dose of ketoconazole of 13.6 mg/kg per day.⁵⁷ In a study in dogs with perianal fistulae, Mouatt⁵⁸ examined the impact of ketoconazole (10 mg/ kg once daily) on CsA concentrations (1 mg/kg twice daily). Samples were collected 12 hours after the last dose (duration not clear). Data were not provided on all dogs, but the author noted that at 1.1 mg/kg twice daily of CsA, all dogs exceeded 200 ng/mL at through (12 hours); nine dogs exceeded 900 ng/ mL, and two dogs exceeded 1500 ng/mL. Concentrations varied by 10% to 40% in the same dog despite no dose change. This may have reflected variability in time to steady state, which took 2 to 4 weeks. A trough concentration of 200 ng/ mL was targeted. Although 8 dogs maintained concentrations of 220 to 520 ng/mL with CsA doses as little as 0.35 to 0.55 mg/ kg twice daily, one dog required only 0.16 mg/kg twice daily to maintain 159 to 225 ng/mL, whereas three others required 0.95 to 1.1 mg/kg twice daily to maintain 120 to 235 ng/mL.

Drug	Impact	Drug	Impact			
ACE inhibitors	Increased nephrotoxicity	Loperamide	Altered absorption			
Acyclovir	Falsely increased CsA	Methotrexate	Decreased clearance, increased CsA			
Allopurinol	Increased toxicity		Increased methotrexate toxicity			
Aluminum	Increased nephrotoxicity and CsA bio-	Metoclopramide	Increased absorption, increased CsA			
	availability	Metoprolol	Beneficial hemodynamics			
Aminoglycosides	Increased nephrotoxicity	Mitoxantrone	Increased mitoxantrone concentrations			
Amlodipine	Increased gingival hyperplasia	Mycophenolic acid	Synergistic immunosuppression			
Antacids	Increased aluminum toxicity	Norfloxacin	Decreased CsA clearance?			
Azithromycin	Increased gingival hyperplasia	Omeprazole	Delayed CsA absorption, decreased CsA			
	Increased CsA		clearance?

	Increased absorption		suppression			
	Increased toxicity	Vitamin D ₃	Additive suppressive effects			
Leflunomide	Synergistic immunosuppression	Voriconazole	Decreased metabolism?			

Table 31-4 Cyclosporine Drug Interactions

ACE, angiotensin-converting enzyme; CsA, cyclosporine A.

From Neoral and Sandimmune Drug Interactions, Novartis package insert, 2007

This marked variability in response to ketaconozole appears to occur in clinical patients as is suggested by samples submitted to the author's therapeutic drug monitoring laboratory. Marked variability occurs not only in concentrations, but in the time to steady-state, which in turn determines when monitoring should be implemented. For example, the author's laboratory has demonstrated prolongation of the half-life of CsA in a patient from 4 hours (as reported in normal dogs) to over 150 hour. Steady state was not achieved in this patient until approximately 4 weeks, causing CsA concentrations to continue to increase despite a decrease in dose that was based on monitoring at 1 week. Yet, in other patients, half-life has been less than 12 hours, despite ketoconazole therapy. Detecting these diffrences requires collection of peak and trough samples such that half-life and time to steady-state can be determined in each patient. The simultaneous administration of ketoconazole with CsA also has been studied in cats. McNaulty and Lensmeyer⁵⁶ prospectively studied the impact of a two doses of ketoconazole (10 mg/kg at 24 and 0.5 hr) before a single dose of CsA (4 mg/kg intravenously) in cats (n = 5) using a randomized crossover design with a 14-day washout. Concentrations of CsA were detected using HPLC. Clearance was reduced from 2.73 ± 0.3 to 1.22 ± 0.18 mL*kg/min, resulting in an elimination half-life prolongation from 10 ± 0.9 to 21 ± 3 hours.

Several studies have examined the impact of cimetidine, an inhibitor of CYP3A4, CYP2D6, and CYP1A2 on CsA concentrations. Cimetidine also is a substrate for P-glycoprotein. The results of the studies are contradictory, perhaps reflecting differences in duration of therapy and species. D'Souza and coworkers⁵⁹ found that 5 days of cimetidine therapy significantly decreased CsA clearance, increased volume of distribution (perhaps by impacting P-glycoprotein in distribution tissues) and prolonged elimination half-life in rabbits, whereas Bar-Meir and coworkers⁶⁰ found that short-term administration of cimetidine had no effect on CsA metabolism in rats. Shaefer and coworkers⁶¹ found that 7 days of dosing with cimetidine or famotidine did not affect CsA pharmacokinetics in healthy men. Daigle⁶² explored the impact of cimetidine (15 mg/kg orally every 8 hours for 8 days) on the disposition of CsA (5 mg/kg orally per day; the last 3 days of cimetidine administration) in dogs using a randomized crossover design with a 14-day washout. Significant differences could not be demonstrated for C_{max} or area under the curve the power to detect a significant change was not addressed. The author's therapeutic drug monitoring laboratory has identified some patients for which a cimetidine-CsA interaction may be present, but, other patients for which no effect could be measured.

Among the other drugs that impair CsA elimination or compete with efflux pumps include itraconazole, the calcium channel blockers such as diltiazem, and the macrolide antibacterial erythromycin.⁵⁰ In humans, diltiazem decreases the CsA dose by approximately 30% to 50%.⁵⁴ Other drugs that influence CYP activity should be expected to potentially affect CsA. For example, in the author's laboratory, a cat receiving azithromycin (5 mg/kg once daily) along with CsA (5 mg/kg twice daily), exhibited peak concentrations exceeded 4500 ng/mL, presumably in part resulting from an elimination half-life that exceeded 150 hours. Azithromycin also competes for P-glycoprotein. Other drugs that induce P-glycoprotein might decrease CsA concentrations. For example, P-glycoprotein is upregulated in the duodenum of dogs receiving glucocorticoids.^{62a}

KEY POINT 31-13 Drugs intended to increase cyclosporine A concentrations are likely to differentially affect animals; both peak and trough concentrations should be measured to determine the full impact.

Side Effects

CsA is characterized by a narrow therapeutic index in human patients, with renal toxicity the primary adverse effect. Renal tubular cells develop hyperuricemia (worsened by diuretics) and hyperkalemia (a renal tubular and erythrocyte ion channel effect).63 Hepatic injury also occurs. Although less common than renal dysfunction, the risk of severe hepatic damage is markedly increased when CsA is used in combination with cytotoxic drugs. CsA also increases the incidence of gallstones in human patients. However, in contrast to humans, renal and hepatic toxicities do not appear to be in dogs and cats. Risk factors, such as concurrent administration of nephroactive or nephrotoxic drugs, or renal transplantation have not been addressed in dogs or cats. Hyperlipidemia also has been a reported side effect in humans, particularly in patients receiving glucocorticoids. Other side effects reported in humans include neurotoxicity, gastrointestinal upset, and hypertension.⁴ Development of B cell lymphoma also has been reported in humans; an incidence 10% has been reported in cats undergoing renal transplantation, with mean time to onset of 9 months. 63a Side effects in dogs include gastrointestinal upset and dermatologic or mucosal abnormalities. Vomiting may occur in up to 40% of dogs, although it may be intermittent and short in duration. Diarrhea occurs less commonly (16% to 18%). Vomiting may be more likely when CsA is combined with ketoconazole, but this may reflect higher CsA concentrations. Dermatologic abnormalities reported in dogs include hair loss (possibly reflecting hair growth and pushing of hair from follicles), gingival hyperplasia, and gingivitis in up to 33% of dogs.⁵⁸ In one study,⁵⁸ hair loss resolved by 7 weeks, although hairy coats were thinner at study end (see Therapeutic Use). Hyperplasia may reflect an imbalance of fibroblast formation and collagen degradation by collagenase, although stimulation of TGF-β also has been suggested.³³ Stimulation of TGF-B also stimulates extracellular matrix and decreases degrading proteases. Treatment with antimicrobials (metronidazole, spiramycin) may be useful for treating hyperplasia.⁵⁸ Skin healing might be supported rather than inhibited, as occurs with glucocorticoids.67

At the doses used to treat atopy, risk of infection does not appear to be increased in dogs. However, the risk apparently has not been assessed at the higher doses used to treat immunosuppressive diseases. A report of central nervous system (CNS) toxoplasmosis has been reported in two cats receiving CsA (3 mg/kg twice daily for approximately 5 weeks and 6 mg/kg twice daily for approximately 8 weeks, respectively); presenting signs were respiratory in nature. Both had have previously been treated with glucocorticoids for a substantial time before diagnosis. A fatal case of toxoplasmosis was reported in a cat afflicted with eosinophilic granuloma complex receiving CsA at 5 mg/kg per day for a month, which was reduced because of anorexia to every other day. After 6 months of therapy, the patient developed fatal acute hepatic failure when the dose was increased to once daily. Toxoplasmosis was detected histologically in a number of tissues.⁶⁷ CsA apparently inhibits insulin secretion in a dose-dependent manner in humans.³³ Although this does not appear to be true in dogs, prudence dictates close monitoring of insulin needs in diabetic animals receiving CsA. 63b In rare cases neurotoxocity, characterized by reversible cortical blindness, has been reported in human patients receiving CsA after bone marrow transplantation.⁶⁴

KEY POINT 31-14 Cyclosporine A is much safer in dogs and other animals than in humans.

Mouatt⁵⁸ reported that 11 of 16 dogs receiving ketoconazole with CsA (Neoral solution) developed hair loss manifested as excessive shedding; five animals also developed metronidazole-responsive gingivitis with hyperplasia. Stef fan^{65} compared adverse events associated with CsA (n = 119; 5 mg/kg per day induction followed by tapering doses) versus methylprednisolone (n = 59; 0.5 to 1 mg/kg/day for 1 week, then every other day for 3 weeks, then tapered) in dogs with atopic dermatitis. The incidence of selected adverse events differed between groups. The most common in the CsA group were gastrointestinal, for a total of 55%. Among these, the most common was vomiting at 37%, which was significantly more than the methylprednisolone group (5%), followed by soft stools and diarrhea (18%). Infections occurred with similar frequency between groups but were more likely to be classified as severe or very severe in the methylprednisolonetreated group and led to more dropouts in that group. Polyuria, polydipsia, and increased appetite were more common in the methylprednisolone-treated group. Gingival hyperplasia was reported in 3% of CsA patients (none in the methylprednisolone-treated group). Serum chemistries indicative of renal function did not change from baseline. Potassium increased by approximately 0.6 mg/dL in the CsA-treated group (and decreased in the methylprednisolone-treated group) but was within normal values.

In their meta-anlysis of clinical trials evaluating the efficacy of CsA for treatment of atopic dermatitis in dogs (10 trials, 672 dogs treated with CsA for a duration of 0.5 to 6 months), Steffan⁶⁶ and coworkers reported that vomiting occurred in 25% of animals and soft stools or diarrhea in 15%. Remaining side effects occurred in less than 3% of the patients. The incidence of infection was not any greater for CsA-treatment groups and may have decreased in the skin and ear.

The commercial form of CsA intended for intravenous use has been associated with anaphylactoid reactions in the dog. The reactions appear to reflect the solubilizing agent. The vehicle of the intravenous preparation is very irritating and must not extravasate.

Monitoring

Monitoring of CsA concentrations can be an important tool to guide effective yet safe CsA regimens. The intent of monitoring should be to establish and maintain the therapeutic range for the patient, and to avoid toxicity or therapeutic failure, including that associated with drug interactions (see Chapter 5). Several points of controversy exist regarding monitoring. Reasons for monitoring in humans include, but are not necessarily limited to, avoiding nephrotoxicity; minimizing the risk of infection; and avoiding therapeutic failure, for which host-versus-graft rejection is the most important. In veterinary medicine monitoring might be implemented for the same reasons, but the need to avoid toxicity might take second stage to the need to assure effective concentrations in the face of marked variability in blood concentrations versus dose relationships. Identifying the intent of monitoring may influence down timing.

KEY POINT 31-15 The laboratory that will provide monitoring should be consulted regarding their therapeutic range. Therapeutic ranges should not be extrapolated from one laboratory to another.

Peak, trough, or midinterval samples are variably collected by veterinarians using the author's laboratory. Yet, the elimination half-life of CsA is short (approximately 5 to 8 hours). Accordingly, the drug generally does not accumulate or only minimally accumulates with multiple dosing. Therefore in most patients, no single sample can accurately predict the concentration throughout the dosing interval to which the patient is exposed. As such, the more critical the maintenance of effective doses throughout a dosing interval, the more helpful both a peak and trough sample might be. Detecting variability in absorption is best accomplished with peak concentrations whereas trough concentrations are influenced by both variability in absorption and elimination. Peak concentrations might be targeted if toxicity is of concern; trough concentrations might be targeted if a minimum effective dose must be maintained. However, trough concentrations run the risk of being nondetectable and failing to predict the marked variability that characterizes CsA absorption particularly with once daily dosing. The least useful sample is that collected mid-interval unless the patient is known to have a very long half-life. Note that if concentrations are to be compared across time (for example, to confirm that a dose increase resulted in higher concentrations), then care must be taken to collect subsequent samples at the same time point in the dosing interval. A difference of two hours can cause concentrations to fluctuate by 25% or more. The farther apart subsequent samples are and the shorter the elimination half-life of CsA in the patient, the less relevant are comparisons between samples collected across time.

KEY POINT 31-16 In addition to toxicity and efficacy, monitoring should be used to monitor drug interactions and to determine a patient's therapeutic range once a response has been realized.

Among the important determinants of whether a peak or trough sample is collected is knowing which concentration most accurately predicts response: peak (generally collected at 2 hrs to assure absorption and distribution have been largely completed), trough (just before the next dose, indicating the lowest concentration to which the patient is exposed during an interval) or area under the curve. Timing of sample collection (peak versus trough) is an area of investigation in human medicine. Monitoring traditionally has focused on trough concentrations (discussed later). However, trough (C_0 , indicating the lowest concentration) correlates poorly to both graft rejection and acute nephrotoxicity.⁶⁸ Thus peak concentrations (C_2 , indicating the highest concentrations anticipated at 2 hours) increasingly are becoming more relevant in humans, not only to predict efficacy but also to avoid toxic effects.⁶⁹ Because toxicity is a lesser concern in animals, trough concentrations might reasonably be preferred to ensure that drug concentrations stay above a minimum effective range throughout the dosing interval. Indeed most animal-based recommendations are based on trough concentrations (see later discussion). However, with the short half-life which characterizes most patients, reaching target concentrations will be easier if a peak sample is consistently collected. This is particularly true if a 24 hour dosing interval is used, for example, when treating atopy. Yet, a half-life of less than 8 hours often results in 24-hour concentrations that are minimally or not detectable. As such, although dose labeled for chronic allergic inflammation (e.g., atopy, asthma), it should not be assumed to be appropriate for autoimmune disorders or graft versus host rejection. For animals in which the CsA half-life is longer than 24 hours, concentrations may not be at steady state. If so, monitoring to establish baseline clearly must be withheld until steadystate concentrations are achieved; monitoring both a peak and trough, however, may be necessary to establish when steady state will occur (see previous discussion).

The impact of drug interactions is another reason for CsA monitoring. If altered clearance is anticipated, elimination half-life is the most likely outcome measure to be impacted that can be monitored. In such instances both a peak and a trough concentration are recommended; if a drug interaction is anticipated (e.g., the addition of ketoconazole), monitoring ideally will occur prior to and approximately 1 week after the inhibiting drug is administered. If a peak and trough concentration cannot be collected, then consistent timing (either a peak or a trough) should be targeted, with a sample before and 1 week after the other drug is changed. Note, however, that if the impact of the drug is to prolong the elimination half-life more than 48 hours, concentrations may not be at steady state at 1 week. The only means by which the duration of time that must elapse before steady state is reached (and thus baseline can be established) is determination of half-life (i.e., both a peak and trough sample). Monitoring should be implemented each time a drug that might alter the disposition of CsA is added or subtracted from the drug armamentarium for the patient.

KEY POINT 31-17 Recommendations for cyclosporine A concentrations are generally based on either a 2-hour peak or 12-hour trough; mid-interval samples are least helpful. Timing of sample collection should be consistent across time for the patient.

A second point of concern is the length of time after CsA therapy has begun that monitoring should be implemented. In general, the half-life of CsA is short enough that monitoring can be determined in 3 to 5 days. However, response to CsA may not occur that rapidly. Accordingly, if the goal of monitoring is to establish a therapeutic range in a responding animal, then monitoring is best implemented once a clinical response has been realized This is particularly relevant in the

absence of concentration-response data in dogs or cats. The time to response (not resolution) is less clear, but several days to 2 weeks might be reasonable for most targets of therapy. However, some disease may require a longer period for maximum response (e.g., 4 months for perianal fistulae).

Among the limitations in CsA use in dogs and cats is evidence for the the actual concentration to be targeted, which in turn is closely related to timing of sample collection as well as the method used to detect CsA and the sample submitted. Guidelines offered in human medicine have served as targets for veterinary patients,⁶³ although the appropriateness of extrapolation has not been addressed. The impact of the assay reflects the presence of active metabolites (AM1, AM9) which may contribute up to 10 to 20% of activity in humans (more at trough concentrations); the concentration may be even greater if the metabolites accumulate. Several methods are available for measuring CsA concentrations, including HPLC, which generally detects only the parent compound. However, the contribution of active (and potentially toxic) metabolites has led to methods that detect both parent and metabolites.³⁹ The more common methods are immunoassays based on antibodies directed toward the parent (monoclonal) or parent and metabolites (polyclonal). These include radioimmunoassays (RIAs) and polarized immunofluorescence, which detect parent drug and metabolites. Immunoassays that are monoclonal (e.g., FPIA by Abbott TDx or ACMIA by Seimens) are less likely to detect in activemetabolites compared with polyclonal antibody-based assays. Either type of assay (HPLC versus antibody based) is acceptable; the choice might depend on cost or availability. The advantages of antibody-based assays are enhanced quality assurance and rapidity of turnaround time. The cost also should be lower. Each assay appears to be clinically useful. However, the target concentrations will vary with the methodology as well as the timing of the sample (i.e., peak or trough) and the sample collected (e.g., whole blood, plasma, or serum). Antibody-based assays will be accompanied by higher concentrations, with polyclonal concentrations higher than monoclonal. For example, in dogs blood concentrations measured by TDx assay are 1.5 to 1.8 times higher than those measured with HPLC assay.^{33,44} However, this increase reflects, in part, detection of active metabolites; as such, monoclonal antibody-based assays that detect the metabolites might be the preferred type. Assays based on HPLC that determine the parent only will have the lowest therapeutic range; HPLC assays that include the metabolites will be higher. A disadvantage of HPLC assays is variability in results among laboratories. Even if similar methods are applied, variability in conditions can result in different concentrations. Thus the importance of using external quality-control programs will be particularly important for laboratories that use HPLC methods.

The sample submitted for CsA quantitation will also influence the concentrations and the therapeutic range. Most CsA in whole blood is located in red blood cells. Accordingly, whole blood is generally the preferred sample. Concentrations based on whole blood will be higher than those measured in plasma or serum. The most important point to be made regarding recommended therapeutic ranges is that they

are laboratory specific, varying with sample timing, tissue collection, and assay method. If the laboratory is using an automated system, then the therapeutic ranges of that laboratory will be those established for the instrument. If the laboratory is using HPLC, then the ranges may be specific for that laboratory and only that laboratory. As an example of what might be expected, in humans recommended trough (before next dose) CsA concentrations (ng/mL) are as follows: for HPLC 100 to 300 (whole blood); RIA, monoclonal antibody methodology 150 to 400 (whole blood) or 50 to 125 (plasma or serum); RIA, polyclonal antibody methodology 200 to 800; fluorescent polarized immunoassay 250 to 1000. These numbers are offered as examples of therapeutic ranges. However, therapeutic ranges might also vary with the disease being targeted. A longitudinal replicate study examining differences between laboratories found marked variability within laboratories,⁷⁰ suggesting that intralaboratory variability is a major contributor to overall variability. Because of these reasons, care should be taken not to extrapolate results based on the methodology unless the laboratory fails to do so. However, the most important point to be made regarding therapeutic ranges is that this population statistic is a guide only. Monitoring should be used to determine the patient's therapeutic range. Once response has been realized, a sample should be collected, the concentration identified, and subsequent samples collected at that same time during the dosing interval.

Monitoring is generally based on 12 hour dosing. The dosing regimen recommended for treatment of atopy⁷¹ should not be assumed to be effective for treatment of immune-mediated diseases. In humans, for which CsA is usually administered by mouth every 12 hours, estimates of drug exposure using the area under the time concentration curve appear to be the most accurate pharmacokinetic measure on which to based dosing in human patients subject to acute rejection episodes. However, the description of area under the curve requires multiple sample collection, which is not only inconvenient but also costly. Two established therapeutic drug-monitoring protocols have been used in humans: the traditional approach, based on trough blood concentrations (C_0) , and the newer strategy, based on a sample taken 2 hours after oral administration (C_2) . Because the greatest contributor to interindividual variability in CsA area under the curve in humans is absorption, monitoring that focuses on peak concentrations is evolving as more predictive for CsA. As was noted previously, the risk of graft-versus-host rejection was markedly reduced when CsA dosing was based on peak rather than trough concentrations in humans. However, the use of this parameter as a predictor of CsA exposure is based on a 12-hour dosing interval.⁷² These recommendations are made regardless of the method of CsA detection (mRIA, EMIT, AxSym, CEDIA, or TDx/Architect) (Abbott FPIA). Mehl and coworkers⁴⁵ investigated the relationship between peak and trough plasma drug concentrations and area under the curve in cats receiving CsA. After 14 days of dosing, 2-hour peak concentrations correlated better than the 12-hour trough concentration with area under the curve during that same time period, which suggests that a 2-hour peak sample is the preferred sample for monitoring.⁴⁵

However, this study was based on predicting blood CsA concentrations and not predicting response.

A plethora of literature is dedicated to determining the best peak or trough target concentrations in humans receiving CsA, primarily for transplant patients but also for those with certain chronic allergic inflammatory disorders. For example, 12-hour concentrations, which probably do not accurately predict either rejection or toxicity but are reasonable for maintenance, range from 500 to 800, depending on the author. A review of the literature reveals that the range might also vary during the stage of disease, with initial concentrations for immune-mediated diseases being substantially higher, whereas lower concentrations are acceptable as targets for maintenance once response has been realized. Most recommendations in humans are based on monoclonal antibody assays.⁷²

The consensus among most investigators is that area under the concentration versus time curve is the best predictor of acute or chronic graft rejection and toxicity.⁶⁹ Mahalati and coworkers68 demonstrated that the initial area under the concentration-time curve (C_0 and C_4 ; or AUC₀₋₄) was a useful tool: ranges between 4400 and 5500 ng/mL per hour for the first 4 hours of dosing significantly reduced the risk of acute rejection and nephrotoxicity in humans. This parameter is more useful with newer microemulsion products because CsA disposition is more predictable with these products. For this study samples were collected at 0 (just before the next dose), 1,2, 3, and 4 hours. A similar approach might be considered for animals during the early, critical stages of immune-mediated disease, with sample collection at 0 and 4 hours. However, collection of sufficient samples to describe the curve completely is generally not practical in either human or veterinary patients. For single point prediction, 2-hour posttreatment (C₂) collection has repeatedly been demonstrated to be the most accurate predictor of area under the curve in humans, although even this time point is controversial. However, Einecke and coworkers⁶⁹ demonstrated that C₂ concentrations were not helpful in identifying patients at risk for rejection, but ranges between 500 and 600 ng/mL (whole blood, CEDIA antibodybased assay) were useful to maintain patients for long periods and avoid toxicity. This study suggests that the target range should vary as treatment moves from the induction to the maintenance mode.

Studies correlating CsA concentrations with efficacy are limited in animals. Perhaps the most supportive is with regard to perianal fistulae. Mouatt⁵⁸ found that dogs with perianal fistulae (n = 14) responded more rapidly if trough concentrations exceeded 600 ng/mL, but time to resolution (generally 4 weeks) could not be predicted by concentrations in this small group of dogs.

Use of monitoring for atopic dermatitis is less clear. In a manufacturer-sponsored study, Steffan⁴⁴ and coworkers investigated the relationship between CsA concentrations and response in dogs (n = 97) with atopic dermatitis. Concentrations were measured between 2 and 24 hours of the last dose at 28 days, and this single point concentration was used to predict the time course of CsA, based on a model generated from

normal dogs (n = 16). Patients were then grouped into one of five categories of CsA exposure, ranging from very low to very high CsA. Clinical response to therapy was based on scoring of skin lesions (canine atopic dermatitis extent and severity index [CADESI]) and pruritis. Response to therapy (CADESI and pruritis scores) was then compared (not correlated) among groups. The study could not demonstrate a differenc in response among the groups, leading the authors to conclude that concentrations did not correlate with response and monitoring was not indicated. However, this study should not necessary be considered evidence against monitoring in dogs with atopic dermatitis. First, a single time point of CsA was used to predict 24-hour exposure of CsA for clinical patients. Second, the model used to predict CsA was based on normal Beagles, of which only eight had received multiple dosing of CsA. Third, variability in the clinical patients was greater than in normal animals, and the predicted model differed from the observed. The variability in peak CsA, in particular, found in this study is profound, and its impact on therapeutic success should be examined. Variability also occurred in pruritis scores, being equal or greater than the median, which may have impacted the power to detect a significant difference was likely low. Because peak concentrations appear to occur in most animals between 1 and 2 hours, a study that correlates actual peak concentrations with scores might be prudent before the use of CsA monitoring for anticipating response of atopic animals to therapy is set aside. Studies are indicated to determine the best sampling time for dogs receiving CsA. Because concentrations are so low at 24 hours and often undetectable, it is likely that some other sampling period is appropriate for 24-hour dosing intervals.

It is important to emphasize that studies that fail to correlate CsA concentrations with therapeutic response do not prove the lack of or preclude the usefulness of monitoring. In ability to demonstrate a significant difference does not equate to "no treatment" effect. Studies may fail to find a connection because of limitations in study design. In the event that a sufficiently well-designed study (or several studies) should fail to find a correlation, the clinician must remember that the most important reason for monitoring is to establish a therapeutic range for the patient. Once the patient has responded, monitoring might be most useful to maintain that concentration in the patient.

In summary, our laboratory offers the following recommendations for monitoring of patients treated every 12-hours: a 2-hr peak and just before the next dose trough sample is recommended within 3 to 5 days of initiating therapy; the more life threating the target disease, the more important a peak and trough sample may be. For less serious situations, or as treatment shifts from induction to maintenance, a singe 2-hr peak sample or, assuming bid dosing, a single 12 hour trough concentration may be sufficient for establishing and maintaining a target. If therapy is initiated such that CsA disposition might change (whether intentional, such as the addition of ketoconazole, or inadvertent, such as co-treatment with diltiazem or azithromycin or others), a peak and trough sample prior to and 1 week after therapy is initiated is suggested. In situations in which alternatve generic preparations are initiated, a single 2-hr peak concentration before and 3 to 5 days after the switch is recommended. For atopy (24 hr and beyond dosing), a single peak sample should be collected. Likewise, if toxicity is a concern, a single peak sample is indicated. However, in patients with a long half-life, both a peak and trough sample may be necessary to fully assess the risk of toxicity. Monitoring is recommended weekly to biweekly in critical patients, then monthly for the first several months of therapy or until concentrations are stable. For long-term maintenance, the frequency of samply may vary with the stability of the patient but should range from 3 to 6 months. Target concentrations vary with the condition but generally, based on a 12-hr dosing interval using a monoclonal antibody-based assay (i.e., as in the author's laboratory), a peak concentration of 800 to 1400 ng/mL and a trough concentration of 400 to 600 ng/mL (monoclonal based assay) is recommended for immune mediated diseases. For renal transplantation, trough concentrations of 750 ng/mL are suggested for the first month and 350 to 400 ng/mL, thereafter. For chronic allergic inflammatory disorders, lower concentrations are recommended: 250 ng/mL trough concentrations for chronic inflammatory bowel disorders, and for perianal fistulae, 12 hour trough concentrations at 100 to 600 ng/mL (the higher for induction, the lower for maintenance).

Therapeutic Use

Chronic Allergic Inflammatory Disorders

Atopy and other dermatologic conditions. The use of CsA for treatment of veterinary dermatologic syndromes has been reviewed.⁷³ Olivry and Mueller⁷⁴ reviewed treatment of atopic dermatitis in dogs in general and found good evidence for efficacy of glucocorticoids and CsA compared with fair evidence for topical triamcinolone, topical tacrolimus, oral pentoxifylline, and oral misoprostol. In the manufacturer-sponsored study, Steffan and coworkers65 prospectively compared the efficacy of CsA (n = 119) and methylprednisolone (n = 59) in dogs with atopic dermatitis using a randomized, blinded (investigators but not owners) parallel study. Dosing began with an induction phase for both drugs, followed by a tapering phase, with the dose determined by CADESI scores. Dosing for CsA was 5 mg/kg once daily for 4 weeks, then tapered on the basis of the CADESI score, and for methylprednisolone, 0.5 to 1 mg/ kg daily for 1 week, followed by every other day for 3 weeks, and then tapered on the basis of the CADESI score. Washouts were required for drugs that might influence response. At the end of the 4-month study period, the percentage of reduction in CADESI scores was approximately 45% in both groups. The proportion of responders (CADESI scores reduced by \geq 50%) was approximatey 58% for methylprednisolone and 66% for CsA; a significant difference could not be demonstrated. Scores worsened in approximately 15% of both groups.

More recently, Steffan and coworkers⁶⁶ reviewed clinical trials evaluating the efficacy of CsA for treatment of atopic dermatitis in dogs. Ten trials met their standards; 799 dogs were treated with either CsA (n = 672 for a duration of 0.5 to 6 months), placebo (n = 160), oral glucocorticoids (n = 74), or antihistamines (n = 23). Further, safety data were available for 660 dogs. Among the concerns the authors addressed well was publication bias (the study was sponsored by the

manufacturer). Treatment success was defined as a 50% or higher reduction in lesion scores after the 4- to 6-week induction period (denoted as high responders). Compared with placebo, but not oral glucocorticoids, the effects of CsA were highly significant. Dosing intervals generally could be prolonged to 48 hours in 40% to 50% of responders after 4 weeks and to twice weekly in 20% to 26% of dogs after 12 to 16 weeks. Predictors of success could not be identified, although initial response was predictive of long-term response. Feeding, age, and body weight did not appear to affect success; the influence of breed could not be assessed. The dose ranged from 2.5 mg/kg twice daily to 5 mg/kg twice weekly. Doses generally begin at 5 mg/kg once daily. The treatment induction period was considered 4 to 6 weeks, although not all studies reviewed treated for that time period. The authors identified those aspects of the meta-analysis that were relevant for clinical practice. They concluded that the severity of skin lesions can be expected to decrease by at least 40% during the initial 4 to 6 weeks of induction therapy at 5 mg/kg. The benefits may be less pronounced in dogs that previously received glucocorticoids. The dose can be reduced, generally by prolonging the interval, after this reduction period if a response has been realized. If clinical signs worsen, the previous dose should be reinstituted. A further reduction in clinical signs may be realized after the 4- to 6-week induction period, with a plateau of 50% to 70% reduction occurring at 2 to 4 months. Unacceptable adverse events (most notably vomiting) should respond to dose reduction if related to the drug. What was not resolved by this meta-analysis is the impact of long-term therapy, as well as the sequelae of discontinuing therapy; response in animals that have not responded to glucocorticoids; and the impact of combination therapies, including topical agents.

Radowica and Power⁷¹ retrospectively studied the efficacy of CsA (5 mg/kg per day) when used for a minimum of 6 (range 6 to 30) months for treatment of atopic dermatitis in dogs (n = 51). Continued therapy was necessary to control clinical signs in at least 55% of dogs, with most of these animals receiving the drug 2 to 5 times weekly, but one out of five requiring daily therapy. Therapy could be discontinued in 24% of animals after 6 to 24 months as a result of clinical response. Adverse events occurred in 22% of animals, including oral growths or gingival hyperplasia and hirsutism.

Other dermatologic indications for CsA include, but are not limited to, perianal fistulae, atopy, and eosinophilic granuloma complex. Mathews and coworkers⁷⁵ found that CsA was effective in eradicating or markedly reducing the size or number of perianal fistulae in 10 of 10 dogs. Initial dosing began at 10 mg/kg orally every 12 hours but was reduced to 5 to 7.5 mg/kg after 1 week because of excessive trough concentrations. Doses were adjusted to a trough measurement of 400 to 600 ng/mL. Duration of therapy ranged from 8 to 12 weeks; remission required another 4- to 6-week trial of therapy in 3 dogs. Remission was persistent in all dogs for at least 6 months and up to 18 months at the time the report was published. A follow-up study of a randomized controlled trial in 20 dogs⁷⁶ found that fistulae recurred in 7 of 17 dogs treated with CsA and required subsequent treatment or surgical excision. CsA was, however, beneficial presurgically to reduce the extent of excision. The investigators also found that trough CsA concentrations between 100 and 300 ng/mL (HPLC) were effective for treatment of perianal fistulae. The most frequently reported side effect in this study was shedding of hair, which was noticeable by 16 weeks. Older hair coats tended to be replaced with a softer coat.

Dogs (16) with perianal fistulae were prospectively evaluated for the efficacy of CsA (1 mg/kg orally twice daily; administered as Neoral liquid administered in a gelatin capsule) when combined with ketoconazole (10 mg/kg orally once daily); blood concentrations of CsA (based on HPLC) were monitored to maintain trough concentrations above 200 ng/mL (FPIA 300 ng/mL). All dogs showed clinical signs of improvement within 2 weeks of therapy; animals whose concentrations were above 600 ng/mL responded more rapidly, but efficacy did not seem to differ, although the power of the study to detect a relationship between cure rates and drug concentrations was not addressed. Lesions resolved in 93% of the animals within the 16-week treatment period, with 50% of the animals remaining cured at 12 months. Recurrence in the remaining dogs occurred within 1 month (21%) or between 8 and 12 months (21%). Although both medications appeared to be well tolerated, 67% of dogs exhibited excessive hair loss that started at 2 weeks but stopped at 7 weeks; hair coats thinned but were normal by study end. Further, 31% of the dogs developed gingival hyperplasia and gingivitis, which responded to metronidazole and spiramycin.58

Inflammatory bowel disease. Allenspach and coworkers⁷⁷ studied the efficacy of CsA (Atopica; 5 mg/kg once daily for 10 weeks) for treatment of canine IBD (n = 14) refractory to steroid therapy (prednisolone, the majority receiving 2 mg/kg orally per day for 6 to 14 weeks or more). CsA concentrations were measured in eight dogs with severe disease during a 24-hour period after the first dose; CsA was detected in whole blood using FPIA; a cohort of healthy dogs was available from a previous study (see Table 31-3). Animals were scored (canine IBD activity index [CIBDAI] criteria) on the basis of clinical signs and histopathologic lesions. Of the 14 dogs studied, eight completely responded within 4 weeks and three partially responded (posttreatment score of 2 to 4). Two failed to respond. Five of the 14 dogs with protein-losing enteropathy partially responded (posttreatment median score of 5). Although body weight increased, histopathologic lesions (nine dogs had repeated biopsies) did not. Overall, CsA was considered effective in 78% of the animals. Concentrations of CsA varied more in the diseased dogs (peak occurring at 1-2 hours of 699 \pm 326 ng/mL compared ot 878 \pm 131 ng/mL in healthy dogs), leading the authors to speculate on the role of previous glucocorticoid therapy, which may have increased P-glycoprotein, thus decreasing absorption. Elimination halflife in the respective diseased versus healthy populations was 5.6 ± 1.2 and 7.8 ± 1.1 hr, respectively. However, the authors did not describe the CsA concentrations in all nonresponders, although one of them had the highest peak and trough concentrations measured in the study. Adverse events not evident before initiation of therapy were vomiting, anorexia (improved by administering with food), gingival ulceration (one dog; resolved after 7 weeks), and alopecia followed by hypertrichosis (full replacement of the hair coat) in the first 2 weeks of therapy.

CsA appeared to act synergistically with dexamethasone for the treatment of IBD in human patients. Each drug appears to target through different mechanisms the chemokines responsible for migration of white blood cells to the site of inflammation.⁷⁸ In humans a 12-hour trough concentrations of 150 to 250 ng/mL has been recommended for CsA when treating IBD.⁷⁹

Asthma. Other potential indications for CsA warrant further investigation. Cats suffering from *A. suum*-induced airway reactivity had decreased reactivity and remodeling after receiving CsA; differences were noted with 24 hours of therapy.⁸⁰

CNS Disorders. Adamo and O'Brien⁸⁴ reported on the successful use of CsA for treatment of granulomatous meningoencephalitis (GME) in a series of three cases. The initial dose of 3 mg/kg twice daily was increased to 6 mg/kg twice daily. Concentrations of CsA (ng/mL) were 235, 337, and 592 (unfortunately, sample timing not provided); variability was assumed to reflect, in part, differences in sampling times, which were not provided. In one dog, the initial dose of 3 mg/ kg twice daily yielded CsA of 82 ng/mL (timing not provided); the dose was increased to 10 mg/kg twice daily. This dog did not sufficiently respond, developed azotemia and an E. coli urinary tract infection; on necropsy, disseminated GME was diagnosed. A different dog also was initiated at 3 mg/kg twice daily; CsA was 117 ng/mL, and the dose was increased to 6 mg/kg twice daily, which was subsequently decreased back to 3 mg/kg after 7 months, resulting in CsA at 215 ng/mL. The dose was tapered to 3 mg/kg once daily, yielding CsA at 63 ng/mL. Several attempts to detect CsA in cerebrospinal fluid revealed no detectable drug; however, its large size and the presence of P-glycoprotein is likely to preclude CNS penetration by CsA. However, efficacy of CsA is not likely to depend on penetration of the CNS. On the basis of this series, 6 mg/kg twice daily might be considered until animals with GME are in remission, with the dose tapered to 3 mg/kg twice daily on response. In humans, CsA has proven useful for treatment of chronic inflammatory demyelinated polyradiculoneuropathy; concentrations were not provided.84a

Immune-Mediated Disease

Systemic use of CsA increasingly is being used for treatment of autoimmune disorders, particularly in those that have not responded to traditional immunosuppressive therapy. However, the labeled doses for atopy should not be assumed to be relevant for other immune-mediated diseases, including dermatologic.

Noli and Toma⁸¹ reported the successful use of CsA for treatment of immune-mediated adnexal skin disease in a series of cases (n = 3; two cats, one dog). In each case response occurred within 1 month of administration at 5 mg/kg once daily, CsA therapy was successful in treating aplastic anemia in three of four dogs⁸² when dosed at 5 to 10 mg/kg every 12 hours (unfortunately, CsA concentrations were not provided).

Font and coworkers⁸³ reported a single case of cutaneous lupus erythematosus that was successfully treated with 4 mg/kg CsA once daily along with ketoconazole (4 mg/kg) once daily. Prednisone therapy was continued at 0.2 mg/kg for 10 days. Lesions resolved in 2.5 months of CsA therapy. Concentrations of CsA associated with response at 10 days was 139 ng/mL; the timing of sample collection was not indicated, although it is possible in the presence of ketoconazole, that this concentration did not vary substantially during the dosing interval. Concentrations were 279 ng/mL at the time ketoconazole was stopped. The dog remained in remission at the end of the 18-month report period, receiving 2 mg/ kg daily. The use of glucocorticoids, ketoconazole, and lack of information regarding the collection of samples complicates correlating concentratiosn to response. A randomized placebo-controlled study on the use of CsA for treatment of spontaneous glomerulonephritis in dogs⁴⁶ failed to document a a significant improvement in treatment groups; the power of the study was not addressed. Packed cell volume was lower in the CsA-treated group; in addition, clinical signs compatible with decreasing renal function appeared to be more severe in animals receiving CsA.

With the availability of renal transplantation at several facilities, CsA is increasingly being used to prevent graft-versus-host rejections. Cats respond better than dogs, with renal allografts being maintained at 7.5 mg/kg every 12 hours coupled with prednisolone (0.125 to 0.25 mg/kg every 12 hours).⁴⁶ Trough concentrations of whole blood should be maintained at 500 ng/mL (HPLC; approximately 750 ng/mL should be expected for FPIA) the first month after transplantation but can be reduced to 250 (375 to 400 FPIA ng/mL) thereafter.

Topical CsA has been used with some success for localized immune-mediated diseases, including pemphigus foliaceus. An ophthalmic preparation is approved for use in dogs to treat keratitis sicca..⁸⁵ Benefits include both immunomodulation and an increase in tear production. A 0.2% CsA compound in a petrolatum–corn oil ointment is commercially available (Schering-Plough) for keratitis sicca in dogs. Application of one drop of the commercial preparation twice daily should be effective in up to 80% of dogs. The frequency of administration can be decreased to every other day for most dogs.

When compared with dexamethasone and indomethacin, topical CsA was equal in suppressing arachidonic acid– induced inflammation,⁸⁶ and studies are under way to evaluate its use in canine dermatologic diseases.

Tacrolimus and Related Drugs

Tacrolimus, like CsA, is a macrolide antibiotic, produced by *Streptomyces*. Like CsA, it inhibits T cell activation, but rather than binding to cyclophilin, it binds to and inhibits an alternative cytosolic protein, FKPB12. Calcineurin-dependent activation of lymphokine expression, apoptosis, and degranulation is inhibited.⁴ The intracellular receptors for tacrolimus are distinct from those for CsA and it is 500 fold more potent than CsA in its effects. This may reflect, in part, a 3-fold greater uptake in lymphocytes for tacrolimus compared to CsA (however CsA)

uptake in RBC is 10-fold higher than tacroliumus).^{86a} The drug is available for both oral and intravenous systemic administration. Toxicities are similar to those of CsA in humans, although gingival hyperplasia may be less prevalent. The drug may be more toxic than CsA in dogs, and its systemic use has not been recommended.87 Tacrolimus disposition has been reported in male Beagle dogs receiving 1 to 4 mg/kg.87a Peak and trough concentrations (ng/mL), respectively, ranged from 0.8 to 1.8 ng/ mL (at 1 mg/kg) to 3.2 to 5.3 ng/mL (2 mg/kg) and 0.25 to 0.8 ng/mL (1 mg/kg) to 0.2 to 2.3 ng/mL (2 mg/kg). For tacrolimus and sirolimus, trough (before the next 12-hour dose) rather than peak concentrations more effectively predict area under the curve.⁷² Tacrolimus is also available as a topical ointment. The 0.1% preparation has been used in dogs to treat localized lesions associated with discoid lupus erythematosus as well as two cases of pemphigus erythematosus either as a sole therapy or adjunctive treatment.88 No side effects were reported, and all animals improved after 8 weeks of topical application, with adjuvant therapy being discontinued in the majority of animals. Tacrolimus ointment also has been used effectively for the treatment of canine atopy.⁸⁹ Using a double-blinded, placebo controlled, cross-over study, dogs (n = 12) were treated with topical 0.1% tacrolimus (maximum dose of 0.1% mL/kg/day) applied topically at sites considered most pruritic for 4 weeks. Following a 2-week washout (based on a 9-hr half-life of tacrolimus in dogs), animals were switched to the alternative treatment. The randomization procedure was not robust (alternating treatment assignments). The mean clinical score improved in both the placebo and the treatment group at 4 weeks compared to baseline, but response was significant for the tacrolimus group. Tacrolimus was detectable in patients (peak concentration at 4 weeks of 1.4 ± 0.2 ng/mL). However, peak concentration of 0.6 ng/mL was also detected at week 4 in the placebo group calling into question the credibility of the report. Tacrolimus may impact intradermal skin testing in dogs, with an effect on the late phase, but not the immediate response. ^{89a}

Griffies and coworkers⁸⁸ reported on the successful use of tacrolimus (0.1%) topically in a series of cases in dogs. The drug was used as either sole agent or as an adjuvant topically for treatment of localized lesions associated with discoid lupus erythematosus or pemphigus erythematosus. Improvement required approximately 8 weeks of therapy, and adjuvant therapy could be discontinued in some dogs.

In contrast to tacrolimus, sirolimus and its derivative, everolimus, do not inhibit calcineurin; rather, they interact downstream from IL-2, targeting the immunophilin with FKBP12. This complex then inhibits mTOR (mammalian target of rapamycin), which prevents progression from the G1 to S phase transaction in the cell cycle, in a manner that prevents cytokine receptors from activating the cell cycle and subsequent signaling.⁹⁰ Its use is primarily replacement of CsA to protect renal function in humans.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is the morpholinoethyl ester prodrug of mycophenolic acid (MPA), which is a product of several *Penicillium* species that possess antibacterial, antifungal, antiviral, antitumor, and immunosuppressive properties. MPA is a potent, selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH). This enzyme is critical for the production of the guanine triphosphate precursor guanine monophosphate, which in turn is necessary for the de novo synthesis of purine nucleotides. As such, the drug is an antimetabolite. Two isoforms of human IMPDH exist. Type I is constitutively expressed in normal, nonreplicating cells, and type II is upregulated in replicating (including neoplastic) cells to the point that it is the predominanting isoform. As IMPDH is inhibited, guanine triphosphate is depleted; failure to make mRNA precludes synthesis of proteins, including cytokines, necessary for cell proliferation. Unlike other anticancer antimetabolites, MMF and its active metabolite MPA are relatively selective for lymphocytes because they are solely dependent on de novo synthesis of purines for DNA synthesis.^{91,92} MMF is the first drug since CsA to be approved in the United States for prevention of renal allograft rejection; it has proved useful for treatment of steroid-resistant acute liver rejection.93 In addition to its antiproliferative properties toward lymphocytes, MPA also impairs proliferation in nonimmune cells, including smooth muscle cells, renal tubular cells, mesangial cells, and dermal fibroblasts.94 Consequently, MMF might be indicated for nonimmune-mediated diseases associated with fibrosis.

A bilateral nephrectomized dog model has been used to study MMF.91 The disposition appears to be characterized by marked variability in dogs. After doses of either 20 or 40 mg/kg, mean peak concentrations of MPA were, respectively, approximately 90 and 130 µg/mL, yet peak concentrations did not statistically differ between the two groups. Based on canine lymphocytes exposed to whole blood containing MPA, 200 µg/mL MPA is necessary to inhibit baseline activity of IMPDH by 50%. The elimination half-life of the drug ranged from 1.45 to 11.09 hours, with a mean of approximately 7 hours, regardless of the dose. The drug also has been studied in normal dogs at approximately 20 mg/kg, Maximum concentrations of MPA after intravenous (2-hour infusion) and oral administration, respectively, were 21 ± 3.6 and $11.8 \pm 6.6 \,\mu\text{g/mL}$; oral bioavailability was 54%.95 The elimination half-life of MPA was about 45 minutes, and mean resistance time was approximately 2 hours. The half-life is substantially shorter than that reported in humans (17 to 19 hours). However, suppression of IMPDH lasted for a mean of about 6.5 hours,⁹⁶ suggesting an 8-hour dosing interval might be appropriate. In human monitoring of trough concentrations has been recommended: trough (predose) concentrations less than 1 µg/mL were associated with acute liver transplantation rejection, whereas concentrations greater than 3.5 µg/mL were associated with a threefold increase in the risk of leukopenia or pneumonia. Therefore trough concentrations between 1 and 3.5 µg/ mL are recommended.90 It may be necessary to increase the dose of MMF in patients with low albumin; the dose had to be increased in human patients by approximately twofold if serum albumin was less than 3.5 gm/dL. However, the dose could be decreased by approximately 40% in the presence of renal dysfunction.90

KEY POINT 31-18 Mycophenolic acid targets both T and B lymphocytes and accordingly should be associated with greater immunosuppression compared with cyclosporine A.

The primary side effects in human patients receiving the drug for allograft rejection are leukopenia, gastrointestinal upset, and cytomegalovirus disease. The incidence is, however, small. Gastrointestinal upset is characterized by nausea, diarrhea, vomiting, and abdominal cramping. Gastrointestinal toxicity (and bone marrow suppression) may reflect the need for IMPDH II because of the normally replicating nature of these tissues.⁹⁷ The drug also appears to be relatively safe in dogs, on the basis of renal and hepatic indices of damage, even when dosed at 80 mg/kg twice daily. At that dose, transient increases in hepatic damage enzymes occurred.98 However, when used chronically at 30 mg/kg orally every 12 hours, severe diarrhea, anorexia, and weight loss occurred in dogs⁹⁵; at 20 mg/kg orally every 12 hours, signs recurred, although the were less severe, within 1 week of initiating therapy. One dog died acutely with necrotizing pneumonia 7 days after initiation of therapy.96 Dysgranulopoiesis, characterized by pseudo Pelger-Huet anomaly has been reported in a series of human cases receiving MMF for heart-lung transplantation; resolution occurred only after the drug was reduced in dose or discontinued.99

Among the indications for MMF is dose sparing of CsA, which probably is more clinically relevant in humans compared with dogs or cats.¹⁰⁰ Initial induction with CsA is followed by the addition of MMF and down titration of CsA. MMF has been used therapeutically in dogs both clinically and experimentally. Clinically, the drug has been used successfully to treat myasthenia gravis,¹⁰¹ although review articles offer anecdotal support for use in other immune-mediated disorders. Experimentally, MMF (10 mg/kg subcutaneously every 12 hours) in combination with CsA (15 mg/kg orally every 12 hours) has been used in dogs to prevent renal allograft rejection.¹⁰²

Leflunomide

Leflunomide is a recently approved immunomodulatory drug that inhibits dihydroorotate dehydrogenase, an enzyme responsible for the de novo synthesis of pyrimidine. Both T and B cell proliferation is inhibited; accordingly, both cellmediated and humoral responses are targeted. Cell adhesion also impaired. Other proposed mechanisms are inhibition of cytokine and growth factors mediated by tyrosine kinase. Like MMF, it is a prodrug, with its activity reflecting a malononitrile metabolite (A77 1726). It has been studied for the treatment of rheumatoid arthritis in humans.¹⁰³ The half-life of the active compound is long in humans, ranging from 1 to several weeks, indicated a long time to steady state. However, a recent disposition study in dogs reveals the elimination half-life of the metabolite to be 14 hrs in the dog. Limited information is available regarding its use in dogs.¹⁰⁴ Anecdotal reports suggest that the drug is effective for treating a number of immune-mediated disorders, including immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia, canine cutaneous histiocytosis, and pemphigus foliaceus (2 to 4 mg/kg orally every 24 hours). Side effects that reportedly occur in dogs include leukopenia, thrombocytopenia, and gastric ulceration. Gregory and coworkers¹⁰⁴ reported on the use of the drug (1.5 mg/kg twice daily to 2 to 4 mg/kg once daily) in dogs (n = 29) afflicted with various immunemediated disorders. These include idiopathic thrombocytopenic purpura (n = 3; good to excellent response), IMHA with idiopathic thrombocytopenic purpura (Evans syndrome), systemic histiocytosis (n = 3; one failure and two total remissions), multifocal nonsuppurative encephalomyelitis (n = 5; good to excellent response), and a variety of other immune-mediated disorders that had not responded to glucocorticoids or azathioprine. Most of the animals had not responded to firstor second-tier immunosuppressants. Side effects included decreased appetite, mild anemia, and bloody vomitus or stools (n = 3). Leflunomide was studied at doses ranging from 2 to 16 mg/kg/day as sole therapy or in combination with CsA (10 mg/kg/day) in dogs undergoing experimental reanl transplantation^{104a} Rejection occurred at 4 mg/kg; mean survival time increased from 9 days (non-immunesuppressed dogs) to 16 days at 4 mg/kg, 28 days at 8 mg/kg. The addition of CsA at 10 mg/kg to leflunomide at 4 mg/kg increased survival time to 68 days. Mean trough leflunomide concentrations ranged from 10 µg/mL (2 mg/kg) to 55 µg/mL (16 mg/kg).^{104b} A recent retrospective study examined the efficacy of leflunomide for treatment of naturally occurring immune-mediated polyarthritis in dogs. 104c At an initial starting dose of 3.0 ± 0.5 mg/kg orally once a day for 1 to 6 weeks, 8 of 14 dogs had complete resolution, and 5 partial resolution. No animal exhibited adverse reactions.

Emerging Drugs

The sphingosine-1-phosphate receptor (S1PR)¹⁰⁵ antagonists are a new class of drugs that decrease recirculation of lymphocytes from the lymphatic system to blood and peripheral tissues. These drugs will not be used as monotherapy, but they have shown efficacy in human medicine when combined with CsA, glucocorticoids, and other drugs. Lymphopenia is the most common side effect and is reversible when the drug is discontinued. However, it may also act as a negative chronotrope.

Hormones

Glucocorticosteroids (see Chapter 30) possess both antiinflammatory and immunomodulatory capabilities. Immunomodulation results in actions at a variety of targets in acquired immunodeficiency syndrome. Selected progestational compounds (e.g., megestrol acetate) have been used for their general immunosuppressive effects. Megestrol acetate (discussed in Chapter 19) may have longer and more potent antiinflammatory effects compared with glucocorticoids¹⁰⁶; however, in the cat, the species for which these products tend to be used, side effects can be dramatic and life threatening. Thus their use is recommended only for conditions that will not or have not responded to glucocorticoids. Medroxyprogesterone exhibits glucocorticoid-like effects, which reflect, in part, actions at the level of DNA transcription. The impact of glucocorticoids on DNA transcription was previously reviewed (see Chapter 30); those glucocorticoids that target trans (rather than cis) repression (rather than activation) are directed toward desirable effects, avoiding many undesirable metabolic effects. Medroxyprogesterone appears to potentially focus on undesirable effects inflammatory responses, being characterized by a preponderance of transrepression activity rather than transactivation or cis activity.¹⁹

Danazol (5 mg/kg 2 to 3 times orally per day) is classified as an androgen but is characterized by weak androgenic activity. In human patients danazol has proved effective in stimulating increased concentrations of complement inhibitor and thus is indicated for treatment of angioneurotic edema.¹⁰⁷ Danazol also has immunomodulatory effects that are of benefit in type II immune complex diseases. Danazol apparently decreases the expression of or blocks Fc receptors on macrophages; initial displacement of glucocorticoids owing to competition of binding sites is less likely to be effective as glucocorticoid clearance increases.¹⁰⁸⁻¹¹¹ The drug has proved useful in a number of type II immune-mediated diseases, including IMHA (autoimmune hemolytic anemia) and immune-mediated thrombocytopenia.^{11,108,112,113}

Cytotoxic Drugs: Antimetabolites and Other Antineoplastic Agents

Antimetabolite and alkylating antineoplastic agents (see Chapter 33) are also used as chemical immunosuppressants by virtue of their effects on actively dividing cells.^{114,115} Their effects should, however, be regarded as nonspecific. Macrophages, activated T and B cells, and NK cells are the targets of most of the drugs. Those most commonly used for their immunomodulatory effects are cyclophosphamide and azathioprine. In general, neither drug is sufficiently immunomodulatory and safe for use as the sole agent.

Cyclophosphamide is a nitrogen mustard. Its immunomodulatory effects reflect the same mechanism of action as its anticancer effects. Cyclophosphamide alkylates DNA in both proliferating and nonproliferating cells; proliferating cells are more susceptible to alkylation. Both B and T cells are impaired. Because B cells recover more slowly, however, cyclophosphamide inhibits the humoral response more than the cell-mediated response.⁴ Note that at very high doses cyclophosphamide can actually induce tolerance to an antigen to which the patient has been exposed. Toxicities of cyclophosphamide are typical of drugs that target proliferating cells. In addition, hemorrhagic cystitis has been reported in dogs receiving the drug. Cyclophosphamide therapy should be discontinued if the neutrophil or platelet counts decrease less than 2000/L or less than 100,000/L, respectively.

Azathioprine interacts with nucleophils to form 6-mercaptopurine, which is converted to nucleotides. The nucleotides interfere with purine synthesis or cause DNA damage. The drug is available for both oral and intravenous administration. Co-administration with allopurinol increases the risk of toxicity. Toxicity results from inhibited growth of

rapidly growing cells, including cells of the bone marrow and gastrointestinal tract. The association of thiopurine methyltransferase (TPMT) activity and risk of azathioprine-induced neutropenia in dogs is not clear. Difficulty in identifying a relationship is compounded by the low incidence of deficiency (not detected in 470 dogs). The lack of relationship is supported by the finding of severe azathioprine-associated myelosuppression (marked leukopenia, neutropenia, or thrombocytopenia) in six clinically ill dogs classified as nondeficient. Further, an intermediate classification of TPMT (14 to 38 nmol/gHb/ hr) in hunting dogs was associated with a decrease in white blood cells after 30 days of azathioprine therapy (2.2 mg/kg orally once daily) but not severe clinical signs of bone marrow depression. As such, a TPMT deficiency may predispose to azathioprine toxicity, but other factors appear to play an important role.116 Cats are much more sensitive to the toxic effects of azathioprine. Although the drug has been used in cats (0.3 mg/kg daily), reformulation may be necessary for accurate dosing. Care must be taken to ensure that the dose is compounded accurately.

Chlorambucil (starting oral dose of 0.1 to 0.2 mg/kg/ day) is also a nitrogen mustard, and its cytotoxic effects are similar to those of cyclophosphamide. The drug is available in an oral preparation that allows accurate dosing in cats.¹⁰⁶ In contrast to cyclophosphamide, chlorambucil's myelosuppression is only moderate and gradual. Toxicities are rare in cats.¹⁰⁶ The incidence of gastrointestinal side effects can be reduced by alternate-day dosing. In human patients, however, excessive doses can cause hypoplastic bone marrow. Its effects (e.g., in chronic lymphocytic leukemia) are gradual in onset.¹¹⁷ Therapeutic indications include chronic, refractory immune-mediated disorders, including pemphigus foliaceus and refractory cases of feline granuloma complex.

Vincristine is used to treat immune-mediated thrombocytopenia because of its ability to cause the maturation and release of mature thrombocytes from the bone marrow by stimulation of megakaryocyte endomitosis. Other anticancer drugs used for immunomodulatory effects include methotrexate, and vinblastine. The nonspecific effects of anticancer drugs on the immune system and other rapidly dividing cells limit their use on account of host toxicity (primarily bone marrow and gastrointestinal). A major indication for immunomodulation of these drugs is combination with glucocorticoids for treatment of autoimmune diseases. Vinblastine is another vinca alkaloid that has been used to treat type II hypersensitivities, specifically IMHA. Like danazol, vinblastine appears to decrease expression of Fc (IgG) receptors on macrophages.^{110,111} The effects of vinblastine (weekly doses during induction followed by monthly doses during maintenance) when combined with danazol (given at 2 to 3 up to 10 mg/kg daily) proved effective for treatment of 63% of human patients with chronic idiopathic thrombocytopenic purpura.¹¹⁰

Gold Therapy

Gold has been used for centuries as an elemental agent for the control of pruritis.¹¹⁸ Gold compounds are characterized by gold attached to sulfur (aurothio group) and include the more

water-soluble compounds aurothioglucose and gold sodium thiomalate and the lipid-soluble compound auranofin. These compounds suppress or prevent inflammation of the joint and synovium associated with a number of infectious or chemical causes. The mechanism of action is not clear but may be inhibition of the maturation and function of mononuclear phagocytes and T cells. Gold is sequestered in mononuclear phagocytic cells. Other proposed but not generally accepted mechanisms include inhibition of prostaglandin synthesis, collagen linkage, complement activation, and a variety of lysosomal and other enzymes.¹¹⁸

The disposition of the gold compounds has not been studied in animals other than humans; these data provide the basis of discussion. Disposition varies with water solubility. Watersoluble compounds (not prepared in oil) are rapidly absorbed after intramuscular administration, with peak concentrations occurring in 2 to 6 hours. Oral absorption is erratic and not predictable for the water-soluble compounds but is more predictable for auranofin, the hydrophobic compound. Distribution varies with the compound and duration of therapy. The gold is bound (95%) to albumin in blood, but eventually concentrations in selected tissues (inflamed synovium) approximate 10 times that in plasma. For the water-soluble gold compounds, elimination rate constants and half-lives also vary with dose. In humans the plasma half-life is 7 days at a 50-mg total dose, but it increases to several weeks to months with prolonged therapy. Concentrations can be detected in the blood for 60 to 80 days after therapy is discontinued and for up to 1 year in the urine. Concentrations probably are detectable in the liver and skin several to many years after therapy is discontinued. Excretion is predominantly (60% to 90%) renal, with the remaining eliminated in the feces. For auranofin plasma concentrations tend to be lower, and accumulation is much less (20%) than that of the water-soluble compounds, probably because of less tissue binding. Auranofin is eliminated principally in the feces.

Toxicity, manifested as skin or mucocutaneous lesions, occurs in 15% of human patients. Lesions include stomatitis, pharyngitis, tracheitis, colitis, gastritis, and vaginitis. Gray to blue pigmentation may occur in the skin. The likelihood of toxicity is concentration dependent but not based on gold concentration. Whereas proteinuria occurs in up to 50% of human patients receiving gold therapy, renal dysfunction (as a result of proximal tubular damage or gold-induced glomerulonephritis) occurs in 10% or less. Lesions tend to be resolvable if therapy is discontinued before damage is too severe. Thrombocytopenia, which is thought to reflect increased destruction, occurs in a very small percentage of human patients. A number of miscellaneous side or toxic effects that resolve when therapy has been discontinued also have been reported. These include encephalitis, peripheral neuritis, hepatitis, and pulmonary infiltrates. In general, although auranofin is better tolerated than the water-soluble compounds, the incidence of gastrointestinal disturbances (diarrhea, abdominal cramping) is greater. The incidence of side effects and their seriousness can be minimized by regular physical examination. In addition, therapy should be initiated with a small dose that is gradually increased to the maintenance dose. As the dose is increased, treatment should temporarily cease until clinical signs of moderate to severe toxicity resolve. The risk of restarting therapy should be balanced with the need for therapy. Antihistamines or glucocorticoids might decrease the incidence. Dimercaprol, a heavy metal chelating compound, can be used if severe side effects persist after therapy has been discontinued.

The major indication for chrysotherapy in human patients is rheumatoid or other arthritis that has not responded to nonsteroidal antiinflammatory drugs or other therapy. The compounds slow the progression but do not cure disease. The usual human dose is 10 mg of the water-soluble compounds the first week followed by 25 mg the third and fourth weeks and 25 to 50 mg weekly thereafter to a cumulative 1-g dose. Response may take several months. The standard human dose for auranofin is 3 to 6 mg up to 9 mg divided in two to three doses or given once daily. Small animal doses are discussed with dermatologic disorders in this chapter. Wolheim¹¹⁹ has discussed mechanisms by which rheumatic human patients become refractory to gold therapy. Induction of the efflux protein P-glycoprotein appears to play a major role.

Immunostimulant Drugs

Immunostimulants are indicated for immunodeficient animals. As with immunosuppressants, immunostimulants can target either humoral or cell-mediated immunity. The lack of specificity has limited the widespread use of immunostimulants. In general, response to immunostimulants is mild.

Immunostimulants of Microbial Origin

Bacteria and fungal microbes generally nonspecifically stimulate several aspects of the immune response. Macrophage, cytotoxic T cell, T_h cell, and B cell activities are enhanced, whereas T cell suppressor activity is decreased. Enhanced activity reflects, in part, increased activity of chemical mediators such as TNF α and IFN. The nonspecific enhancement of immune function can be used therapeutically. Adverse effects can be minimized by administration of killed organisms or selected microbial fractions, which stimulate the response while avoiding infection. A variety of mycobacterial products have been used to nonspecifically stimulate the immune system.^{23,120} The classic biological response modifiers include Bacillus Calmette–Guérin (BCG) and *Propionibacterium acnes* (*Corynebacterium parvum*).

Bacillus Calmette–Guérin

BCG is a live, attenuated strain of *Mycobacterium bovis*.⁴ Components of the bacterial cell wall of this organism activate B and primarily T cells; macrophage and neutrophil recruitment in response to lymphokine release results in a granulomatous reaction. The antiviral state induced by BCG appears to be essentially a nonspecific expression of a more or less prolonged stimulation of the immune system. The most likely mechanism for its antiviral activity is direct stimulation of the mononuclear phagocytic system; however, specifically sensitized T lymphocytes that further activate macrophages are generated after a period of time. Stimulated macrophages release colony-stimulating factor, which contributes to macrophage regulation, and IL-1, which promotes lymphocyte proliferation. The antiviral state is thus an indirect benefit of an essentially pathologic, although temporary, situation; the host is characterized by an increased ability to handle viral infections. BCG requires at least 10 days after inoculation to enhance resistance against viral infections. The state of enhanced resistance is, however, long-lasting; repeated administrations (of nonliving product) may lead to a more prolonged and marked effect.¹²⁰

BCG has been used as an adjuvant in combination with tumor vaccines for dogs and cats. Tumors that undergo remission after BCG therapy may do so as a result of the release of tumor-specific antigens during nonspecific tumor lysis. The use of BCG has been studied in combination with a tumor vaccine. In human patients use of BCG as an adjuvant for anticancer therapy has focused primarily on intravesicular administration in bladder cancer.⁴

Muramyl Dipeptide

Muramyl dipeptide is a peptidoglycan and represents the smallest immunologically active component of the *Mycobacterium* cell wall. Like BCG, it nonspecifically enhances B cell, T cell, and macrophage activities. Because it is rapidly eliminated from the body, it is biologically modified to prolong its actions by incorporation into liposomes or conjugation with glycoproteins. Synthetic production has increased accessibility for clinical use.

Mycobacterium

Regressin-V. An emulsion of mycobacterial cell wall fractions, Regressin-V is licensed for the treatment of mixed mammary tumors and mammary adenocarcinoma in dogs and sarcoidosis in horses. The following information was supplied by the manufacturer. Regressin-V contains trehalose dimycolate and muramyl dipetide, which induce IL-1 and tumor necrosis factor- α secretion from monocytes and macrophages and activate T lymphocytes in a variety of species. In a study of seven dogs with mammary adenocarcinoma, complete remission was induced in five, with tumor-free survival times of 3 to 19 months; dogs were then lost to follow-up. There are no data suggesting that Regressin-V had any effect on metastatic disease.

The manufacturer recommends treating canine mammary tumors once 2 to 4 weeks before surgical excision. Fever and malaise may occur after injection. Surgical removal of the tumor creates cosmetic improvement (necrosis and draining of the tumor may be present for weeks); however, survival time is not significantly improved with surgery. If surgery is not performed, therapy can be repeated every 1 to 3 weeks for up to four treatments.

Mycobacterium vaccae

Ricklin Gutzwiller and coworkers¹²¹ prospectively studied the impact of a single intradermal injection of heat-killed *Mycobaterium vaccae* on the severity of atopic dermatitis in dogs (n = 62). A double-blinded, placebo-controlled, parallel multicenter study design was used. Dogs were evaluated for 3 months. Skin lesions were scored on the basis of CADESI. The treatment was well tolerated. Treatment was effective in patients with mild or moderate dermatitis but did not affect animals classified as severe. Interestingly, the CADESI scores decreased by 22% in the placebo group (versus 33% in the treatment group).

Propionibacterium acnes

A killed suspension containing P. acnes (formerly C. parvum: Immunoregulin) has been approved for veterinary use (15 µg/kg intravenously biweekly for two to three treatments). Like BCG, it causes complex, nonspecific immunostimulation. Macrophage and cytotoxic T cell activities are enhanced, as is antibody production by both thymus-dependent and thymus-independent antigens. Cell-mediated immunity is also stimulated. It is indicated for the treatment of clinical signs associated with virus-induced and bacteria-induced immunosuppression, such as that caused by FeLV. The efficacy of P. acnes in the treatment of feline infectious peritonitis virus is questionable. One study was unable to demonstrate a difference in survival rate or mean survival time between untreated and treated animals experimentally infected with a high dose of feline infectious peritonitis virus. Studies investigating the antitumor effects of Propionibacterium acnes in dogs do not support its efficacy against early neoplasia, although it may be more effective in advanced disease when used in combination with other drugs.²⁵ Cats infected with FeLV and afflicted with various non-neoplastic diseases showed some signs of response to treatment with P. acnes (Immunoregulin), although no cat reverted to an FeLV-negative status.²³ Studies regarding the efficacy of P. acnes in FeLV-induced tumors apparently have not been done.25

Staphylococcal Protein A

Staphylococcal protein A (SpA) is a cell wall polypeptide of S. aureus Cowan I (SAC) that binds rapidly and with great affinity to immune complexes. Other regions of the molecule initiate T lymphocyte and B lymphocyte proliferation as well as secretion of soluble lymphocytic products such as IFN. Circulating immune complexes have been incriminated as "blocking factors" that aid in a tumor's escape from immunologic control. Therapeutic trials of the efficacy of SpA have been based on the hypothesis that removal of specific or nonspecific immunosuppressive molecules such as blocking factors will enhance host immune response to the tumor. Other regions of the SpA molecule initiate T lymphocyte and B lymphocyte proliferation and secretion of soluble lymphocyte products such as IFN. Treatment with SpA is achieved by extracorporeal perfusion of host plasma over whole SAC organisms or through filters containing purified SpA. Studies have shown that SpA or SAC treatment reduces tumor size, decreases levels of circulating immune complexes, and induces the appearance of cytotoxic antibodies directed toward neoplastic cells. A study in which SpA was used to treat FeLV-infected cats found that 50% of cats with FeLV-associated disease improved, and 33% of cats afflicted with malignant disease responded with reductions in tumor size as well as in bone marrow and peripheral blood neoplastic cells.^{23,25,122,123} Viremia was cleared in 28% of treated cats. Circulation of a γ -like IFN was demonstrated in some cats that responded to SpA and was followed by the appearance and rising titer of complement-dependent cytotoxic antibody. The antibody reacted with FeLV-infected cells and was specific for the major viral envelope glycoprotein gp70. The ability of cats to persistently remain FeLV negative appeared to correlate with the magnitude of FeLV antibody titer.²⁵

Mixed Bacterial Vaccines

Mixed bacterial vaccines composed of *Streptococcus pyogenes* and *Serratia marcescens* have been studied in cats with malignant mammary tumors. Although not statistically significant, survival time was greater (875 days) when surgery was combined with mixed bacterial vaccines versus surgery alone (450 days).

Immunostimulants of Natural Origin

Cytokines

Biological response modifiers of natural original also are discussed in Chapter 32. A number of cytokines produced by leukocytes and related cells actively regulate the immune system. Recombinant DNA technology has led to widespread production and greater application of drugs that modulate cytokines or their receptors or transcription factors in the treatment of immunologically based disease. The cytokines most likely to be used for immunostimulatory effects include the IFNs and selected interleukins.

Passive Immunotherapy: Antibodies

Passive immunotherapy with monoclonal or polyclonal antibodies has been investigated for both the diagnosis and therapy of cancers. Antibodies are directed toward surface antigens expressed by tumor cells. Specificity of antibodies (as long as Igs are derived from the species intended to be treated) should limit host toxicity to those cells expressing the antigen (i.e., tumor cells), thus avoiding systemic toxic effects. The antibodies themselves may be directly toxic to the cell or induce complement-dependent cytotoxicity. In addition, antibodies can be conjugated to drugs, toxins, or radioisotopes toxic to tumor cells, thus limiting the specificity of a variety of pharmaceuticals for tumor cells.

Igs available in plasma obtained from donors generally contain detectable antibodies against bacterial, fungal, and viral pathogens.⁴ Passive transfer of resistance to the immunodeficient patient can be accomplished with intramuscular or intravenous administration. In human patients the half-life of transferred Igs is approximately 3 weeks.⁴ Indications for human patients have included congenital or acquired states of immunodeficiency, selected hematologic disorders such as autoimmune hemolytic anemia, infectious viral diseases, and selected neoplastic diseases such as chronic lymphocytic leukemia and multiple myeloma. Potential adverse reactions include anaphylaxis and transfer of infectious organisms.⁴ Studies investigating the efficacy of passive immunotherapy on feline lymphosarcoma have thus far been limited to the use of polyclonal FeLV-neutralizing antibodies, feline oncornavirus-associated cell membrane antigen (FOCMA) antibodies, or both in cats afflicted with lymphosarcoma and leukemia. In one study five of seven cats treated with both antibodies and six of eight cats treated with FOCMA antibodies alone underwent partial or complete regression of their disease.²⁵ Additional studies by Cotter and coworkers¹²⁴ suggest that polyclonal anti-FOCMA therapy combined with previously established chemotherapeutic regimens may improve remission time. Monoclonal antibodies have been used to treat canine lymphosarcoma.

Human intravenous immunoglobulin (hIVIG) has been studied in dogs using in vitro (lymphocytes and monocytes) and in vivo (spontaneous immune-mediated diseases) methods. Prepared from plasma of healthy donors, it contains polyspecific IgG and is intended to treat primary immunodeficiencies. In vitro studies¹²⁵ have shown hIVIG to bind to canine lymphocytes and monocytes and to inhibit through Fc-mediated binding monocyte phagocytosis, including that of antibody-coated red blood cells. It is administered as an intravenous infusion (0.5 to 1.5 g/kg) over 6 to 12 hours, and animals must be closely monitored for signs of anaphylaxis or other adverse reactions (e.g., thromboembolism). Clinical evidence of efficacy exists for treatment of IMHA,126-128 with treated dogs developing an increased hemoglobin and hematocrit concentration up to 4 weeks after therapy. However, 50% of treated animals developed thrombocytopenia and five of seven dogs that died had evidence of thromboembolism. Only 3 of 10 dogs were alive at 12 months, suggesting that longterm survival was not improved. The combination of IgG with IFN α resulted in greater improvement in human patients with hepatitis C.129

Abetimus is a synthetic molecule consisting of four doublestranded oligodeoxyribonucleotides attached to polyethylene glycol (PEG). The nonimmunogenic PEG serves as the carrier. Abetimus induces tolerance to B cells by cross-linking surface antibodies directed toward double-stranded DNA (dsDNA). These antibodies appear to be associated with nephritis associated with systemic lupus erythematosus in humans.¹³⁰ In a preapproval clinical trial, the number of renal "flares" in patients receiving the drug was less than half of that encountered in patients not receiving the drug. The response was so dramatic that the trial was discontinued before its completion, and the FDA granted orphan drug status in 2000.¹³⁰

Allergen-Specific Immunotherpy

Allergen-specific immunotherapy (ASIT) involves the administration of gradually increasing amounts of an allergen extract to patients allergic to the allergen to resolve symptoms associated with subsequent exposure to the allergen.¹³¹ In their review Colombo and coworkers¹³¹ note that when success is defined as a 50% (or greater) increase in the improvement of clinical signs after 4 months or more of therapy, ASIT is successful in 50% to 100% of cases of canine atopic dermatitis. They prospectively evaluated the effect on canine atopic dermatitis of low ($\frac{1}{10}$ the standard) dose induction followed by maintenance ASIT therapy (n = 27) to standard therapy (n = 13). Both groups responded, and neither group emerged as responding better at 9 months. Secondary infections were treated, and use of glucocorticoids was allowed to control severe clinical signs, except during the last 3 months of the study.

Miscellaneous Blood Components

Selective destruction of malignant lymphocytes occurs in several species in response to infusion of blood or blood components.

Antileukemic activity. Antileukemic activity (ALA) of humoral factors in serum, heparinized plasma, and whole blood has been documented in several species.²⁵ Evidence suggests that ALA of blood constituents may be present in high concentrations in cryoprecipitates prepared from heparinized plasma. Physicochemical constituents of the cryoprecipitate that might be the source of ALA include cold-insoluble globulin, fibronectin, cell surface protein, large external transformation-sensitive protein, and opsonic factor.²⁵ A study in 32 cats revealed that of 24 treated with either normal cat serum or whole blood (20 mL/kg), 14 had a complete antileukemic response and 8 had a partial response. Of 10 treated with cryoprecipitate, two completely responded and six had a partial response.¹³²

Fibronectin. Fibronectin injections have resulted in the regression of leukemic nodes in mice, suggesting that fibronectin may be the source of ALA. Fibronectin, a glycoprotein dimer, is a major protein of both blood and tissues; its most important function appears to be tissue remodeling during embryogenesis and wound healing. Antitumor activity may result from immunomodulation and modification of metastasis. Enhancement of opsonization increases the phagocytic ability of macrophages and monocytes, thus enhancing their tumoricidal activity. MacEwen²⁶ studied the efficacy of fibronectin (0.5 to 2 mg/kg intravenously once daily) in 18 cats afflicted with lymphosarcoma. A 50% response rate was reported; one FeLV-positive cat converted to a negative status after treatment.²⁵ A single case of mycosis fungoides in a cat responded to a combination of intravenous and intralesional fibronectin. Intralesional injections caused local epithelial necrosis, which reduced the tumor load by 75% and may have prevented systemic involvement.133

Tumor cell vaccines. Tumor cells are thought to stimulate an immune response. This view is supported by the recognition that some tumors spontaneously regress; tumors are infiltrated with cells of the immune system, and the risk of cancer increases in the patient that is immunosuppressed. The antigenic potential of tumor cells is also the basis for the use of tumor cell vaccines. Tumor cell vaccines are most effective in the presence of residual disease and when combined with nonspecific immunomodulators. Parodi and co workers ^{133a} could not find a statistical improvement in cumulative survival rates in dogs with mammary tumors receiving BCG intralesionally alone (n = 51) or *Corynbacterium parvum* (killed) (n = 120) Jeglum and coworkers have treated cats afflicted with mammary adenocarcinoma using a combination of an autogenous tumor vaccine and BCG. Although not significantly different, the mean survival time for each treatment group was least for those treated with surgery, BCG, and tumor cell vaccine compared with animals treated with either surgery alone or surgery with BCG. Additional studies with tumor cell vaccines are necessary before their efficacy can be established.

Non-steroidal hormonal agents. Hormonal agents may offer a unique avenue of immunomodulation in viral diseases.^{23,134} Hormones investigated for their immunomodulatory effects include prostaglandins and thymic proteins. Prostaglandins are local hormones that modulate both T and B lymphocytes. Prostaglandins, however, particularly prostaglandin E_2 , are also immunosuppressants, and their role in immunopotentiation is limited. Thymosins are a group of endogenous substrates released from the thymus that stimulate the release of several pituitary neuropeptides. Thymic hormones induce maturation of T cell precursors, promote differentiation and proliferation of mature T cells, and thus restore rather than potentiate the immune system. Several synthetic thymic peptides have been synthesized by either chemical means or genetic engineering techniques. The primary clinical application of these proteins is restoration of the immune system in the immunoincompetent (including virally induced) patient.

Acemannan. Acemannan (Acemannan Immunostimulant) is a long-chain polydispersed $\beta_{1,4}$ -linked mannan-based polysaccharide derived from the aloe vera (*barbadensis Miller*) plant. It stimulates the release of IL-1, IL-6, TNF- α , IFN- γ , and nitric oxide from macrophages, leading to tumor apoptosis and necrosis.^{135,136} Other actions include enhancement of macrophage phagocytosis and cytotoxicity and interference with glucosidase I activity, leading to the production of abnormal glycoproteins by neoplastic cells, which appears to be associated with tumor cell death. Direct antiviral activity is associated with modified glycosylation of both virus-infected cells and glycoprotein coats of viruses, leading to inhibition of virus infectivity and replication.

Acemannan is licensed for the treatment of fibrosarcoma in dogs and cats. Intratumoral injection induces tumor encapsulation and necrosis, facilitating surgical excision. The recommended dosage is 2 mg intratumorally and 1 mg/ kg intraperitoneally weekly for 6 weeks. No adverse effects of acemannan have been reported at the recommended dosage. In one report eight dogs and five cats with fibrosarcomas were treated with acemannan, surgical excision, and radiation therapy. Seven animals remained tumor-free at 440 to 603 days, with a median survival time of 372 days.¹³⁷ In an earlier clinical report, a variety of other carcinomas and sarcomas were also reported to respond.¹³⁸ It is not known what effect acemannan has on feline vaccine-associated sarcomas.

Acemannan has been used to treat cats with FeLV and feline immunovirus infections. Clinically affected cats treated with acemannan had improved quality of life and longer survival times than historical controls. Interestingly, oral administration of acemannan appeared to have the same efficacy as parenteral administration of acemannan, which is similar to cats treated with low-dose oral recombinant human IFN- α .

Synthetic Immunostimulants

Levamisole

Levamisole, a phenylimidazothiazide anthelmintic, has been the subject of intense and controversial research as a biological response modifier.^{23,120} It is difficult to summarize the experimental and clinical data regarding the immunomodulating capabilities of levamisole. Levamisole has been regarded by some as a chemical agent capable of mimicking hormonal regulation of the immune system. It appears to stimulate recruitment and function of macrophages and T cells but only within a narrow range of doses and duration of administration in either the normal or immunoincompetent patient. Levamisole appears to alter cyclic nucleotide phosphodiesterases, decreasing cyclic guanosine monophosphate degradation and increasing cyclic adenosine monophosphate degradation. Elevated cyclic guanosine monophosphate in lymphocytes enhances proliferation and secretory responses. Chemotaxis, phagocytosis, lymphokine synthesis, and the ratio of helper to suppressor T cells are increased. Levamisole does not appear to have any effect in immunocompetent animals. The modulatory effects of levamisole range from enhancement to inhibition with much strain, sex, age, and antigen variability. T cell stimulation may be mediated by a soluble serum factor. Experimental studies generally have not supported the benefits of levamisole as have clinical studies. Levamisole (2 to 15 mg/kg) was frequently tested prophylactically in experimental trials, however, as opposed to therapeutically (i.e., in infected patients) in clinical trials, suggesting that potential benefits of levamisole result from restoration of immunocompetence after virally induced immunosuppression. Indications for levamisole in human medicine include Hodgkin's disease and rheumatoid arthritis and as an adjuvant chemotherapy of colorectal cancer.⁴ The use of levamisole for treatment of cancer in animals is not supported. In two studies involving more than 130 cats with malignant mammary tumors, levamisole (5 mg/kg orally on 3 alternate days per week) did not increase survival time or decrease recurrence rate.139 Levamisole causes adverse reactions typical of excessive cholinergic stimulation.

Cimetidine

Histamine exerts immunomodulatory effects, including suppression of cytotoxic T lymphocytes, downregulation of cytokines, and activation of suppressor T lymphocytes.¹⁴⁰ Cimetidine is a histamine (H₂) receptor antagonist that experimentally enhances a variety of immunologic functions. Suppressor T lymphocytes possess H₂ receptors, which, when blocked, result in potentiation of cell-mediated immunity. Although more studies are indicated, cimetidine may be useful in a variety of conditions associated with immunosuppression. Because it selectively inhibits suppressor function, however, cimetidine also may prove deleterious to patients with autoimmune disorders.

The anticancer effects of cimetidine have been studied in selected human cancers. The H_2 receptor blockers have been studied for their effects on gastric cancer cells. Cimetidine,

but not famotidine, exhibits antiproliferative effects on gastric cancer cells. Raniditine showed some inhibitory effects.¹⁴⁰ Cimetidine also appears to inhibit the growth of colorectal carcinoma;¹⁴¹ lymphocyte infiltration increases in the cancers and is associated with an improved survival rate in patients receiving the drug.

Miscellaneous Immunostimulants

A variety of compounds are capable of inducing IFN; however, the immunomodulating effects of the inducers are variable. For example, double-stranded IFN-inducing polyribonucleotides (poly I:C) cause immunostimulation, whereas tilorone, a simple synthetic IFN inducer, enhances antibody production while depressing cell-mediated immune responses. Many other drugs are in the experimental phases of drug development. The following sections address some of the drugs that may or may not ultimately become approved.

ABPP (Bropirimine)

ABPP (2-amino-5-bromo-6-phenyl-4[³H]-pyrimidinone), approved for use in humans, is a potent inducer of IFN in several species. Hamilton and coworkers¹⁴² characterized the kinetics of ABPP and induced IFN in several species. They found that serum levels of IFN after treatment correlated well with serum concentrations of ABPP in the cat. ABPP was lethal in three of eight cats, however, at doses required to achieve minimal detectable levels of IFN. The authors postulated that the toxicity resulted from conversion of ABPP to phenolic derivatives that the cat excretes inefficiently.

Isoniplex

Isoniplex is an antiviral drug (see Chapter 10) that may also be used as an immunopotentiator in viral diseases.^{23,120} Isoniplex enhances immune responses, including promotion of mitogen-stimulated T-lymphocyte proliferation and augmentation of antibody production and delayed-type hypersensitivity. The suggested mechanism of immunopotentiation by isoniplex begins with penetration of lymphocytes and suppression of viral RNA synthesis. It appears to support lymphocyte function by promoting RNA synthesis and translational ability. Further investigations regarding the use of isoniplex in viral infection should be anticipated because its efficacy results from an ideal combination of antiviral activity and immunopotentiation.

Promodulin

Promodulin is an experimental immunomodulating agent that has been subjected to clinical therapeutic trials for the treatment of cats concurrently infected with FeLV and feline infectious peritonitis.²³ Cats were treated with 50 mg/kg (up to 200 mg maximum dose) intravenously once daily for 5 consecutive days. Although promodulin induced rapid remission of clinical signs associated with feline infectious peritonitis, (e.g., anorexia, fever, and serosal effusions), it did not appear to be effective in the treatment of concurrent FeLV infections. Cats that responded did so within 2 weeks of the final injection; the duration of clinical signs after exacerbation of disease did

not respond to a second treatment regimen. Promodulin also was not effective in treating FeLV-induced solid tumors.

Topical immunomodulators. Topical immunomodulators often are characterized by unique mechanisms. These include topical contact sensitizers (e.g., diphencyprone or dinitrochlorobenzene) and induction of mononuclear cell cytokines (IL-12, TNF- α) secretion (imidazoquinolines imiquimod and resiquimod). These latter drugs lead to T_h1-domination and a cell-mediated response used in humans to treat local viral infection and cancers.

Imidazoquinolines

Imiquimod and resiquimod (R-848) are members of the family imidazoquinolines. These drugs have proven antiviral and antitumor effects in a variety of animal models. Their immune actions appear to reflect stimulation of several arms of both innate and adaptive immunity, ultimately resulting in an indirect T_h -1 dominant response. Their ability to enhance cutaneous-adaptive responses and innate immunologic responses are key to their usefulness. Resiquimod is 10- to 100-fold more potent than imiquimod and is also capable of stimulating granulocyte and macrophage colony-stimulating factors and other mediators. Antigen processing also is improved. Indications include cutaneous viral infections and potentially nonmelanoma skin cancers, with the latter having potential therapeutic applications in animals.¹⁴³

TREATMENT OF SPECIFIC IMMUNE-MEDIATED DISEASES

See also discussion of each syndrome in the appropriate chapter.

Chronic Allergic Diseases

Atopy refers to a genetic tendency toward certain hypersensitivity or allergic diseases. Atopic diseases include asthma, rhinitis, and dermatitis. Chronic allergic disease are generally complex in pathophysiology, with inflammatory disease manifested in the organ in which antigen–tissue interactions are initiated. For example, for asthma, inflammation causes airway narrowing associated with contraction and hypertrophy of bronchial smooth muscle, swelling of mucous membranes, and excessive production of mucus.

Mediators released during inflammation are the major contributors to the pathogenesis of pulmonary disease, particularly feline asthma. Mediators important in the pathogenesis of asthma include preformed mediators histamine and serotonin (particularly in cats); mediators formed in situ, including prostaglandins, leukotrienes, and platelet-activating factor; and reactive oxygen species.

The three atopic syndromes are characterized by common cell and mediators of inflammation in humans (see Figure 31-2).^{121,144-147} A similar pathophysiology should be anticipated for other allergic diseases. The role of T (CD4+ helper) cells has been well described in the initiation and maintenance of allergic diseases, particularly asthma. In contrast to systemic immune-mediated diseases, in which T_h1 cells appear to be

the biggest contributors of inappropriate response, T_h2 cells appear to be particularly important to allergic diseases. Their cytokines include interleukins and chemotactants that contribute to the inflammatory process. These include IL-4, which increases IgE synthesis; IL-5, which stimulates eosinophil growth and differentiation; IL-9, which causes mast cell differentiation; and in the lungs IL-13, which causes production of mucus and airway hyperactivity. Of these, IL-4, IL-10, and IL-13 in particular, have antiinflammatory activity. Previously, T_h1cells were thought to be beneficial by downregulating T_h2 cells. However, they are probably proinflammatory and, along with IFN (IFN) γ , contribute to the inflammatory process. The role of leukotrienes, and particularly cyst-LTs, are increasingly being described in atopic diseases.¹⁴⁸ In the lungs they are very potent (being 1000 times more so than histamine), causing marked edema, inflammation, and bronchoconstriction. In the gastrointestinal tract, their effects on neutrophils are necessary for ulcer formation; vasoconstriction and platelet aggregation probably contribute further. Senter and coworkers¹⁴⁹ found that 50% of atopic dogs responded to zafirlukast, supporting the possible role of leukotrienes as targets of treatment for atopy.

Treatment of inflammatory allergic diseases focuses on control of inflammation and clinical signs at the level of the target tissue. However, treatment of all three atopic disorders increasingly focuses on systemic rather than simply a local allergic disease. In particular, the bone marrow response to allergens and subsequent release of eosinophils are recognized to be an important systemic process in allergic inflammation. A central role of eotaxin and IL-5 has been suggested. Eotaxin released from local tissue cells stimulates, exclusively through CC chemokine receptor 3 (CCR3), flux of eosniophils into the target tissue.¹⁵⁰ Both IL-4 and TNF- α stimulate its release. T_h2 cells release IL-5; other sources include mast cells and eosinophils. In response to IL-5, eotaxin is released. In human patients with allergic diseases, both are increased in serum. The effects of these signals are not limited to the affected tissue. Rather, the primary significance may be their effects at the level of the bone marrow stroma, another source of IL-5. Among the functions of IL-5 are differentiation and maturation of progenitor cells to eosinophils and basophils, release of mature eosinophils, promotion of their survival, and inhibition of apoptosis. Activated eosinophil progenitor cells contain granulocyte-macrophage colony-stimulating factor and IL-5. Their circulation increases in allergic human patients and in dogs rendered hypersensitive to A. suum.¹⁵¹

Cysteinyl-LTs are necessary for accumulation of eosinophils in target tissues. However, in addition to their local effects, cyst-LTs may also have a role in bone marrow perpetuation of allergic disease. Cyst-LT receptors are expressed on a number of bone marrow progenitor cells and appear to be involved (based on effects of antagonists) in eosinophil– basophil progenitor differentiation. They appear to stimulate eosinphil proliferation in the presence of stimulatory cytokines.¹⁵²

The commonalities of atopic diseases offer several targets of therapy. The efficacy of glucocorticoids can be appreciated from several aspects, their use is discussed in Chapter 30. However, a number of "second tier" drugs might be used for their glucocorticoid dose-sparing effect or in animals intolerant to or minimally responsive to glucocorticoid therapy (e.g., CsA). Further, the involvement of T_h cells supports the potential role of CsA in their treatment. The role of leukotrienes supports use of receptor antagonists or other drugs (e.g., dualinhibitor nonsteroidal antiinflammatory drugs) that modify their release. In human medicine drugs that target eotaxin, the CCR3, or particularly IL-5 are being explored. Finally, pentoxifylline might be considered for its ability to target TNF. These therapies might be considered for other atopic diseases, including allergic rhinitis and sinusitis perianal fistulae, and others.

Type I Hypersensitivities

Anaphylaxis and Anaphylactoid Reactions

Clinical signs of systemic anaphylaxis include nausea, vomiting, diarrhea, pale mucous membranes, coolness to peripheral extremities, tachycardia, and tachypnea. Localized "anaphylaxis" results in clinical signs referable to the site of localized mast cell degranulation. Examples include angioneurotic edema resulting in swelling of lips, eyelids, and conjuctiva and urticarial lesions (or hives). Treatment is oriented toward preventing further mast cell degranulation, blocking the interaction between histamine (or other mediator) and tissue receptors, and antagonizing the physiologic response to mediators. Drugs that antagonize physiologic response also tend to further decrease mast cell degranulation. The goals of therapy for systemic anaphylaxis include cardiovascular and ventilatory support. Epinephrine is indicated to antagonize bronchoconstriction and provide cardiovascular support. Glucocorticoids (prednisolone sodium succinate) facilitate adrenergic receptor responses and decrease further mast cell mediator release. Histamine 1 (H_1) receptor antagonists (e.g., diphenhydramine) are of benefit only in preventing interaction of histamine and its receptors, not in preventing further mast cell degranulation. Therapy may be more effective if administered in anticipation of mast cell degranulation, although this is somewhat controversial. Perioperative anaphylaxis, including drugs, risk factors, and therapies in humans, has been recently reviewed.153

Type II Hypersensitivities: Antigen- and Antibody-Dependent Cytotoxicity

Immune-Mediated Hemolytic Anemia

IMHA occurs as a result of increased red blood cell destruction mediated by the presence of an antibody on the membrane surface. The antigen to which the antibody binds is either of the red blood cell membrane or an exogenous antigen (e.g., drug or microbe) that has adhered to the surface. Igs associated with IMHA in dogs generally are IgG or, less commonly, both IgG and IgM. In cats IgM tends to be more common, with IgG alone causing IMHA in approximately 25% of cases. Complement activation is more likely with IgM-mediated IMHA. Antibody adherence and complement activation that are insufficient to cause erythrocyte lysis will result in damage and subsequent erythrophagocytosis of the deformed red blood cell (e.g., spherocyte). Intravascular hemolysis occurs when complement activation is extensive, leading to erythrocyte lysis. Released hemoglobin binds to serum haptoglobin, preventing glomerular filtration. If haptoglobin becomes saturated, however, free hemoglobin can be filtered. Renal toxicity can accompany intravascular IMHA as a result of antigenantibody deposition or reaction in the basement membrane; free hemoglobin may also contribute to nephrotoxicity. Direct red blood cell agglutination or intravascular hemolysis increases the risk of thromboembolic disease.

Medical treatment of IMHA focuses on reducing phagocytosis of damaged or antibody-coated erythrocytes by reducing or blocking receptors on phagocytic cells, reducing or preventing the formation of more antibodies, and providing supportive therapy for complications associated with IMHA. Any likely inciting (exogenous) antigen (e.g., drug, microbe) should be removed. Treatment of IMHA is confounded by low survival rates (which range from 10% to 50% discharge survival, with continued patient loss after discharge) and the lack of scientifically based evidence supporting preferred therapies. Several of the clinical trials that address various therapeutic regimens unfortunately are biased in population selection, generally focusing on the worse cases and thus complicating extrapolation of results to less severe cases. Immunosuppressive therapy with glucocorticoids is the cornerstone of therapy; use of immunosuppressants for immune-mediated disorders is reviewed in Chapter 30. Differences of opinion exists regarding the initial route of administration of glucocorticoids, with oral proponents observing that response to glucocorticoids requires 5 to 7 days regardless of route. Although this observation may have some merit (many mechanisms of glucocorticoid require nuclear transcription and protein synthesis; time must elapse before inflammatory cell numbers and function are reduced), many mechanisms (e.g, non-genomic) of glucocorticoid action may occur immediately. Indeed, the importance of glucocorticoid supplementation in shock patients offers support for administration designed to cause immediate response (see Chapter 30). For rapid response dexamethasone (0.1 to 0.2 mg/kg intravenously) or methylprednisolone (11 mg/kg daily for up to 3 days) every 12 to 24 hours is administered initially, followed by oral prednisolone (1 mg/kg every 12 hours) as the animal responds. Choice of prednisone versus prednisolone is addressed in Chapter 30; the latter is strongly encouraged in dogs with life-threatening conditions, and the former should not be used in cats. Further reduction of red blood cell destruction may require administration of CsA, leflunomide or MMF, or their combination; continued failure may require cyclophosphamide or (dogs only) azathioprine. Combination therapy might be considered initially in patients with severe disease (see Chapter 30). Leflunomide doses as high as 8 mg/kg were necessary to prevent renal transplant rejection in dogs. ^{104a} Safety of anticancer drugs can be increased by dosing based on body surface area. Cyclophosphamide can be given as a single intravenous bolus (100 to 250 mg/m²) in patients suffering from intravascular lysis or direct autoagglutination.¹⁰⁸ This regimen also is particularly useful for patients that require a blood transfusion.

However, efficacy of cyclophosphamide may not be realized until antibodies decline as a result of normal catabolism (generally 1 to 2 weeks).¹¹ Oral administration (50 mg/m² every 48 hours) is indicated in dogs that do not respond to glucocorticoids or might be considered as part of initial therapy, particularly in severe cases. Using a randomized prospective design, Mason and coworkers¹⁵⁴ investigated the impact of cyclophosphamide (50 mg/m²) when combined with prednisone (1 to 2 mg/kg orally every 12 hours; n = 8) compared with prednisone alone (1 to 2 mg/kg orally every 12 hours; n = 10) for treatment of severe (based on clinical signs, less than 1 week in duration and packed cell volume less than 20%) idiopathic IMHA in dogs. The mortality rate did not differ between groups, but the power of the study was limited. Reticulocytosis appeared, and spherocytosis resolved more rapidly in the prednisone-only-treated group (within 1 week), leading the investigators to conclude that the addition of cyclophosphamide offered no advantage to prednisolone alone. Long-term cyclophosphamide will increase the risk of thrombocytopenia and neutropenia.11

Human gammaglobulin (0.5 to 1.5 g/kg intravenously over 6 to 12 hours) may prove useful for dogs that fail to respond to therapy.^{127,128} Cost may, however, be prohibitive, and use may be limited by development of thrombocytopenia or thrombosis (see previous discussion). CsA may be of benefit in controlling the sequelae of IMHA that reflect tissue (and thus T cell-mediated) damage.¹¹ Blood transfusions are not recommended for patients with IMHA. Dogs with IMHA are predisposed to destruction of transfused red blood cells. Blood substitutes (oxyhemoglobin) may offer a viable alternative to blood transfusion. Although splenectomy should be considered as a surgical adjunct to medical management, removal of the spleen may also result in removal of an important site of extramedullary hematopoiesis. As with glucocorticoids, danazol (5 to 10 mg/kg orally every 12 hours) may block Fc receptors on phagocytic cells, reducing red blood cell destruction.¹¹¹ However, response may be slow, rendering danazolol lower on the list.

Response to therapy is based on daily hematocrit or platelet counts (or both); initial therapy should be continued or, as needed, improved until the packed cell volume is 15% or more in cats and 20% in dogs or the platelet count is 100, 000/ μ L or more. Drug therapy should be gradually tapered to avoid relapse or rebound; for example, prednisolone and azathioprine tapered to 0.5 to 1 mg/kg every second day is a reasonable target, with monitoring every 2 weeks as a basis of response. Therapy should be continued for another 3 months or so, with gradual tapering off attempted in animals that have been in remission for 3 to 6 months. For nonresponders, supportive therapy may include transfusions, which are more likely to be effective in patients whose disease reflects bone marrow rather than peripheral cellular targets.

Other supportive therapy should be considered. Anemia and reduced oxygen delivery to the gastrointestinal tract may predispose the patient to gastrointestinal induced ulceration. The importance of cyclooxygenase-2 in gastrointestinal healing warrants consideration of gastroprotectants, particularly in the face of glucocorticoid therapy. As such, antisecretory drugs (e.g., H_2 -receptor antagonists, omeprazole) and gastroprotectants (e.g., sucralfate) should be considered as long as concerns regarding drug interactions are addressed. The use of heparin, including fractionated products, is controversial but might be considered (Chapter 15).

Immune-Mediated Thrombocytopenia

Immune-mediated thrombocytopenia is a syndrome that occurs more commonly in dogs than cats and in males than females. It can occur in concert with other immune-mediated disorders, including IMHA.¹¹ Thrombocyte numbers can decline as a result of destruction (i.e., antibody/complement-mediated phagocytosis) or, less commonly, decreased formation of mature thrombocytes as a result of antibody/ complement-mediated destruction of megakaryocytes.¹¹ As with IMHA, antibody can be directed to an endogenous or exogenous antigen adhered to the platelet or megakaryocyte. The primary clinical signs, which include and reflect inappropriate bleeding, generally do not occur until thrombocyte numbers have dropped below 30,000/µL. Bleeding is more likely with a rapid, as opposed to a gradual, decline.

Medical treatment focuses on prevention of bleeding, decreased destruction of thrombocytes, and restoration of thrombocyte numbers (see also Chapters 15 and 30). Any likely inciting (exogenous) antigen (e.g., drug, microbe) should be removed. Glucocorticoids (dexamethasone, methylprednisolone, or prednisolone) are often the first choice of therapy (see earlier discussion of IMHA) and, in general, cause thrombocyte counts to normalize within 1 week. Use of cyclosporine and leflunoamide should be considered as suggested for other immune-mediated disease. Danazol also can be administered to reduce phagocytosis.^{112,113} Vincristine (0.75 mg/m² intravenously) can be administered if platelet numbers fail to increase to sufficient numbers. Once platelet numbers increase, vincristine should be discontinued and glucocorticoids continued for several more weeks.¹¹ Vincristine may also be given after incubation with platelet-rich plasma in cases refractory to glucocorticoids, danazol, and vincristine. Presumably, incubation allows vincristine to bind to platelets. Subsequent phagocytosis destroys the phagocytic cell, causing an overall reduction in platelet destruction.¹⁵⁵ If successful, the treatment may need to be repeated as new macrophages are generated. Platelet-rich plasma also can be administered in an attempt to restore platelet numbers to a concentration that is not life threatening (>50,000/µL). The likelihood of relapse of immune-mediated thrombocytopenia also may be reduced after infusion of platelet-rich plasma.¹¹ The use of vinblastine might be considered in relapsing patients (see discussion of cytotoxic drugs) on the basis of its effectiveness in human patients. Splenectomy is a surgical alternative or adjunct therapy that should be considered in refractory cases. Because of the risk of relapse, patients should be monitored periodically. Surgical neutering, particularly of females, may be indicated once platelet numbers have normalized.

Immune-Mediated Neutropenia

As with other immune-mediated hematopoietic diseases, glucocorticoids are indicated for neutropenia.¹⁵⁶ Treatment can continue as described for IMHA.

The use of recombinant bone marrow growth factors (see Chapters15 and 32) to increase bone marrow production of deficient cells is probably not wise unless the factor is derived from the species to be treated. Even in those situations, studies should confirm a lack of immune-mediated reactions when used in patients affected with an immune-mediated disorder.

Dermatologic Disorders

A number of immune-mediated skin diseases reflect a type II hypersensitivity. Included are pemphigus (foliaceus, erythematosus, vulgaris, vegetans), bullous pemphigoid, and dermatomyositis.

Pemphigus Disorders and Bullous Pemphigoid. Pemphigus disorders reflect the reaction of autoantibodies directed toward antigens located in the intercellular spaces between epidermal cells. The definitive antigen is not known but apparently is located in or near the cytoplasmic membrane.¹¹ The various types may reflect variants, crossovers, or altered presentations of the different forms of the disease. In all variants antibody deposition causes the loss of adhesion between epidermal cells, leading to acanthosis. Complement activation results in local mast cell degranulation and an infiltration of inflammatory cells. Clinical signs vary within and among the variants and include visculobullous eruptions, cutaneous ulcerations, exfoliative lesions, and verrucous proliferations of the skin.¹¹ Bullous pemphigoid results from the generation of antibodies toward the lamina lucida of the basement membrane zone. As with pemphigus, complement activation may worsen the inflammatory response. Clinical signs include vesiculobullous lesions at mucocutaneous junctions; in the oral cavity; on footpads; and on the skin of the trunk, groin, axillae, and abdomen.11

Glucocorticoids can be expected to be effective in 40% of canine cases¹¹ of pemphigus. The initial dose should be high (2 to 3 mg/kg orally every 12 hours for 10 to 14 days); the dose can gradually be reduced over 4 weeks (targeting 1 mg/kg orally every 48 hours) if an adequate response has occurred. Failure to respond or inability to decrease the dose of glucocorticoids is an indication for the addition of a second immunosuppressive drug. Generally, azathioprine (2 mg/kg orally every 24 hours) has been the first choice to combine with prednisolone (1 mg/kg orally every 12 hours). Response within 10 to 14 days will allow alternating the drugs each day at the same dose. Continued remission will allow a gradual reduction in the doses of both drugs to 1 mg/kg orally every other day, alternating the drugs daily.¹¹ Cyclophosphamide (50 mg/m² orally every 24 hours) can be combined with prednisolone (1 mg/kg orally every 12 hours) for 4 consecutive days each week for 2 to 3 weeks. If remission occurs, doses are gradually reduced to 1 mg/kg orally, alternating drugs daily. Chlorambucil (0.1 mg/kg orally every 48 hours) can be used in place of cyclophosphamide; leukopenia and thrombocytopenia are

potential side effects of this drug. Use of cyclosporine and leflunoamide should be considered as suggested for other immune-mediated disease.

The third alternative for immunosuppressive chemotherapy is use of aurothioglucose initially in combination with prednisolone (1 to 2 mg/kg orally every 12 to 48 hours). Chrysotherapy should be initiated only after administration of an intramuscular test dose (1 mg for animals less than 10 kg; 5 mg for animals 10 kg or larger) twice, 1 week apart. Toxicity will be manifested as dermatitis, stomatitis, nephrotic syndrome, blood dyscrasias, eosinophilia, thrombocytopenia, and manifestations of allergic reactions. Therapy can be continued at 1 mg/kg weekly intramuscularly until remission; however, continued therapy should be based on an acceptable complete blood count. At that time, the interval is decreased to alternate weeks and finally monthly. Prednisolone therapy might be gradually phased out.

Pemphigus foliaceus in cats can be treated with chlorambucil as the first choice.¹⁰⁶ Daily therapy (0.1 to 0.2 mg/kg/ day) should be continued until lesions have markedly reduced, which may take 4 to 8 weeks. Alternate-day therapy should be implemented when approximately 75% improvement occurs and continued for several weeks. Complete blood counts should be monitored every 2 weeks of chlorambucil therapy.¹⁰⁶

Dermatomyositis. Dermatomyositis might be classified as an inflammatory muscle syndrome. Unlike polymyositis, which appears to involve a cell-mediated, antigen-specific response, dermatomyositis appears to reflect an abnormality of the humoral response, resulting in vasculitis. In human patients treatment with low-dose methotrexate has proved beneficial^{114,115} Dermatomyositis in veterinary medicine is an inherited idiopathic inflammatory syndrome affecting Collies, Shetland Sheepdogs, and their crosses. Skin lesions include erythema, scaling, and crusting, particularly around the eyes, tips of the ears and tail, digits, and carpal and tarsal regions. Pentoxifylline, a methylxanthine derivative, has been recommended^{157,158} on the basis of its potential efficacy in humans.¹⁵⁹ Studies of the drug in dogs suggest a higher dose than that for humans, and a twice- to thrice-daily dosing interval should be used. Clinically, response may take several weeks. The drug appears to be well tolerated by dogs. Clinical trials in Collies with dermatomyositis are currently under way.

Feline Eosinophilic Granuloma Complex. Eosinophilic granulomas may respond to glucocorticoids. Direct lesional injection of methylprednisolone acetate (2 mg/kg, minimum of 20 mg) every 2 weeks is the preferred method of administration. High oral doses of prednisolone may be an effective alternative.¹⁶⁰ Drugs that target leukotrienes should be considered. Response to chlorambucil has been reported¹⁰⁴ within 6 weeks of therapy (0.1 to 0.2 mg/kg per day). Response to therapy should be followed by a 12-week period during which the dose of chlorambucil is decreased until discontinued. Megestrol acetate is an undesirable alternative unless the patient has proved refractory to other modalities, including chlorambucil. Urine should be monitored for glucose to detect the development of diabetes mellitus. Levamisole (2.2 mg/kg orally every 48 hours) has been reported to cause some (but incomplete)

remission in certain cases.^{160,161} Additionally, accurate dosing is difficult because of the large tablet size (184 mg). Cats often react adversely, with transient anorexia, vomiting, and hypersalivation being the most common side effects. Bone marrow suppression can be marked and is characterized by a long recovery period.

Type III Hypersensitivities: Immune Complex Disease

Systemic Lupus Erythematosus

The deposition of circulating autoantibodies or autoantibody-antigen complexes in the endothelium, particularly that of the glomerulus, appears to initiate complement-mediated inflammation. The inflammatory site is infiltrated by immune cells. In the glomerulus response includes proliferation of capillary cells, thickening of the basement membrane, and scarring. Other vascular beds affected include the skin, serous membranes, synovial tissues, and cutaneous and visceral blood vessels.^{114,115} Soluble immune complexes are more problematic than large immune complexes, which precipitate and are rapidly phagocytized. Soluble complexes are able to penetrate deep into vascular endothelial channels, activate complement, and stimulate an inflammatory response. In humans intravenous cyclophosphamide has been established as the treatment of choice for lupus-induced nephritis. Bolus cyclophosphamide has also, however, proved effective for lupus affecting other body systems, including the CNS, lungs, and arteries. Azathioprine and weekly methotrexate are effective for treating human lupus that does not involve major organs, such as rashes, serositis, and arthritis, or in combination with glucocorticoids to reduce the glucocorticoid dose. CsA apparently has not been studied for treatment of systemic lupus erythematosus, although clinical response has been reported.114,115

Because systemic lupus erythematosus can be polysystemic in its presentation, the sequelae of immune complex deposition associated with systemic lupus erythematosus can affect a number of body systems, resulting in the need for medical management of secondary disease. Examples include but are not limited to glomerulonephritis, arthritis, and vasculitis. The reader is referred to the chapters that address these specific body systems for information on management of the sequelae of inflammatory disease. Treatment for the immunemediated aspect of the disease is the same as for pemphigus skin disorders. Use of cyclosporine and leflunoamide should be considered as suggested for other immune-mediated disease.

Cutaneous Discoid Lupus Erythematosus

Considered a mild form of systemic lupus erythematosus, cutaneous discoid lupus erythematosus is not accompanied by systemic involvement. The most common form presents as a nasal dermatitis; skin surrounding the eyes, pinnae, lips, and feet may also be involved. Treatment includes immuno-suppressive doses of glucocorticoids, as described for other immune-mediated diseases, although a lower initial dose may be effective (1 mg/kg orally twice daily). Vitamin E (400 IU

orally 2 hours before or after a meal every 12 hours; acetate or succinate) may be effective as the sole agent; however, a 30- to 60-day lag time to efficacy mandates that initial therapy include glucocorticoids. Topical glucocorticoids may be effective in mild cases. Minimizing exposure to the sun, including use of topical sunscreen, or other ultraviolet light also will be helpful, particularly in animals with depigmentation. Niacin or tetracycline (5 to 12 mg/kg orally every 8 hours) was reportedly effective in 70% of cases in one study. Use of cyclosporine and leflunoamide should be considered as suggested for other immune-mediated disease; tacrolimus also might be considered.

Rheumatoid Arthritis and Other Arthritides

The rheumatoid factor is an antibody that reacts with IgG that has bound to antigen and subsequently undergone a conformation change. The reason for selectivity in joints is not understood. In humans drugs used to treat rheumatoid arthritis include gold compounds or penicillamine and cytotoxic drugs, including azathioprine, cyclophosphamide, and methotrexate. Since the late 1980s, low-dose weekly methotrexate has become the preferred medication.^{114,115} Methotrexate has proved more rapid in onset. Because it is safer than traditional cytotoxic drugs, treatment generally can progress for a longer period of time. Because functional disabilities and progress of the disease occur rapidly in the first years of disease in humans, cytotoxic drugs are begun early. Drug combinations have been advocated because of the possibility of synergistic effects. Examples include methotrexate with sulfasalazine, CsA, or biological agents. Treatment in animals has not been as well investigated and focuses on control of inflammation with glucocorticoids and, if necessary, aspirin. The use of glucocorticoids is supported by the rapid clinical improvement and decrease in IL-6 activity documented in dogs with juvenile polyarthritis syndrome.¹⁶² The use of other immunosuppressive drugs in animals (azathioprine, cyclophosphamide) has been reserved for severe cases. On the basis of findings in humans, however, a more aggressive approach may be warranted. Disease-modifying agents (e.g., glucosamine and chondroitin sulfates) should be used to support cartilage repair.

Feline chronic progressive polyarthritis is associated with feline leukemia virus and feline syncytium-forming virus and most commonly presents as osteopenia and periosteal bone proliferation around affected joints. Less commonly, joints are characterized by subchondral marginal erosions similar to those of rheumatoid arthritis. Rheumatoid factor cannot be identified, however. Treatment includes immunosuppressive doses of corticosteroids (1 to 3 mg/kg orally every 12 hours). Nonresponders may require treatment with chlorambucil, cyclophosphamide, or azathioprine. As previously suggested, disease-modifying agents may prove beneficial.

In a retrospective study of dogs (n = 39) with immunemediated polyarthritis, 56% of dogs were cured after drug therapy. Response to prednisolone alone was 50% (overall 33%), although response to prednisolone (1 to 2 mg/kg every 24 hours or divided every 12 hours) by itself or combined with another drug was 81%. Duration of therapy was generally 4 to 16 weeks, although continuous medication was necessary in 10% to 18%. Response of animals to leflunomide was previously discussed.^{104a} Drugs combined with prednisolone to which animals responded included antimicrobials and immunosuppressive drugs such as cyclophosphamide or azathio-prine.¹⁶¹ Treatment with levamisole or CsA as sole therapy generally was not successful.

Type IV Hypersensitivities: the Delayed Response Allergic Contact Dermatitis

Allergic contact dermatitis is the most common type IV hypersensitivity recognized in small animals, being responsible for up to 10% of dermatologic cases.¹¹ The syndrome is initiated when the skin comes in contact with the inciting antigen or chemical. Actual chemicals that cause contact dermatitis are not known, but it is likely that the chemical acts as a hapten that subsequently covalently bonds to a protein. The location of the protein is not clear but is probably associated with the class II molecule of an APC, which in the skin is the Langerhans cell. Sensitization generally requires 4 to 10 days; subsequent exposure to the chemical results in a marked T cell-mediated response.¹¹ Treatment is best implemented by removal of the inciting antigen and short-term (7-day) administration of prednisolone (0.5 to 1 mg/kg every 12 to 24 hours).

Inflammatory Myopathies

In humans polymyositis appears to reflect cell-mediated, antigen-specific cytotoxicity, with azathioprine being the only cytotoxic drug to be of benefit in controlled studies. Low-dose methotrexate or azathioprine with high-dose glucocorticoid therapy has become the standard therapy. Combinations of methotrexate and either cyclophosphamide or CsA may be effective and are being studied.^{114,115}

Inflammatory Bowel Disease

Inflammatory bowel disease also is discussed in Chapter 19. The use of immune-modifying therapy for human patients with IBD became popular only in the 1990s.^{114,115,164,165} Controlled clinical trials in humans have focused on azathioprine, 6-mercaptopurine, CsA, and methotrexate. Azathioprine or 6-mercaptopurine has been effective for treatment of Crohn's disease, although efficacy depends on duration of therapy; at least 13 and more often 17 weeks of therapy is required before the drugs reach their full effects.

Intravenous administration of azothioprine may decrease the time to response. CsA has been studied at low doses (<1 mg/kg per day) or high doses (>5 mg/kg per day) to minimize the risk of nephrotoxicity (less of a concern in veterinary patients), but this has proved of little benefit in Crohn's disease. It has been more effective for treatment of ulcerative colitis at high doses (8 to 10 mg/kg per day), although only a few patients have been studied. CsA concentrations in responding patients were above 250 ng/mL. Methotrexate appears to be useful for both induction of remission and steroid sparing in patients with Crohn's disease and ulcerative colitis. Combinations of drugs also have been studied. Azathioprine and 6-mercaptopurine should not be used in combination with methotrexate because of the increased risk of toxicity. CsA and methotrexate have been used in human patients with IBD with some success. Drugs that target leukotrienes should be considered. Pentoxyfylline for treatment of human IBD is discussed in Chapter 19.

Amyloidosis

Primary (or AL) amyloidosis reflects the extracellular deposition of abnormally formed protein associated with a clonal plasma cell dyscrasia.¹⁶⁶ The protein is a monoclonal Ig light chain fragment secreted in an abnormal insoluble fibrillar form; the underlying plasma cell dyscrasia is generally insidious and nonproliferating. The AL amyloid fibrils are derived from the N-terminal region of monoclonal Ig light chains and consist of the whole or part of the variable (VL) domain. The propensity for Igs to form amyloid fibrils is inherent to their structure; unfortunately, they cannot be identified. Those able to form myeloid are capable of existing in partially unfolded states because of the loss of tertiary or higher structure. Aggregation and retention of b-sheet secondary results in the formation of protofilaments and fibrils; initiation of the process, or seeding, appears to facilate exponential progress of the amyloid template by "capturing" precursor molecules. Amyloid deposits exist in a state of dynamic turnover. Accumulation of amyloid progressively disrupts the normal tissue structure and ultimately leads to organ failure, frequently including, but not limited to, the kidneys, heart, liver, and peripheral nervous system. Hereditary forms of amyloidosis also exist, as do secondary forms (e.g., chronic immunologic stimulation). Treatment of the latter is best based on removal of the inciting cause. Because no therapy has successfully targeted amyloid deposition, therapy targets suppression of the underlying plasma cell dyscrasia as well as treatment intended to preserve organ function. A variety of low- and high-dose drug therapies, sometimes as sole agents but more commonly as combinations, have been recommended in humans. Low-dose single agents include melphalan or cyclophosphamide, (with or without prednisolone). However, clinical benefit occurred in only about 20% to 30% of human patients, after a median of 12 months' treatment. Intermediate dose regimens consist of a monthly course of VAD (vincristine, adriamycin, dexamethasone) or similar regimes or intravenous intermediate-dose melphalan 25 mg/m² with or without dexamethasone. Highdose therapy consists of intravenous melphalan (100 to 200 mg/m²) but with stem cell rescue. Other approaches include a pulsed high-dose dexamethasone or thalidomide (with or without dexamethasone). However, thalidomide is a drug of restricted distribution in the United States and therefore cannot be prescribed by veterinarians. In veterinary medicine colchicine has been recommended for prevention in dogs predisposed to amylodids. Presumably, colchicine may block the deposition of amyloid. The dose is based on that used to treat hepatic fibrosis (0.03mg/kg every 24 hours for 2 weeks) with an increase (0.025 to 0.03mg/kg orally every 12 hours) if the drug is well tolerated during the initial therapy. In patients with renal amyloidosis, dimethyl sulfoxide has been recommended, although its efficacy is unsubstantiated.

KEY POINT 32-1 Natural or synthetic biological response modifiers are being developed as therapeutic mediators to increase the effectiveness of the immune response directed toward a pathogen or neoplasm, to stimulate the proliferation of hematopoietic progenitor cells (e.g., in the treatment of chemotherapy-associated neutropenia), or to decrease a chronic inflammatory response (e.g., chronic inflammatory bowel disease).

BIOLOGICAL RESPONSE MODIFIERS AND CYTOKINES

Natural or synthetic preparations given with the intent of altering the response of the host to a pathogen, neoplasm, or inflammatory process have been termed *biological response modifiers*. The goal of therapy may be to increase the effectiveness of the immune response directed toward a pathogen or neoplasm, to stimulate the proliferation of hematopoietic progenitor cells (e.g., in the treatment of chemotherapyassociated neutropenia), or to decrease a chronic inflammatory response (e.g., chronic inflammatory bowel disease). Biological response modifiers are not usually specific in an immunologic sense; rather, they alter physiologic systems through changes in regulatory pathways. They range from bacterial cell wall extracts to molecularly cloned cytokines. As mediators of physiologic processes, interferons, interleukins,

*From Kruth SA: Biological response modifiers: interferons, interleukins, recombinant products, liposomal products, *Vet Clin North Am Small Anim Pract* 28:269-295, 1998. and chemokines are candidates for therapeutic manipulation or even for use as drugs. Several recombinant human, feline, and canine cytokines are commercially available in pharmacologic quantities and are available for veterinary use (Box 32-1). Some generalizations about cytokine biology follow. See the reviews by Oppenheim and Feldman,¹ Nicola,² and Oppenheim and coworkers³ for general discussions of cytokine, growth factor, and chemokine biology and the article by Gangur and coworkers⁴ for a review of chemokines of veterinary relevance.

Cytokines are polypeptides that regulate cell growth and differentiation, apoptosis, inflammation, immunity, and repair. They are of fundamental importance in the pathogenesis and treatment of disease. They transmit information to target cells regarding the physiologic status of the animal, resulting in a biologic response in the target tissue. More than 50 distinct human cytokines and their receptors have been described. Cytokine nomenclature can be bewildering, with several historical names attached to the same molecule (e.g., stem cell factor, c-kit ligand, and mast cell growth factor are all the same cytokine). Cytokines Online Pathfinder Encyclopaedia (COPE) is a useful Internet resource with a large amount of information concerning cytokine, chemokine, and growth factor biology (www.copewithcytokines.de/cope.cgi). Cytokines can be categorized into families on the basis of homology in primary amino acid sequence, three-dimensional structure, induction mechanisms, chromosomal location, similarities in receptor type, and functional homology. Families that are currently clinically relevant in companion animal medicine include interferons (IFNs), which have antiviral and immunoregulatory functions; interleukins (ILs), which have a wide variety of functions; chemokines, which have to do

with chemotaxis and organ development; and hematopoietic growth factors.

Most cytokines are not constitutively produced but are secreted after activation of cells by viral, bacterial, and parasitic infections. The cellular sources of most cytokines are diverse, with production occurring in many types of cells. Production is normally short lived, usually for hours to a few days. Normally, they have autocrine and paracrine (rather than endocrine) effects, with little to no detectable circulating levels. Because of high cytokine-receptor affinity, cytokines are effective in the picogram to nanogram per mL range.

Cytokines typically have pleiotropic and redundant actions. The same activity may be induced by several structurally distinct cytokines acting at unrelated cell surface receptors. For example, IL-1, tumor necrosis factor-alpha (TNF-alpha),* and IL-6 are all mediators of the acute inflammatory response; induce fever and the synthesis of acute-phase proteins in the liver; increase vascular permeability; and induce adhesion molecules, fibroblast proliferation, platelet production, IL-6 and IL-8, and T and B cell activation. Gene deletion experiments reveal that few individual cytokines are absolutely essential to life or even to individual cell function, with notable exceptions such as TNF-alpha and transforming growth factor- β (TGF- β). Also, the cellular response of most cytokines is modulated by other cytokines, with synergistic, additive, and antagonistic interactions described. Cytokines form a complex feedback network by either inducing or suppressing the expression of other cytokines, forming cascades similar to the blood coagulation cascades.

Structurally, most cytokines consist of a single glycosylated polypeptide chain. They interact with cells by binding to specific high affinity cell surface receptors. The intracellular signal transduction cascade initiated by binding of a cytokine to its receptor eventually results in the production of DNAbinding proteins that influence transcription of various genes. In addition to cell surface receptors, soluble receptors have been described for many cytokines. Soluble receptors may be involved in cytokine transport or inhibit cytokine activity.

A number of proteins that inhibit the activity of cytokines have been reported. One of the best characterized is the IL-1 receptor antagonist (IL-1RA), which binds to receptor but fails to activate the cell. IL-1RA is currently being investigated as a therapy for rheumatoid arthritis in humans and may have a role in the treatment of other inflammatory disorders if appropriate delivery systems can be developed. Peptide antagonists of chemokines have shown promise in breaking the cycle of inflammation in experimental models of disease. A second way in which a cytokine can be inhibited is by binding of soluble cytokine receptors that are able to bind the cytokine and neutralize its activity, as discussed earlier.

Recombinant DNA technology has been used to produce cytokines, many of which are now commercially available. The recombinant process involves cloning the cDNA encoding the protein of interest and placing it into an expression system (bacterial, yeast, insect, mammalian cell culture) under conditions that permit large amounts of the protein to be produced. By convention, these products are designated by an "r" preceding the name of the cytokine and a designation of the species of origin (e.g., *rhIL* indicates recombinant interleukin of human origin, and *rfeIFN* indicates are conserved in the evolutionary sense, and biological effects occur when some human recombinant products are administered to companion animals.

It is tempting to administer cytokines in pharmacologic doses; however, several points should be considered. Perhaps most important, systemic levels of a given cytokine will perturb many cytokine cascades, with resultant side effects and toxicity. The use of IL-12 as a therapeutic agent, as discussed later, has been limited by potentially severe hematopoietic and hepatic toxicities in animals and man and was associated with two deaths in a phase 1 trial in humans.⁵ Dosing may be critical; for example, low doses of IFN appear to be immunostimulatory, whereas higher doses are immunosuppressive, and the specific type of IFN influences these effects. This concept of increasing doses of immunostimulatory cytokines leading to depression of the immune response has been demonstrated with IL-12 as well and appears to be due to the magnitiude of downstream IFN-y and nitric oxide that is produced.⁶ Currently, recommended cytokine doses are empirically derived. With the exceptions of rfeIFN- α (in cats) and rhIL-1 (in dogs),

^{*}Tumor necrosis factor-alpha (TNF-alpha) is a multifunctional cytokine with biological activities that include modulation of tumor growth, infections, septic shock/systemic inflammatory response syndrome, and autoimmunity. The TNF family of cytokines is distinct from the IL and IFN families. Canine and feline TNF-alpha have been cloned. They are not discussed in this chapter.

the pharmacokinetics of cytokines in dogs and cats have not been well characterized.

The safety and efficacy of cytokines as biological response modifiers may be improved if they can be delivered directly to target cells. Delivery systems, such as liposomes and replication-defective adenoviruses, have been reported in the literature, with encouraging results. In some cases the cDNA for the cytokine of interest can be delivered (using a variety of methods) directly to the tissue of concern (usually a neoplasm), and controlled expression of the gene may confer clinical benefits. Both agonistic and antagonistic peptides have been sought for various cytokines in attempts to achieve systemic oral administration or suppress harmful effects.

INTERFERONS

Interferon Biology

Interferons are cytokines secreted by virus-infected cells and were originally characterized by their nonspecific antiviral activity. Interferons bind to receptors on other cells and induce antiviral proteins, protecting those cells from infection. It is now known that IFNs induce a wide range of pleiotropic effects, including antiviral, antitumor, antiparasitic, and immunomodulatory effects.

Two distinct classes of IFNs have been described. Class I interferons are subdivided into alpha, omega, and beta interferons (a subclass of omega interferons, the tau interferons, has been described in ruminant embryos and is important in maintaining pregnancy). Class II interferons are composed of a single protein, IFN- γ . IFN- α and IFN- ω were originally described as being secreted by leukocytes, but they are likely produced by all nucleated cells. Humans have at least 24 different alpha and omega genes, dogs have two alpha genes and no omega genes, and the genetic complement of cats has not been reported. Feline IFN- α cDNA has been cloned and the cytokine produced in a silkworm-recombinant baculovirus system, and its pharmacokinetic properties have been studied.7-10 The pharmacokinetic data suggest that rfeIFN has similar pharmacokinetic properties to human IFNs and that it is distributed primarily to the liver and kidneys, is rapidly catabolized mainly in the kidneys, and is excreted in the urine without residual accumulation in the body. Since feline IFN- α was initially cloned, 14 additional subtypes have been described.^{11,12} IFN-β is classically described as being produced by fibroblasts; however, many other cells can be stimulated to secrete the cytokine. Humans and dogs have one IFN- β gene. Synthesis of IFN- α and IFN- β can be induced by live or inactivated viruses, bacterial cell walls, synthetic oligonucleotides, IL-1, IL-2, and TNF-alpha. IFN- α and IFN- β compete for similar receptors. IFN- γ is produced by activated T and natural killer (NK) cells and is structurally and functionally distinct from IFN- α/β . All mammals investigated have only one IFN- γ gene. IFN- γ binds to a receptor distinct from the α/β receptor. Canine IFN-y has been characterized, the cDNA and chromosomal gene have been cloned, and production and characterization of recombinant canine from Escherichia coli has been described.¹³⁻¹⁵ Feline IFN-y cDNA has also been cloned.^{16,17} After receptor binding, IFNs induce the transcription of a set of genes called *IFN-stimulated genes* (ISGs). Nearly 30 different ISGs have been identified. Induction of ISGs by IFN- α/β is rapid and transient, lasting for 3 to 4 hours. IFN- γ requires several hours of exposure before gene induction occurs. After the initial induction, ISG transcription declines and returns to basal levels.

IFNs inhibit the growth of almost all known viruses by interfering with viral RNA and protein synthesis. IFNs are induced by viral nucleic acid and bind to the receptors of nearby cells. The development of resistance to virus infections occurs within a few minutes and peaks within a few hours. Several proteins are induced, including RNase L (which cleaves viral RNA); nitric oxide synthetase (nitric oxide has antiviral activity); a protein kinase that phosphorylates an initiation factor called elL-2 (which inhibits viral protein synthesis by preventing the elongation of viral double-stranded RNA); and the Mx protein, which inhibits translation of viral mRN.¹⁸ IFN- γ inhibits viral replication by stimulating the release of other IFNs. IFNs are also induced by bacteria, fungi, and some protozoa, and the activation of phagocytic cells is important in the host response to these pathogens.

IFNs induce increased expression of class I and class II major histocompatibility complex (MHC) molecules on antigen-presenting cells, leading to enhanced antigen presentation. They increase phagocytosis and intracellular and extracellular killing by macrophages and neutrophils. The IFNs also modulate T, B, and NK cell function, with IFN- γ having the most potent immunomodulating activity.

IFNs have several effects on neoplastic cells, including modulation of oncogene expression. Downregulation of c-myc, c-fos, c-Ha-ras, c-mos, and c-src have been described in various models. IFN- α augments NK cell cytotoxicity against neoplastic cells and acts synergistically with IL-2 to increase NK activity. Antiangiogenic activity has also been described.

Large-scale production of IFNs is accomplished by culturing stimulated cells, leading to the production of "natural" or "native" IFN (denoted by *N*) products. Alternatively, IFNs can be produced by recombinant methods. Human IFNs from both sources are commercially available, and recombinant feline and canine IFN- α and IFN- γ are commercially available (see Box 32-1). Natural IFNs are less concentrated and may contain a mixture of IFN types with other cytokines.

Interferons as Therapeutic Agents

In humans IFN- α has been approved for the treatment of hairy cell leukemia, melanoma, chronic myelogenous leukemia, Kaposi sarcoma, basal cell carcinoma, renal cell carcinoma, and genital warts. Effects on metastatic melanoma, endocrine–pancreatic tumors, metastatic colorectal and ovarian carcinoma, and bladder cancer have also been reported. IFN- β is also licensed for the treatment of chronic hepatitis B and hepatitis C infections. IFN- γ bound to polyethylene glycol (peg-IFN) has an increased circulating half-life and has shown improved efficacy in treating hepatitis C infections.¹⁹ IFN- β has been approved for the treatment of multiple sclerosis and IFN- γ for the treatment of chronic granulomatous disease. Experience using IFN therapy has generally shown that these products are most effective when combined with other antiviral or cytotoxic treatment modalities.²⁰

Using a feline in vitro system, Weiss and Oostrom-Ram²¹ showed that low levels of rhIFN- α had no effect on lymphocyte blastogenesis, whereas higher levels significantly suppressed blastogenic responses. In vivo, cats given 10^2 or 10^4 IU/kg had significantly enhanced blastogenesis, whereas cats given 1×10^6 IU/kg had depressed lymphocyte stimulation. In cats the immunomodulating effects of rhIFN- α appeared to be dose dependent.

Five feline IFN- α subtypes have been recently cloned, expressed, and characterized in feline cell lines.^{11,22} All subtypes were shown to have antiviral effects on feline calicivirus and vesicular stomatitis virus in vitro. Additionally, they showed a species-specific antiproliferative effect on a feline tumor cell line. The IFN-α inducible Mx gene was upregulated 24 hours after administration to cats, demonstrating in vivo efficacy. In vitro work has also demonstrated the antiviral activity of IFN- α against feline herpesvirus-1 in the absence of any cytopathic effect on the cultured corneal cells.²³ Activity of rfeIFN- ω , a closely related cytokine to rfeIFN- α against rotavirus, feline panleukopenia virus, feline calicivirus, and feline infectious peritonitis coronavirus, was documented in cell cultures of feline origin. The antiviral effect was more pronounced when the cell cultures were treated continuously than when they were pretreated only before challenge. RfeIFN- ω did not have activity in canine cells challenged with vesicular stomatitis virus, implying species specificity of action,²⁴ yet de Mari and coworkers²⁵ described clinical benefits of another rfeIFN-ω preparation in dogs with parvoviral infection (discussed later). Recombinant feline IFN- ω is marketed in Japan as Intercat^R (Toray Industries, Tokyo, Japan), and a second rfeIFN-ω product is licensed in Europe as Virbagen omega (Laboratory Virbac, Carros, France).

Feline Infectious Peritonitis

Parenterally administered rhIFN- α and IFN- β , with or without Propionibacterium acnes (which enhances IFN responses and augments T and NK cell activities) given prophylactically or therapeutically, did not significantly reduce the mortality rate of experimentally induced feline infectious peritonitis virus (FIPV) infection. Cats treated with high-dose IFN, 10 U/kg daily for 8 days and then on alternate days for an additional 2 to 3 weeks, however, had temporary suppression of clinical signs and decreased serum antibody responses to FIPV, and the mean survival time of cats treated with highdose rhIFN- α was increased by a few weeks over that of untreated cats. IFN-related toxicities were not reported.²⁶ It is possible that the benefits of the high-dose protocol were due to the dose-dependent immunosuppressive effects of IFN. The increase in survival times in this study using experimental challenge was only 2 to 3 weeks, and there are few data documenting the response of cats with naturally occurring disease. There are anecdotal reports of orally administered low-dose rhIFN-a therapy (as described later) inducing remissions from clinical FIP, but there is currently no published data. A

study of subcutaneous rfeIFN- ω administered to 12 cats clinically diagnosed with FIP demonstrated long-term survival in 4 animals.²⁷ As the authors acknowledge, this was not a case-controlled study and histologic confirmation of the disease was available only for those animals that died during the study. A recent placebo-controlled, double-blind trial in which rfeIFN- ω was administered subcutaneously to cats naturally infected with FIPV did not demonstrate any clinical, hematopoietic, or survival benefits to the therapy; conventional therapy with cytotoxic drugs and corticosteroids remains the treatment of choice.^{28,29}

Feline Leukemia Virus and Feline Immunodeficiency Virus

Recombinant hIFN- α has been shown to inhibit the production or release (or both) of feline leukemia virus (FeLV) in tissue culture systems.³⁰ The parenteral administration of rhIFN- α alone or in combination with zidovudine (AZT) beginning 12 weeks after exposure to FeLV resulted in significant and sustained decreases in circulating virus levels. The anti-FeLV effect was limited by the production of anti-rhIFN- α antibodies detected 7 weeks after the start of therapy. IFNassociated toxicity was not observed.³¹ In a subsequent study, treatment of FeLV-infected cats with AZT, IFN-α, and adoptive transfer of lectin/IL-2-activated lymphocytes resulted in clearance of circulating virus in four of nine cats despite the appearance of anti-rhIFN- α antibodies. Combination therapy appeared to reconstitute antiviral humoral immunity, counteracted immunosuppression, and induced the reversal of retroviremia.32 Unfortunately, because of the problem of antibody induction, parenteral rhIFN-α appears to have little clinical utility as a monotherapy for FeLV infections. In vitro work supports the antiviral effects of rfeIFN- α and rhIFN- α but not rfeIFN-y on feline immunodeficiency virus (FIV) replication.³³ Ovine IFN-τ has demonstrable effects on the in vitro replication of both FIV and human immunodeficiency virus (HIV).³⁴ A study of subcutaneous rfeIFN-α therapy in cats naturally infected with FeLV or co-infected with FeLV and FIV showed significant decreases in clinical scores and mortality rate during the 12 months of follow-up in the treated cats.³⁵ Recently, low-dose oral IFN- α (as described later) was shown to improve clinical condition and survival in cats naturally infected with FIV.36

Canine Parvovirus

Two studies, one with experimental infection and one with naturally occurring infection, have examined the efficacy on rfeIFN- ω (Virbagen, Laboratory Virbac, Carros, France) on the outcome of canine parvoviral enteritis. Ten 8- to 9-week-old dogs inoculated with parvovirus were divided into rfeIFN- ω or placebo treatment groups and received three daily injections. All five of the placebo-treated dogs succumbed to fulminant enteritis, whereas four of five rfeIFN- ω -treated dogs survived and eventually recovered fully.³⁷ In the second study of naturally occurring disease, 43 dogs were assigned to receive three daily intravenous injections of rfeIFN- ω , and 49 dogs received placebo treatment. There was a significant

improvement in clinical signs and a significant decrease in mortality in the dogs receiving IFN therapy.²⁵

Low-Dose Oral Recombinant Human Interferon-α

In 1988 Cummins and coworkers ³⁸ reported that after experimental infection with the Rickard strain of FeLV, the administration of 0.5 or 5 U of natural hIFN- α orally once daily for 7 consecutive days on alternate weeks for 1 month was associated with survival in 70% of IFN-treated cats, whereas 100% of placebo-treated control cats died. However, 12 of 13 cats treated with IFN did develop persistent viremia. In another report, four cats with FeLV-associated nonregenerative anemia were treated with 100,000 U bovine IFN- β orally for 5 consecutive days on alternate weeks. General clinical improvement, reduction in circulating antigen levels, and normalization of hematocrit levels were reported in all cats,³⁹ and one cat cleared its viremia. Similar findings were reported by Steed,40 who treated four FeLV-infected cats with low-dose natural hIFN- α or bovine IFN- β . Weiss and coworkers⁴¹ reported on 69 FeLV-infected cats with clinical signs treated orally with either low-dose rhIFN- α or bovine IFN- β . Cats treated with rhIFN had significantly higher survival rates than did cats given bovine IFN; both groups had increased survival rates compared with historical controls. In general, clinical responses were observed within the first or second week of oral IFN administration, with increased appetite, greater activity, weight gain, resolution of fever, improved hemogram and leukocyte counts, and quicker recovery from secondary bacterial infections when antibiotics were administered. Most cats remained viremic.

In contrast to the aforementioned reports, Kociba and coworkers⁴² reported that low-dose oral hIFN- α had no significant effects on viremia, course of the disease, or differential leukocyte counts in experimental FeLV infection. In their system the Kawakami–Theilen strain (A, B, and C subgroups, which consistently induce fatal erythroid aplasia) was administered to 12-week-old kittens. Methylprednisolone acetate was also given the day of inoculation. Neither rhIFN- α nor human natural IFN- α induced any significant benefit compared with placebo. A second study administering low-dose oral rhIFN- α showed a similar lack of benefit clinically or biochemically in naturally infected, clinically ill FeLV-positive cats.⁴³

Pedretti and coworkers³⁶ recently reported that FIVinfected cats given a daily oral dose of 10 IU/kg rhIFN- α had a significantly prolonged survival rate compared with placebotreated cats. In addition, clinical remission of many of the typical immunopathologic lesions occurred despite no significant reduction in circulating viral levels. This study selected FIV-infected cats that presented with evidence of immunosuppression and clinical signs of acquired immunodeficiency syndrome (AIDS) and utilized a mixture of multiple human IFN- α subtypes. Two large, double-blind, placebo-controlled trials of low-dose oral IFN- α failed to show any efficacy in ameliorating clinical signs, increasing CD4+ T cell counts, or decreasing mortality rates in HIV-infected humans.^{44,45}

If orally administered low-dose human IFN- α has any effect in cats with retroviral infections, a direct systemic antiviral effect is unlikely. It may be possible that IFN may be acting as a biological response modifier after binding to cellular receptors in the oral cavity/pharynx, triggering cytokine cascades that have systemic immunomodulatory effects. Appetite stimulation may be due to direct central nervous system effects. When it was used orally in cats, adverse effects have not been reported, and anti-rhIFN- α neutralizing antibodies do not appear to develop.

Interferons as Therapy for Cancer

IFNs inhibit cell proliferation of both normal and malignant cells and have numerous immunomodulating effects. Several human cancers respond to IFN therapy. At present, there are only preclinical data suggesting that IFNs may have some utility in the treatment of cancer in companion animals. When canine mammary tumor and melanoma cell lines were incubated with canine IFN-y, significantly increased expression of MHC antigen class I and II antigens and tumor-associated antigens were observed.⁴⁶ Increased expression of these antigens may be of benefit in tumor cell recognition and rejection by the immune system. Pretreatment of canine macrophages with rcIFN-y resulted in increased in vitro tumor cell killing in canine models of melanoma and osteosarcoma.47,48 In another study growth of canine and feline tumors was inhibited by rhIFN- α and rhIFN- γ in vitro. Sensitivity to IFN varied according to the type of neoplasm, with round cell tumors being most sensitive.⁴⁹ Recombinant rfeIFN was found to have a dose-dependent inhibitory effect on cell growth and colony formation on cell lines derived from canine acanthomatous epulis, benign mixed mammary tumor, squamous cell carcinoma, and malignant melanoma.⁵⁰ Recent work has demonstrated that intratumoral injection of rfeIFN-ω in cats with fibrosarcomas is safe and feasible; subsequent studies will be necessary to determine efficacy.⁵¹

INTERLEUKINS

Interleukin Biology

There are currently 35 defined ILs, named in order of discovery and classified into groups according to their structure, function, or both. ILs are a diverse group of cytokines, with functions including enhancement or suppression of various cells of the immune system (e.g., IL-1, IL-2, IL-4, IL-9, IL-10, IL-12, IL-13, IL-17, IL-23, IL-27), hematopoietic growth factor activity (e.g., IL-3, IL-11, IL-17, IL-32, IL-34), and the regulation of leukocyte function (e.g., IL-5 modulates eosinophil function; IL-8 is chemotactic for neutrophils). Some are growth factors for cells of the immune system (e.g., IL-7, IL-11, IL-14, IL-15), whereas others enhance the acute phase response (e.g., IL-1, IL-6). Most ILs have multiple effects on various cells and are part of complex regulatory cascades. Depending on the specific IL, they are produced by T and B lymphocytes, macrophages, dendritic cells (DCs), fibroblasts, and other stromal cells.

Examples Of Interleukin Therapy in Dogs and Cats

Interleukin-1

Human rIL-1 α was shown to be chemokinetic and chemotactic for canine neutrophils in vitro and to cause dose-dependent and selective neutrophil infiltration after intradermal administration.⁵² The pharmacokinetics of a single dose of human IL-1 has been studied in the dog. IL-1 was rapidly distributed, with a volume of distribution approximately twice that of the total body water of a lean dog. The terminal half-life was less than 30 minutes. Within approximately 1 hour after dosing,⁵³ IL levels were below the quantifiable limit of the enzyme-linked immunosorbent assay (ELISA). As IL-1 is a central mediator of inflammation, these data are useful for studying the physiology of IL-1; however, pharmacologic efforts will focus on inhibition of IL-1 activity, with applications in the therapy of acute and chronic inflammatory disorders and septic shock. The canine IL-1 receptor antagonist, which functions as a competitive inhibitor of IL-1, has been cloned.⁵⁴

Interleukin-2

IL-2 synthesis is triggered by antigen-induced activation of T lymphocytes, and its most important activity is the promotion of clonal expansion of antigen-specific T cells. In NK cells and macrophages, IL-2 also promotes proliferation, production of IFN- γ , and cytolytic activity. It also induces growth of B cells as well as immunoglobulin secretion. An important clinical consideration is the observation that NK cells cultured in the presence of IL-2 have enhanced cytotoxic activity, with increased capability for lysis of neoplastic cells. These activated cells are called *lymphokine-activated killer (LAK) cells*. IL-2 is thus an attractive agent for the therapy of neoplastic disorders; however, parenteral administration of IL-2 is associated with significant hepatic, hematopoietic, and vascular toxicity, which appears to be largely due to the secondary release of TNF-alpha and nitric oxide.⁵⁵⁻⁵⁷

IL-2 was licensed in the United States in 1992 for the treatment of metastatic renal cell cancer, becoming the first biological agent approved for treatment of any cancer in humans. The availability of recombinant IL-2 spurred the development of *adoptive immunotherapy*, which refers to the transfer to the tumor-bearing patient immune cells that mediate antitumor effects. Adoptive immunotherapy has been performed with LAK cells and tumor-infiltrating lymphocytes. IL-2 is necessary for the generation of these cells in vitro and in vivo and is also administered systemically along with these cells in an effort to keep them functioning in the patient. More recently, IL-2 gene therapy for various cancers has been developed.

Several in vitro studies have demonstrated that rhIL-2 has activity in companion animals similar to the activity recognized in humans. Feline lymphocytes responded appropriately to the cytokinetic action of systemically administered rhIL-2,⁵⁸ and adoptive immunotherapy of FeLV-infected cats with lectin/rhIL-2–activated lymphocytes, IFN- α , and AZT led to reconstitution of antiviral humoral immunity, counteracted immunosuppression, and induced the reversal of retroviremia in a subset of treated cats.³² Feline IL-2 cDNA was cloned, and the recombinant protein was shown to promote proliferation of feline, but not human, cells.^{59,60} Helfand and coworkers⁶¹ demonstrated that the immunobiology of IL-2 in the dog is similar to that of humans. Tumor cytotoxicity was induced in vitro in canine lymphocytes with rhIL-2, demonstrating that

functional and morphologic changes compatible with LAK cells could be obtained in dogs.⁶²⁻⁶⁴

Infusion of rhIL-2 into normal dogs resulted in lymphocytosis and enhanced in vitro lysis of a canine tumor cell line. Side effects included vomiting, diarrhea, and inactivity.⁶⁵ Recombinant human TNF and rhIL-2 were administered in a sequential schedule to 30 dogs with a variety of spontaneous neoplasms. Objective tumor responses were seen in dogs with oral melanomas and cutaneous mast cell tumors. Doselimiting toxicities were primarily gastrointestinal.⁶⁶

In an effort to develop a delivery system that would be associated with less toxicity, Khanna and coworkers⁶⁷ nebulized free rhIL-2 and rhIL-2-containing liposomes into normal dogs. Free IL-2 resulted in increased peripheral blood mononuclear cell activation compared with saline-treated control dogs. IL-2 liposomes resulted in significantly increased bronchoalveolar lavage (BAL) effector leukocyte numbers and activation compared with empty liposomes. In dogs with primary and metastatic lung cancer, nebulized IL-2 increased the total number of BAL macrophages, eosinophils, and lymphocytes compared with pretreatment levels, and there was increased expression of CD3 on BAL lymphocytes. Mean BAL cytolytic activity increased compared with pretreatment activity during therapy to a maximum at day 15, and then it decreased (despite continued aerosol therapy) to pretreatment levels at day 30. Antibodies reacting with hIL-2 developed in the serum of all treated dogs, possibly accounting for the decrease in BAL cytolytic activity at day 30 compared with day 15. Toxicity was not recognized with either IL-2 preparation. Complete regression of pulmonary metastases in two of five dogs with metastatic osteosarcoma was maintained at greater than 370 and 700 at day 68. A phase I trial of liposome-complexed canine IL-2 administered parenterally to dogs with chemotherapyresistant, metastatic osteosarcoma was recently completed.⁶⁹ The liposome formulation resulted in preferential expression of the IL-2 within the lung. The weekly injections were well tolerated, and 3 of the 14 dogs completing the 12-week therapy had partial or complete radiographic regression of metastases, with an additional four dogs showing stable disease. Despite the limitations in interpreting efficacy in a phase I pilot study, there was a significant increase in overall survival times in the treated dogs compared with historic controls with similar tumor staging.

Quintin-Colonna and coworkers⁷⁰ reported that dogs with oral melanoma treated with local resection, 45-Gy radiation therapy, and repeated local injections of xenogeneic Vero cells transfected with an hIL-2–expressing plasmid had longer median survival times than did dogs treated with resection and radiation therapy alone; dogs treated with surgery, radiation therapy, and nonengineered Vero cells; or dogs treated with surgery, radiation therapy, and injection of rhIL-2 into the tumor bed. Similar results were seen in cats with fibrosarcomas. An unexpected observation was the development of metastatic fibrosarcoma in three of five cats that relapsed in the group treated with engineered cells. Complications seen in some dogs and cats included anaphylaxis associated with injection of Vero cells and local inflammatory reactions.⁷⁰ Canarypox virus and attenuated vaccinia virus vectors have been used to deliver rfIL-2 and rhIL-2, respectively, to cats with soft tissue sarcomas.⁷¹ The injections were well tolerated, and there was a significant reduction in tumor recurrence rate with either of the virus delivery systems compared with controls 12 months after treatment.

IL-2 therapy appears to have a place in the immunotherapy of feline and canine cancers, particularly when administered in a manner that concentrates expression within the tumor, thereby limiting systemic toxicity. Adenoviral delivery and incorporation into liposomes appear to be particularly promising modes of therapy. Canine and feline IL-2 cDNA have been cloned^{59,72,73} and are commercially available (see Box 32-1).

Interleukin-12

IL-12 is a proinflammatory cytokine that has shown great promise as a therapeutic agent in experimental models of infectious disease and cancer. Multiple lines of evidence indicated that IL-12, a heterodimer produced in response to endotoxins, intracellular parasites, and CD40 ligation, is pivotal in initiating a cell-mediated immune response.74-76 Direct contact with microbial products or activated T cells can prompt antigen-presenting cells (e.g., macrophages, DCs) to release IL-12. In turn, IL-12 induces the synthesis of IFN- γ by T and NK cells. This early IL-12 generation is critical to early host containment of many intracellular pathogens, including Toxoplasma gondii,⁷⁷ Listeria monocytogenes,⁷⁸ Leishmania major,79 and Mycobacterium tuberculosis. 80 To date, most veterinary studies using IL-12 have been designed to characterize the adjuvant effect of IL-12 in boosting the cell-mediated immune response to FeLV, FIV, and FIPV vaccination. Two studies administering intradermal FIV DNA showed protection from FIV infection in three of four cats when IL-12 was included in the vaccination, whereas all four cats that received the DNA vaccine alone became infected.^{81,82} Similar DNA vaccinations protocols against FeLV challenge showed increased protection only when IL-12 was co-administered with IL-18, another cytokine known to enhance cell-mediated immunity.83 Vaccination of cats against FIPV in combination with co-delivery of feline IL-12 encoding plasmids did not enhance protection and may have actually potentiated the infection.⁸⁴ There is precedence for the inhibition of cell-mediated immunity when IL-12 is administered at high doses,^{6,85} and this may have played a role in the outcome of this study. Lasarte and coworkers⁶ demonstrated that the depression of cell-mediated immunity at high IL-12 doses was related to the generation of large amounts of nitric oxide.

IL-12 is one of the most widely studied cytokines in cancer immunotherapy and has been found to eradicate experimental tumors, elicit long-term antitumor immunity,⁸⁶⁻⁸⁸ and possess antiangiogenic properties.^{89,90} The role of IL-12 as chemotherapeutic agent has been limited because of its toxicities. In mice, daily administration of 0.1 to 10 µg of recombinant murine IL-12 for up to 2 weeks resulted in liver function abnormalities; gastrointestinal toxicity; and hematopoietic changes, including anemia, neutropenia, lymphopenia, and thrombocytopenia.⁹¹⁻⁹³ In humans the toxic effects include fever, anemia, neutropenia, lymphocytopenia, thrombocytopenia, liver function test abnormalities, rhinitis, stomatitis, and colitis.⁹⁴ In a phase II clinical trial in renal carcinoma using rhIL-12, two deaths were reported.⁵ The authors have seen dose-dependent hematopoietic toxicities (anemia, neutropenia, and thrombocytopenia) in preclinical trials of systemic administration of a replication-defective adenovirus encoding murine IL-12 in cats.^{94a}

One approach that can be used to avoid the systemic toxicity of IL-12 is to use local intratumoral IL-12 gene therapy. A replication-defective adenovirus containing feline IL-12 under the control of the heat-shock promoter has been developed and characterized in vitro.95 An added advantage of employing the heat-shock promoter is that IL-12 expression can be temporally induced by providing external hyperthermia to the tumor. A phase I dose escalation trial with feline soft tissue sarcomas was recently completed. A maximum tolerable dose was reached, although all cats completed the treatment regimen. At the highest dose of adenovirus, fever, anemia, and thrombocytopenia were reported.96 Further follow-up and expanded studies will be required to determine clinical efficacy of this cytokine treatment. Intramuscular injection of a plasmid DNA expression vector of canine IL-12 induced enhanced peripheral blood mononuclear cell production of IFN-y in treated dogs.97 Recombinant mIL-12 has been shown to significantly inhibit the growth of a canine hemangiosarcoma cell line transplanted into mice.⁹⁸ It is unclear whether the growth inhibition was mediated mainly through antiangiogenic mechanisms, NK cell activation, or a combination of both.

IL-12 is a potent immunostimulant that holds tremendous promise as a vaccine adjuvant or cancer immunotherapeutic. The very potency of this cytokine contributes to its limitations, and continued studies designed to diminish systemic toxicities will be necessary before it can be commonly employed. Both feline and canine IL-12 have been cloned and expressed,^{99,100} and the recombinant proteins are currently commercially available (see Box 32-1).

Other Interleukins

IL-6 is a proinflammatory cytokine (along with IL-1 and TNF- α) with pleiotropic activity, including effects on B and T cells and induction of acute phase proteins. Elevated levels of IL-6 have been reported in Chinese Shar-Peis with recurrent febrile illnesses, and IL-6 dysregulation has been postulated to play an etiologic role in the syndrome.¹⁰¹ Systemic inflammatory response syndrome (SIRS) and sepsis are associated with increased IL-6 production, and high plasma IL-6 levels are negatively correlated with outcome in canine SIRS patients.¹⁰² Cranial cruciate ligament rupture in dogs results in increased levels of synovial fluid IL-6.¹⁰³ Dogs with juvenile polyarteritis syndrome were also found to have increased levels of serum IL-6 activity during acute illness but undetectable levels during convalescence. Treatment of acutely ill dogs with prednisone resulted in rapid clinical improvement accompanied by a decrease in IL-6 activity; withdrawal of prednisone resulted

in reappearance of signs and high serum IL-6 activity. Clinically, the most important inhibitors of IL-6 expression are glucocorticoids.¹⁰⁴ Specific blockade of IL-6 or the IL-6 receptor (or both) is a potentially promising means of controlling clinical disease in chronic inflammatory conditions.¹⁰⁵ IL-6 also has marked effects on megakaryocyte and platelet physiology. In dogs 80 µg/kg per day of rhIL-6 increased platelet counts modestly and enhanced the sensitivity of platelets to activation in response to thrombin and platelet-activating factor.¹⁰⁶ Other investigators have shown that IL-6 promoted increases in plasma fibrinogen and von Willebrand factor (vWF) and a decrease in free protein S concentrations.¹⁰⁷ These effects on the clotting mechanism may result in an overall prohemostatic tendency, which may prove beneficial for the amelioration of bleeding associated with a variety of conditions. Additional investigation is required to determine if IL-6-mediated alterations of hemostasis may lead to pathologic thrombosis. The cDNAs for feline and canine IL-6 have been cloned, the recombinant proteins have been described,108-110 and they are commercially available (see Box 32-1).

IL-11 is a pleiotropic cytokine that enhances the activity of primitive, erythroid, and megakaryocyte progenitor cells and the production of hepatic acute phase proteins, and it supports growth of the intestinal epithelium. In animal models rhIL-11 has been shown to be effective in reconstituting platelet levels after the administration of chemotherapy or radiation therapy and in protection against radiation- or drug-induced damage to the intestinal epithelium. IL-11 has also been shown to increase circulating levels of vWF and rhIL-11 increases vWF in dogs with von Willebrand disease (vWD) with kinetics that are more gradual and sustained than desmopressin.¹¹¹ Unlike the release of preformed vWF from platelets induced by desmopressin, administration of IL-11 results in the increased production of vWF RNA. Phase II trials of IL-11 in human patients with vWD have recently been completed.¹¹² Clinically, rhIL-11 has also been used to support platelet levels in human cancer patients and in the management of Crohn's disease and ulcerative colitis. A side effect that limits the administration of rhIL-11 is plasma volume expansion, resulting in edema, a fall in hematocrit levels, and cardiac arrhythmias. In dogs rhIL-11 increased platelet counts, platelet size, ploidy, and the number of megakaryocytes in marrow and peripheral blood. Pneumonitis may be a dose-limiting side effect in dogs.¹¹³

CHEMOKINES

Chemokine Biology

Chemokines are largely responsible for leukocyte chemotaxis, mediating inflammation and coordinating the host response to infection. The chemokines can be divided into two large and two small subfamilies on the basis of the pattern of cysteine residues found at the amino terminal end. The two large groups consist of the CXC subfamily, in which one amino acid is interspersed between the two cysteines, and the CC subfamily, in which the two cysteines are directly apposed. The two minor subfamilies consist of chemokines in which a single cysteine is found at the amino terminal end (XC) and ones in which the cysteines are separated by three amino acids (CX₃C). Chemokines bind to one or more seven transmembrane, G protein-coupled receptors that, again, fall into two major and two minor subfamilies. In an attempt to standardize the nomenclature, the chemokines are grouped as CCL, CXCL, XCL, and CX₃CL, and the receptors as CCR, CXCR, XCR, and CX₃CR, where L denotes ligand and R denotes receptor and numbers are added in the order in which they have been described.¹¹⁴ In this chapter chemokines are referred to according to the standard nomenclature with their former names provided in brackets if they have been commonly used in the literature. Currently 46 chemokines and 19 chemokine receptors have been identified.¹¹⁵ Canine and feline CXCR4 and CCR5 have been isolated and demonstrate significant sequence homology and tissue distribution with their murine and human counterparts.116-118

Chemokines play a central role in inflammatory and allergic diseases. In response to signals such as lipopolysaccharide (LPS) from gram-negative bacteria or some of the inflammatory cytokines described earlier, such as IL-1 or TNF- α , chemokines are released at the site of injury, setting up a chemotactic gradient. Fibroblasts, smooth muscle cells, and epithelial cells have all been shown to be significant sources of chemokines. Neutrophils will move toward high levels of the chemokines CXCL1-3, CXCL6,7 and CXCL8 (IL-8); eosinophils respond to CCL5 (RANTES), CCL11,24,26 (eotaxin-1,2,3), CCL13 (MCP-4), and CCL28; and monocytes, DCs, and lymphocytes are attracted to CCL6 (C10), CCL2 (MCP-1), CCL3 (MIP1- α), and CCL4 (MIP1- β). There is a high level of overlap and promiscuity in the types of cells recruited by a particular chemokine based, in part, on the ability of some chemokines to bind multiple receptors and some receptors to bind multiple chemokines.

In addition to directing leukocytes to the site of inflammation or injury, chemokines provide the necessary gradients for DC trafficking to lymph nodes. Immature DCs circulate and act as sentinels for pathogens. In the immature state, they express a chemokine receptor repertoire that is poised to respond to many of the inflammatory chemokines. After recruitment to the site of inflammation, DCs encounter antigen and associated inflammatory cytokines and undergo maturational changes, including the expression of the chemokine receptor CCR7. The ligands for CCR7 are CCL19 (MIP3 β) and CCL21 (6Ckine), which are expressed within the T cell–rich areas of lymphoid follicles. The end result is that the antigenloaded, mature DC is preferentially drawn to the draining lymph node, where it will encounter T lymphocytes, thereby activating a specific cell-mediated response to the pathogen.

To describe chemokines in terms of leukocyte recruitment only would be to ignore their other important physiologic roles. The normal development of lymphoid organs depends on signals derived from chemokines, as does structural development of the fetal neurologic system^{119,120} and intestinal vascular networks.¹²¹ Chemokines have been proposed to play a role in embryo implantation and menstruation.¹²² Many tumors express chemokine receptors, and they have been shown to play a role in tumor growth and in directing organ-specific metastasis.^{123,124} The discovery that HIV uses the chemokine receptors CCR5 and CXCR4 as co-receptors for viral entry into target cells has helped highlight the way in which some pathogens exploit chemokine pathways.^{125,126}

Therapeutic Manipulation of Chemokines

Inflammatory Diseases

Elevated chemokine levels have been demonstrated in a variety of inflammatory and autoimmune diseases in humans, including asthma, inflammatory bowel disease, rheumatoid arthritis, and sepsis. Because much of the pathology associated with these diseases is due to the cascade of effects caused by the ongoing chemotactic stimulus, chemokine antagonists have emerged as potential therapeutics.¹²⁷ The CC chemokine receptor CCR1 and its ligands CCL3 (MIP1- α) and CCL5 (RANTES) have been shown to be important in the pathology of models of rheumatoid arthritis, respiratory syncytial virus infection and sepsis. Serum levels of both CCL3 and CCL5 are elevated in septic humans,¹²⁸ and mice lacking CCR1, the receptor for these chemokines, were significantly more likely to survive experimental sepsis.¹²⁹ Limiting viral replication is clearly important in virally mediated pneumonia, but blocking chemokine-mediated recruitment of inflammatory cells has also shown dramatic benefits in experimental systems. In a murine model of respiratory syncytial virus infection, either blocking CCR1 signaling or deleting CCR1 expression in conjunction with antiviral treatment dramatically enhances survival compared with antiviral treatment alone.¹³⁰ Antagonists of CCR1 have been developed, and despite the species specificity of some antagonists,¹³¹ cross-species efficacy has been demonstrated for other compounds. Liang and coworkers¹³² have developed a selective peptide antagonist of CCR1 that has efficacy in both human and rat systems, although the binding affinity of the peptide is significantly lower in rats. Additionally, this peptide was shown to have good oral bioavailability in dogs. Relatively minor modifications of antagonist structure have been shown to improve activity across divergent species.¹³³

CXCL8 (IL-8)-induced neutrophil influx into tissues by way of CXCR1 and CXCR2 is clearly beneficial in controlling the early stages of bacterial infection. There are other instances in which CXCL8 expression potentiates the pathology of diseases such as sepsis/peritonitis, acute respiratory distress syndrome, exacerbations of human chronic obstructive pulmonary disease and bovine pneumonic pasteurellosis.¹³⁴⁻¹³⁷ CXCL8 is expressed in increased levels in several bacterial diseases of ruminants and in equine chronic obstructive pulmonary disease.⁴ Li and coworkers¹³⁸ generated a potent CXCL8 antagonist that blocks signaling through both CXCR1 and CXCR2 in bovine neutrophils. They have shown efficacy in vitro against the neutrophil chemotactic activities of fluids from bovine pasteurella pneumonia and endotoxin- induced mastitis and in vivo against intradermal neutrophil influx in response to endotoxin.¹³⁹ Because this antagonist also effectively blocks human CXCL8 activities on human neutrophils, it may have uses in feline and canine inflammatory diseases.

Neoplasia

Introducing chemokines into tumors could be advantageous in recruiting immune effector cells to help destroy the tumor, and this has been shown to be true in murine cancer models. CCL16, CCL20, MIP3a, CCL21 (6Ckine) expression within murine tumors all resulted in increased infiltration of DCs, increased tumor immunogenicity, and decreased tumor growth.140-143 Bringing DCs and T lymphocytes into the tumor is not always sufficient, and providing a simultaneous activation stimulus helps overcome the otherwise immunosuppressive tumor microenvironment. This has been accomplished by delivering the chemokines in adenoviral vectors where the virus itself provides an immune stimulus¹⁴⁰ or by simultaneously blocking immunosuppressive cytokines or providing innate immune system stimuli.^{143,141} Because there is significant cross-species sequence homology in many of the chemokines¹⁴⁴ and precedence for cross-species efficacy between mice and humans with chemokines such as CCL20,¹⁴⁰ some of the currently available murine and human chemokines may prove useful in veterinary cancer applications.

The converse to the potentially beneficial aspects of tumor chemokine expression is the documented role that chemokines and tumor chemokine receptor expression play in the natural course of tumor progression. Chemokines can act as tumor growth factors either directly or through the recruitment of leukocytes. Some tumor cells both express the chemokine receptor and produce its ligand, allowing autocrine enhancement of proliferation and survival. Melanoma cells expressing CXCR2 and producing CXCL1 and CXCL8 (IL8) are one such example.¹⁴³ Macrophages recruited to tumors can elaborate tumor cell growth factors and increase angiogenesis within the tumor.144 Chemokine receptor expression by tumor cells has also been shown to play a substantial role in metastasis. Tumor cells expressing chemokine receptors will move toward chemokine gradients, resulting in metastasis to draining lymph nodes or distant sites. CCR7 expression by melanoma cells is correlated with metastasis to draining lymph nodes.145,146 It appears that the tumor cells are taking advantage of the normal chemokine gradient for activated, CCR7expressing DC homing to draining lymph nodes. CXCR4 is expressed by a wide variety of tumors, including mesenchymal, epithelial, and hematopoietically derived cancers.¹⁴⁷ Malignant mammary tumors have been shown to express high levels of CXCR4, and its ligand, CXCL12 (SDF1), is preferentially expressed in common target tissues for mammary tumor metastasis such as lung, liver, bone marrow, and lymph nodes.¹⁴⁸ Oonuma and coworkers¹⁴⁹ have demonstrated increased expression of feline CXCR4 in metastatic mammary tumors of cats and high levels of CXCL12 production in feline lymph node, lung, and liver. Additionally, they demonstrated increased in vitro tumor cell migration toward CXCL12 gradients and inhibition of this migration when CXCR4 peptide antagonists were added. The same CXCR4 antagonist has shown efficacy in inhibiting the number of lung metastases in a mouse model of mammary carcinoma.¹³² Some cases of canine osteosarcoma have been shown to express CXCR4 and migrate toward CXCL12 in vitro.¹⁵⁰ Selective chemokine

receptor antagonists hold promise as potential in vivo therapeutics to minimize cancer metastasis, and feline mammary tumors appear to be an appropriate system to apply these compounds. The documented role of chemokine receptor expression in human squamous cell carcinoma,¹⁵¹ melanoma,^{152,153} and prostate carcinoma¹⁵⁴ awaits exploration in dogs and cats.

Retroviral Infections

The discovery that HIV uses the chemokine receptors CXCR4 and CCR5 as co-receptors for viral entry^{125,126,155} has prompted the search for and development of drugs to inhibit virus binding. Subsequent work has shown that FIV uses CXCR4, but apparently not CCR5, as a co-receptor as well.¹⁵⁶ Bicyclams are potent CXCR4 antagonists, and one such compound, AMD3100, has been shown to inhibit in vitro replication of FIV.^{157,158} Antagonists of feline CXCR4 have been developed and tested successfully in vitro.¹⁵⁹ The number of CXCR4 antagonists is continually expanding,¹⁶⁰ and FIV-infected cats may well benefit from these compounds in the future.

Rapid advances in the understanding of chemokine biology have allowed the exploration of ways to manipulate these factors in a wide variety of diseases. Whether they are used to recruit immune effector cells to tumors or their actions are blocked in an attempt to minimize inflammation or viral infection, manipulation of chemokines has the potential to be a powerful therapeutic tool.

HEMATOPOIETIC GROWTH FACTORS

In humans the hematopoietic system produces in the order of 10¹¹ cells daily and is able to rapidly increase production even further when stimulated by hematopoietic growth factors. Hematopoietic growth factors include erythropoietin (EPO), granulocyte colony-stimulating factor (G-CSF), granulocyte/ macrophage colony-stimulating factor (GM-CSF), monocyte colony-stimulating factor (M-CSF), thrombopoietin, stem cell factor (SCF), and most of the ILs. Hematopoietic growth factors act synergistically at various levels in the hematopoietic developmental system, and their actions are rarely restricted to a given lineage. The cDNAs for all of the known human factors, and some of the canine and feline factors, have been cloned. Recombinant hG-CSF (filgrastim), rhGM-CSF (sargramostim), and rhEPO (epoetin) are commercially available. For humans this has led to significant advances in the management of a variety of hematologic and neoplastic disorders. Canine and feline G-CSF, GM-CSF, and SCF have all been cloned and expressed,161-165 and canine and feline GM-CSF and SCF are commercially available (see Box 32-1).

Recombinant Erythropoietin

In dogs EPO is secreted by cells adjacent to the proximal convoluted tubules in response to renal hypoxia. EPO stimulates the proliferation and maturation of erythroid progenitor cells, primarily colony-forming unit erythroid cells. Megakaryocytes are also stimulated by EPO. Recombinant human EPO was the first commercially available hematopoietic growth factor released for clinical use in humans and is indicated for the treatment of anemia secondary to chronic renal failure, anemia secondary to the treatment of HIV with AZT, and anemia secondary to cancer chemotherapy. The use of recombinant human, feline, and canine EPO in small animals is addressed elsewhere in this text (see Chapters 15 and 18).

Growth Factors Affecting Myeloid Lineages Granulocyte Colony-Stimulating Factor

G-CSF is produced by fibroblasts and endothelial cells stimulated by IL-1 or TNF and by macrophages stimulated by bacterial endotoxins. Its major effects are on neutrophils and neutrophil progenitors. Recombinant hG-CSF is commercially available and for humans is indicated to decrease the incidence of infection in patients with nonmyeloid malignancies receiving myelosuppressive chemotherapy with or without bone marrow transplantation, congenital neutropenia, and cyclic neutropenia.

In normal dogs rhG-CSF induces rapid and marked neutrophilia but, similar to the situation with rhEPO, also induces antibodies that react with both rhG-CSF and endogenous canine G-CSF, leading to chronic but reversible neutropenia.166,167 Whether dogs with cancer receiving immunosuppressive chemotherapy are able to mount an immune response to rhG-CSF has not yet been determined. In dogs treated with total body irradiation, rhG-CSF therapy was associated with earlier recovery of neutrophils and platelets and reduced the lethality of the hematopoietic insult compared with untreated irradiated controls.¹⁶ In gray Collies with cyclic hematopoiesis, rhG-CSF eliminated neutropenic episodes but did not correct abnormalities in platelet aggregation or serotonin content or decreased neutrophil myeloperoxidase activity.^{167,169} Recombinant hG-CSF has also been used to treat drug-induced pancytopenia in a dog.170

Canine G-CSF has been cloned but is not commercially available. In normal dogs rcG-CSF was shown to induce rapid and marked increases in neutrophils, moderate increases in lymphocyte and monocyte counts, and bone marrow hyperplasia. For example, five normal dogs were given 5 µg/kg rcG-CSF per day subcutaneously for 4 weeks. The mean neutrophil counts increased from 6537/µL to 26,330/µL within 24 hours after the first injection to a maximum of 72,125/µL by day 19. Blood counts returned to normal within 5 days after discontinuation of rcG-CSF, and clinically significant toxicoses were not associated with rcG-CSF administration. The induction of neutrophilia was induced again on repeated administration.171-173 Recombinant cG-CSF prevented neutropenia and associated clinical signs in cyclic hematopoietic dogs but did not completely eliminate the cycling of neutrophils in cyclic hematopoietic dogs. Also, the time to bone marrow reconstitution was not decreased in dogs treated with rcG-CSF after autologous bone marrow transplantation, emphasizing that rcG-CSF action depends on the presence of progenitor cells in the bone marrow.174

To evaluate the utility of rcG-CSF in the management of chemotherapy-induced neutropenia, myelosuppression was induced with mitoxantrone in normal dogs and then treated with daily rcG-CSF for 20 days. None of the dogs receiving rcG-CSF developed serious neutropenia, whereas four of five untreated dogs did. These findings demonstrate that rcG-CSF is capable of reducing the duration and severity of mitoxantrone-induced myelosuppression.¹⁷⁵ The optimal cost-effective timing and duration of treatment for the management of therapy-induced myelosuppression has not been determined for canine or human origin cytokines, and it may only be necessary to treat when neutrophil counts fall below 1000 cells/µL, and only a few days of therapy may be necessary.¹⁷⁶ In addition to cancer treatment-induced neutropenia, rcG-CSF has been used to accelerate the rate of recovery from neutropenia in dogs with parvovirus. It has not been useful in dogs without neutrophil progenitors, such as those with aplastic anemia secondary to ehrlichia infections or estrogen toxicity.177 Historical and bone marrow evaluations are important in determining which animals are likely to respond to therapy with any hematopoietic growth factor.

Recombinant G-CSFs of both human and canine origin have been studied in normal cats. In one study, 5 µg/kg rcG-CSF per day was administered to healthy cats for 42 days. Mean neutrophil counts increased from 10,966 cells/µL to 30,688 cells/µL within 24 hours after the first dose. Neutrophil counts increased and remained elevated until cytokine administration was discontinued at 42 days. No adverse effects were reported.¹⁷⁸ Normal cats given rhG-CSF developed neutropenia before the end of 3 weeks of therapy, presumably because antibodies developed against the growth factor.¹⁷⁹ Neutropenia has not been observed in cats given rcG-CSF, likely because of greater homology between the cat and dog cytokines.¹⁷⁸ It is not known if cats with immunosuppressive disorders or cats receiving antineoplastic chemotherapy are able to form antibodies that react with human-derived cytokines. Cats with Chédiak-Higashi syndrome treated with rcG-CSF had increased neutrophil counts and improvement in neutrophil function.¹⁸⁰ Recombinant G-CSF (of any species origin) may also be useful in the management of feline panleukopenia, neutropenia associated with FeLV and FIV infections, and sepsis.

Granulocyte/Macrophage Colony-Stimulating Factor

GM-CSF is produced by the bone marrow stroma and T and B cells and is a regulator of the intermediate stages of hematopoiesis. It supports the expansion and growth of both granulocytic and macrophage lineages and also enhance the function of mature macrophages and neutrophils.181 In humans rhGM-CSF is indicated for the acceleration of hematopoietic reconstitution after autologous bone marrow transplantation in lymphoproliferative disorders. Recombinant hGM-CSF induces leukocytosis (primarily neutrophils but also eosinophils and monocytes) in normal dogs. In dogs undergoing total body irradiation and supported with rhGM-CSF, there was decreased severity and shortened duration of neutropenia, indicating that rhGM-CSF can be effective monotherapy for radiation-induced bone marrow failure in dogs. Anti-rhGM-CSF antibodies developed in 1 to 2 weeks and persisted for at least 150 days. Another potential concern with rhGM-CSF is that platelet counts dropped to nadirs of 20% to 30% normal levels.182,183

Canine GM-CSF has been cloned and its activity investigated in normal dogs, where it induced significant increases in neutrophil and monocyte levels. As with the human recombinant product, mean platelet counts decreased significantly. Further investigation into the mechanism of thrombocytopenia suggested that GM-CSF activates hepatic macrophages, with resultant increases in phagocytosis of platelets.^{184,185} After otherwise lethal total body irradiation, rcGM-CSF was not effective in promoting hematopoietic recovery or improving survival.¹⁸⁶ In studies of partial body irradiation in dogs, 7 days of treatment with rhG-CSF resulted in a more efficient and rapid reconstitution of neutrophil numbers than similar treatment with rhGM-CSF.187 It is thought that G-CSF results in an increase in the production of migratory hematopoietic progenitors from the protected marrow sites and an enhanced seeding of these progenitors into the regions of damaged marrow. These results suggest that, in situations of severely limited stem cell response, G-CSF may be more effective than GM-CSF in eliciting a rapid neutrophil recovery.

In an effort to avoid daily systemic administration of recombinant GM-CSF, direct intramarrow injection of adenoviral vector-cGM-CSF constructs (AdcGM-CSF) in normal dogs has been carried out.188 Replication-deficient adenoviral vectors efficiently transduce marrow stromal cells and induce high levels of cytokine production. In vivo, high levels of protein production are found in bone marrow aspirates 72 hours after direct intramarrow administration of AdcGM-CSF. Localized myeloid expansion of marrow and significant peripheral leukocytosis have been identified in all treated dogs, and peripheral blood changes last for up to 3 weeks after a single intramarrow injection. It appears that adenoviral-mediated cytokine expression from the marrow of a single large bone (ileum) leads to compartmentalized expression of GM-CSF and an increase in hematopoiesis. Recent studies have demonstrated that intravenous administration of canine GM-CSF ligated to silica nanoparticles results in detectable GM-CSF for up to 10 days and prevented or restored vinblastine-induced neutropenia in dogs.^{189,190} None of the dogs had detectable anti-GM-CSF antibodies 28 days after injection.

GM-CSF has been used to expand DC precursors from peripheral blood and bone marrow for potential therapeutic purposes. Ex vivo expanded DCs have been stimulated with antigen and reintroduced in experimental models of infectious and neoplastic diseases.^{191,192} Both human and feline GM-CSF have been used to culture myeloid DCs from feline peripheral blood and bone marrow,193,162,194 and canine GM-CSF has been used with canine peripheral blood and bone marrow.^{195,196} In vitro culture, antigen stimulation, and reintroduction of bone marrow-derived DCs from three dogs with melanoma have been performed.¹⁹⁷ These cells were cultured with a combination of rhGM-CSF, SCF, and FLT3 ligand, matured with rhTNF- α and administered in conjunction with radiation therapy. One dog developed antigen-specific cytotoxic T cell activity and remained tumor free 48 months after therapy. It is likely that more studies employing DC vaccination will be carried out in canine and feline patients in the near future.

GM-CSF is a mediator of antibody-dependent cellular cytotoxicity and increases MHC expression, giving GM-CSF potential utility as a modulator of antitumor immunity. A vaccine consisting of irradiated hGM-CSF transfected canine melanoma cell line has been reported to produce GM-CSF at the site of intradermal injection for extended periods in normal dogs.¹⁹⁸ A phase I clinical trail using autologous tumor cells in dogs with melanoma and soft tissue sarcomas showed significant tumor infiltration of neutrophils and macrophages in treated tumors.¹⁹⁹

Stem Cell Factor

SCF (c-kit ligand, mast cell growth factor) is produced primarily by bone marrow stroma, with effects on a wide range of precursor cells at different stages of differentiation, including primitive hematopoietic stem cells. It has little activity as a single agent; however, it is a potent co-stimulatory molecule when administered in combination with other hematopoietic growth factors. Canine SCF cDNA has been cloned and studied in long-term bone marrow cultures. Alone, rcSCF was nonstimulatory for committed marrow precursors. Synergistic stimulation of granulocyte/macrophage colony-forming units was demonstrated between rcSCF, rhGM-CSF, and rhIL-6.200 In vivo, rcSCF induced neutrophilia in normal dogs and supported hematopoietic recovery in normal dogs undergoing total body irradiation without marrow transplant; however, results were similar to those obtained with rcG-CSF.²⁰¹ Recombinant canine SCF also prevented neutropenic periods in gray Collies with cyclic hematopoiesis.²⁰²

Hematopoietic growth factors have proved quite useful in small animal veterinary medicine for managing cytopenias and anemias. The recent cloning and expression of canineand feline-specific reagents will help alleviate the problem of antibody generation with repeated use. Additional uses of factors such as GM-CSF in cancer chemotherapy and in the in vitro generation of DCs will expand the clinical utility of this class of growth factors.

SUMMARY

The concept of enhancing the normal immune response against infections and tumors has been considered for decades. The administration of various natural and synthetic products to simulate systemic infections has largely given way to the idea that specific cytokines can be used effectively when administered locally or systemically. IFNs, ILs, chemokines, and hematopoietic growth factors may offer substantial clinical benefit in chronic viral infections and in cancers. EPO has been shown to have great utility in the management of chronic renal failure. The recent increase in the commercial availability of canine and feline reagents allows for increased exploration of their efficacy in diseases of dogs and cats. These products may have significant clinical impact on several highly fatal disorders of dogs and cats. When administered systemically, cytokines perturb complex regulatory pathways, and serious side effects may occur. Innovative delivery methods, such as liposomes, adenoviral delivery, and even oral administration, may increase the therapeutic index of these molecules. Biological response modification, cytokine biology, and associated delivery systems are rapidly changing fields, and the small animal veterinarian will need to watch for significant advances in these areas over the next several years.

METRONOMIC CHEMOTHERAPY COMMON SIDE EFFECTS OF CHEMOTHERAPY

Myelosuppression Gastrointestinal Side Effects Phlebitis and Necrosis Alopecia Reproductive Side Effects Palmer–Plantar Erythrodysesthesia Human Health Hazards

DRUGS USED IN CHEMOTHERAPY

Alkylating Agents Mitotic Inhibitors Antitumor Antibiotics Antimetabolites Platinum Drugs Miscellaneous Drugs

Throughout the centuries the sufferers of this disease have been the subject of almost every conceivable form of experimentation. The fields and forests, the apothecary shop and temple have been ransacked for some successful means of relief from this intractable malady. Hardly any animal has escaped making its contribution in hide or hair, tooth or toenail, thymus or thyroid, liver or spleen in the vain search for a means of relief. — Bainbridge, The Cancer Problem, 1914

Before appropriate treatment for a particular cancer can be instituted, the tumor must first be diagnosed by cytology or histopathology. Testing is then conducted to allow staging of the tumor—to determine if there is clinically visible evidence of metastatic spread. Lymph node cytology or biopsy, radiographs, ultrasound examinations, and computed tomography or magnetic resonance imaging scans may be used as staging procedures. The biological behavior typical for the cancer must be considered. If, as a rule, the tumor tends to remain localized, surgery or radiation therapy-or a combination of the two-may be the best way to obtain cure or control. If the tumor is likely to metastasize by lymphatics or hematogenously, however, some form of systemic therapy must be added to make a cure more likely. Systemic therapy involves the administration of biological agents, hormones, or cytotoxic chemotherapy. Theoretically, cancer chemotherapy is given to kill or suppress the growth of malignant cells without killing normal cells; in fact, however, most of the commonly used drugs are capable of killing both normal and malignant cells, depending on the dose administered. To be useful in clinical practice, an antineoplastic drug must possess selective toxicity-that is, it should be more toxic to cancer cells than to normal host cells at conventional doses. Finally, the clinician must determine whether the patient has concurrent diseases, with a complete blood count (CBC), biochemical panel, urinalysis, and possibly testing for feline leukemia virus and feline immunodeficiency virus. This section of the chapter

addresses the principles of chemotherapy and the side effects seen in dogs and cats.

Drugs used in chemotherapy cause their anticancer effects by interacting with important substrates or enzymes that are related to DNA synthesis or function. Therefore most anticancer drugs are ineffective against cells that are not actively proliferating. Tumors with a high mitotic index (e.g., lymphoma) are much more likely to be sensitive to chemotherapy than those in which mitotic activity is low. Because chemotherapeutic drugs are effective principally on cells that are actively replicating, it is important to have an understanding of the phases of the cell cycle before discussion of individual drugs (Figure 33-1). The part of the cell cycle in which active mitosis occurs has been termed the M phase; it is quite short in all cells, generally lasting less than 1 hour. The period during which DNA synthesis occurs for chromosome doubling in preparation for mitosis is called the S phase and ranges from 8 to 30 hours. When scientists began to learn about cell division, they realized that there were other phases in the cell cycle; because they initially did not understand what was occurring in the cell at these times, the phases were called G (G_1 and G_2) for gap. G_1 follows mitosis, and protein synthesis and RNA transcription occur during this phase. G₁ is extremely variable in length depending on the cell type, ranging from 7 to 170 hours. G₂ precedes the next mitotic event and is usually brief, ranging from 1 to 4 hours. G₀ has been used to describe those cells that are not actively cycling. Certain cell types, such as myocytes and neurons, enter G₀ and never cycle again. Other cell types, such as hepatocytes, proliferate in young animals and then cease cycling at maturity but are capable of beginning to cycle again if cell replacement is necessary. Fibroblasts become terminally differentiated in connective tissue, but stem cells remain in the tissue. These can become reproductively active again to repopulate the tissue if a wound occurs.

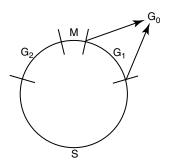

Figure 33-1 Cell generation cycle: M-mitosis; S-DNA content is being doubled in preparation for mitosis; G_1 and G_2 -gaps. Protein synthesis and RNA transcription are occurring in these phases; G_0 -cells that are not actively cycling.

Chemotherapeutic drugs can be classified into three groups on the basis of their activity in the phases of the cell cycle (Box 33-1). Agents that are considered to be lethal to cells in all phases of the cell cycle, with resting cells as sensitive as proliferating cells, are called cycle nonspecific. Examples include nitrogen mustard (the first chemotherapy agent; its activity was discovered in 1919 with the effects of mustard gas on the troops in World War I) and high-dose cyclophosphamide. Agents that are capable of damaging both resting and cycling cells (although cells in cycle are much more sensitive) include conventional-dose cyclophosphamide and doxorubicin. These drugs spare resting cells and are called cycle specific. Agents that are *phase specific* exert their lethal effects exclusively or primarily during one phase of the cell cycle, usually S or M; resting cells and cells in the other phases of the cell cycle are not killed. Examples include methotrexate, cytosine arabinoside, vincristine, and vinblastine.

There are three phases in the development of a new chemotherapeutic drug (Box 33-2). Many artificial chemicals and naturally occurring compounds are screened (generally by the National Cancer Institute or by industry) for cytotoxicity, first in cultures of cancer cells and then in mice or rats. If a particular compound looks promising, a phase I trial is conducted, providing an initial pharmacologic evaluation. The appropriate mode of administration is established for the drug, and common side effects are discovered. Patient tolerance of increasing dosage is also determined. Phase I trials are conducted on very small numbers of patients, generally with advanced and ultimately terminal cancers for which no conventional treatment is available, and doses tolerated by these patients may be below the ultimate therapeutic range. If the compound shows no prohibitive toxicity and shows even slight efficacy (a partial response in a few patients), the phase II trial begins. In this phase screening for efficacy of the drug against a variety of tumors is conducted. After the spectrum of activity is determined, dose-response relationships are determined. The phase III trial is then used to determine drugs that work effectively together, and the new combination protocol is ultimately compared with the existing best treatment. Phase IV trials are known as postmarketing surveillance trials. They involve safety surveillance after the necessary authorities permit the drug to be sold. This surveillance may be required by

Box 33-1

Sites of Action of Chemotherapeutic Drugs

- Class I: *Cycle nonspecific* —Agents lethal to cells in all phases of the cell cycle. Resting cells are as sensitive as proliferating cells. Examples: radiation, nitrogen mustard
- Class II: *Phase specific*—Agents that exert their lethal effects exclusively or primarily during one phase of the cell cycle, usually S or M. Resting cells are spared. Examples: methotrexate, cytosine arabinoside, vincristine
- Class III: *Cycle specific*—Agents that are capable of damaging both resting and cycling cells, although cells in cycle are much more sensitive. Examples: cyclophosphamide, doxorubicin

Box 33-2

Development Phases for New Chemotherapeutic Drugs

Phase I Trial

Initial pharmacologic evaluation Establishment of mode of administration Establishment of tolerance of a schedule at increasing dosage

Phase II Trial

Screening for efficacy of a drug against a variety of tumors

Phase III Trial

Determination of effective drug combinations Comparison of new protocol to existing "best" treatment

Phase IV Trial

Postmarketing safety surveillance to detect rare or long-term adverse effects

regulatory authorities. The chemotherapy agent may not have been tested for interactions with other drugs, for example. The safety surveillance is designed to detect any rare or long-term adverse effects over a much larger patient population and longer time period than was possible during the phase I through phase III clinical trials. Harmful effects discovered during phase IV trials may result in a drug being removed from the market.

Most cancers in animals and humans are diagnosed only after they are well advanced. In the 1960s, Skipper and coworkers¹ used the rodent L1210 leukemia to illustrate this point and determine cell kill kinetics in tumors. The L1210 leukemia is a rapidly growing tumor with a growth fraction of 100% and a doubling time of only 12 hours. At this rate of growth, a billion cells would accumulate in the rodent only 19 days after injection of a single cell. After treatment of the leukemia with chemotherapy, the investigators determined that cytotoxic drugs kill by log kill kinetics—that is, a given dose of an effective drug kills a constant fraction of cells and not a constant number, regardless of the number of cells present. This principle is known as the fractional kill hypothesis. For example, if a certain drug is known to kill 90% of the tumor cells present, it will kill 90% of the cells whether the beginning

Table 33-1Tumor Depopulation Related to Successive Drug Cycles Assuming a 90% Fractional Cell Kill in a Model System			
Drug			
	Number of Tumor Cells	Tumor Cells Surviving	
1	10,000,000,000 (1010)	1,000,000,000	Clinical
2	1,000,000,000 (10 ⁹)	100,000,000	Disease
	Complete Clinical Remission		
3	$100,000,000 (10^8)$	10,000,000	Subclinical
4	10,000,000 (107)	1,000,000	Disease
5	$1,000,000(10^6)$	100,000	
6	$100,000 (10^5)$	10,000	
7	$10,000 (10^4)$	1,000	
8	1,000 (10 ³)	100	
9	100 (10 ²)	10	
10	$10(10^1)$	1	
11	$1(10^0)$	0	

number is 10 cells or 10 billion cells (Table 33-1). Thus it should be theoretically possible to cure with chemotherapy, with rapid successive administration of chemotherapy drugs. In fact, antineoplastic drugs kill an extremely variable fraction of cells, ranging from a very small fraction to a maximum of 99.99%; for many tumors the fractional kill is disappointingly small. What prevents theoretical "cures" with chemotherapy is (1) the inability to give drugs in rapid succession, because of host toxicity, and (2) the development of a drug-resistant population of tumor cells during the course of treatment.

Tumors as small as 1 g (109 tumor cells-a billion) may be detected in the body, especially if they are located in areas such as the skin or mouth. However, it is far more common for tumors to escape detection until they are $10 g (10^{10} tumor cells)$ or more. The maximum malignant tumor mass compatible with human life is about 1 kg (1012 tumor cells). If it is assumed that a given tumor originates from a single cell, then a 1-g tumor (10^9 cells) has gone through 30 doublings from the original cell. To get to 1 kg, only about 10 more doublings will take place.² It should be clear from these sobering numbers that a large, unresectable tumor burden with only modest sensitivity to chemotherapy cannot be cured or, in many cases, even palliated with conventional chemotherapy administration protocols. The average volume doubling time for various human solid (e.g., nonleukemic) tumors is about 2 months. However, for certain rapidly growing tumors such as embryonal nephroma, seminoma, lymphoma, and leukemia, the volume-doubling time is less than 1 month. For other tumors the volume-doubling time is as long as 1 year. Because chemotherapy affects rapidly dividing cells, tumors with short volume-doubling times are generally chemotherapy sensitive, whereas tumors with long volume-doubling times are generally chemotherapy resistant.

With regard to the efficacy of chemotherapeutic drugs, criteria have been described for measuring response; these are called RECIST (*Response Evaluation Criteria in Solid*

Tumors). To evaluate a tumor's response to treatment, the clinician must have a marker lesion, a repeatably measurable tumor mass or parameter that can be periodically rechecked and remeasured (preferably with the same person doing the repeat measurements). This may be a lymph node or nodes that can be measured with calipers, a liver lesion measured by ultrasound, nodules visible on a radiograph, a biochemical value such as the calcium level, and so forth. The evaluation as to efficacy of treatment is conventionally made after two cycles of chemotherapy or an appropriate trial of another agent has been administered:

Complete response (CR)—Resolution of all measurable neoplastic disease (or return of marker to normal, if there is no measurable disease), with appearance of no new lesions. A chemotherapeutic drug that can cause a CR in a significant number of animals with a specific cancer is quite likely to increase disease-free survival, especially when used as an adjuvant agent.

Partial response (PR)— Reduction in measurable tumor dimensions of 30% or greater, with no appearance of new lesions. Although a temporary PR may provide the patient with some decrease in discomfort from the cancer, it is unlikely to have a significant effect on survival. However, this drug might be useful in other patients at an earlier stage of disease or in patients in which the tumor can be surgically removed before chemotherapy. A PR proves that the drug does have *some* activity against the tumor that is being treated.

Stable disease (SD)—No significant change is noted in measurable tumor dimensions, or a response is seen that is less than a PR. Actual values are less than a 30% decrease in marker lesion size and less than a 20% increase in marker lesion size.

Progressive disease (PD)—The tumor is clearly growing (20% or greater increase in lesion size), or new lesions appear.

Certain criteria may be useful for declaring a treatment protocol ineffective or unsafe in a specific patient. Progressive growth (usually greater than 20%) in a measurable tumor lesion or the appearance of new lesions after two cycles of chemotherapy would suggest that the drug or protocol is not at all useful for the tumor being treated. Severe toxicity with irreversible, cumulative, or unpredictable manifestations also generally suggests that the drug should no longer be used in this particular patient. If symptoms from the cancer cause the patient's condition to deteriorate, with the only response to drug treatment being SD or PR, the drug should be discontinued and another treatment selected if possible.

The common cancers in dogs and cats can be broadly divided into three categories:

(1) Tumors in which the cells are exquisitely sensitive to chemotherapy. In these tumors CR can usually be obtained, and chemotherapy is therefore the accepted treatment of choice. Cure or solid long-term remission can be expected, and surgery or radiation therapy will not generally be necessary to decrease cell numbers before chemotherapy is administered. An example is the transmissible venereal tumor, in which an extremely high cure rate is possible with vincristine administration even when metastatic disease is present. Another example is lymphoma, in which rapid and complete response is seen with chemotherapeutic treatment. In most patients with lymphoma, however, remission lasts only for only months (generally 12 months or less), insofar as a drug-resistant population of tumor cells develops during treatment. For this reason chemotherapeutic treatment of canine and feline lymphoma is generally considered to be palliative, not curative.

(2) Tumors in which the cells are only modestly sensitive to chemotherapy. PR may be obtained in some of these tumors, whereas in others response to drug treatment may be minimal. Chemotherapy may play a part in management of these cancers but only with previous or concurrent surgery or radiation therapy. An example of this type of tumor is canine osteosarcoma, in which carboplatin or doxorubicin are often used as an adjuvant treatment after amputation. Some soft tissue sarcomas with a high mitotic rate are also considered good candidates for chemotherapy treatment. Adju*vant chemotherapy* is given along with or after another treatment modality, such as surgery or radiation therapy, to increase the percentage of curative resections or long-term responses; in other words, it is used in hopes of converting a palliative treatment to a cure. Neoadjuvant chemotherapy is administered before surgery or radiation therapy in an attempt to shrink the tumor and make it more amenable to removal or irradiation. Neoadjuvant treatment with chemotherapy drugs also allows an assessment as to whether the drugs that are available will produce a response; if so, then more chemotherapy treatments are given after surgery or radiation is completed, in hopes to "clean up" remaining microscopic tumor cells. Realistically, however, cures may occur but are rare in tumors with only modest sensitivity to chemotherapy. Palliation with some prolongation of life is generally the best result that can be expected.

(3) Tumors in which chemotherapy is only rarely of any value for palliation or cure. Progression of the cancer despite chemotherapeutic treatment will be the outcome for most of these cancers. Many carcinomas and some sarcomas of dogs and cats fall into this category. In principle, all cells that are actively cycling in the body should be sensitive to chemotherapy; however, the fact that chemotherapy is generally only modestly effective speaks to the fact that this is not entirely true. In many cancers the tumor cells are actually less sensitive to cytotoxic drugs than are the hematopoietic cells within the marrow cavity. This forces the clinician to give a chemotherapeutic drug and wait to evaluate the toxic effects produced before another course of treatment can be administered. During the interval of time in which the patient's neutrophil or platelet count is too low to give another drug, endogenous hematopoietic growth factors are being produced, mediating proliferation of stem cells, the bone marrow recovers, and peripheral cell counts return to normal. Return of blood cell counts to normal after chemotherapy is

the usual point at which another course of treatment may be given. It is important not to give another cycle of chemotherapy when peripheral blood counts are extremely low because stem cells are actively proliferating at this time; treatment with cytotoxic drugs administered when stem cells are actively dividing increases the chance that the stem cell population may be killed and recovery may never occur. In humans this is the point at which bone marrow or stem cell transplantation is performed.

Unfortunately, tumor cells may recover from chemotherapeutic injury and begin to proliferate again before the animal's marrow recovers. Even when a tumor is exquisitely sensitive to drug treatment and an apparent complete response is obtained, a line of drug-resistant cells often develops. It is a common clinical experience to find that a tumor may respond quite well to the first treatment with a drug, with progressively less impressive responses as the drug is given repeatedly. Classically, multidrug resistance occurs when large numbers of the cells in a tumor overexpress a gene (the MDR1 gene) that encodes P-glycoprotein, a transmembrane protein important in cell transport. This protein pumps chemotherapeutic drugs from the inside of the cell to the extracellular environment so that they cannot act within the cell; P-glycoprotein is a transmembrane drug efflux pump. Other mechanisms leading to acquired drug resistance include (1) the development in the tumor cell of alternative metabolic pathways to avoid the chemotherapeutic drug's mechanism of action; (2) the fraction of tumor cells actively dividing decreases after several cycles of treatment, thus protecting the remaining noncycling cells against damage; and (3) tumor cells may enter a biological "sanctuary site" in which they are protected from injury because of a lack of drug diffusion into that area (e.g., brain, eye, testicle, spinal cord).

Delaying administration of chemotherapy because of hematopoietic or gastrointestinal toxicity often results in a patient appearing to be in remission, with no visible neoplastic disease but with large amounts of microscopic tumor. Thus drug resistance sometimes develops as a result of chemotherapy being administered in a regimen that is "too little, too late." The highest possible doses of chemotherapy given as frequently as can be tolerated by the patient, early in the course of the neoplastic disease (when smaller numbers of cells are present), should have a much higher chance of producing a cure or long-term remission than chemotherapy given after a large number of tumor cells have infiltrated various organs. In human patients the wait for marrow recovery has been overcome with the use of bone marrow or stem cell transplants, performed after chemotherapy treatment is given in doses high enough to kill tumor cells as well as ablate normal marrow cells. The extreme expense, technical difficulty, and high morbidity rates associated with this procedure do not allow for its use in dogs and cats as a routine clinical procedure, at least at this time. In veterinary oncology in the early twenty-first century, clinicians are usually limited to palliation of tumors; only rarely can they expect to cure their patients.

A regimen of chemotherapy treatment can be divided into several phases. The period of *induction* is the initial intensive

chemotherapy intended to produce remission. Remission is defined as the point at which no measurable tumor mass can be found; for lymphoma remission is declared when the enlarged lymph nodes, liver, and spleen have returned to normal size and malignant cells have disappeared from the peripheral blood and bone marrow. This does not mean that all (or even most) tumor cells have been killed, however, and consolida*tion* therapy with different drugs may be given after apparent clinical remission to produce a larger tumor cell kill. For some tumors such as lymphoma, the animal may be given "pulse" doses of drugs after induction and consolidation to maintain the gains obtained with the induction protocol; this is called the maintenance phase of chemotherapy. Recently, intensification protocols have been described for tumors in which drug resistance is common. These protocols are administered during the maintenance period, when the patient is in apparent remission, and are an attempt to kill developing drug-resistant clones of cells by using one or two new drugs at high doses.

Combination chemotherapy is, in general, more effective than single-agent therapy. Using multiple drugs sequentially provides additive antitumor effects without greatly increasing host toxicity, especially if drugs are selected carefully for different toxicities. Combination chemotherapy may delay tumor resistance to drugs compared with single agents. Selecting different drugs that have effects on more than one cell cycle phase may also result in a greater fractional cell kill per cycle of chemotherapy.

Traditionally, in estimating the appropriate dose of a drug to administer to a patient, clinicians have used body weight of the patient as the main criterion; the dose has been figured as the number of mg/kg to be given. In a series of studies begun in the 1880s, however, it was demonstrated that many physiologic parameters could better be estimated on the basis of body surface area (BSA). Basal metabolic rate, blood volume, cardiac output, and renal function parameters were found to correlate much more closely to the individual's BSA than to weight. It was then found that drug doses calculated per unit of body weight were greater in smaller animals and children than in larger animals and adults, whereas doses calculated per unit of surface area were similar for all species and ages. On the basis of the findings in these studies, researchers concluded that BSA might be useful as a standard for calculating drug doses in cancer chemotherapy. The calculation for determining BSA for a given species is made by using the following formula:

BSA in m² =
$$\frac{K_m \times W^{2/3}}{10^4}$$

In the preceding formula, K_m is a factor based on the different metabolic rate of each species; for the cat it is 10, and for the dog it is 10.1. *W* is the body weight in grams. Because the *K* values for dogs and cat are quite close, a table has been formulated that permits quick estimation of the BSA on the basis of the animal's weight in kilograms. The appropriate dose of the chemotherapeutic agent to be administered is calculated by multiplying the dose/m² by the patient's BSA (m²) taken from the table. A serious and potentially fatal mistake made by some clinicians when using a nomogram or table to estimate the BSA has been to use the animal's weight in *pounds* rather than in kilograms. To avoid this error, a good rule is to calculate the dose of a chemotherapeutic drug and then ask another person to calculate it again separately before the drug is administered.

More recently, the use of BSA as a means of calculating doses for all chemotherapeutic agents has been questioned. For many chemotherapy drugs, myelosuppression is the most common toxicity and is dose limiting; it has been found that BSA does not correlate well with either stem cell number in the bone marrow or with resulting hematopoietic toxicity. In fact, correlation is highly significant between bone marrow effects of the cytotoxic drugs and body weight. A phase I study in dogs was performed to evaluate toxicity of doses of intravenous melphalan calculated by BSA. A significantly greater number of small dogs experienced significant toxicity than did large dogs. Another study compared marrow toxicity induced by doxorubicin given at 30 mg/m² to that induced by the drug given at doses calculated at 1 mg/kg. It was found that a disproportionately greater number of dogs weighing less than 10 kg developed severe myelosuppression at the 30 mg/m^2 dose than at the 1 mg/kg dose.³ Limited toxicosis was seen in dogs weighing more than 10 kg with either of the dosing schemes, however. Plasma doxorubicin concentrations were less after treatment at the 1 mg/kg dose in both large and small dogs than in those given 30 mg/m², and it is possible that 1 mg/kg may be an inappropriately low dose for treatment of animals with cancer. For drugs that may produce severe myelosuppression, measurement of hematopoietic stem cell numbers for each individual patient would clearly provide the most information to prospectively calculate doses for chemotherapeutic agents. Until such a test is available, however, clinicians must use the doses available in the literature, always carefully taking into account the individual animal's response to the previous drug dose before administering the next treatment. If a doxorubicin dose of 1 mg/kg is well tolerated by a dog or cat weighing less than 10 kg, the next dose may be increased slightly, gradually approaching the dose calculated by BSA; this is called dose escalation. In daily clinical practice veterinarians judge the adequacy of therapy by measuring the response of visible, measurable masses; only much later are they able to evaluate the results of their treatment by survival results. In a rodent model for osteosarcoma, reduction in the dose intensity of melphalan and cyclophosphamide caused a marked decrease in the cure rate long before there was a reduction in the rate of complete clinical remission. On average, it is estimated that a dose reduction of approximately 20% leads to a loss of 50% in the cure rate. A positive relationship between dose intensity and response rate has been demonstrated in many human tumors, including lymphoma and ovarian, colon, and breast cancers. Clinicians should administer the highest dose of a chemotherapeutic drug that can be tolerated by the patient if they are attempting to cure; if palliation is the only goal, a dose that will produce clinical remission without dose escalation may be appropriate, however. Careful patient monitoring for therapeutic response and toxicity is still the best way to titrate the drug dose for each individual patient (Box 33-3).

Box 33-3

Timing of Chemotherapy (Dose–Schedule Relationships)

- Intermittent high-dose ("pulse") therapy with cycle-specific and phase-specific agents produces more therapeutic benefit with less cumulative toxicity.
- 2. Intermittent therapy permits repair of normal tissues in the drug-free interval between doses.
- 3. Greater tumor cell kill may result from high drug gradients produced by intermittent high-dose therapy.
- Timing of one drug in relation to another may permit some degree of tumor cell synchronization, followed by increased killing of such cells by a subsequent pulse of another phasespecific drug.
- 5. Pulse therapy is generally used in rapidly growing tumors, whereas continuous therapy using agents that kill at the resting phase is recommended for tumors that have a low growth fraction.
- 6. Continuous therapy is most effective with phase-specific drugs (cytosine arabinoside is often given by continuous ambulatory infusion for acute leukemias in humans), and pulse therapy is most commonly used for cycle-specific drugs.

Because chemotherapeutic drugs are quite toxic, the following guidelines for making the decision to begin chemotherapy are critically important:

- Use chemotherapeutic agents only when a diagnosis of malignancy has been established definitively, either by cytology or histopathology.
- 2. Determine whether the particular tumor is known to respond to the treatment in a reasonable percentage of cases, with toxicities that will be tolerated by the patient and its owner.
- 3. Follow objective measurements of the tumor or its markers (e.g., hyperglobulinemia, hypercalcemia) if at all possible to determine whether the chemotherapy being administered is of benefit or should be discontinued.
- 4. Do not use chemotherapy in a patient unless proper supportive facilities are available for monitoring and treatment of any complications.
- Do not use chemotherapy unless the animal's owner is likely to be compliant with instructions for drug administration and monitoring and will be observant of early signs of complications.

METRONOMIC CHEMOTHERAPY

Most chemotherapy targets rapidly dividing cells (preferably tumor cells, but inevitably some normal cells are also affected), and it is given at maximum tolerated doses (MTDs). Chemotherapy drugs also have another target: endothelial cells that form the lining of newly formed blood vessels, such as those whose creation is orchestrated by tumors to fuel their growth. There is a considerable body of evidence that even very low, almost nontoxic doses of chemotherapy drugs, when delivered frequently for a prolonged period of time, can retard tumor blood vessel growth (or angiogenesis) by destroying endothelial cells. Treatment approaches along these lines are now being tested in clinical trials, and they have been coined *metronomic chemotherapy*.

The treatment targets endothelial cell precursors (endothelial progenitor cells) that are recruited from the bone marrow and circulate to various sites in the body. Metronomic chemotherapy is given in very low doses repetitively (usually daily) over a long period of time compared with the MTD therapy that has been traditionally used. These repetitive low doses of chemotherapy drugs (cyclophosphamide at 10 mg/m² per day has been used most often in veterinary medicine) are designed to minimize toxicity and target the endothelium or tumor stroma, as opposed to targeting the tumor. Thus the treatment is theoretically useful to stabilize or slow tumor growth rather than kill tumor cells. Studies conducted in cell lines and animal models have also suggested that combining metronomic chemotherapy with targeted antiangiogenesis agents (e.g., piroxicam) is more effective than metronomic chemotherapy alone.

Metronomic chemotherapy will probably be most useful in slow-growing, indolent tumors, such as soft tissue sarcomas with a low mitotic index and well-differentiated carcinomas, particularly after debulking to microscopic disease. There is a low incidence of side effects, and the treatment is relatively inexpensive. The hope is that this treatment will allow some cancers to be treated as manageable chronic conditions.

COMMON SIDE EFFECTS OF CHEMOTHERAPY

Most clients are extremely satisfied with their experience with chemotherapeutic treatment of their pet's cancer. Fewer than one in four animals are reported to have significant side effects of chemotherapy, and only 5% will have a serious event that requires hospitalization. However, if a pet does experience a serious reaction, there are certainly adverse consequences. The animal's quality of life is decreased, at least for a time; there may be unexpected expenses for the owner associated with hospitalization and costly treatments; and it may be necessary to delay the next scheduled chemotherapy session, which sometimes allows the cancer to visibly return in the delayed interval between treatments. All this is likely to result in clients who are less enthusiastic about the idea of chemotherapy for their pet than they were before the occurrence of the unexpected side effect.

Many adverse effects of chemotherapy can be minimized or prevented by careful management, but some animals experience unanticipated side effects that no amount of care or forethought could have prevented. Certain breeds, especially Collies and rarely Australian Shepherds and Shetland Sheepdogs, are carriers of a mutation of the P-glycoprotein multidrug resistance 1 (MDR1) gene. If dogs that are homozygous for this gene are given anthracyclines or vinca alkaloids, the cellular excretion of the drugs is diminished, and they have increased drug exposure and thus increased toxicity. It is estimated that 70% of Collies in the United States are heterozygous for this mutated gene, and 31.2% of Collies are homozygous, with much lower percentages for Australian

Box 33-4

Three Growth Classes of Body Tissue

Static: Highly differentiated and have lost capacity to divide (e.g., nerve, muscle)

- **Expanding:** Differentiated cells that survive for the lifetime of the organism and do not require replacement. With injury, however, the organ can replace lost cells (e.g., liver).
- **Renewing:** Differentiated with a short life span requiring constant renewal (e.g., bone marrow, gastrointestinal mucosa, hair follicle)

Shepherds, Shetland Sheepdogs, and other herding dogs. A test for the mutation status of this gene is available through the Veterinary Clinical Pharmacology Laboratory at the College of Veterinary Medicine, University of Washington (http://www.vetmed.wsu.edu/depts-vcpl/). If this test is not performed, dogs of these breeds with cancer should be given conservatively low doses of anthracyclines and vinca alkaloids, or the drugs should not be given at all.

Cells of normal tissue are damaged by chemotherapy; most, given time, will recover. Tissues that are especially affected include those in which the cells have a short life span and require constant renewal (e.g., bone marrow, gastrointestinal mucosa, gonads, hair follicles). Box 33-4 provides a brief overview of the classes of body tissue and, if applicable, typical renewal properties.

Myelosuppression

Myelosuppression and subsequent infection are the most common dose-limiting toxic effects of chemotherapy. Drugs that can be particularly myelosuppressive in dogs and cats include lomustine (CCNU), cyclophosphamide, carboplatin, doxorubicin (particularly when used in combination with another chemotherapeutic agent), and vinblastine. In some cats vincristine has been noted to produce a marked and prolonged neutropenia.

Many mechanisms contribute to infection after chemotherapy. Certain chemotherapeutic agents prevent phagocyte mobilization or impair function of these cells. Some cancers infiltrate the bone marrow, producing myelophthisis and contributing to cytopenias. Suppression of leukopoiesis by chemotherapy drugs may lead to associated barrier disruptions of the skin, oral cavity, and alimentary tract mucus, and the normal pulmonary "mucociliary elevator" may not function effectively to clear bacterial organisms. Endogenous bacterial infections may develop, caused by the host's native microbial flora; these are commonly due to aerobic and anaerobic gramnegative bacteria from the gastrointestinal tract or Staphylococcus organisms from the skin. In addition, hospitalized patients frequently develop catheter-related bacteremias, often caused by microbes transmitted to the susceptible patient from the hospital environment or from another animal; these organisms may be antibiotic resistant. Patients with absolute neutrophil numbers greater than 1500/µL are generally protected against endogenous infections. If the number is between 1000 and 1500/µL, the owner is advised to monitor the animal's

condition and report any fever or anorexia. If the number is between 500 to 1000/µL, prophylactic antibiotics are generally dispensed unless the period of neutropenia is anticipated to be very short. When the absolute neutrophil number is less than 500/µL, treatment with granulocyte colony-stimulating factor (G-CSF, filgrastim, Neupogen, Amgen) or granulocyte/ macrophage colony-stimulating factor (GM-CSF, sargramostim, Leukine, Berlex) may be considered (discussed later), although many patients recover without the administration of one of these cytokines-of course, antibiotics should also be administered. If the patient is not febrile, it should probably not be hospitalized because its likelihood of acquiring a hospital-acquired resistant bacterial infection is high. If the patient is febrile, however, it should usually be hospitalized for blood cultures and intravenous antibiotic administration. In general, antibiotics should not be given prophylactically for neutropenia unless they are necessary, because they increase the risks for development of bacterial resistance and fungal infection in these immunocompromised patients. When necessary, choice of an empirical antibiotic regimen should take into account the type of infection the patient is likely to have: home acquired (probably endogenous) or hospital acquired (likely to be exogenous and possibly antibiotic resistant). Appropriate antibiotic combinations for use in the febrile neutropenic patient would be an aminoglycoside (e.g., amikacin) plus an antipseudomonal penicillin (ticarcillin, carbenicillin, piperacillin) or cephalosporin (cephalothin, cefazolin, cefoxitin). The third-generation cephalosporin ceftazidime is an antibiotic with an excellent spectrum of efficacy against gram-negative bacteria and Pseudomonas, and it is moderately effective for treatment of Staphylococcus infections. Because it has poor efficacy against anaerobic organisms, it must be combined with a drug such as clindamycin, metronidazole, or an antipseudomonal penicillin; these combinations are very useful in treating infections in neutropenic cancer patients. Imipenem is useful as a single agent in these patients, with excellent efficacy against enteric gram-negative bacteria, Pseudomonas, anaerobes, and Staphylococcus, but the high cost of this antibiotic limits its use in veterinary medicine at this time. It is also an antibiotic that should probably be reserved for use in humans with antibiotic-resistant infections.

If myelosuppression is severe and life-threatening, recombinant G-CSF or GM-CSF is often administered. These products are human glycoproteins that regulate production of neutrophils within the bone marrow; they are produced in Escherichia coli bacteria. Both stimulate neutrophil progenitor proliferation, differentiation, and functional activity with minimal toxicity. Long-term (i.e., longer than 30 days) use of human G-CSF in the dog or cat results in antibody formation, however, with significant and prolonged decreases in neutrophil counts. At a daily dose of 5 µg/kg subcutaneously, the effects of canine G-CSF on the normal canine bone marrow are rapid and predictable: Mean neutrophil counts in normal dogs increased to 26,330/µL after one injection, with a maximum count of 72,125/µL by day 19 of administration. The neutrophil counts returned to normal in these dogs within 5 days after daily therapy was discontinued.⁴ Canine G-CSF is not

commercially available, but recombinant human G-CSF has resulted in similar elevations of neutrophil counts in the dog. In cats 10 to 14 days of human G-CSF resulted in maximum neutrophil counts ranging from 20,370 to $61,400/\mu$ L.⁵ Thus a short course of G-CSF may be used in dogs or cats either *before* aggressive chemotherapy, in an attempt to ameliorate or prevent myelosuppression, or as a rescue *after* chemotherapy has induced significant neutropenia.

Gastrointestinal Side Effects

Another frequent side effect of chemotherapy relates to the gastrointestinal toxicity of these drugs; anorexia, vomiting, and diarrhea may be noted in some individuals treated with cytotoxic agents. These side effects are not noted in dogs and cats as predictably as in humans, but they can occur in sensitive individuals with most of the commonly used drugs. Agents with a high potential for acute nausea after administration include cisplatin, dacarbazine, and high-dose cyclophosphamide; those with a moderate potential include carboplatin, conventional-dose cyclophosphamide, doxorubicin, mitoxantrone, and occasionally vincristine. In animals with only mild to moderate nausea, metoclopramide (0.2 to 0.5 mg/kg orally or subcutaneously thrice daily), or prochlorperazine (0.3 mg/ kg orally or subcutaneously thrice daily) may be effective. Premedicating with subcutaneous administration of butorphanol at 0.4 mg/kg will sometimes block the postadministration vomiting caused by cisplatin. In animals with severe nausea and vomiting caused by chemotherapy (which is rare, fortunately), one of the serotonin 5-hydroxytryptamine (5-HT) receptor antagonists may be given either orally, subcutaneously, intramuscularly, or rectally. The most commonly available member of this class of drugs is ondansetron, but several newer antiemetics of the class are now also available (e.g., dolasetron), and the price of the drugs has dropped to make them reasonable to use now that ondansetron is available as a generic. The dose of ondansetron in the dog is 0.1 to 0.3 mg/ lb intravenously or subcutaneously twice daily (oral dose is 0.5 to 1 mg/kg every 12 to 24 hours), and the dose of dolasetron is 0.5 to 0.6 mg/kg subcutaneously or intravenously every 24 hours. The serotonin receptor antagonists act more specifically than other antiemetics to prevent the vomiting induced by chemotherapy or radiation. Serotonin receptors of the 5-HT type are located on vagus nerve terminals and in the chemoreceptor trigger zone. Serotonin is released from enterochromaffin cells in the small intestine when they are severely damaged. The released serotonin stimulates vagal afferents through the 5-HT receptors, and nausea and vomiting ensue. Ondansetron and dolasetron block the 5-HT receptor site, which prevents the serotonin effect.

A new antiemetic that is proving to be very effective in the control of chemotherapy-induced nausea and vomiting is maropitant (Cerenia). It is a neurokinin-1 (NK-1) receptor antagonist and is available both in injectable form and as tablets; the dose is 1 mg/kg subcutaneously once daily or 2 mg/kg orally once daily. The NK-1 receptor antagonists drugs work at NK-1 receptors in the emetic center to block both peripheral and central stimuli that cause emesis, by inhibiting the binding of substance P. Substance P is found in significant concentrations in the nuclei that make up the emetic center and plays a central role as a neurotransmitter in the afferent pathways of the emetic reflex.

Other gastrointestinal side effects may also occur as sequelae to chemotherapy drug administration. Diarrhea occurs much less often than vomiting and nausea and is generally readily treated with loperamide (0.08 mg/kg orally thrice daily). Doxorubicin sometimes produces a severe hemorrhagic colitis in dogs, for which hospitalization and symptomatic treatment with antibiotics and intravenous fluids may be necessary; rarely, this side effect caused by doxorubicin can be life-threatening. Anorexia may be noted with several drugs, especially in cats with doxorubicin or vincristine administration. Appetite stimulation with drugs such as cyproheptadine may help in these cats, but enteral feeding is sometimes necessary.

Phlebitis and Necrosis

Several commonly used chemotherapeutic drugs will produce phlebitis or local necrosis (or both) at the site of administration if extravasated. Drugs that can be expected to produce severe reactions include the vinca alkaloids, doxorubicin, and dactinomycin; moderate reactions may be seen with bleomycin, cisplatin, dacarbazine, and mitoxantrone. These cytotoxic drugs may irritate the lining of access veins during administration, producing phlebitis, or may escape the cutaneous vasculature and spread throughout the surrounding tissues, causing a local inflammatory reaction (chemical cellulitis). Alternatively, some of the drugs will produce local tissue necrosis if extravasated. Doxorubicin produces the most dramatic and severe reactions. Extravasation will produce marked epidermal hyperplasia, with mitosis of many epidermal cells at the margins of the lesion; the reaction will contain individual necrotic keratinocytes, lobular panniculitis, and reactive fibroblasts and endothelial cells. No inflammatory reaction will be seen. In the area of direct extravasation, pan-epidermal, dermal, and subcutaneous tissue necrosis will be present. This necrosis begins 1 to 2 weeks after the drug is extravasated and may continue for up to 4 months. With all these drugs, extreme precautions should be taken to prevent extravasation, particularly with venipuncture and catheter placement. A "first-stick" catheter should always be used; infusion through a preexisting catheter is not advised. The animal should be observed closely (and possibly restrained) during the entire time of the infusion, in case movement should dislodge the catheter.

Infusion of the chemotherapy drug should be terminated immediately if the patient shows signs of pain during drug administration or if there is blebbing at the catheter or needle entrance site. If the catheter or needle is still present, the clinician should aspirate any fluid from the extravasated area. A continuing dilemma in the management of extravasation injuries is the absence of evidence-based management strategies. Almost all the recommendations in the literature are (of course) based on anecdotes; even knowing for sure that an extravasation occurred is sometimes difficult, so assessing

whether there has been a positive response to a particular treatment is also questionable. However, the current recommendations for vinca alkaloid extravasation are to inject 150 units of hyaluronidase (if available; hyaluronidase has become difficult to obtain) through the patent catheter or needle and then apply local heat for 15 to 30 minutes four times daily for 48 hours. For anthracycline extravasation, the clinician should apply an ice pack for 15 to 30 minutes four times daily and 90% dimethyl sulfoxide (DMSO) topically several times daily for 7 to 14 days; surgical removal should be considered if the area of extravasation is confined. DMSO is a free radical scavenger that causes potent vasodilation and has pain reduction and antiinflammatory mechanisms. Dexrazoxane is a drug that has been used to prevent anthracycline-induced cardiotoxicity. It may also decrease free radical formation, and when given intravenously immediately after extravasation (1000 mg/ m² intravenously, repeated at the same dose the next day), it appears to prevent the tissue necrosis associated with anthracycline extravasation. Growth factors regulate and coordinate wound healing, and they may also be helpful in altering damage from chemotherapy drug extravasation. In animal models both G-CSF and GM-CSF have been shown to be significantly better than saline or no treatment in decreasing the severity and extent of necrosis with doxorubicin extravasations. In one human patient who did not respond to injected dexrazoxane, GM-CSF injected into an ulcerated area of extravasation led to tissue granulation and complete healing within 8 weeks. With any luck, clinicians will never have to use the following protocol: A 1-mL vial of GM-CSF was diluted with saline. Several small injections were then given within the borders of the ulcer. As new granulation tissue formed, GM-CSF injections were given three times weekly for 2 weeks, then twice a week for 2 weeks. Because treatment of extravasation injuries is not yet uniformly effective in preventing the local irritation and necrosis caused by extravasation of these drugs, prevention is the best answer.

Alopecia

Alopecia is common in certain breeds of dogs after chemotherapy, particularly after administration of doxorubicin or cyclophosphamide. Hair loss is predictable in Poodles and in mixed-breed dogs of Poodle lineage; it is also commonly seen in Terriers and Old English Sheepdogs. Occasionally, it may be noted in other breeds as well. It is common for cats to lose their whiskers during chemotherapy. For some owners the alopecia induced by chemotherapy is very distressing, and owners of breeds in which this is likely to occur should be prepared for this possibility. Hair regrowth begins 1 to 2 months after chemotherapy is discontinued. However, an alteration in the color or texture of the new hair may be noted; the regrown hair may be a lighter or darker shade and may be softer or curlier than the animal's previous hair.

Reproductive Side Effects

Although generally less important in dogs and cats with cancer than in humans, the effects of chemotherapy on gonadal function should be explained to owners considering treatment, particularly if the animal is shown or has been used for breeding. Most chemotherapy drugs will cause hypofertility or infertility by impairing production of sperm and oocytes. In the male animal, loss of libido may result from Leydig cell dysfunction and decreased testosterone levels, especially with corticosteroid treatment for lymphoma. Owners should consider cryostorage of sperm from the dog before beginning chemotherapy. However, it is common to find on semen evaluation that general debility from the cancer itself has resulted in poor semen quality even before chemotherapy drugs have been given. Reversibility of gonadal dysfunction produced by chemotherapy is variable depending on the agent administered, the dose intensity of the protocol used for treatment, and the age of the patient itself. During chemotherapy and for a variable period after the treatment is completed, a male dog or cat should not be used for breeding and a female should not become pregnant because congenital malformations may result in the offspring.

Palmar–Plantar Erythrodysesthesia

Palmar-plantar erythrodysesthesia (PPES), also known as hand-foot syndrome in humans, has been seen with constant-rate infusions of doxorubicin, cyclophosphamide, ifosfamide, 5-fluorouracil, and other agents in humans. In dogs PPES has been most commonly associated with the administration of liposome-encapsulated doxorubicin (Doxil).⁶ PPES is a primarily a dermal toxicity characterized by reddening of the skin. It is followed by edema and eventual ulceration of the skin. PPES tends to occur in areas of friction, such as the weight-bearing portions of the feet and the axillary regions. Histologically, these lesions are described as focal areas of parakeratosis, acantholysis, and chronic active inflammation of the skin and underlying dermis. PPES often resolves quickly after discontinuation of the drug but may recur if the drug is reinstituted. Oral pyroxidine may help ameliorate some of the side effects, although it will not completely prevent PPES.7

Human Health Hazards

Exposure of hospital personnel and owners to carcinogenic, mutagenic, and teratogenic drugs and drug-containing animal waste must be considered. In the days before clinicians took appropriate precautions when mixing and administering chemotherapy, there were many reports in the human literature of fetal loss and birth of infants with congenital defects among nurses and pharmacy staff members who were frequently exposed to chemotherapy drugs.^{8,9} Proper storage, preparation, and administration of chemotherapeutic agents, as well as proper disposal of cytotoxic drug waste and urine and stool of the animal being treated, should be a concern of every clinician who treats an animal for cancer.^{8,9} Reviews on proper handling of chemotherapy in the workplace are available; the Occupational Safety and Health Administration (OSHA) publication "Controlling Occupational Exposure to Hazardous Drugs" may be downloaded from OSHA's website (www.osha.gov/dts/osta/otm/otm_ vi/otm_vi_2.html).

The following sections cover drugs commonly used in veterinary oncology for the treatment of canine and feline neoplasia (Table 33-2). Included are cautionary comments regarding administration, toxicity, and effectiveness. Note that dosages for chemotherapy drugs vary greatly depending on tumor type and protocol used. It is extremely important that a clinician considering the use of one of these drugs as a single agent or in a combination protocol carefully consider all of the drug's possible toxicities rather than merely look up a dose from a chart or formulary.

Alkylating Agents

Nitrogen Mustards

Cyclophosphamide

Mechanism of action. Cyclophosphamide is a classic alkylating agent that is extensively metabolized in the liver to the active cytotoxic metabolites phosphoramide mustard and acrolein. The metabolite phosphoramide mustard is responsible for most of the antineoplastic effects of the drug. Cyclophosphamide is cell cycle specific at normal dosing schedules but may be cell cycle nonspecific at extremely high doses. Resistance to treatment with cyclophosphamide does develop in tumor cells, probably related to increased ability of the tumor cells to produce glutathione and obtain protection from oxidative damage. Excretion takes place principally by the kidneys, and modification of dose and dose interval should be considered when a patient has significant renal disease.

Preparations. Cyclophosphamide is available as 25-mg and 50-mg tablets for oral administration as well as an intravenous preparation in vials containing 100 mg, 200 mg, or 500 mg. The drug is equally effective when given orally or parenterally. Cyclophosphamide cannot be used for intracavitary treatment because it must be metabolized to its active form in the liver.

Side effects. Cyclophosphamide has the potential for extremely dangerous marrow suppression as well as nausea and vomiting. Of all the chemotherapeutic drugs in common use in veterinary oncology, neutropenia occurs most predictably with cyclophosphamide. As a result, the drug must initially be administered with great caution; the degree of myelosuppression varies from patient to patient but may be early and profound. For this reason neutrophil counts must be carefully assessed whenever the drug is used for the first time in a patient. Some animals will develop myelosuppression after a week of cyclophosphamide; in others the drug will have to be discontinued after 3 to 5 days because of severe neutropenia or thrombocytopenia. A baseline total white blood cell count, differential, and platelet estimate should be taken before the drug is administered. Usually, depression in the absolute neutrophil count begins on the third day of administration, so the next blood count is taken on that day. From that day on during the first cycle of cyclophosphamide therapy, a total leukocyte count, differential, and platelet estimate are obtained every day until the cycle of cyclophosphamide therapy is completed. If the absolute neutrophil count drops below $3000/\mu$ L, the drug is discontinued entirely for that cycle; on the next cycle, it is reinstituted at a dose 25% less than the initial daily dose. If the neutrophil count drops to less than $1500/\mu$ L, the drug is stopped and reinstituted on the next cycle at a dose 50% less than the initial dose. If the number of neutrophils drops to less than 1000/ μ L and fever ensues, empirical antibiotic therapy should be begun. Recombinant human G-CSF may also be given for several days if necessary until the animal's neutrophil count returns to normal. After the animal's individual tolerance for cyclophosphamide is determined, fewer CBCs will need to be checked during therapy. In maintenance protocols one CBC per cycle before administration of the drug begins is generally adequate.

Hemorrhagic cystitis may result from cyclophosphamide administration, usually after long-term use; however, it has been reported after one intravenous administration.¹⁰ It is caused by the metabolite acrolein, which is excreted in urine and reaches a urine level of 100 to 200 times the serum concentration; this metabolite is extremely irritating to the bladder mucosa and produces necrosis of smooth muscle. Chronic cystitis leading to bladder fibrosis may occur with long-term use. Affected dogs and cats will present with clinical signs of gross hematuria, often with blood clots, and will be reported to be straining to urinate. Concurrent treatment with prednisone decreases the incidence of hemorrhagic cystitis, probably by causing polydipsia and polyuria. Lymphoma patients rarely develop this complication, insofar as prednisone administration is generally a part of the treatment protocol. Any animal that is to receive cyclophosphamide should have a urinalysis performed before the drug is administered to rule out preexisting hematuria caused by bacterial cystitis or prostatitis. The client should be warned to watch for hematuria during the course of treatment with cyclophosphamide, and administration should cease immediately if the problem is noted. Several precautions can help prevent this problem while an animal is receiving cyclophosphamide. The animal should be encouraged to drink more fluids; salting food and offering beef or chicken bouillon may help increase fluid intake. Because the cystitis is caused by acrolein producing local irritation on the bladder mucosa, the owner should encourage frequent urination by walking his or her dog more frequently and should make sure that the dog is allowed to urinate before retiring for the night. It is better not to administer cyclophosphamide in the evening because acrolein will then concentrate in the urine overnight. Although the free radical scavengers acetylcysteine and mesna have been reported to prevent cyclophosphamideinduced hemorrhagic cystitis in humans treated with highdose cyclophosphamide before bone marrow transplantation, it is not clear that they are necessary in dogs and cats treated with standard chemotherapy protocols. The incidence of this side effect seems to be low with most current cyclophosphamide dosing regimens, which use intermittent "pulse" doses of cyclophosphamide rather than continuous daily dosing of the drug.

Alopecia occurs in susceptible dogs as another side effect of cyclophosphamide. When cyclophosphamide is used in

Table 33-2 Co	Indications	Doco	Route	Common Side Effects	
Drug	Indications	Dose	Route	Common Side Effects	
Alkylating Agents Cyclophosphamide	LSA, MCT, carcinoma, sarcoma	Given orally divided over 4 days or intravenously at 200-250 mg/m ² Metronomic: 10 mg/m ² per day	PO or IV	Myelosuppression, gastrointestinal upset, alopecia, sterile hemor- rhagic cystitis	
Chlorambucil	Small cell LSA, CLL, thymoma, MCT, IBD, in place of cyclophospha- mide	20 mg/m ² PO every 14 days 15 mg/m ² per week divided into 3 doses 0.8 mg/kg in COP protocol 1.4 mg/kg in the CHOP protocol	РО	Myelosuppression, gastrointestinal upset, alopecia	
Dacarbazine	LSA rescue	200 mg/m ² IV slow push daily for 5 days; 1000 mg/m ² IV over several hours every 3 weeks	IV	Vesicant, myelosuppression, vomiting during administration, gastrointestinal upset, alopecia	
Lomustine	LSA rescue, cutaneous LSA, MCT, histiocytic neoplasia, brain tumors, GME	50-70 mg/m ² PO every 21 days	РО	Severe myelosuppression, hepatotoxicity, possible renal toxicity	
Mechlorethamine	LSA rescue	3 mg/m ² IV in the MOPP protocol	IV	Vesicant, myelosuppression, gastrointestinal upset, alopecia	
Melphalan	Multiple myeloma, plasma cell tumors, anal sac adenocarcinoma, melanoma	For multiple myeloma dose 0.1 mg/kg daily for 10 days, then decrease to 0.05 mg/kg daily every other day. Pulse dosing: 7 mg/m ² daily for 5 days every 3 weeks	РО	Myelosuppression (can be severe), mild gastrointestinal upset, alopecia.	
Antimetabolites					
5-Fluorouracil	Carcinomas and sarcomas, gastro- intestinal tumors	150 mg/m ² once weekly	IV, topi- cally	Fatal to cats, myelosuppression, neurotoxicity, alopecia, gastrointestinal upset	
Cytosine arabino- side	LSA, GME, renal LSA in cats	150 mg/m ² SC bid for 2 days (consecutively) or 600 mg/m ² IV once weekly	SC, IM or IV	Myelosuppresion, gastrointestinal upset, alopecia	
Methotrexate	LSA, OSA	0.8 mg/kg in combination with other chemotherapy drugs	IV or PO	Myelosuppression and gastrointesti- nal upset	
Antitumor Antibioti	cs				
Doxorubicin	LSA, various sarcomas and carcinomas	30 mg/m ² IV every 14-21 days (dogs); 1 mg/kg IV every 14-21 days (cats and small dogs)	IV	Vesicant, myelosuppression, cardiovascular (dogs), nephro- toxic (cats), hypersensitivity-like reactions, hemorrhagic colitis, alopecia, gastrointestinal upset	
Mitoxantrone	TCC, Prostatic carcinoma, in place of doxoru- bicin, malignant effusions	Cats: 6 mg/m ² IV every 21 days gastrointestinal up		Myelosuppression, alopecia, gastrointestinal upset, blue color to urine, sclera or saliva	
Actinomycin D	LSA, in place of doxorubicin	0.75-0.8 mg/m ² IV every 21 days	IV	Vesicant, myelosuppression, alopecia, gastrointestinal upset	
Antitubululin Agents	s				
Vincristine	LSA, MCT, TVT, ITP,	0.5-0.7 mg/m ²	IV	Vesicant, peripheral neuropathies, myelosuppression, alopecia, gastrointestinal upset	
Vinblastine	MCT, in place of vincristine	2-2.3 mg/m ² IV weekly or every other week	IV	Vesicant, alopecia, gastrointestinal upset	
Vinorelbine	Primary lung tumors	12-15 mg/m ² weekly or every other week	IV	Vesicant, alopecia, gastrointestinal upset	

Drug	Indications	Dose	Route	Common Side Effects
Paclitaxel	Carcinomas	Dogs: 132 mg/m ² every 21 days; Cats: 80 mg/m ² every 21 days	IV	Not recommended in cats because of hypersensitivity reactions (also seen in dogs, but less severe), arrhythmias, myelosuppression, alopecia, gastrointestinal upset
Docetaxel	Carcinomas	1.25 mg/m ² IV every 21 days	IV	Hypersensitivity, acceptable in cats, arrhythmias, myelosuppression, alopecia, gastrointestinal upset.
Platinum Agents				
Cisplatin	OSA, seminoma, thyroid carci- noma, SCC, malignant effusions	70 mg/m ² IV every 21 days	IV or IC	Fatal to cats, nephrotoxicity, immediate emesis, myelosup- pression, gastrointestinal upset, alopecia, ototoxicity
Carboplatin	OSA, carcinomas	250-300 mg/m ² every 21 days (dogs); 200-250 mg/m ² every 21 days (cats)	IV	Myelosuppression, dose reduction in animals with renal insufficiency, gastrointestinal upset, alopecia
Miscellaneous Dru	ıgs			
Hydroxyurea	Polycythemia vera, brain tumors, myelodysplastic disease	50 mg/kg per day tapering to every other day once in remission (dogs);10 mg/kg/day tapering to every other day once in remission (cats)	РО	Toe nail sloughing, myelosuppres- sion, alopecia, gastrointestinal upset (mild)
L-Asparaginase	LSA	400 IU/kg or 10,000 IU/m ²	SC, IM, or IP	Myelosuppression when given with vincristine, hypersensitivity
Procarbazine	LSA	50 mg/m ² daily for 14 days with the MOPP protocol	РО	Myelosuppression and gastrointesti- nal toxicity
Receptor Tyrosine	Kinase Inhibitors			
Toceranib	MCT, various other tumors	3.25 mg/kg every other day or Monday/Wednesday/Friday schedule	РО	Myelosuppression, proteinuria, gastric ulceration, diarrhea, vomiting, rash, muscle pain
Masitinib	MCT, various other tumors	12.5 mg/kg daily	РО	Myelosuppression, proteinuria, gastric ulceration, diarrhea, vomiting, skin rash

LSA, Lymphosarcoma; MCT, mast cell tumor; IV, intravenously; PO, by mouth; CLL, chronic lymphocytic leukemia; IBD, inflammatory bowel disease; COP, cyclophosphamide, vincristine, prednisone; GME, granulomatous meningoencephalitis; MOPP, mechlorethamine, oncovin, procarbazine, and prednisone; SC, subcutaneously; IM, intramuscularly; OSA, osteosarcoma; TCC, transitional cell carcinoma; IC, intracavitary; TVT, transmissible venereal tumor; ITP, immune-mediated thrombocytopenia; SCC, squamous cell carcinoma; IP, intraperitoneally.

combination with doxorubicin or dactinomycin, cardiotoxicity of these compounds may be potentiated.

Dosing regimen. Cyclophosphamide is usually given in doses from 50 to 100 mg/m² daily orally for 4 to 7 days per week according to the particular tumor protocol. It may also be given intravenously at 200 mg/m² once weekly, but this protocol is likely to be dangerously myelosuppressive in some dogs.

Melphalan (phenylalanine mustard)

Mechanism of action. Melphalan is an alkylating agent that is a phenylalanine derivative of mechlorethamine, the first chemotherapeutic agent discovered. In World War I, it was noted that troops who had received poisoning with mustard gas often had aplastic anemia and severe lymphopenia, with depletion of lymphocytes in the spleen and lymph nodes. This finding caused clinicians to study the effects of nitrogen mustard on lymphoma, first in the mouse and later in humans. Many derivatives of this original compound have been discovered, but melphalan remains one of the most useful.

Spectrum of activity. In dogs and cats, melphalan is generally used for the treatment of plasma cell tumors, either plasma cell myeloma or extramedullary plasmacytoma.¹¹

Preparations. Melphalan is available for oral use as a scored 2-mg tablet and for intravenous injection as a 50-mg vial. In dogs and cats, the drug is conventionally used orally.

Side effects. Myelosuppression is the most common side effect of melphalan, but it is not generally severe. Monitoring of a CBC should be done every 2 weeks during induction and then monthly during maintenance.

Dosing regimen. The recommended dose for melphalan is 0.1 mg/kg daily for 7 to 10 days, then 0.05 mg/kg daily until remission is achieved. The drug is then given as a maintenance agent for 7 days out of every month at 0.1 mg/kg per day. Because food can apparently decrease the oral absorption of

the drug, it should be given several hours before the animal is fed.

Mechlorethamine

Mechanism of action. Mechlorethamine (Mustargen), is the prototypical nitrogen mustard. These drugs alkylate DNA by initially losing a chlorine molecule and allowing the β -carbon to react with the nucleophilic nitrogen atom to form the cyclic, positively charged, and very reactive aziridinium moiety. The reaction between this aziridinium ring and the electron-rich nucleophile creates the initial alkylated product. Cross-linking of the DNA occurs when a second aziridinium ring is formed by the remaining chloroethyl group, allowing for a second alkylation.

Spectrum of activity. In dogs it is used as a rescue agent in the MOPP protocol (*mechlorethamine*, *oncovin*, *procarbazine*, and *prednisone*) for high-grade lymphoma.

Preparations. Mechlorethamine is available in 5-g and 25-g bottles for reconstitution. It is also available in a topical preparation for mycosis fungoides; however, because of the risk of human exposure, the topical preparation is not recommended for veterinary use.

Side effects. Myelosuppression is the most common side effect of this drug; however, it is a potent vesicant and is irritating topically. The gastrointestinal side effects appear to be more severe with this drug than the other nitrogen mustards. A CBC should be performed 7 to 10 days after each dose and before each dose.

Dosing regimen. In the MOPP protocol, this drug is dosed at 3 mg/m^2 on days 1 and 7 of the 28-day protocol.

Chlorambucil

Mechanism of action. Chlorambucil is another of the derivatives of nitrogen mustard; it is the slowest acting and least toxic of the alkylating agents commonly used in veterinary medicine. The drug is easily absorbed by passive diffusion when administered orally, so any food given with it may interfere with its absorption.

Spectrum of activity. Chlorambucil is used as a mainstay for treatment of chronic lymphocytic leukemia,¹² small cell lymphoma, Waldenström's macroglobulinemia, and thymoma in dogs and cats. It has been substituted in combination chemotherapy protocols for cyclophosphamide when hemorrhagic cystitis has ensued but is not especially effective for maintenance therapy of high-grade lymphomas. Activity may also be seen against plasma cell myeloma and ovarian carcinoma.

Preparations. Chlorambucil is available as a 2-mg tablet for oral administration only.

Side effects. Marrow suppression is quite late, gradual in onset, and rapidly reversible in dogs and cats but may be profound if it is not discovered sufficiently early. In general, myelosuppression is not seen until the drug has been given daily for at least 1 month; it is recommended that a CBC be obtained once every 2 weeks during induction. As soon as remission occurs, the drug should be administered only intermittently as a maintenance protocol (i.e., alternate weeks or 1 week out of 4). Chlorambucil should not be administered with food. **Dosing regimen.** The dose for chlorambucil is 0.1 to 0.2 mg/kg orally per day for 4 to 7 days, then 0.1 mg/kg daily until remission occurs. Alternatively, the drug may be given once every 2 weeks at a dose of 0.4 mg/kg. After remission is obtained, a maintenance protocol may be started, with the drug administered intermittently as indicated by the tumor treated (e.g., 0.1 mg/kg daily for 7 consecutive days, followed by 21 days off).

Nitrosoureas

Mechanism of action. CCNU (lomustine) and BCNU (carmustine) are drugs that are very lipid soluble and cross the blood-brain barrier with ease. Excretion is primarily renal, so dose modification must be considered if the patient has renal disease.

Spectrum of activity. Although CCNU and BCNU are used in humans to treat certain lymphomas, the drugs find their principal use in veterinary medicine for treatment of central nervous system (CNS) neoplasia.^{13,14} The two drugs are unique in their ability to attain therapeutic levels in brain tissue. Recent information suggests that CCNU may also have some efficacy in treatment of canine mast cell tumor.

Preparations. BCNU is available in a 100-mg vial for intravenous administration; CCNU is given orally and is available as 10-, 40-, and 100-mg capsules.

Side effects. Both the nitrosoureas may be quite emetogenic immediately after administration. The vomiting and nausea usually last less than 24 hours after administration, and the animal's discomfort can generally be ameliorated with butorphanol given subcutaneously at 0.4 mg/kg thrice daily. In some cases, ondansetron will be necessary to relieve symptoms.

Prolonged bone marrow suppression is common with both of the nitrosoureas. Neutropenia may be noted as early as 1 week after administration but may persist for up to 6 weeks. In some cases neutropenia is severe enough to adversely affect the animal's quality of life, and treatment with intravenous antibiotics and recombinant human G-CSF may be necessary if the animal becomes febrile.

Dosing regimen. BCNU must be given intravenously. The product is reconstituted with alcohol and then added to saline or 5% dextrose in water to be given as an intravenous infusion over 1 to 2 hours. Severe pain may be seen at the injection site even if no extravasation is occurring; a longer infusion time may help decrease discomfort from the administration. The conventional dose of BCNU is 50 mg/m² given intravenously once every 6 weeks. CCNU is available as an oral preparation, and it is given as a single oral dose of 75 to 100 mg/m² once every 6 to 8 weeks.

Dacarbazine

Mechanism of action. The major mode of action of dacarbazine against tumor cells appears to be alkylation of nucleic acids. Its complete chemical name is 5-(3,3-dimethyl-1triazeno)-imidazole-4-carboxamide, which is why it is also called *DTIC*. Dacarbazine is cycle specific.

Spectrum of activity. Dacarbazine is not often used in veterinary oncology. At one time, it was suggested as a treatment for canine melanosarcoma, but results were disappointing. Dacarbazine has its major use for treatment of relapsed lymphoma in combination with doxorubicin.¹⁵

Preparations. Dacarbazine is available for intravenous administration in vials of 100, 200, and 500 mg.

Side effects. Local pain is often seen during administration; concentrated solutions of the drug are very irritating to veins, and extravasation will produce severe phlebitis. Myelosuppression is mild and does not occur until the second or third week after treatment, but a CBC should be checked before each subsequent treatment is administered. Vomiting and nausea are common during the first few days of treatment but can usually be blocked by prior administration of chemoreceptor trigger zone–blocking antiemetics. These gastrointestinal symptoms may be lessened by using a lower dose initially and gradually escalating the dose during the course of treatment, but the signs seem to subside after 1 or 2 days of treatment despite continued therapy with dacarbazine.

Dosing regimen. Dosage is 150 to 250 mg/m² given slowly intravenously for 5 days. Treatment is repeated every 3 weeks.

Mitotic Inhibitors

Vinca Alkaloids

Mechanism of action. The vinca alkaloids are extracted from the common periwinkle plant, Vinca rosea. This plant was originally investigated by pharmacologists because of its reported ability to lower blood glucose levels in several native populations. Although its efficacy as a hypoglycemic agent proved unimpressive, it was discovered that extracts of the plant had cytotoxic effects. Eventually, vincristine and vinblastine came into common clinical use as anticancer agents; the two compounds differ only slightly, with vincristine having a formyl side chain and vinblastine having a methyl side chain on the larger parent molecule. A third vinca alkaloid has recently become more popular in the veterinary market. Vinorelbine (Navelbine) acts similarly to the other vinca alkaloids, with the exception that it achieves very high concentrations within the lung parenchyma. All of the drugs appear to act as spindle poisons by binding to microtubular proteins within cells. The spindles are thus unable to act during mitosis, leading to arrest of the cell in metaphase. Generally, vincristine is thought of as a phase-specific drug effective only in the M phase of the cell cycle. Vinblastine, however, also blocks the cell's utilization of glutamic acid, thus inhibiting purine synthesis. For this reason vinblastine acts against cells in active mitosis but also in other phases of the cell cycle.

Spectrum of activity. Vincristine and vinblastine have their major use in veterinary medicine in combination chemotherapy protocols for treatment of lymphoma and lymphoid leukemias. Some efficacy of vincristine may be seen either as a single agent¹⁶ or in combination with doxorubicin and cyclophosphamide for treatment of soft tissue sarcomas,¹⁷ and vincristine is the drug of choice for treatment of transmissible venereal tumors.^{18,19} Although it was previously suggested that vincristine might be effective in the treatment of mast cell tumor in the dog, a recent report has discounted the drug's role in management of this tumor; only 2 of 27 dogs with mast cell tumors had even a partial response to vincristine given at

0.75 mg/m².²⁰ The principal use of vinblastine in veterinary oncology at this time is in the treatment of mast cell tumors. It has been shown to be much more effective than vincristine at treating this disease, with reported response rates of 40% when combined with prednisone.²¹ It may also be used as a substitute for vincristine in a combination chemotherapy protocol when a vincristine-induced neuropathy has been noted. Vinorelbine has been used primarily against primary lung tumors, especially well-differentiated ones such as bronchogenic carcinomas and bronchoalveolar carcinomas.

Preparations. Vincristine is available for intravenous use in 1-mg, 2-mg, and 5-mg vials. Vinblastine is also for intravenous administration only and is supplied in 10-mg vials. Vinorelbine comes in 10-mg or 50-mg vials of a 10 mg/mL solution.

Side effects. Because of its phase-specific effects, vincristine is not generally myelosuppressive in the dog; occasionally, it may produce significant neutropenia in the cat.²² Anorexia and nausea are sometimes seen in both dogs and cats treated with vincristine, especially at the higher levels of the dose range. Unlike vincristine, vinblastine is quite myelosuppressive, and the interval between doses is often prolonged because of the duration of neutropenia produced by the drug. Vinorelbine is similarly myelosuppressive to vinblastine.

Local phlebitis and severe pain occur if any of the vincas is extravasated. Although a catheter may be placed, conventionally a butterfly needle is used to administer vincristine, vinorelbine, or vinblastine. The vein is punctured with the butterfly needle in the usual fashion, and blood flow is observed into the tubing. Several mL of saline are infused into the vein so that leakage may be observed. The vinca alkaloid is then given as a bolus injection and is followed by several more mL of sterile saline to ensure that not a drop of the drug remains on the tip of the needle.

One of the principal limitations of long-term treatment with vincristine in clinical practice is the development of a drug-induced sensory and motor neuropathy, the pathogenesis of which is poorly understood. The cat may be more sensitive to the development of this phenomenon than the dog.²³ Severe nerve fiber degeneration may be seen, as well as focal axonal swellings with secondary demyelination of peripheral nerves.^{24,25} Vincristine administration should be discontinued immediately as soon as any signs of neuropathy are noted because further treatment may produce severe, generalized motor weakness. The neurotoxicity will generally improve within several months after the drug is discontinued, but some of the signs may be irreversible. Although neurologic problems are rare with vinblastine administration, they may rarely occur with this drug as well.

Dosing regimen. The appropriate dose of vincristine is 0.5 to 0.75 mg/m^2 intravenously once weekly according to the treatment protocol used. Treatment with vinblastine should begin at 2 mg/m² by intravenous injection once every 2 weeks. At each cycle, the clinician should increase the vinblastine dose in increments of 0.25 mg/m^2 until myelosuppression is seen (absolute neutrophil count less than $3000/\mu$ L). Then a maintenance dose of vinblastine, which is *one increment smaller than the dose that produced leukopenia*, should be administered.

Because vinblastine is so myelosuppressive, the clinician should not administer the drug when the animal's absolute neutrophil count is less than $3000/\mu$ L. The dose range for vinorelbine is 10 to 12.5 mg/m² intravenously, using the same dosing schedule as vinblastine.

Taxanes

Mechanism of action. The taxanes are one of the most significant additions to the anticancer arsenal added during the twentieth century. Paclitaxel, the parent drug, was discovered by a National Cancer Institute program in which extracts from thousands of plants were evaluated for anticancer activity. Paclitaxel is derived from the bark of the Pacific yew tree (Taxus brevifolia). Paclitaxel and its semisynthetic analog, docetaxel, have demonstrated significant antitumor activity in humans. Both drugs have a unique mechanism of action compared with other microtubule inhibitors. The taxanes bind to the interior surface of the microtubule lumen at the N-terminal 1-31 amino acids and residues 217-233 of the β -tubulin subunit. Binding to this site does not interfere with the binding of other microtubule inhibitors to their respective sites. Ultimately, the taxanes disrupt microtubule dynamics by suppression of microtubule instability and treadmilling. Like the vinca alkaloids, these drugs are considered to be cell cycle specific for the M phase; however, the majority of cell death occurs in the S phase.

Spectrum of activity. In humans these drugs have been used primarily as anticarcinoma agents with Food and Drug Administration approval for carcinomas of the breast, ovarian carcinomas, prostatic carcinoma, head and neck carcinomas, gastric carcinoma, Kaposi's sarcoma, and non-small cell lung cancer. In dogs paclitaxel has been reported to have activity against mammary tumors, squamous cell carcinoma, transitional cell carcinoma, osteosarcoma, and malignant histiocytosis.^{26,27} In vitro, paclitaxel has shown activity against a number of feline vaccine–associated cell lines; however, no in vivo information exists. Docetaxel has similar uses but is safer for cats. Paclitaxel has also been used with some success as an inhalation chemotherapy agent, although administration is difficult and not routinely available.²⁸

Preparations. Paclitaxel is available in various sizes of a 20 mg/mL solution available for intravenous administration (30-mg, 100-mg and 300-mg multidose vials). This drug is not water soluble and therefore must be dissolved in a specific carrier, Cremophor. Docetaxel is available in various sizes of a 40 mg/mL solution for intravenous administration (20mg and 80-mg single dose vials). Docetaxel must also be dissolved in a carrier solution of Polysorbate 80. These carriers are responsible for a number of the side effects seen, including hypersensitivity reactions. This drug is available in the United States only in an injectable form. It has low oral bioavailability on account of the high numbers of ABC transporters and P-glycoprotein efflux pumps within the intestinal lumen cells, as well as significant first-pass metabolism by the liver. Nonetheless, oral fomulations available in Europe have shown real promise against high-grade mast cell tumors. These formulations are given in conjunction with oral modulators of ABC transporters or cytochrome P-450 (or both).

Side effects. Side effects in dogs are fairly consistent with those seen in humans. Myelosuppression is common and typically occurs 5 to 7 days after injection. Gastrointestinal upset, including anorexia, nausea, diarrhea, and vomiting, can be seen as well. Alopecia has not been reported in the dog with this particular drug, although it stands to reason that this could be a possible sequela of drug administration. Peripheral neuropathies are more common with the vinca alkaloids, but they can be seen with administration of the taxanes as well. In humans arrhythmias are a common side effect of this drug. Indeed, the Taxus species of plants are known for causing arrythmias in cattle who ingest their bark. Though this has not been a reported side effect in the dog, it is recommended that an electrocardiogram be performed before administration. If underlying arrhythmias are noted, the clinician is advised not to use the taxanes in these patients. One of the most significant side effects of these drugs is hypersensitivity. This is related to the carriers (Cremophor and Polysorbate 80) that are necessary to keep these drugs in solution. Careful administration and monitoring during drug administration are recommended. Because of the severe hypersensitivity reaction of cats to paclitaxel, it is recommended that this drug be avoided in the species all together. Docetaxel has been safety administered to cats and is the preferred taxane for this species. This drug is not extremely myelosuppressive, and its myelosuppression is typically resolved at the next dose, 3 weeks later. The dose should be delayed if the mature neutrophil count is less than 2000 cells/µL.

Dosing regimen. The dose for paclitaxel is 165 mg/m² intravenously every 3 weeks. The dose range for docetaxel is 25 to 30 mg/m² given intravenously every 3 weeks. A specific premedication protocol is necessary to prevent severe hypersensitivity reactions. Animals are premedicated the night before treatment with 1 mg/kg of prednisone. Approximately 30 to 60 minutes before injection, diphenhydramine (4 mg/kg) is given intramuscularly, cimetidine (4 mg/kg) is given intravenously, and dexamethasone SP (1.5 to 2 mg/kg) is given intravenously. The diluted taxol (diluted 10:1 0.9% saline to drug) is started at a rate of 30 mL/hr for 30 minutes. If no allergic reaction is seen at that time, then the rate is increased to 60 mL/hour. The catheter is flushed with 25 to 30 mL of 0.9% saline afterwards. If signs of a hypersensitivity reaction do occur, the clinician should stop the infusion, medicate if necessary, and then restart at a slower rate. Therapy should be discontinued if severe hypersensitivity reactions occur.

Antitumor Antibiotics

Doxorubicin

Mechanism of action. Doxorubicin is an anthracycline glycoside derived from *Streptomyces peucetius*. It is directly cytotoxic, binding irreversibly with DNA and preventing both RNA and DNA synthesis. Cellular damage caused by doxorubicin results in enzyme-catalyzed, iron-mediated free radical formation, which produces further tissue damage. Ultimately, these effects result in induction of apoptosis in both normal and neoplastic cells. After intravenous administration doxorubicin is metabolized in the liver to active and inactive metabolites. The drug is excreted primarily in the bile but persists in plasma for prolonged periods.

Spectrum of activity. Doxorubicin has been proved effective in the treatment of a number of tumors of the dog and cat, including lymphoma, leukemias, and certain sarcomas and carcinomas.²⁹⁻³³ It appears that doxorubicin may be synergistic with cyclophosphamide in the treatment of some sarcomas,³⁴ and it is combined with cytosine arabinoside as an extremely effective (although very myelosuppressive) protocol for leukemia.

Preparations. Doxorubicin is available for intravenous use only in vials of 10, 20, and 50 mg.

Side effects. Cardiotoxicity is generally the dose-limiting factor for doxorubicin administration in dogs.³⁵ It results from free-radical damage to the myocardium, with oxidation and death of myocardial cells in the presence of iron. Doxorubicin is an active iron chelator, and the resulting iron-doxorubicin complex catalyzes free radical reactions, leading to myocardial damage. Acute cardiac toxicity may occur at any time and after any dosage; it commonly takes the form of an arrhythmia, which resolves with time in most animals. Arrhythmias are more common if there is previous cardiac disease, previous or concurrent thoracic irradiation, or concurrent cyclophosphamide administration. The second form of cardiac toxicity induced by doxorubicin is congestive heart failure, with myocardial degeneration and cardiac muscle fibrosis leading to heart failure; this generally occurs with cumulative doses greater than 240 mg/m². Once congestive heart failure induced by doxorubicin is present, patients may respond to aggressive therapy for heart failure, but some patients will die despite all treatment. Many attempts have been made in humans to diagnose incipient cardiac toxicity before clinical manifestations of heart failure begin, but it remains impossible to predict which patients will develop these changes. Echocardiographic measurement of ventricular fractional shortening and serial electrocardiography are probably the best methods to monitor dogs and cats that are receiving treatment with doxorubicin.

Both humans and dogs have shown a great deal of individual variation in susceptibility to doxorubicin-induced cardiotoxicity. Even though clinical cardiac disease may not be evident after treatment with doxorubicin, subclinical damage to the heart is common. In a study of 115 children with lymphoblastic leukemia treated with doxorubicin and followed for many years, 57% had abnormal cardiac function later in life.³⁶ The EDTA-derivative drug ICRF-187 (dexrazoxane), given at 0.8 mg/kg 30 minutes before doxorubicin administration, apparently decreases cardiotoxicity without reducing cancer cell cytotoxicity,³⁷ but no large clinical trials of this compound in dogs or cats with cancer have been reported. Dexrazoxane acts as a cardioprotectant by chelating iron, helping to prevent the free radical–induced damage caused by doxorubicin; the product is not commercially available at this writing.

Although cats do not generally show clinical cardiac disease associated with doxorubicin treatment, histologic and echocardiographic evidence of damage to the myocardium occurs in cats treated with cumulative doses of 170 to 240 mg/m².³⁸ Renal damage also occurs in cats after chronic treatment with doxorubicin; this is manifested by azotemia, dilute urine, and gradually decreasing creatinine clearance values during the course of administration.³⁹ Another serious side effect in cats is the profound anorexia that may accompany administration of doxorubicin at the conventional dose given to dogs (30 mg/m²); cats given this dose do not act as though they are nauseated, but they may not eat voluntarily for weeks, sometimes requiring placement of a feeding tube. Small dogs weighing less than 10 kg may also experience unexpected nausea and anorexia at this treatment dose. For cats and small dogs, a doxorubicin dose of 1 mg/kg has proved to be much better tolerated.

Myelosuppression may occur several days after administration, usually beginning on day 4. Peak action on the bone marrow occurs from days 10 to 14. Because doxorubicin has a high affinity for mast cells, causing them to degranulate, anaphylaxis, urticaria, generalized erythema, and head shaking have been seen in the dog. To prevent this, the patient may be premedicated with antihistamines and steroids before administration. Alopecia may also occur in susceptible breeds of dogs.

Extreme phlebitis and necrosis occur if doxorubicin is extravasated. This necrosis begins 1 to 2 weeks after the drug is extravasated and continues for 1 to 4 months. Doxorubicin also produces an unusual "radiation recall" effect; if previous radiation damage has occurred, even years before, doxorubicin administration will cause its recurrence. This is not likely to be a problem in dogs and cats, given that radiation therapy to the thorax is rarely performed in these species, but it is often a serious complication of doxorubicin treatment in humans. Radiation to the thoracic cavity (when the heart is in the radiation field) may also potentiate the cardiotoxicity of doxorubicin, which could be an important consideration for dogs and cats with thymoma or mediastinal lymphoma.

Dosing regimen. Although the conventional dose of doxorubicin in medium-size to large dogs is 30 mg/m² given every 3 weeks, in very small dogs or cats this dose may produce profound myelosuppression and anorexia. For this reason the dose in very small animals (less than 10 kg) should be reduced to 1 mg/kg every 3 weeks. Doxorubicin should be administered slowly into the tubing of a freely running intravenous infusion of saline or 5% dextrose solution. The tubing should be attached to a catheter that was placed on the first stick to prevent any leaking of drug through holes in the vein. At least 5 minutes should be taken to give the drug. Alternatively, doxorubicin may be mixed in a small volume of saline (50 to 100 mL) and dripped intravenously over 20 to 30 minutes. Because doxorubicin is physically incompatible with many other drugs, including heparin, aminophylline, cephalothin, dexamethasone, diazepam, hydrocortisone, and furosemide, care should be taken not to give other drugs through the same line during the doxorubicin infusion.

Doxorubicin Analogs

Mechanism of action. Because doxorubicin is so cardiotoxic, much effort has been devoted to development of analogs that might have less toxicity but that would maintain the level of tumor response. Epirubicin (4'-epidoxorubicin) is an analog that has been claimed to be less cardiotoxic in humans for equivalent doses. The mechanism of this drug is similar to that of doxorubicin. Idarubicin (4-demethoxydaunorubicin) is another anthracycline glycoside that is unusual in that it is the only antitumor antibiotic that can be given orally.

Spectrum of activity. The spectrum of canine and feline tumors that will respond to epirubicin therapy is probably similar to that for doxorubicin. Epirubicin's principal use has been as a single agent in dogs with canine lymphoma; response rate and duration of response are not significantly different from what would be expected with doxorubicin therapy.⁴⁰ Idarubicin has been used orally in cats for maintenance therapy of lymphoma after remission is obtained with other drugs.⁴¹

Preparations. Epirubicin is not commercially available at this time. Idarubicin is commercially available only in an injectable form, in 5-mg, 10-mg, and 20-mg vials.

Side effects. The claim that epirubicin has an advantage over doxorubicin in lessened toxicity has not proved to be particularly persuasive. Myelosuppression is similar, with the neutrophil nadir seen 10 days after administration. A significant number of dogs treated with epirubicin still show evidence of cardiotoxicity, as measured by ventricular fractional shortening on echocardiography. Idarubicin may produce gastrointestinal signs and myelosuppression in treated cats, and dose modification may be necessary. Because idarubicin is very cardiotoxic in humans, it presumably has the same effect in dogs and cats; appropriate precautions and monitoring should be considered.

Dosing regimen. Epirubicin is given intravenously at a dose of 30 mg/m² for dogs weighing more than 10 kg and 1 mg/kg for dogs less than 10 kg. Similar precautions for administration to those taken with doxorubicin should be followed. Idarubicin has been given orally at 2 mg/cat daily for 3 days once every 3 weeks; injectable doses of idarubicin for dogs and cats have not been reported.

Dactinomycin (Actinomycin D)

Mechanism of action. Dactinomycin is one of the actinomycins, a group of antibiotics produced by various species of *Streptomyces*. The drug binds to DNA by intercalation and causes single-strand DNA breaks. Ultimately, dactinomycin causes apoptosis in susceptible tumor cells. As with doxorubicin, drug resistance to dactinomycin is caused by overexpression of P-glycoprotein; it is therefore unlikely that response to dactinomycin will be seen in lymphomas in which the tumor cells have become resistant to doxorubicin.

Spectrum of activity. Dactinomycin has chemotherapeutic activity against canine lymphoma; activity has been seen in some drug-resistant lymphomas but generally only when the tumor is not yet doxorubicin resistant. Partial responses have been seen with dactinomycin treatment of nephroblastoma and botryoid rhabdomyosarcoma in the dog. Certain carcinomas may also respond, including anal sac adenocarcinoma, squamous cell carcinoma, thyroid carcinoma, and transitional cell carcinoma.⁴² The principal use of dactinomycin, however, is as a substitute for doxorubicin when a potentially cardiotoxic cumulative dose of doxorubicin has been reached and it is desirable to continue administration of an antitumor antibiotic.

Preparations. Dactinomycin is administered intravenously and is supplied in vials containing 0.5 mg.

Side effects. Dactinomycin is extremely necrotizing when extravasated, similar to the effects produced by doxorubicin; it must be given through a "first-stick" catheter. Minimal myelosuppressive activity is noted when the drug is given as a solitary agent. Nausea and vomiting may occasionally occur during the first few hours after administration but may be partially prevented by administration of chemoreceptor trigger zone–blocking antiemetic agents. As with doxorubicin, dactinomycin potentiates the effects of radiation therapy and has a radiation-recall effect. Cardiotoxicity is extremely rare with this drug.

Dosing regimen. Dactinomycin is given intravenously at a dose of 0.5 to 1 mg/m^2 once every 3 weeks. Because it is extremely corrosive to soft tissue, catheter placement should be meticulous. The calculated dose should be mixed with normal saline or 5% dextrose in water and dripped intravenously over 20 to 30 minutes.

Bleomycin

Mechanism of action. Bleomycin is an antitumor antibiotic derived from a strain of *Streptomyces* first isolated from the soil of a Japanese coal mine. Its cytotoxic effect is mediated by DNA binding and fragmentation, with single- and double-strand breaks. Interestingly, bleomycin seems to be more damaging to nonproliferating cells than to those actively proliferating. It has a unique lung toxicity in most animal species studied.

Spectrum of activity. Bleomycin is most effective for treatment of squamous cell carcinoma in cats and dogs;⁴³ remissions are usually partial and of short duration, however. Recently, impressive results were obtained with intralesional injections of bleomycin into acanthomatous epulides in three dogs.⁴⁴ These benign oral tumors are generally treated with surgical removal, sometimes involving a partial mandibulectomy or maxillectomy. The tumors were markedly smaller after three weekly bleomycin injections and had disappeared by 8 to 10 injections. No recurrence was noted in any of the cases during the follow-up periods, which ranged from 1 to 2 years. Bleomycin is also effective in humans as a sclerosing agent in the treatment of malignant pleural effusion, but there are no reports of this use in dogs or cats.

Preparations. Bleomycin is given intravenously or by intralesional or intracavitary injection; it is supplied in 15-mg or 30-mg vials.

Side effects. Unlike the other antitumor antibiotics, myelosuppression is unlikely with bleomycin. Chronic administration of bleomycin to dogs every other day for more than 8 months resulted in the development of a pneumonitis, which progressed to pulmonary fibrosis.⁴⁵ The earliest symptom was dyspnea, with patchy opacities of the lung fields noted on radiographs. Microscopic changes included squamous metaplasia of the bronchiolar epithelium, fibrinous edema, and a diffuse interstitial fibrosis. Cutaneous ulceration and loss of nails also occurred in these dogs. Because bleomycin in clinical patients is principally used for short-term palliation of tumors, none of these chronic changes is likely to occur in clinical patients.

Dosing regimen. Bleomycin is given subcutaneously at a dose of 10 to 20 U/m² once weekly.

Mitoxantrone

Mechanism of action. Mitoxantrone is a derivative of anthracene and is related to doxorubicin and daunorubicin. It intercalates into DNA and causes cross-linking, with inhibition of both DNA and RNA synthesis. It is cell cycle specific but phase nonspecific.

Spectrum of activity. Partial and complete remissions have been reported when mitoxantrone is used as a solitary chemotherapeutic agent in lymphoma.⁴⁶ Because the drug is very expensive, it is not generally used for induction or maintenance therapy. Its principal use is in lymphomas in which the tumor cells are resistant to other drugs; a response rate of 26% can be expected.⁴⁷ Rare partial remissions and even rarer complete remissions are associated with administration of mitoxantrone to dogs and cats with various carcinomas and sarcomas, but the use of this drug in tumors other than lymphoma has been generally disappointing.

Preparations. Mitoxantrone is supplied in 20-, 25-, and 30-mg vials for intravenous use only.

Side effects. Side effects of mitoxantrone administration are mild to moderate gastrointestinal toxicity and myelosuppression. Although the myelosuppression associated with mitoxantrone is generally not marked, some dogs and cats will develop dangerously low neutrophil and platelet counts; for this reason it may be prudent to begin treatment at the lower end of the dose range, with gradual escalation of the dose as treatment proceeds. Extravasation of the drug may result in severe local reactions, including ulceration and cellulitis. Although mitoxantrone is a relative of doxorubicin, its cardiotoxicity in dogs appears to be much less; no clinical evidence of cardiac effects was noted in a study of mitoxantrone administration in 129 dogs with different malignancies.⁴⁸ However, because mitoxantrone does induce both acute and chronic congestive heart failure in humans, it probably is not a good choice for dogs or cats in which the maximum safe dose of doxorubicin has been reached or in patients with preexisting cardiac disease. A blue-green color may be noted in the sclera and urine of treated animals after therapy.

Dosing regimen. The dose of mitoxantrone in dogs and cats is 5 to 6.5 mg/m² given once every 3 weeks. The drug is diluted to at least 0.5 mg/mL in sterile saline and is given through a catheter over at least 3 minutes.

Antimetabolites

Methotrexate

Mechanism of action. Methotrexate is one of the antimetabolites, which as a class act as structural antagonists of normal metabolites or as cofactors of nucleic acids, generally having their greatest effect on cells in the S phase of the cell cycle. Methotrexate exerts its cytotoxic effect by competing

for a binding site on the enzyme dihydrofolate reductase. This reversible binding prevents the synthesis of folate, which is important in production of the purine nucleotides and thymidine. An "antidote" for methotrexate cytotoxicity is leucovorin (citrovorum factor), which provides folate for biochemical activity in the cell. Methotrexate is principally eliminated in urine; in humans 80% to 90% of the administered dose is excreted unchanged in the urine within 24 hours. Assessment of renal function is important before administration of methotrexate, and dose modification in patients with compromised renal function may be necessary to prevent toxicity caused by delayed drug clearance. Because the antimetabolites have a short half-life in the body, they are most effective when given by constant-rate infusion, thus killing cells as they enter the S phase; however, a protocol for safe and effective constant-rate infusion of methotrexate has not been published for the dog.

Spectrum of activity. Although methotrexate has been widely used in human oncology, often at very high doses with "leucovorin rescue," it has found only limited use in veterinary medicine as a part of combination protocols for lymphoma.

Preparations. Methotrexate sodium may be administered intramuscularly, subcutaneously, or intravenously; the product for injection is available in 20-mg, 50-mg, 100-mg, 200-mg, 250-mg, and 1-g vials. For oral administration it is supplied as 2.5-mg scored tablets. Leucovorin calcium is available in vials of 100 mg for parenteral administration as well as 5- and 15-mg tablets for oral administration.

Side effects. Gastrointestinal side effects are the most important toxicities produced by methotrexate, with nausea occurring commonly. Oral ulceration and diarrhea may also be seen, and methotrexate should be used with great caution or not at all in patients with ulcerative colitis. Myelosuppression is mild at low-dosage ranges. With long-term, low-dose therapy, hepatic dysfunction is a significant problem in humans, and methotrexate hepatotoxicity has been reported in the dog.⁴⁹ Because nonsteroidal antiinflammatory drugs and aspirin may decrease renal excretion of methotrexate and thus increase its toxicity, these drugs should not be given along with methotrexate. Concurrent administration of methotrexate with a trimethoprin–sulfa antibiotic would be likely to lead to severe folate deficiency and therefore increase the severity of myelosuppression.

Dosing regimen. The oral dose of methotrexate is 2.5 mg/ m^2 given daily for 5 days, followed by a 2-day rest period. This is repeated weekly until remission is achieved; 10 mg/ m^2 given twice weekly followed by a 7-day rest period would be another acceptable protocol. Toxic hematopoietic effects may be reversed by 6 to 12 mg of leucovorin given subcutaneously four times a day for 4 doses.

Cytosine Arabinoside (Cytarabine, ara-C)

Mechanism of action. Cytosine arabinoside is highly specific for the S phase of the cell cycle, and its effectiveness is therefore dependent on maintaining constant drug levels; constantrate infusion or frequent, closely-spaced doses are necessary for successful treatment of tumors using this drug. Cytosine arabinoside is transported into the cell and metabolized to 5'-triphosphate ara-C, which inhibits DNA polymerase. The metabolite is then incorporated into DNA, preventing templating from DNA and inhibiting DNA repair. Cytosine arabinoside is one of the few chemotherapeutic drugs that crosses the blood-brain barrier easily, and it can therefore be used to treat CNS lymphoma, as well as to kill leukemic cells in the cerebrospinal fluid.

Spectrum of activity. In veterinary oncology cytosine arabinoside is generally used in combination protocols for treatment of canine and feline lymphoma. It may also be used to treat acute leukemias of both lymphoid and nonlymphoid types.⁵⁰

Preparations. Cytosine arabinoside is available for intravenous or subcutaneous injection in vials containing 100 mg, 500 mg, 1 g, or 2 g.

Side effects. Because of its specificity for cycling cells in the S phase, cytosine arabinoside will usually cause myelo-suppression, with the degree of myelosuppression increasing with the frequency and duration of administration. When large intravenous doses are given by bolus injection intravenously rather than by infusion, nausea and vomiting are common.

Dosing regimen. For lymphoma single-agent cytosine arabinoside may be given at a dose of 600 mg/m² intravenously once a week; lower doses of 200 to 300 mg/m² weekly should be used if cytosine arabinoside is part of a combination drug protocol. For treatment of acute leukemias, 100 mg/m²/day given by constant-rate infusion or divided into 4 daily subcutaneous injections repeated for 5 days will produce the greatest response against leukemic cells. It is important to note that cytosine arabinoside, especially when used with doxorubicin, is extremely effective in clearing the bone marrow of tumor cells in leukemia patients. In general, patients will have a period of severe bone marrow aplasia for 7 to 21 days after the cycle is completed, often with neutrophil numbers less than 1000/ μ L and platelet counts less than 50,000/ μ L. Infection or hemorrhage may ensue during this period, and treatment with recombinant human G-CSF should ideally be used daily along with chemotherapy.

5-Fluorouracil

Mechanism of action. 5-Fluorouracil is a pyrimidine analog that exerts its cytotoxic effect by inhibiting thymidylate synthetase and thus DNA synthesis and, to a lesser extent, RNA synthesis. The cytotoxic effects of 5-fluorouracil are greatest on cells in the G_1 and S phases; with longer periods of exposure to the drug, cells in other phases of the cell cycle may also be killed. Because the drug is erratically absorbed from the gastrointestinal tract, it is generally given intravenously. It is also available as a topical cream.

Spectrum of activity. In humans 5-fluorouracil is the drug of choice for gastrointestinal carcinomas; it is effective in the palliative management of carcinoma of the colon, rectum, stomach, and pancreas. In the dog and cat, however, it has found limited usage because of neurotoxicity.

Preparations. For injection 5-fluorouracil is available in 500-mg vials. For topical use it is supplied in 25-g tubes.

Side effects. 5-Fluorouracil treatment in dogs is often accompanied by CNS reactions (behavior changes such as barking incessantly, running in circles, aggressiveness)⁵¹⁻⁵³; continuing administration of the drug in the face of such neurologic signs may lead to seizures and death.⁵⁴ Mild myelo-suppression and nausea are sometimes noted. Stomatitis and mucositis resembling pemphigus vulgaris may be seen in dogs receiving several weeks of treatment. Because unprovoked rage, extreme dementia, and sudden death may occur in cats treated with 5-fluorouracil, it should not be used in this species.⁵⁵

Dosing regimen. 5-Fluorouracil may be given intravenously at 150 to 200 mg/m² for 3 days, then 100 mg/m² on the fifth, seventh, and ninth days. No drug is given on the fourth, sixth, and eighth days. Blood count should be monitored at the end of the cycle and before the next cycle begins. If gastrointestinal signs, stomatitis, neurologic signs, or falling white blood cell count (less than $4000/\mu$ L) are noted, the drug should be discontinued. Generally, cycles of 5-fluorouracil are repeated monthly. In the dog 5-fluorouracil is useful for small skin carcinomas or solar keratosis as a topical cream. This is applied twice daily until there is an erosive inflammatory response with ulceration (usually 2 to 4 months), at which time use of the drug should be stopped. Healing may take several months after the topical treatment is discontinued. Owners should wear gloves while administering the cream. 5-Fluorouracil should not be used in cats.

Hydroxyurea

Mechanism of action. Hydroxyurea inhibits ribonucleotide reductase, leading to depletion of essential DNA precursors; cells accumulate in the S phase of the cell cycle.

Spectrum of activity. Hydroxyurea is used for the palliative treatment of chronic myelogenous leukemia,⁵⁶ eosinophilic leukemia–hypereosinophilic syndrome in cats,⁵⁷ and basophilic leukemia in dogs.⁵⁸ It is also effective for management of polycythemia vera in the dog and cat.⁵⁹

Preparations. Hydroxyurea is available in 500-mg capsules for oral administration.

Side effects. Side effects of hydroxyurea are generally mild and well tolerated and include nausea and myelosuppression. In the dog loss of toenails may occur with chronic hydroxyurea administration, and a seborrhea sicca-like syndrome may be noted.

Dosage regimen. Hydroxyurea is given orally at a dose of 35 to 50 mg/kg once daily for 7-10 days, then every other day until remission. After remission is obtained (leukemic cell counts are reduced in leukemia patients, or packed cell volume is normal in patients with polycythemia vera; neutrophil and platelet counts are in the normal range), a dose of hydroxyurea is determined that will maintain remission. In some patients daily administration of hydroxyurea will continue to be necessary, but at a lower dose—20 mg/kg/day, for example. In other patients administration of a higher dose (such as 50 to 75 mg/kg) twice weekly will be adequate. The dose of hydroxyurea is titrated to the patient's CBC results.

Platinum Drugs

Cisplatin

Mechanism of action. Cisplatin is a very useful drug in human and veterinary oncology. Its complete chemical name is *cis*-dichlorodiammineplatinum (DDP), reflecting the fact that it is formed by platinum surrounded by chlorine and ammonia atoms in the *cis* position of the horizontal plane. Its cytotoxic effects are thought to be due to alkylation of DNA.

Spectrum of activity. Cisplatin has been shown to produce objective responses in many types of carcinomas in the dog.⁶⁰⁻⁶³ Administration of cisplatin as an adjuvant agent with amputation in canine osteosarcoma has produced significantly longer survival times than seen with amputation alone.^{64,65} Complete remission has also been seen in dogs with metastatic seminoma. Intracavitary cisplatin has resulted in complete and durable palliation of pleural effusion resulting from mesothelioma and carcinomatosis of unknown origin⁶⁶; intraperitoneal treatment with cisplatin for patients with carcinomatosis caused by ovarian carcinoma would also be reasonable.

Preparations. Cisplatin is available for parenteral injection in 50-mg and 100-mg vials.

Side effects. Treatment of cats with cis-platinum is contraindicated; dyspnea and death with pulmonary edema occur within 48 and 96 hours after cisplatin administration, even with only one treatment.⁶⁷ Cisplatin is *extremely* nephrotoxic in the dog, especially if prehydration is not performed with treatment. Before each treatment, blood urea nitrogen (BUN) and creatinine evaluations and a urinalysis should be performed; elevation of BUN and creatinine in the face of a dilute urine should signal the onset of renal toxicity, and additional treatments of cisplatin should not be given. Carboplatin, which is much less nephrotoxic, may be substituted for cisplatin.

Acute gastrointestinal toxicosis with nausea, anorexia, and vomiting is common after cisplatin administration, usually beginning 2 to 4 hours after treatment (most dogs will vomit for less than 6 hours); the severity of the emesis can be decreased with administration of butorphanol or ondansetron. Hypomagnesemia, hypocalcemia, hyponatremia, hypokalemia, and hypophosphatemia may occur after repeated doses of cisplatin, probably as a result of renal tubular damage. Myelosuppression is generally mild but lengthy, with a double neutrophil nadir at 6 and 15 days after treatment. A CBC should be performed before administration of each cisplatin treatment; neutropenia may persist as long as 28 days after a single treatment, causing delay in the administration of the next course of therapy.

Dosing regimen. The dose for cisplatin in dogs is 60 to 70 mg/m² given once every 21 days. An antiemetic such as butorphanol (0.4 mg/kg) is generally given before beginning the treatment; another dose may be given 2 hours later if vomiting becomes a problem. Intravenous saline solution should be given to prehydrate the patient at the rate of 25 mL/kg per hour for 3 hours (18.3 mL/kg per hour for 4 hours in dogs that might become volume overloaded), followed by a 20-minute intravenous infusion of cisplatin mixed in saline. This is

followed by additional fluids given for an additional hour (2 hours for a heart failure patient because the fluid rate is lower) at the same rate. Needles or intravenous sets containing aluminum parts that may come into contact with cisplatin should not be used for preparation or administration because a precipitate will form, causing loss of potency. For intracavitary treatment of mesothelioma or carcinomatosis, the animal is prehydrated with intravenous saline, as previously described. For intraperitoneal therapy 50 mg/m² of cisplatin is diluted in 0.9% NaCl to a total volume of 1 L/m²; for intrapleural delivery the dose is 250 mg/m^2 . The solution is warmed to body temperature and instilled through an aseptically placed catheter over 15 minutes, and posttherapy hydration is performed in the manner previously described. Treatments are repeated once every 4 weeks as needed to maintain remission. Cisplatin must not be given to cats.

Carboplatin

Mechanism of action. Because of the effectiveness of cisplatin in the treatment of many tumors, great interest developed in the search for another platinum compound that would maintain the same level of cytotoxicity without being as toxic to the patient. Carboplatin was developed at Michigan State University to fulfill these requirements; it is similar to cisplatin in pharmacology and antitumor effects. The major route of elimination of carboplatin, like cisplatin, is renal excretion; however, carboplatin causes significantly less renal toxicity, so fluid diuresis before and after administration is not required.

Spectrum of activity. In the treatment of human cancers, carboplatin and cisplatin appear to share the same spectrum of activity; this is presumed to be the case also in the dog. Because of its very different level of toxicity compared with cisplatin, carboplatin is a logical alternative to cisplatin for patients with renal disease or in patients with cardiac disease, in which the large amount of fluids administered with cisplatin treatment might be dangerous. Carboplatin is also safe to use in cats, unlike cisplatin, and intralesional injections of a carboplatin–oil emulsion into squamous cell carcinomas of the nasal planum in cats have resulted in objective responses and apparent cures in some cats.⁶⁸

Preparations. Carboplatin is available for intravenous infusion in 50-, 150- and 450-mg vials.

Side effects. Carboplatin is significantly less nephrotoxic than cisplatin and only rarely produces nausea and vomiting. However, dose-dependent neutropenia and thrombocytopenia are common, and the myelosuppression produced by the drug may be prolonged. In general, carboplatin treatment should not be repeated until neutrophil and platelet counts are in the normal range. Toxicity in the cat is principally associated with myelo-suppression, as in the dog.⁶⁹ Although carboplatin has limited renal toxicity, concomitant treatment with aminoglycosides may result in enhanced kidney toxicity as well as hearing loss.

When carboplatin in purified sesame oil has been used to treat squamous cell carcinomas in cats intralesionally, systemic toxicosis was not observed in any of the cats. Plasma concentrations of carboplatin did not significantly increase during the course of treatment. Water in sesame oil emulsions have been shown to be effective carriers for intratumor administration of antineoplastic agents, preserving drug activity and enhancing concentration of drug locally by allowing slow release into tissues. This allows for intensification of carboplatin chemotherapy without dose-limiting adverse effects.

Dosing regimen. Carboplatin is given as a 15- to 20-minute intravenous infusion at a dose of 250 to 300 mg/m² once every 3 to 4 weeks for dogs; unlike cisplatin, intravenous carboplatin is safe for cats at a dose of 150 to 200 mg/m² once every 3 to 4 weeks. As with cisplatin, aluminum reacts with carboplatin, causing a precipitate; needles with aluminum parts should not be used for the preparation or administration of carboplatin.

For intralesional injection of the nasal planum in cats with squamous cell carcinoma, treatments should be done with the animal under general anesthesia because of the pain that the injection procedure is likely to produce. Carboplatin is prepared in a water–oil emulsion that includes 10 mg of carboplatin in 1 mL of water mixed with 2 mL of sterile, purified, medical-grade sesame oil; a viscous, yellowish liquid is created by this mixture. The emulsion is injected into the tumor and surrounding borders so that approximately 1.5 mg of carboplatin is injected per cubic centimeter of tumor tissue. Four weekly doses are given.

Miscellaneous Drugs

Receptor Tyrosine Kinase Inhibitors

Mechanism of action. A new class of drugs, receptor tyrosine kinase inhibitors (RTKIs), has now entered the veterinary market. Receptor tyrosine kinases are a family of receptors expressed on the surface of all cells. These receptors play a large role in normal cell signal transduction and, when functioning normally, are tight regulators of cellular growth and differentiation. The ligands for these receptors are typically growth factors that are secreted by the cells themselves, released from the extracelluar matrix, or are secreted by other cells in the vicinity.⁷⁰ Once activated, these receptors work by phophorylating proteins on tyrosine residues using adenosine triphosphate (ATP) in the process. They can activate tyrosine residues on themselves or other proteins as part of the initiation of a cell signaling process that will eventually lead to alterations in gene transcription. Small molecule inhibitors such as the RTKIs inhibit the phosphorylation of tyrosine residues, thereby stopping the signal transduction process. In many neoplastic cells these receptors are overexpressed, mutated to be constitutively turned on, or both. In most cases these small molecule inhibitors competitively bind the ATP binding site on the receptor, preventing the binding of ATP that is necessary to drive the phosphorylation of tyrosine residues.⁷⁰ Two RTKIs are currently available or will soon be available to the veterinary market: toceranib (Palladia) and masitinib (Kinavet) has been recently approved by the FDA and will be available soon in the United States.

Spectrum of activity. Toceranib has been shown to have activity against members of the split kinase family of RTKs and inhibits vascular endothelial growth factor receptor, platelet-derived growth factor receptor, and c-kit (CD117).⁷¹ This drug is thought to have antiangiogenic and antitumor effects. It is labeled for use against mast cell tumors in dogs;

however, anecdotal reports suggest that it may be useful against other tumors as well (anal sac adenocarcinomas, osteosarcomas, and soft tissue sarcomas). Masitinib has been shown to have activity against c-kit and platelet-derived growth factor receptor. This drug has been approved in Europe for canine mast cell tumors and is currently undergoing approval by the Food and Drug Administration for use in the United States.

Preparations. Toceranib is available in 10-mg, 15-mg, and 50-mg oral tablets. Masitnib is available in 50-mg tablets, although smaller formulations may be available soon. Currently, toceranib is available only to board-certified veterinary pathologists; however, Pfizer plans to release the drug to general practitioners sometime in 2011.

Side effects. Although RTKIs have relatively targeted mechanisms of action, they also produce quite a few toxicities. It is important to remember that these drugs are still considered chemotherapy and should be treated with as much care and respect as other oral chemotherapy drugs.

Procarbazine

Mechanism of action. The mechanism of action of procarbazine is not clearly understood, although it is thought to work through DNA alkylation and methylation, thereby decreasing DNA and RNA synthesis. The drug is metabolized by the liver and excreted almost entirely in the urine.

Spectrum of action. Procarbazine is typically used as a part of the MOPP rescue protocol for lymphoma (see the section on mechlorethamine).

Preparations. Procarbazine is available in nonscored, unbreakable 50-mg tablets. It may be necessary to compound for smaller sizes in small dogs and cats.

Side effects. Myelosuppression is the primary side effect associated with procarbazine. Gastrointestinal side effects may also be seen. As with all chemotherapy drugs, alopecia is an additional possible side effect.

Dosing regimen. This drug is used at 50 mg/m² daily for 14 days.

L-Asparaginase, Pegaspargase

Mechanism of action. L-asparaginase, an enzyme derived from E. coli, exploits a qualitative biochemical defect found in some tumor cells. In acute lymphoid leukemia and lymphoma, most malignant cells depend on an extracellular source of asparagine for survival. Normal cells, however, are able to synthesize asparagine and thus are affected less by the rapid extracellular depletion of asparagine produced by L-asparaginase. Although most susceptible tumors respond with dramatic reduction in size with the first administration of L-asparaginase, drug resistance of these cells develops quickly; a population of tumor cells is selected for in which the enzyme asparagine synthetase is present, asparagine can be made intracellularly, and the tumor cells are therefore unaffected by the enzyme's administration. Pegaspargase is modified from L-asparaginase by covalently conjugating monomethoxypolyethylene glycol to the enzyme, forming the active ingredient PEG-L-asparaginase; pegaspargase produces fewer hypersensitivity reactions with administration than does conventional L-asparaginase.

Spectrum of activity. L-asparaginase is principally useful in the treatment of lymphoma and lymphoid leukemia. Because hypersensitivity and drug resistance develop relatively rapidly, L-asparaginase is a useful agent for induction of remission or in relapsed lymphoid malignancies, but it should not be employed as part of a maintenance protocol.

Preparations. L-asparaginase is available in vials containing 10,000 IU for parenteral administration. Pegaspargase is supplied in vials containing 3750 IU.

Side effects. Because asparaginase is a foreign protein, severe allergic reactions may be seen on repeated administration. In humans this is a significant problem, and it is recommended that an intradermal skin test be performed if the drug is to be given repeatedly; in the dog, however, anaphylactoid reactions are rare.72 Extreme facial edema and swelling or pain at the site of injection have been noted in some dogs within 24 hours after L-asparaginase administration, however, presumably as a manifestation of an allergic reaction to the drug. Pegaspargase was developed in an attempt to decrease the allergic reactions associated with administration of the drug; it is conjugated with polyethylene glycol and is indicated when L-asparaginase therapy is necessary despite a hypersensitivity reaction to previous treatment. Studies with the polyethylene glycol-modified enzyme in dogs have indicated that it is also active against lymphoma.⁷³ The necessity for its use in veterinary medicine is limited because of the comparative rarity of allergic drug reactions with the use of conventional L-asparaginase.

Side effects associated with the administration of L-asparaginase in the dog are quite rare. Hyperamylasemia occurs in some patients and may progress to acute necrotizing pancreatitis.⁷⁴ L-asparaginase administration in humans causes a temporary but fairly dramatic inhibition in protein synthesis by the liver, resulting in reduced levels of clotting factors. Levels of antithrombin III and fibrinogen in dogs with lymphoma after L-asparaginase administration have not been found to be abnormal, however, and other clotting parameters were not significantly affected either.75,76 Clinically important bleeding or thrombosis may occur in the dog but is extremely rare.⁷⁷ L-asparaginase deaminates extracellular asparagine to L-aspartic acid and ammonia. In patients with preexisting hepatic disease or significant liver function abnormalities related to tumor infiltration, treatment with L-asparaginase may result in a syndrome resembling ammonia encephalopathy, with confusion and stupor. If serum ammonia levels are found to be high in these patients, treatment with lactulose should be instituted until signs abate.

Dosing regimen. Dosage is 10,000 to 20,000 IU/m^2 or 400 IU/kg (maximum dose is 10,000 IU) weekly or as part of a combination protocol. The drug may be given subcutaneously, intramuscularly, or by intravenous administration. If L-asparaginase is given intravenously, the drug should be given over a period of not less than 30 minutes through the side arm of an already running infusion of sodium chloride or 5% dextrose.

Piroxicam

Mechanism of action. Piroxicam is a nonsteroidal antiinflammatory agent that has antiinflammatory, analgesic, and antipyretic properties in animals; edema, erythema, and tissue proliferation can be inhibited by the administration of the drug. Piroxicam inhibits the generation of thromboxane B2 in the blood of dogs by more than 70%, and more than 50% inhibition was maintained in most of the dogs for 48 hours.⁷⁸ The drug has also been reported to have antitumor activity in animal models and in metastatic tumors in humans. The exact mechanism for the role of piroxicam in cancer treatment is not established at this time, but it is unlikely that the effects can be attributed to a direct cytotoxic effect.⁷⁹

Spectrum of activity. Piroxicam has produced objective responses in several types of carcinomas, including transitional cell carcinoma, ⁸⁰ squamous cell carcinoma, mammary adenocarcinoma, and pulmonary metastatic carcinoma.⁸¹ Its principal use is in palliation of transitional cell carcinoma of the urinary tract; relief of stranguria and hematuria often associated with transitional cell carcinoma may be seen for 4 to 11 months after the beginning of treatment.

Preparations. Piroxicam is supplied as 10-mg and 20-mg capsules for oral administration.

Side effects. Serious gastrointestinal toxicity with mucosal ulceration and bleeding, sometimes with perforation, may occur with piroxicam administration, especially if the drug is given daily. If daily administration of piroxicam is necessary, concurrent misoprostol at a dose of 5 μ g/kg orally thrice daily should be considered to prevent gastrointestinal ulceration. Nephrotoxicity with renal papillary necrosis has also been reported with higher doses.

Dosing regimen. Dose is 0.3 mg/kg given orally once daily for 5 days, then every other day indefinitely, as long as efficacy is noted.

Corticosteroids

Mechanism of action. Several glucocorticoid hormones are used in the treatment of patients with cancer. In increasing order of potency, these are hydrocortisone, prednisone, and dexamethasone. The antiinflammatory effects of these hormones may help control pain in patients with terminal disease. Reduction of edema in the CNS with primary brain tumors or brain metastases occurs, especially with dexamethasone; barrier permeability within the tumor is decreased, thus reducing the rate of edema formation.

Corticosteroids are effective in lymphoid tumors by producing a direct lymphocytotoxic effect, apparently binding to intracellular receptors and inducing apoptosis. However, a population of steroid-resistant tumor cells (possibly lacking steroid receptors) develops rapidly if the steroid is used as a single agent, usually within 3 to 4 months after treatment of lymphoma begins. Because glucocorticoids are transported out of the cell by the multidrug resistance gene product P-glycoprotein, remission may be shorter and more difficult to achieve with certain other chemotherapeutic agents after steroid resistance develops.⁸²

Spectrum of activity. Corticosteroids are most useful for their direct cytotoxicity in the management of lymphomas, lymphoid leukemias, thymomas, and plasma cell tumors. They are also important in the symptomatic management of mast cell tumors, shrinking these tumors by decreasing

edema and inflammation and by reducing the eosinophilic and neutrophilic infiltrate commonly seen in these tumors. Whether neoplastic mast cells are actually killed by corticosteroid administration has not been determined. Corticosteroid administration may produce a dramatic improvement in clinical signs when used in patients with intracranial and spinal cord neoplasms, relieving signs of compression temporarily. These hormones are also useful in relieving the general debility, fever (noninfectious), and anorexia of cancer. Because corticosteroids produce a kind of euphoria, their administration to animals with terminal metastatic disease may improve quality of life transiently, even though tumor growth is not inhibited by the drug.

Preparations. Prednisone and dexamethasone are available for oral and parenteral use in a variety of tablet and solution strengths. The drugs are also available in preparations for oph-thalmic administration.

Side effects. Side effects associated with the high doses of corticosteroids used in cancer treatment are numerous. For most dog owners, polydipsia and polyuria are the side effects of lymphoma or mast cell tumor treatment that are most difficult to accept; methylprednisolone, although much more expensive, may produce less polydipsia and polyuria. Owners should also be warned of the ravenous appetite often associated with steroid administration in dogs and cats. Temporal muscle atrophy, gastrointestinal ulceration and perforation, impaired wound healing, endocrine alopecia, increased incidence of bacterial infections, acute necrotizing pancreatitis, and personality changes are all occasional side effects seen with steroid administration, especially in dogs. Owners should be warned not to discontinue steroid treatment suddenly if their pet has been receiving corticosteroids for longer than 2 weeks because the hypothalamic-pituitary-adrenal axis is probably suppressed at the high doses being given.

Dosing regimen. Steroids may be administered orally, subcutaneously, intramuscularly, or intravenously, depending on the patient's condition. A conventional dose of prednisone for treatment of lymphoma would be 30 to 40 mg/m² orally once daily through induction, then on alternate days during maintenance. Edema induced by intracranial or spinal neoplasia may be treated with prednisone at the aforementioned dose or with dexamethasone at 0.1 mg/kg twice daily.

Monoclonal Antibodies

In humans, monoclonal antibody (Mab) therapy has been used successfully to treat non-Hodgkin's lymphoma (NHL) and colon cancer. Monoclonal antibodies such as rituximab (an anti-CD20 antibody) and bevicizumab (an anti-VEGF antibody) have been used successfully and are approved for use in human oncology. However, in the dog, these humanized antibodies do not have broad enough specificity to cross species. Two studies in the dog have evaluated the ability of rituximab to bind to canine CD20, a B-cell marker. However, in both studies, this antibody failed to bind CD20 and no tumor cell killing was identified.^{83,84} Canine CD20 is not similar enough to human CD20 for cross reaction. Likewise, a study evaluating the efficacy of bevacizumab in canine mast cell tumors failed to

show down regulation of VEGF and failed to decrease proliferation in this cell line.⁸⁵ Therefore, specific canine monoclonal antibodies for these receptors will have to be developed before these therapies will be made available for veterinary oncology.

Immunotherapy

Currently, only one FDA-approved anti-cancer immunotherapy is available for dogs, and no therapies are approved for cats. The Merial ONCEPT melanoma vaccine is the first DNAbased vaccine for canine cancer.

Mechanism of action. The canine melanoma vaccine uses a plasmid with DNA for a non-canine tyrosinase protein inserted. Tyrosinase is a protein found ubiquitously in melanocytes and functions in the packaging of melanin granules within the cells. The foreign tyrosinase produced by the vaccine is different enough from canine tyrosinase that it can break tolerance and be recognized by the dog's immune system as a foreign protein inducing an active immune response.^{86,87} Cross-reactivity between the foreign tyrosinase response and canine tyrosinase can occur leading to destruction of neoplastic melanocytes.

Spectrum of activity. This drug is only approved for canine melanoma in the microscopic disease setting. Therefore, ideally, it should be combined with more local therapies such as radiation or surgery to delay or prevent the development of metastasis. This vaccine is often used in an extra-label fashion in the gross disease setting; however, long-term survival analyses, and response rates are not available. There are anecdotal reports of the vaccines use in other species such as horses and cats with no noted adverse events, however, efficacy data in these species is lacking.

Preparations. The melanoma vaccine is available in single dose vials and is administered at a total volume of 0.4 mL per dog intradermally using the specific applicator, the Canine Transdermal Device. The vaccine is administered initially once every other week for a total of 4 doses at induction and then a booster is administered once every 6 months for the remainder of the dog's life.

Side effects. The side effects of this immunotherapy are very minimal. A local pain reaction with vaccine administration may be seen in some dogs. The area may also appear red for 24 to 48 hours after vaccination. Additionally a transient low-grade fever may be seen in some dogs.

Other Immunotherapy

Many experimental treatments using immunotherapeutic principles are being explored including autologous T cell infusions, bone marrow transplantation, and dendritic cell vaccines. These therapies are only in the earliest stages of canine clinical trials and will likely not be commercially available for several years to come.

SUMMARY

Chemotherapeutic drugs can become common place in any general practice as long as the proper safety and handling precautions are instituted. These drugs can be dangerous to the veterinary hospital staff as well and the patient if handled or administered incorrectly. No one should ever administer a chemotherapy drug that they are uncomfortable handling for any reason. These drugs have varied clinical uses and side effects and a good understanding of each and every drug is necessary before administration. That being said, clinicians at veterinary hospitals who do not administer chemotherapy still need a basic knowledge of the side effects and their management for patients whom they have referred for chemotherapy elsewhere. Many clients will come to their general practitioner first for these conditions. Additionally, clients often seek advice from a trusted general practitioner regarding their options about cancer treatment in animals. The decision to treat their pet is often an emotional one, and a good understanding of the drugs and therapies that can be offered to them will put an owner at ease.

Cancer chemotherapy is a field that is constantly changing. New information is available almost daily and new drugs are approved every year. Indeed, cancer therapy is one of the most dynamic research fields. It is recommended that a practitioner who commonly uses chemotherapy frequently review the literature for new administration techniques, new drugs, and new uses for conventional chemotherapy drugs.

THE FOOD AND DRUG ADMINISTRATION

The Food and Drug Administration (FDA) is one of several agencies that regulate the use of drugs, biologics, and medical devices in humans and nonhuman animals (Table 1). The FDA focuses its activities on ensuring the efficacy and safety of drugs to animals (including humans), drug handlers, and the environment. As such, the FDA develops and enforces regulations and written policies for statutory responsibilities in protecting public health through public hearings, public notices, and consultants. The history of the FDA begins in the mid-1800s, although the United States Pharmacopeia (USP) was established earlier by 11 physicians in 1820. The USP was the first organization to address drugs through the formulation of the first compendium of drug standards in the United States, which is one of many activities it continues to do today. The activities of the FDA began when the Bureau of Chemistry was formed as part of the newly created US Department of Agriculture (USDA) during Abraham Lincoln's presidency. Its primary function was analysis of agricultural products. The regulatory activities of the FDA were formalized to include prohibition of interstate commerce of misbranded or adulterated drugs with the passage of the Pure Food and Drug Act of 1906. In 1927, the agency was named the Food, Drug and Insecticide Administration, and its current name was acquired in 1930. In 1937, 107 persons, including many children, died after ingestion of the antibiotic sulfanilamide prepared in a diethylene glycol vehicle. In response to this incident, Congress empowered the FDA to assure safety of drug products with passage of the Federal Food, Drug, and Cosmetic Act in 1938. In 1962, in

response to birth defects associated with the sleeping pill thalidomide, Congress passed the Kefauver-Harris Drug Amendment, which not only empowered the FDA to have greater input regarding drug safety but also provided regulation for assurance of drug efficacy. It was not until 1968, with passage of the Animal Drug Amendment, that animal drugs were defined and placed under the regulatory actions of the FDA. The current offices of the FDA are delineated in Figure 1. Other acts involving the FDA's oversight of veterinary or human issues can be found at the FDA website (see Table 1).

Laws regarding food and drugs are not passed by the FDA; rather, they are passed by Congress and enforced by the FDA through its regulations. Current activities of Congress, including those related to drugs, are noted in the *Federal Register*. FDA regulations (Table 2) also are printed in Title 21, Code of Federal Regulations (21CFR), which is updated on April 1 of each year. These books can be purchased from the US Government Printing Office. To facilitate implementation of its regulations by field officers, the FDA also publishes compliancy policy guidelines. Although not legally binding, they do provide insight into the Agency's current thinking.

The Center for Veterinary Medicine (CVM) identifies itself as a consumer protection agency that fosters public and animal health by approving safe and effective products for animals and by enforcing other applicable provisions of the Federal Food, Drug, and Cosmetic Act and other authorities. The organization of the FDA reveals that only a fraction of its efforts are directed toward the CVM. The organization of the CVM is shown in Figure 1. The CVM website at the

Medical Devices		
Agency	Function	
Department of Interior: Environmental Protection Agency (EPA)	Regulates human drugs, biological devices, radiation products and issues, and food safety	
Food and Drug Administra- tion (FDA)	Regulates human drugs, biological devices, radiation products and issues, food safety, cosmetics, and veterinary drugs (through the Center for Veterinary Medicine [CVM])	
US Department of Agricul- ture: Animal and Plant Health Inspection Service	Regulates animal biologics, helps the FDA monitor proper use of drugs in animals, prohibits repackaging and relabeling of veterinary biologics for over-the-counter (OTC) sale or distribution	
Department of Justice: Drug Enforcement Agency (DEA)	Regulates and enforces the Controlled Substances Act of 1970	
Department of Interior	Controls licensing of topical animal pesticide use and distribution under the Federal Insecticide, Fungicide, and Rodenticide Act	

Table 1	Federal Regulatory Agencies Dealing
	with Animal Drugs, Biologics, and
	Medical Devices

time of printing was http://www.fda.gov/AnimalVeterinary/ default.htm. A publication, *FDA and the Veterinarian*, is available at the FDA website.

Several publications define the FDA's laws and regulations: *Requirements of Laws and Regulations Enforced by the U. S. Food and Drug Administration*, which can be obtained from the US Department of Human Health Services, and *Code of Federal Regulations* (CFR). A more user-friendly account of the laws regulating veterinarians can be found in *FDA and the Veterinarian*. The most recent issue was published in 1989, but a newer version is being prepared. Finally, James E. Wilson, DVM, JD, has written a book, *Law and Ethics of the Veterinary Profession*, that provides a more focused perspective on the use of drugs in animals.

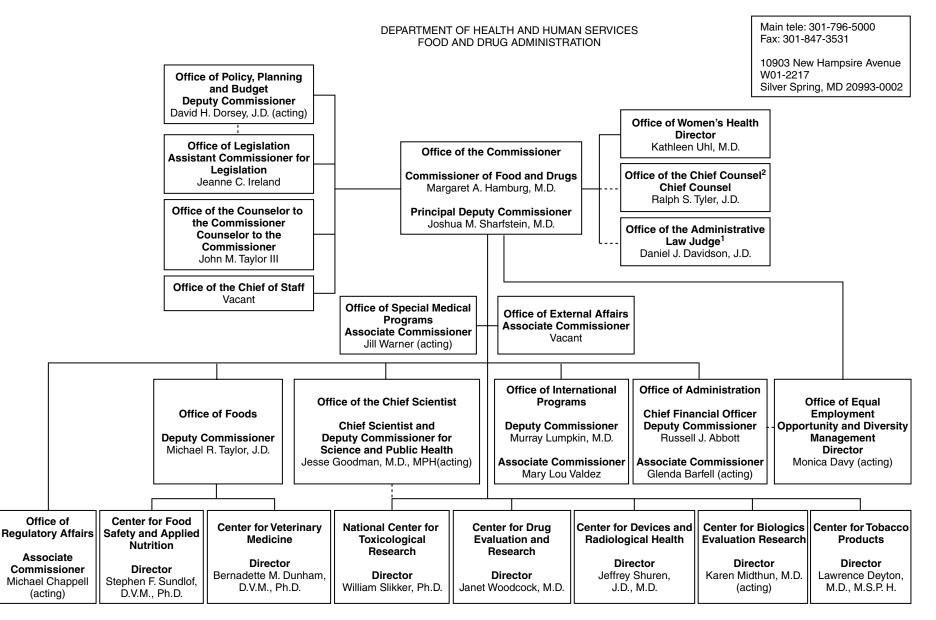

Keeping abreast of changes in the FDA's response to veterinary use of drugs can be difficult. Generally, the *Journal of the American Veterinary Medical Association* and the American Veterinary Medical Association (AVMA) have done an excellent job in putting together and publishing symposia that delineate and discuss the implications of FDA actions. In addition, the American College of Veterinary Clinical Pharmacology and the American Academy of Veterinary Pharmacology and Therapeutics provide guidance through publications and consultation. Finally, the FDA appears to be willing to answer any questions or concerns one might have regarding the use of drugs in animals. In the CVM, the Office of New Animal Drug Evaluation consists of the Division of Therapeutic Drugs for Non-Food, which in turn contains a section for Companion and Wildlife Drugs. Note that there are other federal agencies that regulate the use of drugs in animals, including the Environmental Protection Agency (EPA), the Animal and Plant Health Inspection Service, and others (see Table 1).

Drugs Defined

A drug is well defined by the FDA (see Table 1). It must be recognized as such (e.g., by the USP); intended for diagnosis, cure, mitigation, or prevention of disease in humans or other animals (note that the FDA defines humans as animals); intended to affect body structure or function; or a component of any of these. In 1968, the FDA first made a distinction between human and veterinary-labeled drugs. As with most regulations since that time, the distinction reflected a concern for human food safety. At that time, an animal drug was adulterated if used in an extralabel fashion. Thus a veterinarian could not modify a dosing regimen, therapeutic intent, and so on of a drug without being liable in both criminal and civil courts. Currently, a new animal drug (NAD) is "any drug intended for use in animals other than man ... not recognized ... as safe and effective under conditions on the label." A drug's label includes the label on the product, as well as any accompanying material (see Box 1). A prescription drug is defined by whether or not adequate directions can be prepared for use of the drug by a layperson. Any drug for which this is possible must be sold as an over-the-counter (OTC) preparation; any other product is a prescription (Rx) product that must bear the phrase: "Caution: Federal law restricts this drug to use by or on the order of a licensed veterinarian." Trying to identify the approval status of a drug can be difficult. Obviously, if the label has this cautionary statement, a new animal drug application (NADA) exists for the drug and it can be used legally according to the label specifications. Determining whether an NADA exists for a drug can, however, be difficult. If the drug is listed in the veterinary versions of the Physician's Desk Reference (i.e., the Veterinary Drugs and Biological Products, published by Medical Economics, or the Compendium of Veterinary Products, published by Bayer Animal Health [both basically are copies of package inserts]), then the drug has an NADA. Note that drugs listed in veterinary textbooks, including formularies, pharmacology texts, internal medicine texts, and so on, do not necessarily have an NADA. Other sources include members of the American College of Veterinary Clinical Pharmacology, the FDA Green Book (http://www.fda.gov/AnimalVeterinary/ Products/ApprovedAnimalDrugProducts/ucm042847.htm, last accessed May 25, 2010), or the Handbook of New Animal Drugs, published by Shotwell and Carr.

The Drug Approval Process

From discovery of a new compound (including isolation and synthesis) through its development (including establishing safety and efficacy) to its marketing involves researchers and clinicians and a consortium of regulatory, industrial, and often academic investigators.

¹Reports directly to the Secretary, HHS ²Reports to the General Counsel of the HHS, advises the Commissioner of Food and Drugs January 25, 2010

Approved by the FDA Reorganization Coordinator and Principal Delegation Control Officer

Figure 1 Extralabel drug use algorithm offered by the Food and Drug Administration (FDA) to veterinarians. *Record requirements include animal identification (individuals or as group; species; number treated; condition; drug name and active ingredient; dosing regimen; duration; and specified withdrawal, withholding, or discard time(s) (both label and that specified by veterinarian) when applicable (meat, milk, eggs, or animal-derived food). **Label requirements include name and address of prescribing veterinarian, name of drug, specified direction for use (class/species; identification of the animal or group; dosing regimen including route; and duration of therapy), and cautionary statements. ***The compounding of preparations from bulk drugs is generally considered by the FDA to be illegal.

Law or Guideline	Year	Action
Federal Pure Food and Drug Act	1906	Established standards for safety and purity.
Federal Food, Drug, and Cosmetic Act	1938	Prohibited marketing of new drugs until adequately tested under label conditions for safety.
Durham-Humphrey Amendment to the Food, Drug, and Cosmetic Act	1952	Defined over-the-counter (OTC) products by distinguishing them from prescription-only products.
Kefauver-Harris Amendment to the Food, Drug, and Cosmetic Act	1962	Required scientific proof of efficacy and safety before marketing of a drug and that the Food and Drug administration (FDA) be notified before testing of drugs in humans. Investigational new drug (IND) applications established. Safety and efficacy data needed retroactive to all drugs introduced between 1938 and 1962. Drugs introduced before 1938 are considered "grandfather" drugs as long as labeled use does not change (e.g., phenobarbital, levothyroxine, digoxin).
Animal Drug Amendments to the Food, Drug, and Cosmetic Act	1968	Animal drug regulations placed under one section of the Food, Drug, and Cosmetic Act; the use of animal drugs is restricted to the species and usage as specified on the label.
Poison Prevention Packaging Act	1970	Required that hazardous substances be dispensed in child-resistant containers.
Comprehensive Drug Abuse Prevention and Control Act (Controlled Substances Act)	1970	Controlled the manufacture and prescription of habit-forming drugs.
Orphan Drug Act	1983	Addressed the development of drugs indicated for rare diseases.
Compliance Policy Guidelines	1984	Addressed extralabel use of new animal drugs in food-producing animals and dis- tribution and use of human-labeled drugs for animals. Note, however, that the policies and guidelines were in contradiction to the Food, Drug, and Cosmetic Act. Created the legal veterinary prescription.
Drug Price Competition and Patent Restoration Act	1984	Addressed new drug applications for generic drug products.
Generic Animal Drug and Patent Term Restoration Act (GAPTRA)	1988	Extended to veterinary products the right of companies to produce and sell generic versions of animal drugs approved after October 1962 without duplicating research done to prove them safe and effective.
Compliance Policy Guides	1991	Same as the 1984 Guidelines.
Animal Medicinal Drug Use Clarification Act (AMDUCA)	1994	Legalized extralabel drug use of certain approved animal drugs and approved human drugs for animals as long as specified criteria are met. Final act effective in 1996.
Dietary Supplement Health and Education Act	1994	Established specific labeling requirements, provided a regulatory framework, and authorized FDA to promulgate good manufacturing practice regulations for dietary supplements. This act defined "dietary supplements" and "dietary ingre- dients" and classified them as food. The act also established a commission to recommend how to regulate claims. The Center for Veterinary Medicine (CVM subsequently determined that this act does not apply to products intended for use in animals.
Animal Drug Availability Act (ADAA)	1996	Provided additional legislation to address the lack of legally available animal drugs Facilitated approval of new animal drugs through flexibility in the approval process.
Food and Drug Administration Modernization Act (FDAMA)	1997	Enhanced FDA's mission in ways that recognized the Agency would be operating in a twenty-first century characterized by increasing technologic, trade, and public health complexities. Many issues were addressed in the ADAA.

Table 2 Drug Laws or Guidelines Affecting the Use of Human and Veterinary Drugs

Human Drugs

The approval process for human drugs in the United States has been described as the most vigorous in the world, costing on average \$359 million to move a drug from the laboratory to the patient. After identification and isolation of a compound, its safety is established in laboratory animals. *Preclinical testing* studies include acute and chronic toxicity studies focusing on the reproductive status, mutagenicity, and carcinogenicity of the drug. A safe dosing range is established, requiring both pharmacokinetic and pharmacodynamic (dose-response) studies. At this point, if the compound is considered a potential candidate for approval, an investigational new drug (IND) is filed by the sponsor, with protocols for clinical testing. This phase requires approximately 5 to 8 years, and generally only 1 drug in 5000 evaluated succeeds in this phase. At this point, if the compound is considered a potential candidate for approval, an IND is filed by the sponsor, along with protocols for clinical testing. Approximately 2000 INDs are filed with the FDA each

Box 1

Package Drug Inserts/Labels

Defined

The drug package insert (DPI) is a legal document that accompanies a finished dosing form of an approved drug product. As such, it applies only to the approved product that it accompanies. The DPI for a product includes the label on the product itself as well as any and all accompanying materials (i.e., inside the package. All information included must be approved by the Food and Drug Administration). The label does not include technical monographs or advertisements that might be distributed by a manufacturer. Although the manufacturer may sponsor post-market surveillance studies that can be cited in and provide the basis for information in monographs used for promotion of the product, care must still be taken not to promote a use not stated on the label. Changes to labels that might accommodate new findings regarding the disease targeted by the drug or its use require approval by regulatory agencies, a cost the manufacturer may not want to pursue. Any use of the product beyond that specifically delineated in the label constitutes extra label drug use (EDLU). Data provided in current drug package inserts (DPIs) might be categorized as Product Description, Product Efficacy, or Product Safety with some overlap among the categories.

Product Description: Drug or Drug Product Name

- Finished dosing form: The approved product includes the combined presentation of the (a) active pharmaceutical ingredient (API; often referred to as the drug substance, which may or may not include the salt [co-ion] or ester modification); (b) the route (which may not be included if implied by the dosing form); the dosage form (tablet, solution, topical); and release characteristics (e.g., extended-release tablets), if appropriate. Each drug label provides three names to the product: a generic name for the drug product, which includes the generic name for the API, and the trade name for the specific drug product (see Box 2). In addition to the API, the product description includes any excipients, including fillers, stabilizers, or preservatives. These should be assessed as well for components that may contribute to allergies (i.e., meat flavoring) or adversities (benzyl alcohol as preservatives for cats, xylitol as flavoring agent or carrier in dogs).
- 2. Dosage and administration: USA dosing units for veterinary products have not been standardized to kilogram (kg) and thus are often offered in terms of pounds (lbs) and kg. Attention should be given to the basis of dosing for API modified as salts or esters: is the dose based on the total weight or the active ingredient? Newer drugs generally are named and dosed based on the active ingredient. However, older drugs may be described and dose on either the active ingredient or the salt/ester.
- 3. Preparation for use and storage conditions: Any variation beyond that stated on the label may increase the risk of loss of activity. The impact of freezing, refrigeration, or other storage conditions should not be assumed; queries should be directed toward the manufacturer. Products provided in protective packaging generally should be assumed to need the packaging to remain stable.
- 4. **Expiration date:** Generally, the expiration date should be respected, although the manufacturer may have additional information and may be willing to share this if specifically queried.
- Indications: The approved indication often is not the applied indication. However, any deviation from the approved indication reflects ELDU. Efficacy and to a lesser degree, safety information can be used to support an ELDU indication.

Product Efficacy

- Mechanism of action (MOA): The FDA requires scientific support for the MOA that is claimed on the DPI. As such, a MOA may not be provided.
- 2. Clinical pharmacology: As important as it may be to understanding the proper use of a drug in healthy and unhealthy animals, important pharmacokinetic information may not be provided on the package insert: studies may not have been performed and may not have been required by the FDA. Example of information that may or may not be included follows: bioavailability, non-linear clearance or kinetics (a) Absorption: Both rate and extent, Cmax, (the maximum plasma drug concentration) that occurs at T_{max},; area under the curve (AUC); oral bioavailability (F = fraction); the impact of food (or other factors) on absorption; first pass metabolism; the potential impact of P-glycoprotein. (b) Distribution: volume of distribution (Vd); fraction of drug not bound to plasma proteins (f_{ub}) ; tissue drug concentrations (note that tissue homogenate data can be misleading because it includes both intracellular and interstitial tissue). (c) Elimination: Clearance (Cl, the organ of clearance should be identified, including the role of hepatic metabolism; and non-linear clearance identified); elimination half-life $(t_{1/2})$, or elimination rate constant, kel). The mean elimination halflife may be arithmetic, harmonic (mean is determined from the inverse of half-life, which is averaged and then inversed again) or geometric (for numbers that increase non-linearly).
- 3. **Microbiology:** Pharmacodynamic data (MIC) should be based on an adequate sample of the target population (i.e., >100 isolates). The FDA may not allow microbiologic data for organisms not included in the approved use. Data generally includes the range, the MIC 50 (median) or MIC 90 (90th percentile).
- 4. Effectiveness: field trials: Efficacy field trials focus on the approved indication, reflect use as intended in target animals, and must be controlled. Controls may be, negative placebos, for which superiority must be demonstrated and accompanied by ethical constraints or positive controls for which non-inferiority is generally the target.

Product Safety

- Adverse reactions: Adverse drug reactions in the medical literature generally refer to reactions that can cause harm to a patient and as such, may require a therapeutic intervention. This includes *all* side effects observed in all studies of the drug Side effects generally are not associated with harm but may be undesirable and may be sufficient to cause the drug to not be used. Foreign marked adverse reaction information reflects information that may have emerged as a result of the study or use of the drug in foreign markets.
- Safety information: Three sources of safety data may be present on a package insert. (a) Toxicity studies: Collected in normal animals, as directed for each drug by the FDA, generally reflecting several magnitudes of the dose (i.e., 3, 5, or 10 X) and a duration several magnitudes beyond that recommended. Sample size is small. The FDA may compel inclusion of studies implemented but not necessarily in support of the approved indication. (b) Field studies: The drug is studied in animals with spontaneous disease, for the approved indication, under expected conditions. Sample size often exceeds 100 to 200 for each indication;

Box 1

Package Drug Inserts/Labels—Cont'd

response generally is compared to negative control (placebo) or positive control. **(c) Post-market surveillance:** This process may be added after approval if warranted sufficiently important by the FDA.

- 3. **Contraindications** represent the strongest warning and are established situations under which the drug should not be used. Such use should be expected to result in an adverse even. These might include, medical conditions such as kidney problems or known or anticipated allergies.
- 4. Warnings cover possible serious side effects that may occur.

- 5. **Precautions** explain how to use the medication safely, including physical impairments and potential drug interactions.
- 6. **Information for the owner** is not included for all drugs, but may emerge during post market surveillance in an attempt to reduce the risk of adversity. This information may be provided as a separate document that may be sent home with the client.
- 7. **Drug Interactions** may or may not be included; the absence of described drug interactions should not be interpreted as the lack of clinically relevant interactions.

Box **2**

What's in a (Drug) Name?

A drug by any other name may not be the same. The name of the *active moiety* (AM; drug substance) must be distinguished from the *drug product name*. The AM will have a *chemical name* (determined by the Chemical Analytical Society [CAS] based on its structure) and a *generic name*. In contrast, the drug product will have a *non-proprietary (established) name* and *proprietary (brand) name*. In the United States, the generic AM is initially named by the United States Adopted Name [USAN] Council. Ideally, the name will also be approved by the International Nonproprietary Name (INN) Expert Committee, such that the generic name is globally applicable. As such, only one generic name should exist for any AM, although exceptions exist (e.g., epinephrine versus adrenaline; acetaminophen versus paracetamol, and occasional differences in spelling [alfa versus alpha]).

The generic AM name consists of three parts that logically apply to the AM activity. The stem, generally located at the end of the name, is the most important. It indicates an action unique to and shared by all drugs with the same stem. The stem can be based on a chemical relationships (e.g., azepams, cefalosporins), therapeutic activity (terone for antiandrogens or poietins for erythropoiten), or mechanism of action (statin for cholesterol-lowering drugs). Currently more than 300 stems exist. The prefix of a generic AM is used to discriminate among members having the same stem (e.g., diazepam, *clon*azepam). The importance of racemates in the past decade has led to the use of logical prefixes indicating the enantiomer status of an AM. These include dextrorotatory (dextromethorphams) or R (arformeterol), and levorotatory (levofloxacin, levatiracetam) or S (esmolol). The infix of the drug name is irrelevant unless further subclassification is necessary. Because many approved drug products may have the same AM, it is the generic AM that is preferred for general use in order to facilitate the flow of scientific information within and among nations.

Some drug substances are accompanied by a salt or ester. In such cases, USAN will also provide an API that contains the AM (e.g., zonisamide, pancuronium, triamcinolone, or penicillin) is added to the associated salt (e.g., *sodium* zonisamide or pancuronium *bromide*) or ester (e.g., triamcinolone *acetate* or *procaine* penicillin). The AM (or API) becomes part of the *established (non-proprietary)* *drug product name*, which is established nationally (e.g., the United States Pharmacopeia) and approved by the regulatory agency (e.g., the FDA). Generally, the non-proprietary drug product name includes the USAN generic AM or API (with the choice by USP depending on how important the salt or ester is to drug use), the route of administration (e.g., oral [excluded if implied by the dosing form], topical, ophthalmic) and the dosage form (e.g., tablet, solution, lotion, suspension, aerosol).

Other descriptors (e.g., altered release rate [e.g., delayed, extended release] or delivery system [e.g., transdermal patch) may be included. It is the USP generic drug product name (e.g., carprofen tablet, enrofloxacin otic solution) that is generally on the package insert of the drug product approved by the Food and Drug Administration. The USAN names and the possible options for drug product names can be found in the United States Pharmacopeia Dictionary and National Formulary (USP-NF), respectively, each published annually by the USP. Note that the AM (API) is likely to be only one of several ingredients found in the finished drug product that is approved by the regulatory agency (e.g., the Food and Drug Administration [FDA] in the United States); other ingredients might be excipients intended as filler, stabilizers or antibacterial.

The proprietary or brand name of the approved drug product (e.g., Rimadyl, Baytril Otic) belongs to the manufacturer, although the FDA offers guidelines that are intended to avoid inappropriate public perceptions of drug action or safety based on the brand name. A generic drug product that has been demonstrated by the manufacturer to be therapeutically equivalent to the pioneer proprietary drug product may be subsequently approved by the FDA. The two products will have the same USP established drug product name. However, the generic drug product must either not have a brand name or have a brand name that differs from the pioneer drug product (e.g., Novox as a generic Rimadyl). Finally, it is important to note that a manufacturer may actually change the AM (or API) associated with a brand name product; this is particularly common to over-the-counter products (e.g., Kaopectate). For other information that may be found on a package drug inserts, see Box 1.

year. Long-term safety studies continue in animals as the drug enters Phase I clinical trials in humans.

The clinical phase of drug approval involves three distinct phases of clinical trials that provide the basis of the drug label. Phase I is conducted on a small number of normal volunteers (generally 20 to 80; most commonly, young adult Caucasian males are studied) to determine a safe dosing range and the disposition of the drug (pharmacokinetics). Phase II begins studies in clinical effectiveness and safety in several hundred persons with target illnesses. In Phase III, the number increases to several thousand to establish risk:benefit ratios. Phases I through III last approximately 3 to 10 years; if the drug demonstrates a favorable risk:benefit ratio, the sponsor can submit a new drug approval (NDA). A typical NDA is approximately 100,000 pages or more in length. The FDA, by law, must review the NDA within 6 months, although generally this time period is exceeded. During this phase, the sponsor and FDA determine the detailed information that will accompany the label, including contraindications, precautions, side effects, dosages, routes of administration, and frequency of administration. Only one of five drugs studied for human use receives FDA approval.

After *approval*, the manufacturer can promote the drug, but large-scale clinical trials will continue to further define the safety profile. Additional *Phase IV* studies may be required. Once the drug is in widespread use, adverse effects previously undetected may be recognized. Occasionally, if the adversities are serious (fatal), the drug may be withdrawn from the market. Postmarket studies also may identify efficacy for indications not previously identified during the approval process. New information from postmarket studies are used to update the NDA. During this time period, reports of adverse reactions, particularly those not previously recognized or unexpected, are important to evaluating the safety of the drug. For human drugs, reports can be made on the Drug Experience Form, through MedWatch (a voluntary reporting program), and through the sponsoring pharmaceutical company.

Animal Drugs

The approval process for new animal drugs is not as clear cut as for human drugs. This reflects in part the variabilities presented by species differences, economic considerations, and the importance of food (human) safety. Thus, although the legal standards for safety and efficacy data are the same for both human and animal drugs, design of safety and efficacy studies and the criteria for approval differ, and the approval process for an NAD generally is tailored to the particular drugs. The differences are most marked for food animal drugs for which efficacy and safety data in the target species must be weighed in the context of economic considerations. The path of human drug approval does not apply to animals, although many of the same data are collected. The regulations for the approval of an animal drug can be found in 21CFR 514.1; however, several recent drug laws (e.g., the FDA Modernization Act and the Animal Medicinal Drug Use Clarification Act) and the Generic Drug Law of 1988 have impacted several aspects of this law, which is currently being updated by the FDA.

The approval process for animal drugs is changing but currently occurs in two distinct phases. (http://www.fda.gov/ AnimalVeterinary/GuidanceComplianceEnforcement/Guida nceforIndustry/ucm123821.htm; last accessed May 25, 2010). During the investigational new animal drug (INAD) phase, five technical areas are reviewed by the FDA. These include composition, manufacturing, and chemistry (CMC, basic manufacturing data); target animal safety; evidence of clinical efficacy; environmental considerations; and human food safety, which includes tissue residue data, for animal tissues intended for human consumption. During this phase, the FDA, in concert with the sponsor, determines product development plans, reviews protocols for the study design, implements the studies, and generates the raw data intended to support approval; the FDA then decides whether the data are sufficient to address concerns. The protocols for toxicology and tissue residue chemistry studies are straightforward, but more creative and innovative approaches are taken for target animal safety and efficacy because of the diverse issues surrounding new animal drugs.

Once the technical sections are completed, the second phase, the NADA is filed. This phase is in transition and represents a new approach to drug approval by the FDA (an "administrative" NADA) in that the majority of data supporting the approval of a drug may have already been reviewed by the time this phase is begun. The drug may be known to be approvable before this phase is reached because of the phased INAD review. The review process becomes largely interactive through the phased review process (http://www.fda.gov/downloads/ AnimalVeterinary/GuidanceComplianceEnforcement/ GuidanceforIndustry/UCM052464.pdf).

Orphan Drugs

The Orphan Drug Act of 1983 provided incentive for development of drugs used to treat rare diseases, which did not present sufficient economic incentive for a sponsor to undergo the traditional approval process because they benefit only a small number of patients. The added incentives include tax advantages and marketing exclusivity to the sponsoring company. The National Institutes of Health often participates in the development of orphan drugs. Examples of the 300 human drugs given orphan status include erythropoietin, α_1 antitrypsin, and human growth hormone. Criteria that a drug must meet to become an orphan drug include intent to treat a serious or life-threatening disease; lack of a comparable or satisfactory alternative; involvement in a clinical trial as an IND; and active pursuit of full approval by the sponsor. If these criteria are not met, the drug may still be obtained for compassionate use. The clinician in essence becomes the investigator by submitting a treatment IND.

Generic Drugs

Pharmacists can dispense an equivalent, less expensive, nonproprietary (generic) drug without prescriber approval. An exception occurs if a state has a mandatory substitution law or if the brand name product is dispensed along with a Dispensed as Written (DAW.) order. Generics may be pharmaceutically equivalent but may not be therapeutically equivalent. Those tested by the FDA and found to be therapeutically equivalent are listed in *Approved Drug Products with Therapeutic Equivalence Evaluations*, known as the *Orange Book* (http://www. accessdata.fda.gov/scripts/cder/ob/default.cfm; last accessed May 25, 2010). Generic products not only contain the same active ingredient as the proprietary drug but also meet bioequivalence standards. Substitutions of generic drugs for proprietary drugs are recommended only for those drugs shown to be therapeutically equivalent. Examples of drugs that are not therapeutically equivalent to their brand name counterparts include digoxin, phenytoin, conjugated estrogens, and slow-release theophyllines. The Orange Book addresses therapeutic equivalence in human medicine. Veterinary clinicians should not mistake therapeutic equivalence established in humans to be the same in animals.

The Drug Availability Crisis

In the mid-1990s, the Animal Health Institutes focused on an issue they termed the *drug availability crisis*. It is based on the fact that veterinarians are faced with the need and desire for improved veterinary care for their patients; there is a great availability of human-labeled drugs but fewer NADA applications. Simplistically, the FDA requirements of NAD approval have not allowed for flexibility in keeping up with the scientific advancements in the diagnosis, treatment, and prevention of animal diseases. For example, in 1994, for dogs, there were only 369 Rx drug products and 67 OTC drug products. For cats, there were only 169 Rx and 40 OTC drug products. For cats, these 209 products reflect only 84 drugs, many of which are no longer used. Approximately 15% of drugs discussed by the author used to treat or prevent illnesses in dogs are approved for that use; the number is even smaller for cats (less than 10%).

Two potential reasons preclude pharmaceutical companies pursuing the approval of human drugs for animals. First, adverse reactions that may occur in animals receiving the drug may impact the human market even if the adverse reaction is not likely to occur in humans. The second detractor is economic recovery. The cost of approving drugs has progressively increased, in part because of the "moving target" presented by the FDA to pharmaceutical companies. Requirements are constantly changing, and it is often difficult for the company to predict or keep up with changes. All changes are costly. A common misconception is that veterinary drugs do not have to undergo the same intensive scrutiny for approval as do human drugs. In fact, the opposite might be considered true. Because of the concern with tissue residues, far more time and effort might be put into animal drug approval, particularly food animal approval, than human drug approval. Environmental impact studies may also be more intense. Thus the cost for approval of an animal drug is disproportionately higher than of a human drug, particularly when the cost is compared with the recovery of costs. The animal market is very small compared with the human pharmaceutical market (millions compared with billions). The time for development of a drug (from identification of a potential compound to its final FDA approval) is 5 to 10 years, and the cost is approximately 1 to 2 million dollars per year (the longer time for food animals). As drug approval costs increase,

the number of NADAs may decline. Extralabel use of human generic versions of animal-approved drugs or compounding in lieu of prescribing approved drugs are also disincentives for manufacturers to pursue approval of a veterinary drug.

Extralabel Drug Use

If a new NADA exists for a drug, to use the drug in a legal manner the veterinarian must adhere to the specifications noted on the label (which includes both the label adhered to the medication and the accompanying package insert). Otherwise, an NAD is used in an extralabel manner. In 1994, Congress passed the Animal Medicinal Drug Use Clarification Act (AMDUCA), which legalized extralabel drug use (ELDU) by veterinarians as long as specific criteria or restrictions are met (see Table 2). ELDU, whether actual or intended, occurs when the drug is used in a manner that is not in accordance with the approved label directions. This includes but is not limited to a different dose, interval, route, indication, or species. Veterinary ELDU is legalized by AMDUCA (see Table 2) only for approved drugs (human or animal) and not for products intended for use as drugs but are not approved drugs. The latter substances are perceived by the FDA to be unapproved drugs and as such, fall under their regulatory jurisdiction. This includes novel ingredients, such as herbs and nutraceuticals, as well as products compounded outside the stipulations of AMDUCA. However, the FDA recognizes that there are diseases in animals for which there is no approved drug treatment and that strict enforcement of their law precludes the practice of veterinary medicine. To address these concerns, in 1984 and 1991, the FDA published Compliance Policy Guidelines for ELDU, including ELDU of animal drugs (Compliance Policy Guideline 7125.06) and ELDU of human drugs in animals (Compliance Policy Guideline 7125.35). The guidelines focused on ELDU in food animals and have been updated (http://www.fda.gov/AnimalVeterinary/ResourcesforYou/ FDAandtheVeterinarian/ucm077390.htm). These include EDLU is permitted only by or on the order of a veterinarian; it is allowed only for FDA-approved animal and human drugs (which excludes compounded products; see Compounding); it must be implemented in the context of an existing valid veterinaryclient-patient relationship (VCPR; (Box 3). For food animals,

Box 3

Requirements of a Valid Veterinary-Client-Patient Relationship (VCPR) as Defined by the Food and Drug Administration (FDA)

- 1. The veterinarian has assumed responsibility for making clinical judgments about the health of the animal.
- 2. The client has agreed to follow the veterinarian's instructions.
- 3. The veterinarian has sufficient knowledge to initiate a preliminary diagnosis of the animal's medical condition.
- 4. The veterinarian has examined the patient and is personally acquainted with the keeping and care of the animal.
- 5. The veterinarian is readily available for follow-up evaluation in the event of an adverse reaction to the treatment or therapeutic failure.

further restrictions apply. An interactive algorithm is available from the AVMA that directs the veterinarian using ELDU (http://www.avma.org/reference/amduca/amduca1.asp).

Compounding

The guidelines regarding the compounding of pharmaceuticals under the direction of a veterinarian are delineated in Compliance Policy Guideline 7125.40. Conditions under which compounding is legal are specified in the AMDUCA. Compounding includes any manipulation of the drug beyond that stipulated on the label (such as reconstitution of a powdered drug) (Table 4). Conditions under which compounding is not subject to regulatory actions include a legitimate practice (pharmacy or veterinary; includes licensure), operation within the conformity of state law, for pharmacists in response to a prescription, and for veterinarians in response to a valid VCPR. Compounding is likely to result in conversion of an approved animal drug into one that is unapproved. Compounding of human drugs and occasionally bulk drugs into appropriate dosage forms may be acceptable in certain circumstances (e.g., combinations of anesthetics to titrate administration, dilution of drugs for pediatric or small exotic animals). A legitimate medical need must be identified (e.g., health or life of the animal is threatened or suffering may occur). Additionally, there must be no marketed, approved animal or human drug, regardless of whether it is used in a labeled or extralabeled fashion that may be substituted for the compounded agent. Occasionally, other rare circumstances may be considered.

The compounded product must be dispensed by a veterinarian or prescribed and subsequently dispensed by a pharmacist. For companion animals, the safety and efficacy of the compounded drug must be consistent with current standards, appropriate steps should be taken to minimize the risk of human exposure to harmful ingredients, patient records must be kept, and the compounded drug must bear labeling information to ensure adequate and proper use of the product (including name and address of the veterinarian; the active ingredient; date dispensed and expiration date; directions for use; cautionary statement; and if dispensed by the pharmacist, appropriate pharmacist information). The compounded preparation cannot be sold to another veterinarian or pharmacist.

A number of pharmacists throughout the United States compound drugs for veterinarians. The Professional Compounding Center of America (PCCA) is a resource for education in compounding drugs for both human and veterinary medicine. Veterinarians seeking compounded products would be prudent to work with a pharmacist who is a member of the PCCA to be more certain of quality control concerns. The PCCA can be reached at 800-331-2498.

Compounded products are not regulated; assurance of quality, safety and efficacy is incumbent on the prescribing veterinarian. Because compounded products may be less safe that an approved product (other than increase accuracy in dosing), attention to patient response is important. Therapeutic failure may be a common adverse event that is easily forgotten with compounded products. Care must be taken to not misinterpret the availability of a compounded product as evidence of safety or efficacy. The discerning clinician should ensure, through contact with the pharmacist, that state pharmacy laws are followed. Sources of drugs should be confirmed with regard to quality. Manufactured products should be avoided for both ethical and safety reasons. The Pharmacy Compounding Accreditation Board (http://www.pcab.info/) offers accreditation to pharmacies willing to meet a robust set of criteria that ensure products meet both quality and ethical standards as intended by both the Food and Drug Administration and the pharmacy associations. Veterinarians are encouraged to identify those pharmacies that are PCAB accredited.

Alternative Mechanisms for Use of Human Drug in Animals

There are two other mechanisms by which a practitioner can legally use a human drug. Regulatory discretion (discretionary enforcement) has been applied by the FDA to selected drugs with no NAD. Recommendations for regulatory discretion of a drug are made by the Division of Drug for Non-Food Animals to the Division of Compliance. Digoxin is an example for which regulatory discretion has existed for a long time; labeling for animal use is even allowed for this product because it is so old. Newer regulations, however, prevent labeling for animals without an NADA. If a drug has been shown through illegal use to be safe and efficacious for the treatment of a disease in animals, the FDA will allow its use without an NADA (notification by letter). Examples include potassium bromide for treatment of refractory seizures, 4-methylpyrrazole for treatment of ethylene glycol toxicity, and calcium ethylene diaminetetra-acetic acid for treatment of lead poisoning. To obtain regulatory discretion, the practitioner needs to contact the Division of Compliance (see Box 3).

An alternative route to using a drug in an extralabel fashion legally for an animal is to procure an INAD application from the Division of Drug for Non-Food Animals (301-594-1722). The INAD provides statutory authority to exempt the drug from the NADA requirement. It limits the use of the drug to experts qualified by training and experience. A compassionate use INAD can be obtained in 1 day by calling the previous telephone number to treat an animal whose life is threatened. Note that the INAD is not necessary if the drug is approved for use in any species. The INAD is needed only if the drug is *unapproved*, meaning that there is no approved version for humans or animals (i.e., a drug approved in Canada, Mexico, or Europe but not the United States). Occasionally, the FDA may recommend that an INAD be obtained for the use of a drug recently approved for use in humans because data regarding the safety of the drug are probably still being collected for humans. An INAD may also be recommended if the drug is toxic (especially carcinogenic) or it is scheduled (regulated by the Drug Enforcement Agency). If an INAD is obtained, veterinarians must keep records regarding the use of the drug and must notify the FDA every time a shipment is requested or an adverse reaction occurs.

Extrapolation of human drugs to animals should be accompanied, whenever possible, by scientific studies that support proper dosing regimens. Recommendations regarding the extrapolation of dosing regimens among species is addressed in Chapter 2.

Schedule Drugs

Drug (substances) considered to be associated with a potential for abuse or physical dependence are restricted (controlled) by the FDA. The Controlled Substances Act delineates requirements that must be met when such drugs are administered, dispensed, or prescribed. The Drug Enforcement Agency (DEA) is charged with enforcement of the act, its amendments, and their regulations. The act includes federal requirements regarding the purchase, storage, prescription, and record keeping for controlled substance use. States may have additional requirements regarding purchase, dispensing, inventory, record keeping, and storage. Requirements are likely to vary from state to state (http://www.legislature.state. al.us/CodeofAlabama/1975/50719.htm).

Requirements for controlled substance use vary for practitioners, researchers, teachers, and pharmacists. Practitioners dispensing or prescribing Class I and II substances annually must obtain both federal and state registration; an exception is made if done in the confines of an employer (hospital)/employee (student) relationship and the employer is registered. Federal registration occurs through the DEA. For practitioners, use of Classes III to V must be preceded by a notice of intent to the DEA, although registration also may be required for Classes III to V, if certain conditions are not met (www.dea.gov). Registering practitioners must submit evidence of a professional degree. Licensure must be voluntarily surrendered on retirement. Mechanisms for state registration also vary; in the state of Alabama, registration of veterinarians occurs through the State Board of Veterinary Medical Examiners.

The DEA publishes a Practitioner's Manual (http://www. deadiversion.usdoj.gov/pubs/manuals/pract/index.html; last accessed May 25, 2010), which delineates requirements for the use of these substances. Among the major requirements, selected states require a special prescription blank (and often multiple copies). Generally, both state controlled substance registration (SCSR) and federal (DEA) numbers must appear on prescriptions. Purchase of controlled substances also requires a special triplicate form obtained from the DEA. All actions with controlled substances must be within the confines of a veterinary client-patient relationship. Containers must be designed such that children under the age of 5 cannot open the product, and a label stating "This Package for Households Without Young Children" must be applied when a childproof container is not used. Specific requirements also vary with the class or schedule of the controlled substance.

The classification of controlled substances reflects the perceived level of potential abuse or physiologic or psychological dependence (Table 3). The schedule of a controlled substance is indicated on the label of the product. Schedule I drugs have the highest potential of abuse and physical dependence. These drugs have no acceptable or safe medical use in the United States and are not to be prescribed, but they can be obtained for research purposes. Heroin is the most notable example. Schedule II drugs, exemplified by cocaine and morphine, are considered to have a high potential for abuse and dependence but have some medicinal worth. These drugs must be stored

Table **3** Scheduled Drugs

Schedule I	Definition Highest risk of	Drugs (lists are NOT inclusive) Heroin, hallucinogens (LSD,
	abuse and dependence and no medicinal use	mescaline, marijuana), amphetamines
П	High risk of abuse and dependence and limited medicinal use	Carfentanil, cocaine, codeine, diprenorphine, etorphine, fentanyl, hydrocodone, hydro- morphone, methylphenidate, morphine, meperidine, opium extracts and so on, oxymorphone, pentobarbital, sufentanil, thebaine
III	Moderate potential for abuse and dependence, but accepted thera- peutic use	Anabolic steroids, barbiturates, buprenorphine, codeine combinations, hydrocodone combinations, ketamine, morphine combinations, pentobarbital combinations, thiamylal, thiobarbiturate, tiletamine-zolazepam
IV	Low potential for abuse or depen- dence	Alprazolam, butorphanol, chlo- ral hydrate, chlordiazepoxide, clonazepam, clorazepate, diazepam, flurazepam, loraz- epam, midazolam, oxazepam, pentazocine, phenobarbital, propoxyphene
V	Lowest potential for abuse	Diphenoxylate; selected (low strength) codeine prepara- tions; hydrocodone and so on, as part of drug combination product; low-strength opium preparations

From http://www.justice.gov/dea/pubs/scheduling.html (last accessed May 25, 2010); note that the list of drugs may vary with some states.

in a securely locked, well-constructed cabinet or safe. Loss or theft requires immediate contact of the nearest DEA field office. Prescription refills are not allowed for these drugs, and they cannot be prescribed by telephone unless in an emergency (with a follow-up written prescription provided within 72 hours). Schedule III drugs, exemplified by selected opioids and barbiturates, have an accepted therapeutic use. Although abuse of the substance may lead to moderate or low physical dependence, the risk of abuse is less than that of Schedule I or II drugs. Schedule IV drugs, exemplified by diazepam and butorphanol, are considered to present a low potential for dependence or abuse. These drugs can be refilled but only to a maximum of five times; the prescription is effective only for 6 months. Schedule V drugs, such as diphenoxylate, have the lowest potential of abuse or dependence. Restrictions for drugs in this schedule are limited to age (humans), distribution by a pharmacist, and purchase in limited quantities. Schedule V

drugs include narcotics in Schedules II to IV included as part of a combination with other drugs (e.g., antitussives, antidiarrheals) with restrictions, including the concentration of the substance in the final product.

Reporting Adverse Drug Reactions

Adverse drug reactions are described in Chapter 3. Report of adverse reactions is an important means of monitoring the safety of products, as well as communicating unexpected adversities. In addition to the vehicles listed here, letters to the editors or case reports in veterinary journals or continuing education programs can be effective tools for reporting adverse drug reactions. Additionally, the adversity should be reported to the pharmaceutical company. Note that adverse events to biologics and pesticides should be reported to the respective agency (see Table 1). The steps to reporting an adverse event include contacting the technical services of the appropriate pharmaceutical manufacturer, if it is an animal-approved drug. If it is not an FDA-approved product for animals or if direct reporting to the FDA is desired, a report may be submitted via telephone at 1-888-FDA-VETS, or more appropriately, to the FDA on Form 1932a: Veterinary Adverse Drug Reaction, Lack of Effectiveness, Product Defect Report (postage prepaid and preaddressed). The form can be downloaded at the CVM website (http://www.fda. gov/downloads/AboutFDA/ReportsManualsForms/Forms/Ani malDrugForms/UCM048810.pdf; last accessed May 25, 2010) or can be obtained by written request at ADE Reporting System, Center for Veterinary Medicine, US Food & Drug Administration,7500 Standish Place, Rockville, MD 20855-2773.

Prescription Writing

Prescriptions are intended to provide direction to the pharmacist regarding the dispensing of a specific medication to a specific patient and must be written for all legend drugs. Specific guidelines regarding who may legally issue a prescription vary among states; however, licensed professionals may prescribe only within the profession in which they are licensed. Prescriptions must be issued only in the context of a valid VCPR (see Box 3). Prescriptions should be written in ink (includes typewritten and computer-generated forms) and must be signed by the prescriber. Pharmacies are not likely to stock veterinary drugs but may be willing to order them or infrequently used human products. The basic elements of a prescription (Box 4) may vary among states. Common mistakes made in prescription writing that can lead to mismedication include the inappropriate use of decimal points (a decimal point with a zero [e.g., 1.0] should not be used after a whole number because the decimal may be missed; a zero is always used to designate a fraction [e.g., 0.5] because the decimal may be missed) and the use of abbreviations that are similar (e.g., use of U for units [easily mistaken for a 0]). Writing numbers as words in lieu of or in addition to numerals may facilitate safety, particularly with toxic drugs.

Labels for prescription drugs should include the name, address, and phone number of the prescriber; the patient and owner's name (and for controlled substances, address and phone number); animal name (if appropriate) and species; dispensing date; drug name, quantity, and strength; instructions

BOX 4	

Basic Elements of a Prescription

Standard Prescription

Prescriber name (legible), address, phone number Animal owner name, address Animal description, name (if appropriate) Date written Drug name, dosage form (e.g., tablet, capsule, suspension, injection), strength Quantity to dispense Directions for use: how much, how often, route, special instructions (e.g., with food, before food) Signature of prescriber, with professional degree Refills if appropriate Other: indication for generic substitution, treatment indication Controlled Substances All scheduled drugs Owner address Quantity written as word and number Schedules III-IV Drug Enforcement Agency (DEA) number of prescriber Schedule II May require specific prescription form Check regarding duration that records must be kept	Standard Trescription

	Show regulating autonom that records must be hept			

for use; and appropriate precautionary statements. State regulations regarding the contents of the drug label may vary. Drugs should be dispensed in a childproof container unless requested otherwise by the owner; a signed request should be kept in the record if so requested.

ETHICAL CONSIDERATIONS IN CLINICAL TRIALS*

Assurance of Ethical Use of Animals

The use of animals in prospective research studies is becoming increasingly controversial. In this section, considerations for client-owned animals are contrasted with experimental animals that are owned by the research facility. Included in this latter group are animals that have been donated by clients. This section also discusses ethical consideration for humans, experimental animals, and client-owned animals in clinical trials. General ethical considerations for all clinical trials are also be presented.

Rights of Human Subjects

It is not unreasonable to expect the same concern and consideration for veterinary patients that is given human patients used as clinical research subjects. Human patients involved in clinical research are very well protected against inhumane use. The Nuremberg Code of Ethics in Medical Research (1948)

^{*}Excerpted from Boothe DM, Slater M: Proper implementation of clinical trials. In Dodds WJ (ed): *Veterinary medical specialization: bridging science and medicine*, vol 39 (*Advances in Veterinary Science*), Orlando, 1995, Academic Press.

emphasizes the rights of the experimental human subject. The Declaration of Helsinki (1964) as adopted by the World Medical Association went further and mandated the following:

- 1. Such research must conform to scientific principles.
- 2. Design and performance of the research must be clearly formulated in a protocol and transmitted to a specially appointed, independent committee.
- 3. Publication of results should accurately reflect the results of the study.

The Declaration emphasized the right of informed consent and specifically addressed human medical research that is combined with professional patient care. Research facilities, such as academic institutions that direct clinical research in humans, are guided by Institutional Review Boards whose primary charge is to ensure compliance with the Nuremburg Code and Declaration of Helsinki. With minor modifications, most of the guidelines delineated in these two documents also are applicable to the veterinary patient (client-owned animal) used in clinical research. Like human medical counterparts, veterinary clinical research facilities should institute a mechanism by which adherence to these guidelines is assured.

Welfare of Experimental Animals

Experimental animals are protected by guidelines offered by the Animal Welfare Act of 1966 and its subsequent amendments. The Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals (i.e., the National Institutes of Health Policy) requires compliance with this act of all institutions receiving PHS funds. Most research facilities (academic institutions) have laboratory animal care committees that assure compliance by individual investigators with the PHS policy. However, these committees are not necessarily charged with the care of client-owned animals and often (as at Texas A&M University) agree that research involving client-owned animals does not fall under their purview.

Welfare of Client-Owned Animals

To protect the welfare of client-owned animals, some type of review board should be in place. In a university setting, a Hospital Review Committee evaluates clinical trials and other types of clinical research. The term Health Review Committee (HRC) is used in this manuscript to distinguish from Institutional Review Boards (IRB) that address human subjects in clinical research. The goals of an HRC should be to protect the patient, client, institution and attending veterinarian(s) from the intended or inadvertent application of investigations that are inhumane or unethical and to promote the advancement of science through clinical research. The HRC functions to safeguard the welfare of the patient through the approval of proposals involving clinical research. Although its mission is not to provide rigorous review of the scientific merits of a proposed study, decisions regarding the ethical nature of a proposed clinical trial may require the HRC to question the scientific basis and the scientific and statistical design of any proposals.

General Ethical Considerations

General considerations on the ethical use of animals in clinical trials arise from the human research guidelines. Some of the following considerations are most applicable for clinical trials using client-owned animals. An over-arching truth is that it is more ethical to perform a randomized clinical trial than to use treatments of unproven efficacy. The patient's best interest cannot be forsaken for the sole purpose of "therapeutic progress"; rather, treatment of the patient is the priority. Completion of the trial must not be rushed if it creates risks to the patient. In the study design phase, protocols should be developed for use in the situation where the risk:benefit ratio of the therapeutic intervention becomes too high during the course of therapy (e.g., the trial will be terminated, the currently recommended therapy will be used, and so on). Trials should include methods to evaluate the incidence, frequency, type, and severity of side effects of test treatments. This is especially important if client-owned animals are used.

In determining the treatment protocol, if periodic therapeutic withdrawal or use of a placebo is planned, assurance must be provided that the subjects' life or comfort is not threatened. The use of an inactive placebo is not appropriate (except in very unusual, experimental situations) if there is a standard treatment protocol for the disease to be investigated. The doubleblind technique (defined here as blinding of the investigator and client or caretaker) should be abandoned if one treatment can be clearly recognized by the investigators to be preferred because of its beneficial effects, or if a treatment entails any risks that prove to be unreasonable. The code indicating a subject's treatment must always be available to appropriate participants in case of an emergency. For trials using client-owned animals, if a client withdraws an animal from the study, assurance should be given that patient care will remain available. There should be a system of verification of results that avoids the possibility of manipulating results after the study.

Additional questions regarding the scientific merits of the study that should be answered by the investigator include the following:

- Is there a need for the study? The answer to this question includes evaluation of the importance and clarity of the primary objective without unnecessary duplication of previous studies (in target or other species). Consideration of the applicability of the results is also important.
- 2. What is the justification for the study? Considerations include the inclusion of appropriate numbers of patients and controls, explicit inclusion/exclusion criteria, and ethical risk:benefit ratios.
- 3. Are the risks to the subject reasonable in relation to the possible benefits to the subject and/or the importance of the knowledge that may be reasonably realized from the study? A sound research design that does not unnecessarily expose subjects to risk is critical to address this question. Currently accepted or proven procedures that are already available for diagnostic or therapeutic purposes should be applied when available.

4. Has informed consent been obtained? The legal client representatives of the animal patients must be informed regarding the study and allowed voluntary choices. Informed consent should be sought from each prospective animal patient's legally authorized representative and should be properly documented.

Guidelines for Completing an Informed Consent

The informed consent should be perceived as a document that provides information to the owner, in layman's terms. The information should be pertinent to the study and should include anything that is likely to be important to the animal owner. This recommendation might seem nebulous and needlessly all-inclusive. However, the intent of the consent form might best be appreciated by answering the following questions: If you (or your child) were the subject of this study, what would you want to know about it? Is there anything left out of the consent form that the client is likely to get mad about when he/she finds out? The informed consent should be succinct, clear, and above all else informative to the animal owner. Bolding might be used to emphasize points that the investigator feels are particularly important to the client.

The following consent form is organized for purposes of discussion. The organization should be tailored to the study in a manner that is not confusing to the animal owner. Use of lay terminology that the client can understand is paramount to an appropriate informed consent. Information should be clear and succinct.

Suggestions regarding generation of an informed consent follow. The first paragraph identifies the animal and animal owner. The reason for the animal's inclusion should be stated. Additional information might be included in a brochure, which should be submitted along with the protocol. Note that information in the brochure is not part of the informed consent and cannot replace the information required in the consent document. The second paragraph should provide information about the experimental protocol. The following information should be included:

- 1. The study name and study location (this might include both the central location and the site where the animal is to be studied).
- 2. Statement that the study constitutes research; an explanation of its purposes and the expected duration of involvement.
- 3. Description of the procedures to which the animal will be subjected.

Those that are experimental should be noted as such. Additional information might include the funding agency and the number of animals to be studied.

The third paragraph might focus on the risks and benefits associated with the study. The following must be included:

- 1. A description of the risks and discomforts that are reasonably foreseeable (this should include the clinical signs that the animal owner will recognize).
- 2. A description of the possible benefits to the animal and animal owner, as well as other animals.
- 3. A description of appropriate alternative treatments.

If a placebo or negative control is included in the study, it must be clear to the animal owner that there is a possibility that the animal may receive no therapeutic benefit from the study.

Additional information that might be included in this section is as follows:

- 1. A statement regarding the approval status of the drugs/ therapies/tests to be studied.
- 2. A statement that unforeseen risks may occur.
- 3. A statement about the safety of the test intervention.
- 4. A description of the costs of the study assumed by the investigators (e.g., 50% of all clinical laboratory tests).
- 5. A description of the obligations of the animal owner.

This last statement might include costs to be incurred by the owner for participating in the study, the number of followup visits to a veterinarian, record-keeping, and telephone calls.

The fourth paragraph may focus on client options should an adverse reaction occur or client withdrawal be desired. Relevant information that should be included in this section is as follows:

- 1. An explanation of whether compensation or treatment will be available if injuries occur.
- 2. A statement regarding the client's right to withdraw at any time with no change in patient care.
- 3. Who is to be contacted in the event of an adverse reaction/injury or if questions regarding the study arise.
- 4. Conditions that might lead the investigators to withdraw a patient from the study (e.g., noncompliance, poor record keeping or "escape criteria," such as a worsening of the disease being tested).
- 5. A statement regarding financial obligations of the client should his or her animal be withdrawn from the study.
- 6. A statement allowing the client to seek a second opinion regarding the cause of death should his or her animal die while participating in the study.

The fifth paragraph ensures the confidentiality of the study. Points to be included are as follows:

- 1. A statement that assures that the data collected from the animal will be kept confidential.
- 2. A statement regarding notification of findings that might affect the willingness of the client to continue participation.
- 3. A statement regarding notification of the results of the study on its completion.
- 4. A statement verifying that the client has participated in this study willingly.

Each page of the informed consent should be numbered and accompanied by a place for the client's initials next to the number.

Informed consent may be *waived* under extenuating circumstances if the investigator and an unbiased clinician (one not participating in the study) certify in writing all of the following:

- 1. The patient is confronted with a life-threatening situation that necessitates the use of the intervention being tested.
- 2. Informed consent cannot be obtained from a legal representative of the patient (i.e., stray animals).

- 3. There is not sufficient time to obtain informed consent from the patient's legal representative.
- 4. There is no alternative method of approved or generally recognized therapy that provides an equivalent or greater likelihood of saving the patient's life.

REPORTING AND REVIEWING CLINICAL TRIALS

Data Reporting

A clinical trial is not complete until the information is disseminated. Publications of results should be prepared and made available as soon as possible. Although most manuscripts are prepared after closeout, in certain instances, interim publications are prepared.

Interim publications provide access to study results as they occur. Additional benefits might include easier preparation of the final manuscript and greater exposure of the study to the public. However, there are several disadvantages to interim reporting (Meinert, 1986). Results that are inconclusive may be confusing. If the results are discouraging, investigator enthusiasm may wane. Most critical is the possibility of bias in subsequent treatment assignment and data collection. Finally, data analysis and presentation may differ from and thus diminish the impact of the final report. Results of the study can be disseminated through publications in peer-reviewed journals and presentations at national meetings. Some journals (those that focus predominantly on human medicine) do not publish papers that have been presented nationally. The time gap between presentation and publication should be minimal. The choice of journal should be limited to referred journals that are covered in Index Medicus and Index Veterinarius. Unreferred journals should be avoided if they lack a critical review process. Such journals may reach a smaller public and thus may be more difficult for other investigators to identify or retrieve. A specialty journal (i.e., Internal Medicine, Neurology, or Surgery) might be considered if the results are of primary interest to the specialty group.

The potential importance of many veterinary clinical trials is not realized because of failure to publish the appropriate information. The goal of the publication should be to provide a clear, concise description of the study. Studies that report statistically insignificant findings should also be published. The clinical trial may only result in a single manuscript that is published on completion of the trials. The organization of the manuscript varies with the targeted journal. Typical components include the following.

The *title* is one of the most important components of the publication. It should be concise and as short as possible while indicating the main thrust of the paper. The term *clinical trial* should be included in the title. The title section should also include the authors, source of financial support, acknowledgements, and address for reprints. Finally, a list of key words selected by the author should be included to allow for retrieval.

The *abstract* is often the only part of a paper that is read and as such should provide a summary of the paper. The abstract will be included in Medline, the computerized version of *Index Medicus*, or other computerized databases. The abstract should include the study purpose or objective, primary outcome measure, intervention; type of control, method of allocation, blinding procedures, number of animals enrolled and studied, and conclusions.

The *introduction* should be short and succinct. Its purpose is to provide a historic background for the study. Included is a literature review, what led to the initiation of the study, the study objectives, and the rationale for the study. This might include a rationale for the study design, intervention, or outcome measurements.

The *methods section* should be sufficiently detailed to allow readers to make informed judgments regarding the quality of the methods. Citation of a previously published paper describing the methods can reduce the content if the paper was devoted primarily to the design and methods of the trial.

The *results section* is generally the longest. The crux of the paper should be represented by tables, charts, and figures, which should be understandable without reference to the text.

The *discussion* should highlight the important findings of the study. Positive and negative findings should be reported. The clinical implications of these results and consistency with previous findings should be discussed.

The *conclusion* may either stand alone or complete the discussion. The conclusions must be drawn from the results of the trial. If appropriate, the statistical power of the study should be noted if the conclusion favors the null hypothesis. Finally, a statement regarding the extent of generalization should be included.

References should be limited to those that support the rationale of the objectives and document methods of data collection and analysis. The journal of publication will dictate the organization of the references. Original articles should be referenced whenever possible. Secondary sources are acceptable if the primary cannot be found; if the primary is published in a foreign language; or if the secondary expands on information provided by the primary paper. Checks of accuracy of title name, spelling of author's name, and so on should be based on the article itself and not on citations listed in other bibliographies (e.g., Medline).

The *appendix section* is optional and may not be allowed by some journals. Contents should be limited to information regarding methods that is too technical or detailed to include in the body of the text. Examples of information to be contained in the appendices are details of sample size calculations; sample data forms; data collection schedules; special charts, figures, and equations; consent statements; and data listings.

The submission process can be facilitated if the manuscript is reviewed before submission. Authors should review the paper for inconsistencies in format and style (including tables and figures), for redundancy, and for reporting deficiencies. Figure and table numbers should match text citations. Citations should be reviewed to ensure that information cited is correct. Colleagues should provide the second review. Their primary function is to identify confusing aspects of the manuscript. Total rewrites may result from this internal review. The final review by the authors should focus on the format of the journal to which the manuscript is to be submitted. The number of copies and prints submitted, title page, style and format, and so on should match the specifications set forth in the journal's "Instructions to Authors." After publication, the primary authors should establish an archive consisting of all documents related to the paper, beginning with raw data and finishing with a copy of the printed manuscript. This information should be kept at least 3 years (Meinert, 1986).

Reviewing a Clinical Trial

When reviewing a manuscript that reports the results of a clinical trial, the reviewer should be unbiased regarding the results. The reviewer's opinion should be based on the merits of the study rather than on the opinions and critiques of others. The purpose of the clinical report should be strongly

considered, particularly if sponsor support was critical to the study and the sponsor stands to gain financially from it. The information provided in the report should allow adequate review of methodology so that critical aspects of the report can be evaluated. Reproducibility of results and generalization of results to a large population (rather than a small subset) should be assessed. Exclusion of patients should be well justified. The study design should be well safeguarded against biases during the assignment and administration of the intervention and during data collection and analysis. Methods used to edit the data for errors or inadequacies should be cited. Statistical methods should be appropriately sophisticated. Major differences in baseline group comparability, dropout rates, or compliance should be evaluated for a possible role in treatment differences.

Appendix

Conversions, Equivalents, and Abbreviations

 Table 1
 Metrologic and Pharmaceutical Weights and Measures*

The Metric System of Weight	
1 microgram (mcg) = 0.000,001 gram (g) (μg)	
1 milligram (mg) = 0.001 g = 1000 mcg (µg)	
1 gram (g) = 1.0 g = 1000 mg	
1 kilogram (kg) = 1000.0 g	
The Metric System of Liquid Measure	
1 milliliter (mL) = 0.001 L	
1 liter (L) = 1000 mL	
The Avoirdupois System of Weights	
437.5 grains (gr) = 1 ounce (oz)	
16 oz = 1 pound (lb) = 7000 gr	
Apothecaries' System of Weights	
20 gr = 1 scruple	
3 scruples (ϵ) = 1 dram = 60 gr	
8 drams = 1 oz = 480 gr	
12 oz = 1 lb = 5760 gr	
Apothecaries' System of Liquid Measures	
(U.S. Wine Measure)	
60 minims = 1 fluid dram	
8 fluid drams = 1 fluid ounce (fl oz)	
16 fl oz = 1 pint	
8 pints = 1 gallon (cong.)	

Remarks:

The avoirdupois system of weights is used in buying and selling in commerce. This includes drugs.

The apothecaries' system is used only for writing, compounding, and dispensing prescriptions.

The grain is identical in both the avoirdupois and apothecaries' systems, but the ounce and pound are not.

One minim does not weigh 1 grain, and 1 fluid ounce does not weigh 1 ounce, and 1 pint does not measure 1 pound.

The scruple and apothecaries' pound may be disregarded insofar as they are seldom used. When *pound* is used, it usually means an avoirdupois pound. When *ounce* is used, it usually means an apothecaries' ounce.

Appendix Outline

DOSE CALCULATIONS SOLUTIONS

PERCENT SOLUTIONS CONCENTRATION TERMS

DOSE CALCULATIONS

Dose may be calculated by the following formula:

Dose per unit of body weight

 $\frac{1}{\text{Unit of drug per mL}} = \text{Total dose in mL}$

To convert pounds to kilograms, divide by 2.2 or multiply by 0.454.

$$\frac{20 \times 0.454 \times 10}{20} = 4.54$$

Example: If an animal weighs 20 lb and the clinician wants to administer 10 μ g/kg of 1:50,000 solution, what is the dose in mL?

SOLUTIONS

Concentration of an analyte in solution is routinely generally is expressed as percent solution, molarity, molality or normality.

See also: DoseCalcu Online http://www.meds.com/ Dchome.html

Percent Solutions

Definitions

Percent solutions are equal to parts per hundred or the amount of solute per 100 total units of solution. Three expressions of percent solution are as follows:

- 1. Percent weight in weight (w/w) expresses the number of grams of active constituent in 100 grams of solution.
- 2. Percent weight in volume (w/v) expresses the number of grams of an active constituent in 100 cubic centimeters of solution and is used in prescription practice regardless of whether water or some other liquid is the solvent.
- 3. Percent volume in volume (v/v) expresses the number of cubic centimeters of an active constituent in 100 cubic centimeters of solution.

When *percent* is used in prescriptions without qualification, it means the following: for mixtures of solids, percent weight in weight; for solutions of solids in liquids, percent weight in volume; for solutions of liquids in liquids, percent volume in volume; and for solutions of gases in liquids, percent weight in volume. For example, a 1% solution is prepared by dissolving 1 gram of a solid or 1 cubic centimeter of a liquid in sufficient solvent to make 100 cubic centimeters of the solution. A solution of approximately the same strength may be prepared by apothecary weight and measured by dissolving 4.5 grains of a solid or 4.8 minims of a liquid in sufficient solvent to make 1 fluid ounce of the solution.

Appendix

Calculation of Percent Concentrations

The following formula may be used to calculate percent composition:

$$\frac{\text{The part}}{\text{The total}} \times 100 = \% \quad \text{or} \quad (x/y) \times 100 = z$$

If any two quantities are known, the third can be easily calculated by the preceding formula.

Consider the following examples:

1. What is the w/v strength of a solution made by dissolving 6 grams of a drug in sufficient water to make 300 mL?

$$6/300 \times 100 = x$$
 (x = 2)

- 2. How many mL of a 5% w/v solution can be made with 10 grams of drug?
- 3. How many grams of a drug are needed to make 200 mL of a 6% w/v solution?

$$10/x \times 100 = 5$$
 (x = 200)

 $x/200 \times 100 = 6$ (x = 12)

4. What is the w/v percentage strength of a solution containing 50 mg per mL?

$$50 \text{ mg}/1\text{mL} = 0.05\text{g}/\text{mL} = 5\text{g}/100\text{mL}$$

$$5/100 \times 100 = 5\%$$

^{*}Can be substituted for body surface area or m^2 using conversion factor found in Appendix 2.

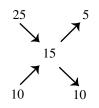

Dilute with a pure diluent

Example: Dilute a 5% solution to a 2% solution.

Take two parts of 5% solution, and dilute to 5 parts. This will yield a 2% solution.

Proof : 2 parts $\times 0.05 = 0.1$; $0.1/5 \times 100 = 2\%$

Mixing of two solutions or solids of unequal concentrations. Example: Mix a 10% and a 25% solution in proper portions to make a 15% solution.

Solution by Pearson's Square

=	1 part of 25 $\%$		3 total
=	2 part of 10%	15 Total	3 Total

Subtract 10 from 15 to determine parts of 25% solution. Subtract 15 from 25 to determine parts of 10% solution.

Proof :1parts	25% = 25
2 parts	10% = 20
3 parts	15% = 45

Algebraic solution:

let a = parts of 25 % b = parts of 10 % 15(a+b) = parts of 15 %

$$25 + 10b = 15a + 15b$$

 $10a = 5b$
 $2a = b$

Mixing of three or more solutions or solids of unequal concentrations:

Example: Mix 14%, 12%, 6%, and 4% solutions to make a 10% solution.

14 = 6 = 3 parts of 14% 12 = 4 = 2 parts of 12%

6 = 2 = 1 parts of 6%

4 = 4 = 2 parts of 4%

8 parts of 10%

Proof : 3 parts 14% = 422 parts 12 = 241 parts 6 = 62 parts 4 = 88 parts 10 = 80 Algebraic solution:

let a = parts of 14% b = parts of 12% c = parts of 6% d = parts of 4%

10(a + b + c + d) = parts of 10% 14a + 12b + 6c + 4d = 10a + 10b + 10c + 10d 4a + 2b = 4c + 6d2a + b = 2c + 3d

By substituting values for any of three, the fourth can be found. This formula can give a great number of possible combinations. For example, if a = 3 parts, b = 2 parts, and c = 1part, then d = 2.

Concentration Terms

A *dilute* solution is one with relatively little solute, whereas a *concentrated* solution contains a large amount of solute in solution. A *saturated* solution contains an excess of undissolved solute particles, whereas a *supersaturated solution* has an even greater concentration of undissolved solute particles and therefore is thermodynamically unstable. The *density* of a substance is expressed in terms of mass per unit volume and often is referred to as *specific gravity* (usually expressed as gm/mL). Temperature and the presence of other ions can influence the solubility constant for a given solution and thus the saturation. Thus, in dispensing prescriptions, slight changes in volume owing to variations in room temperatures may be disregarded.

Molarity

Molarity (*M*) refers to the number of moles *per liter* of solution (i.e., the compound is added and the volume is brought up to 1 liter total), with one mole equaling the gram molecular weight of the compound. The traditional molar concentration of the solution is moles of solute per volume of solution, with volume generally given in terms of liters: mol/L, mmol/L (millimol), μ mol/L (micromol), and nmol/L (nmol).

Example: How may grams are needed to make 1 liter of a 1.5 M solution of hydrochloric acid (HCl)?

GMW HCl = 1 + 35.5 = 36.5

1M = 1GMW/L

 $1.5M = 1.5 \text{ GMW/L} = 1.5 \times 36.5 \text{ g HCl} = 54.75 \text{ gm HCl}$ added to sufficient solvent to make 1 liter

Molality

Molality (*m*) is the *amount of solute per kg* of solvent (i.e., the total amount of solution might exceed 1 liter compared with molarity). It is distinguished from molarity in that it is always expressed as weight per weight, or moles per 1000 gm of solvent. The preferred expression for molality is moles per kilogram (mole/kg).

Example: What is the equivalent weight, in grams, of NaCl, HCl, and H₂SO₄?

NaCl	HCI	H_2SO_4
Na = 23	H = 1	H ₂ = 2
C = 35	Cl = 35	$SO_4 = 32 + 4(16)$ = 96
Total = 58	Total = 36	Total = 98
Valence = 1	Valence = 1	Valence $= 2$
Equivalent weight = 58	Equivalent weight = 36	Equivalent weight = 49

Normality

Normality (*N*) is the number or gram equivalent weights per liter of solution. An equivalent of an electrolyte is the amount that produces one mole of either positive or negative charges when dissolved. The number of equivalents of an electrolyte is calculated by multiplying the number of moles of electrolyte by the total number of positive charges produced when one formula unit of the electrolyte dissolves. Alternatively, an equivalent weight is equal to the molecular weight of a substance divided by its valence. The valence of a molecule is the number of units that can combine with or replace one mole of hydrogen ions. *Normality* is not a commonly used expression; rather, milliequivalents per liter (mEq/L) or millimoles per liter (mmol/L) are used to express electrolyte concentrations.

Osmolarity

Osmolarity (Osm) is the total number of solute particles in a liter of solution (rather than relative weights of the specific solutes). It is calculated from the number of moles of solute particles that are present when 1 mole of the solute dissolves.

Nonelectrolytes (glucose, etc.) do not dissociate, thus n=1 (i.e., molarity = osmolarity). However, electrolytes dissociate and their osmolarity is greater than their molarity, the magnitude depending on the number of ions produced upon dissociation (e.g., the Osm CaCl2 = $3 \times M$).

Table 2 Role	Table 2 Role of Vitamins in Pharmacology		
Vitamin	Forms	Role	Comments
Vitamin B ₇ , biotin (water-soluble vitamin)		Cofactor for enzymes that catalyze incorporation of bicarbonate into carboxyl groups. Substrates include pyruvate, acetyl coenzyme A (CoA), propionyl CoA, and β-methylcrotonyl CoA. Critical for fat and carbohydrate metabolism.	Bound tightly to avidin in raw egg white. Clinical deficiency rare due to micro- bial formation.
Vitamin B ₉ , folic acid (a water- soluble B vitamin)	Folates: all containing pterolglu- tamic acid	Transfer of methyl groups; DNA and protein synthesis.	Deficiencies in cells with rapid turnover, with macrocytic anemia most com- mon followed by atrophy of intestinal mucosa. Supplementation may reduce homocysteine (humans), leading to atherosclerosis.
Vitamin B ₃ , niacin (or niacinamide) (a water-soluble B vitamin)		Present as nicotinamide dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP) serving as cofactor for enzymes catalyz- ing oxidation-reduction reactions needed for cellular electron transfer; electron carrier for enzymes oxidizing fuel substrates (NAD); transfer of adenosine triphosphate–ribosyl moi- eties to proteins; hydrogen donor for reduction reactions such as fatty acid synthesis (NADP).	Deficiency results in pellagra ("raw skin" [humans]), seen in predomi- nantly grain diets. Marked over- supplementation can cause toxicity.

Table 2 Role of Vitamins in Pharmacology – cont'd			
Vitamin	Forms	Role	Comments
Vitamin B ₅ , panto- thenic acid (a water-soluble B vitamin)	Pantoic acid linked to β-alanine	Synthesized to acyl carrier protein CoA, which is a cofactor for enzyme-catalyzed transfer of acetyl. Acetyl CoA is necessary for oxidative metabolism of carbohydrates, gluconeogenesis, fatty acid metabolism, synthesis of steroids and porphyrins, and posttranslational modifications of proteins.	
Vitamin A (fat soluble)	All- <i>trans</i> -retinol (parent); acid form: retinoic acid; aldehyde form: rentinal Plant precursors: carotenoids Synthetic forms: etretinate (no longer available?), arotinoids	Retinol: gene expression of facial structures and limb buds Retinoic acid: epithelial tissues, bone, embryologic development, cell differentiation Retinal: retinal function	Carotenoids have antioxidant proper- ties and have been advocated for prevention of cancer and heart disease. β -carotene may promote certain types of cancer. Doses 100- fold may produce acute toxicity (nausea, vomiting, vertigo, muscular incoordination), while 10 times the dose may cause chronic toxicity (skin changes, hepatomegaly, bone and joint disease).
Vitamin B ₁ , thiamine	Purimidine and thia- zole nucleus linked by methylene bridge	Carbohydrate metabolism; in phosphorylated form, active as coenzymes, particularly in nonoxidative decarboxylation of α -ketoacids.	Deficiency referred to as <i>beri beri</i> (humans) leading to cardiac disease (hypertrophy and dilation of right heart); profound neurologic defi- ciencies, including polyneuropathy, ophthalmic disorders.
Vitamin B ₂ , riboflavin	Precursor to flavin mononucleotide and flavin adenine dinucleotide	Act as coenzymes for flavoprotein enzymes catalyzing oxidation-reduction reactions critical for energy production; participates in cytochrome P450 metabolism (dehydrogena- tions, hydroxylations, oxidative decarboxylations, reductions, and so forth).	Deficiency associated with increased lipid peroxidation, altered metabo- lism of other B vitamins (folic acid, pyridoxine, niacin) and vitamin K leading to liver disease, anemia, sto- matitis, glossitis, seborrheic derma- titis, and, with prolonged deficiency, neuropathy.
Vitamin B ₆	Pyridoxine Pyridoxal Pyridoxamine	Cofactors for over 100 enzymes, especially aminotransferases, decarboxylases, decarboxyl- ations with carbon–carbon bond formation, side-chain cleavages, dehydratases, and racemoses.	Deficiency results in seborrheic skin rash, glossitis and stomatitis. High doses may cause peripheral neuropa- thy.
Vitamin B ₁₂ , vari- ous cobalamins (cyanocobala- min) (minimally absorbed)	Dietary form (must be activated)	DNA synthesis; facilitates folic acid metabolism	Cyclical structure similar to hemoglobin, with cobalt rather than iron in center. Deficiencies rare (see text) but result in <i>combined systems disease</i> or perni- cious anemia that targets gastrointes- tinal tract, blood cells, and neurologic system.
Vitamin C (water soluble), ascorbic acid		Reducing agent, serving as an electron donor for enzymatic reactions, especially hydroxylation and amidation. Synthesized in most mam- mals (exceptions: humans and other primates, guinea pigs). Particularly important for collagen synthesis, conversion of lysine to carnitine, and folic acid to folinic acid; converts ferric iron to ferrous iron, assisting iron absorption from gas- trointestinal tract. Antioxidant	Few scientific studies support claims regarding prevention or treatment of cardiac disease or cancer.

T | | **A**

Vitamin	Forms	Role	Comments
Vitamin D (fat soluble)	Ergocalciferol: vitamin D ₂ cholecalciferol: vitamin D ₃ 25-Hydroxy- cholecalciferol: calcifediol 1,25-Dihy- droxycholecalciferol: calcitriol (vitamin D ₂) Dihydrotachysterol (iso- mer of vitamin D ₂)		Excessive consumption may result in hypercalcemia, anorexia, nausea, vomiting, polyuria, thirst, muscular weakness, joint pain, and bone demin eralization
Vitamin E (fat soluble)	Tocopherols (alpha and gamma) and tocotrienols	Free radical scavenger, preventing oxidation of polyunsaturated fatty acids and thiol-rich proteins in cell membranes; T lymphocyte maturation; decreased oxidation of low-density lipoproteins; protects against free radical damage to retina and nervous system	Overdosing may interfere with vitamins A and K absorption; bleeding disor- ders may occur
Vitamin K	Phylloquinone (chloro- phyll-containing plants) Menaquinones (bacteria)	Activates clotting factors VII, IX, and X	

Table 2 Role of Vitamins in Pharmacology-cont'd

Data from Atkinson RL: Nutritional aspects of pharmacology. In Brody TM, Larner JL, MinnemanKP, editors: Human pharmacology: molecular Mosby, St Louis, 1998, pp 843-860.

Table 3 Role of Microminerals* in Pharmacology			
Microminerals	Role	Comments	
Chromium	Glucose and insulin homeostasis; RNA synthesis (?)	Ubiquitous nature renders deficiency rare.	
Copper	Red blood cell production; cofactor for enzymes, espe- cially monoamine oxidase (inactivates catecholamines), cytochrome- <i>c</i> -oxidase; needed to incorporate iron into hemoglobin.	Anemia; increased sensitivity of cardiac muscle to cat- echolamines; collagen and elastin synthesis impaired: capillary fragility, weak arterial walls.	
Iron	Critical for hemoglobin structure and promotion of electron transfer in cytochromes and other iron-dependent enzymes, especially NADH dehydrogenase.	Most common nutritional deficiency (in humans); char- acteristic microcytic anemia due to iron depletion of red blood cells. See text.	
Selenium	Antioxidant; component of several enzymes, most notably glutathione peroxidase.	Deficiency results in muscle degeneration, liver necrosis, growth retardation, reproductive failure.	
Zinc	Component of more than 50 metalloenzymes; stabilization of RNA, DNA, and ribosomes; productive binding of hormone receptor complexes; tubulin. polymerization; necessary for growth and reproductive function; participates in smell and taste; critical for night vision.	One of the most important trace elements. Deficiency causes growth retardation, failure of sexual maturity, fetal deformities, immunosuppression, corneal opaci- ties, loss or impaired smell and taste, impaired glucose tolerance. Interrelated with vitamin A.	

*Sodium, potassium, calcium, and magnesium are considered macrominerals and are important in the ionic movement across cell membranes. All macrominerals function in energy metabolism, membrane transport, and the maintenance of membrane potential by Na⁺, K⁺ -ATPase. Calcium is critical to the skeletal system, neuromuscular transmission, cellular signaling, and blood coagulation. Magnesium is critical in more than 300 enzymatic reactions; deficiency results in osteomalacia (humans), neuromuscular disorders, seizures, and cardiac dysrhythmias.

INTRODUCTION

- I. Toxicants are just another etiology of a disease process.
- II. Toxicants are capable of mimicking bacterial or viral processes.
- III. History is very important in diagnosing toxicoses.
- IV. With few exceptions, it is more important to treat the animal than worry about the diagnosis (i.e., the diagnosis is important, but saving the animal's life is more important).
- V. Do not let the client or anything else make the diagnosis for you.
- VI. Important toxicants in veterinary clinical practice:
 - A. Rodenticides
 - B. Insecticides
 - C. Organic compounds, such as antifreeze, halogenated hydrocarbon
 - D. Inorganics: metals
 - E. Plants

MANAGEMENT AND TREATMENT OF TOXICOSES

When the task at hand is treatment of intoxications, the primary emphasis should be on prevention, not treatment. Therefore client education is at the top of the list, whether the client is a producer or an individual animal owner. Client education should emphasize proper handling as well as storage techniques.

Primary Goals of Therapy

- I. Emergency intervention and prevention of further exposure
 - A. Removal of the animal from the toxicant, or the toxicant from the animal; washing the animal
 - B. Maintenance of normal respiratory and cardiac function
- II. Establishment of a tentative diagnosis on which to base rational therapeutic measures
- III. Delaying of further absorption
- IV. Application of specific antidotes and remedial measures
- V. Hastening the elimination of the absorbed toxicant
- VI. Supportive therapy
- VII. Determination of the source of the toxicant
- VIII. Client education

Telephone Instructions

The owner should do the following until the animal is taken to the veterinarian or until the veterinarian sees the animal(s).

- I. Do not waste time.
- II. Protect the animal from injuring itself, and protect the people and other animals in the vicinity. It is important that the animal owner protect himself or herself if externally applied chemicals (pesticides) are involved.
- III. Bring suspect material, with original container, if possible along with any vomitus. Clean glass containers are best. This is especially important if medical/legal aspects are involved.
- IV. If there will be a time delay, and if the owner is insistent about treating the animal with some "medication" and if the animal is not sedated or unconscious, then the owner can be advised to do the following:
 - A. Administer milk.
 - B. Administer activated charcoal if available.
 - C. Administer water.
 - D. The owner may be advised to wash dermally exposed animals with soap and water, but the owner should use proper precautions.
 - E. 5 mL of hydrogen peroxide (1 tsp) on base of tongue or ½ to 1 tsp of syrup of ipecac; clinician must explain precautions about vomition as well as toxicity of syrup of ipecac.

TREATMENT AFTER THE ANIMAL

Emergency Intervention: Keep the Animal Alive

- I. Establish patent airway.
- II. Assess and maintain myocardial activity.

Delay Absorption

- I. Remove external contaminants
- II. Induce emesis
 - A. Of little value after 2 to 4 hours of ingestion
 - B. Syrup of ipecac
 - 1. 1 to 2 mL/kg, maximum of 15 mL for largest dog
 - 2. Only 50% effective in dogs, may repeat after 20 minutes. If emesis does not occur after second dosage, the syrup of ipecac must be removed by gastric lavage.
 - 3. Syrup of ipecac must not be used when activated charcoal will be used in the treatment regimen.
 - C. Copper sulfate —dangerous
 - D. Table salt —dangerous
 - E. Hydrogen peroxide —5mL on base of tongue
 - F. Apomorphine —Lilly
 - 1. Most reliable
 - 2. Most effective
 - 3. 0.04 mg/kg intravenously or
 - 4. 0.08 mg/kg intramuscularly
 - 5. Disadvantages
 - a) Protracted emesis
 - b) May deepen respiratory depression, but if respiration is depressed, then central nervous system

depression is also present; therefore induction of emesis would be contraindicated.

- c) May be effectively controlled by appropriate narcotic antagonists administered intravenously
 (a) Narcan —0.04 mg/kg
 - (a) Narcan -0.04 mg/kg (b) Lorfan -0.02 mg/kg
 - (c) Nalline -0.1 mg/kg
- d) It is a *Schedule II* drug that *is no longer manufactured*. It may be rereleased at some unspecified time in the future. Even though it is no longer being marketed, it is still found in many clinics.
- III. Contraindications for INDUCTION OF EMESIS
 - A. Unconsciousness or central nervous system depression (respiratory depression)
 - B. Intoxication of petroleum distillates?
 - C. Use of tranquilizers or antiemetics
 - D. If > 2 to 4 hours since ingestion
 - E. Ingestion of acids or alkalis: weakened stomach wall, retching may rupture, also reinjure esophagus and oral cavity.
- IV. Activated charcoal may be used with emetics to increase the efficiency of both techniques.
- V. Vomitus should be saved.

Gastric Lavage

- I. Animal is unconscious: light anesthesia, with endotracheal tube (cuffed) extended beyond teeth.
- II. Lower head and thorax.
- III. Measure oral-gastric tube from muzzle to xiphoid cartilage and mark.
- IV. Use same size oral–gastric tube as endotracheal tube 1 mm = 3 French; use as large a tube as possible.
- V. Use 5 to 10 mL/kg of lavage solution for infusion.
- VI. Aspirate solution from stomach using a large aspirator bulb or 50-mL syringe.
- VII. Repeat cycle 10 to 15 times; activated charcoal will increase efficiency.
- VIII. Precautions:
 - A. Use low pressures; do not force fluid.
 - B. Reduce volume in obviously weakened stomachs.
 - C. Do not rupture esophageal or gastric walls.

Adsorbents

- I. Activated charcoal
 - A. Vegetable or petroleum origin, not animal origin
 - B. Activated by increasing surface area and heating
 - C. Sources:
 - 1. SUPERCHAR —Gulf Biosystems, Dallas (This is currently off the market (as of early 1991). A Japanese company has purchased it and is considering rereleasing it in the future.
 - 2. TOXIBAN —Vetamix, Shenandoah, Iowa
 - 3. Use a bathtub or another easily cleaned area
 - 4. Make a slurry with water, 1 gm/5-10 mL water
 - 5. Dosage = 2 to 8 g/kg BW
 - 6. Administer by oral-gastric tube using funnel or large syringe

- 7. Administer a saline cathartic 30 minutes after charcoal.
- 8. For best results, activated charcoal should be re-administered qid for several days after an intoxication.
- D. *Remember:* Do not use with syrup of ipecac
- E. Universal Antidote not effective
 - 1. Activated charcoal –2 parts
 - 2. Magnesium oxide -1 part
 - 3. Tannic acid —1 part
 - 4. "Burnt" toast -- not effective

Cathartics

- I. Saline cathartic —best
 - A. Sodium sulfate -1 g/kg best
 - B. Magnesium sulfate
- II. Mineral oil and/or vegetable oil may be contraindicated; always follow with a saline cathartic.

Colonic Lavage or High Enema

- I. Sources of activated charcoal -see Table 1
- II. Locally acting antidotes —see Table 2
- III. Systemic antidotes —see Table 3

ELIMINATION OF ABSORBED TOXICANTS

General

- I. Kidneys-easiest to manipulate
- II. Bile, feces
- III. Lungs

Renal Elimination

- I. Requires adequate renal function: minimum of 0.1 mL/ kg/min of urine production
- II. May require hydration: fluid therapy
- III. Diuretics
 - A. Furosemide —Lasix 5 mg/kg, every 6-8 hours
 - B. Mannitol —2 gm/kg/hr
 - C. Manipulation of pH
 - 1. For an acid, $pH = pKa + \log I$ U
 - 2. For a base, $pH = pKa + \log U$
 - 3. Many chemicals are weak acids or bases.
 - 4. Degree of ionization depends on pH of medium and pKa of compound.
- IV. Facts about pKas of compounds
 - A. Acid with low pKa = strong acid
 - B. Acid with high pKa = weak acid
 - C. Base with low pKa = weak base
 - D. Base with high pKa = strong base
 - E. At pHs above pKa
 - 1. Acids = ionized
 - 2. Bases = un-ionized
 - F. At pHs below pKa
 - 1. Acids = un-ionized
 - 2. Bases = ionized

- G. Compounds that are un-ionized at physiologic pHs could be expected to traverse membranes if the compound is lipid soluble.
- H. The gastrointestinal tract and the kidney are the organs where clinicians can take advantage of the pH differences. "ION TRAPPING"
 - 1. Drugs are readily absorbed from the gastrointestinal tract if the non-ionized form is lipid soluble and if:
 - a) an acid with pKa > 2

b) a base with pKa < 11

- I. Exceptions:
 - 1. 2-PAM —completely ionized, absorbed from stomach but will not readily cross blood–brain barrier
- J. Examples of "ION TRAPPING"
 - 1. Acid—Acetylsalicylic acid (aspirin) and some barbiturates remain more ionized in alkalinized urine.
 - 2. Bases—amphetamines and other basic compounds remain more ionized in acidic urine.
- K. Urinary acidifying agents
 - 1. Ammonium chloride 200 mg/kg per day in divided doses
 - Ethylenediamine dihydrochloride, Chlorethamine —1-2 tabs, tid
 - 3. Physiological saline (PSS) intravenously
- L. Urinary alkalinizing agents
 - 1. Sodium bicarbonate —5 meq/kg/hr

Peritoneal Dialysis

- I. For use when kidneys do not function
- II. Time consuming
- III. Infusion of dialyzing fluids into peritoneal cavity, allowing the fluid to stay there for 30 to 60 minutes before removal
- IV. May insert dialysis catheter, or just use 18-gauge needle
- V. May alter pH of dialyzing fluids if type of offending agent is known (e.g., acid or base, pKa)

SUPPORTIVE MEASURES IN THERAPY OF INTOXICATIONS

- I. Body temperature control
- II. Respiratory support measures
 - A. Analeptics
 - 1. Doxapram (Dopram): 3 to 5 mg/kg
 - 2. Short acting
 - 3. May induce convulsions
 - B. Respirate: "GRAB THE CHEST"
 - 1. Patent airway—cuffed endotracheal tube
 - 2. Tracheotomy
 - 3. Respirator
- III. Cardiovascular support
 - A. Requirements
 - 1. Adequate circulating volume
 - 2. Adequate cardiac function

- 3. Adequate tissue perfusion
- 4. Adequate acid–base balance
- B. Immediate concern blood volume and cardiac activity
 - 1. Hypovolemia: give whole blood if there loss of cells and volume
 - 2. Hypovolemia: fluid loss—lactated Ringer's, plasma expanders
- 3. Cardiac activity massage, pharmaceutical agents
- IV. Acid-base balance
- V. Pain
- VI. Central nervous system disorders
 - A. Depression: see respiratory depression
 - B. Hyperactivity: managed by central nervous system depressants
 - 1. Pentobarbital sodium —agent of choice for convulsions and hyperactivity (precautions)
 - 2. Inhalant anesthetics: disadvantages and advantages
 - 3. Skeletal muscle relaxants
 - a) Glyceryl guaiacolate, Guaiafenison
 - b) Methocarbamol, Robaxin
 - c) Diazepam, Valium: 0.5-1.5 mg/kg, intravenously or intramuscularly
 - 4. Place in quiet, dark room to cut visual and auditory stimuli.

RODENTICIDES

Strychnine

- I. Spinal convulsant
 - A. Competes with glycine
 - B. Reduces inhibitory postsynaptic potential
- II. Signs occur 10 minutes to 2 hours after ingestion.
- III. Apprehension, nervousness, tenseness, stiffness, tetanic convulsions with intermittent relaxation.
- IV. Animal may die after 1 convulsion or may convulse for 1 to 2 hours before death occurs.
- V. Affected animals almost never vomit. (i.e., full stomach at necropsy).
- VI. Treatment:
 - A. After ingestion, before convulsions, with some signs:
 - 1. Diazepam 2-5 mg/kg intravenously
 - a) Apomorphine intravenously, 0.04 mg/kg
 - b) Pentobarbital as needed
 - 2. After onset of convulsions
 - a) Pentobarbital to effect
 - b) Gastric lavage
 - c) Place in quiet room
 - d) Animal should be observed for several days after apparent recovery.

Sodium Fluoroacetate (Compound 1080)

- I. Biotransformed to fluorocitrate, blocks aconitase
- II. Convulsant toxicant, not induced by external stimuli
- III. Attempts to vomit, micturate, and defecate after onset of early nervous signs

IV. Convulsions can be controlled by pentobarbital, but it is extremely difficult to prevent death.

Anticoagulant Rodenticides

- I. Competes with vitamin K, causes deficiencies in clotting factors II, VII,IX, X
- II. Signs: hypovolemic shock, bleeding from body orifices, subcutaneous hemorrhages, pale mucous membranes, blood in body cavities
- III. Treatment
 - A. Handle animals carefully.
 - B. Blood transfusion: whole blood or plasma blood transfusion, 25 mL/kg.
 - C. Use small needles.
 - D. Vitamin K_1 (Aqua-MEPHYTON, 5-mg caps, Merck & Co.)(Vita K_1 , Eschar, 25-mg caps). Give 3-5 mg/ kg/day with canned food. Treat 7 days for warfarintype, treat 21 to 30 days for second-generation anticoagulant rodenticides. Oral therapy is more efficacious than intravenous therapy.

Cholecalciferol (Vitamin D₃) Quintox^R, True Grit Rampage^R, Ortho Rat-B-Gone^R

- I. Active ingredient: cholecalciferol, 0.075% baits
- II. Mechanism of action: mobilizes calcium from bones into the blood, causing a "calcium-like" toxicity to the heart. Lower dosages over a long time can cause an actual vitamin D toxicoses.
- III. Toxicity: mice = 84 mg/kg (lethal dose); rats = 50 mg/kg (lethal dose); dogs = >100 g/kg.
- IV. Clinical signs: cessation of eating, lethargy, nausea, vomiting, diarrhea, polyuria, profuse sweating, polydipsia, and neurologic disturbances. Vasoconstriction and hypertension may be seen along with a shortened QT interval and prolonged PR interval. Serum calcium >11.5 mg/dL with increased BUN, creatine, and phosphorus.
- V. Lesions: Acute = heart stops in systole; chronic = calcium deposits in soft tissues, aorta, tendons, muscle
- VI. Reported by pest control personnel as safe around pets.
- VII. No good antidotes; potassium chloride can be used if ECG monitoring is undertaken. No antidote for calcification
- VIII. Treatment: Induce vomiting, and administer activated chrcoal. A saline cathartic should be used in cases of recent (within 3 hours) exposure. Moniter the serum calcium after 24 hours to determine if further therapy is necessary. Fluid therapy should include normal saline (intravenous) and furosemide as a diuretic. Thiazide diuretics are contraindicated. Corticosteroids have several beneficial effects and should be used. Also, calcitonin can be administered in microgram quantities (4-6 IU/kg) subcutaneously every 2 to 3 hours initially. Treatment with diuretics and cortisone should continue until serum calcium level remains normal. Check the serum calcium level 24 hours after treatment is stopped. Longterm therapy, for 2 weeks or more, may be required.

INSECTICIDES

Chlorinated Hydrocarbon Insecticides

- I. Not as common, but still in use
- II. Signs:
 - A. Abnormal posture
 - B. Fine tremors to gross convulsions
 - C. Salivation
- III. Treatment
 - A. General treatment
 - B. Control convulsions: pentobarbital, might try diazepam (intravenous) first

Rotenone

- I. Botanical insecticide: Derris spp.
- II. Low toxicity: 1 to 3 grams/kg
- III. Signs: vomiting caused by gastric irritation
 - A. Incoordination
 - B. Muscle tremors
 - C. Clonic convulsions
 - D. Respiratory failure
- IV. Treatment: General treatment

Pyrethrum and Synthetic Pyrethroids

- I. Names: allethrin, cyfluthrin, cypermethrin, deltamethrin, decamethrin, fenpropathrin, fenvalerate, flumethrin, kadethrin, permethrin, resmethrin, terallethrin, tetramethrin (*-rin* suffix)
- II. Low toxicity, except in fish and some tropical birds
- III. Increased sensitivity to external stimuli: fine tremors to gross tremors to prostration
- IV. Pawing, burrowing, salivation to writhing, convulsions
- V. Treatment = diazepam

Diethyltoluamide (DEET)

- I. History: DEET was synthesized in 1954 and used as an insect repellent. It is effective against mosquitoes, biting flies, gnats, chiggers, ticks, and fleas. The content of DEET in various products has ranged from 5% to 100%. The Hartz Company used DEET in dog and cat flea collars in their Blockade product line. Hartz withdrew its Blockade products from the market primarily because of consumer pressure and negative publicity. Some pets were reported to have died after exposure to Blockade.
- II. Clinical signs and symptoms: In animals and humans, DEET is absorbed through the skin. It has been known to produce blisters, skin necrosis, erythema, central nervous system disturbances, and death in animals. In humans it also produces blisters, skin necrosis, a burning sensation, erythema, ulcerations, slurred speech, confusion, convulsions, and (without treatment) even death. It seems to be more toxic to female humans than male humans. This may be an occupational phenomenon of female association with dipping and spraying animals.
- III. Although neurologic signs in animals and humans may resolve, the parent compound and its metabolites are detectable for up to 2 weeks after an episode.

Organophosphates and Carbamates

- I. Signs: overstimulation of parasympathetic nervous system (cholinergic, nicotinic, central nervous system)
 - A. Salivation, lacrimation, sweating
 - B. Muscular involvement
 - C. Constricted pupils
 - D. Respiratory involvement
 - E. Gastrointestinal involvement
 - F. Urinary incontinence
 - G. Central nervous system signs
- II. Treatment organophosphates = Atropine + 2-PAM
 - A. Atropine: 0.2-0.4 mg/kg (¼ intravenously, remainder subcutaneously)
 - B. 2-PAM: 20-50 mg/kg intramuscularly (of no value after enzyme has "aged".
 - C. Neither atropine nor 2-PAM will control all of the signs: *do not overtreat*
- III. Treatment of carbamates: atropine only; some carbamates are just as toxic as organophosphates; extensive treatment not required, as with organophosphates
- IV. Diazepam may be used to control some of the central nervous system signs.

ORGANIC COMPOUNDS

Ethylene Glycol (Antifreeze)

- I. Biotransformed---> glycolic acid ---> oxalic acid ---> calcium oxalate (alcohol dehydrogenase)
- II. Antifreeze = 95% ethylene glycol
- III. Toxic dose = 2 to 10 mL/kg
- IV. Early signs = depression, central nervous system signs, nausea, vomiting, polydipsia, polyuria, dehydration
- V. May return to normal within 12 hours
- VI. Signs return within 24 hours, with more severe, metabolic acidosis. Animals surviving 24 hours will have renal problems: signs of uremia, progressive increase in BUN, hyperkalemia, and acidosis; urine sediment may have birefringent crystals.
- VII. Lesions: hemorrhages in gastrointestinal mucosa, swollen and congested kidneys, hyperemia and edema of lungs
- VIII. Treatment:
 - A. Activated charcoal (if within 8 hours)
 - B. 20% ethanol, 5 mL/kg intravenously every 5-8 hours for 48-72 hours (causes central nervous system depression)
 - C. 5% sodium bicarbonate, 8 mL/kg, every 8 hours as needed > 48 hours.
 - D. 4-Methylpyrazole (5% solution) may be used *instead* of ethanol. It is better than ethanol because it does not induce central nervous system depression. As with ethanol, best results are obtained if treatment is initiated within 4 to 6 hours. *Do not use in cats.*
 - 1. Initial dosage 20 mg/kg
 - 2. 15 mg/kg 12 and 24 hours after ingestion
 - 3. 5 mg/kg 36 hours after ingestion.

Polyhalogenated compounds

- I. Polyhalogenated biphenyls
 - A. Induce enzymes
 - B. "Multiple Diseases"
 - 1. Chick edema disease, reduced hatchability embryotoxic
 - 2. Acneiform dermatitis
 - 3. Interferes with poryphrin metabolism
 - 4. "Cola-colored" babies in Japan, "Yusho"
 - 5. Tolerances in food for human consumption
- II. Dioxins
 - A. Common contaminant in chlorinated hydrocarbons
 - B. Extremely toxic in laboratory animals, not as toxic in humans
 - C. Diseases
 - 1. Liver
 - 2. Rapidly proliferating tissues
 - 3. Spermatogenesis
 - 4. Gastrointestinal mucosa
 - 5. Cancer
 - 6. Teratogenesis: animals, humans
 - D. Episodes
 - 1. Seveso, Italy
 - 2. Missouri (several episodes)
 - 3. Oregon
 - 4. Michigan

INORGANICS

Lead

- I. Most common heavy metal toxicant in the world
- II. Animals affected: cattle, young dogs, exotic birds
- III. Age: Nursing animals are more susceptible
 - A. Dogs: 2 to 8 months usually
 - B. Bovine: any age
 - C. Birds: any
- IV. Signs:
 - A. Gastrointestinal disturbances: vomiting, abdominal pain, anorexia
 - B. Neurologic signs: 3 to 4 days after lead colic in dogs, abnormal behavior, pica, hysteria convulsions; cattle and birds: neurologic signs.
 - C. Laboratory
 - 1. Hematopoietic: late in syndrome nucleated red cells, other red blood cell abnormalities
 - 2. Radiographic
 - a) Gastrointestinal tract
 - b) Lead line in Bones
 - 3. Blood lead > 0.6 ppm, 0.05-0.25 = normal
- V. Treatment:
 - A. Remove lead from gastrointestinal tract
 - B. Calcium disodium EDTA: 75-100 mg/kg per day, intravenously or intramuscularly
 - C. Penicillamine 100 mg/kg per day if owner refuses to hospitalize
 - D. Bronchoalveolar lavage 4 mg/kg qid with EDTA w/ severe nervous signs
 - E. Thiamine HCl: 5 mg/kg, intravenously bid for 1 to 2 weeks

Mercury (Possible Problem in Grains or Dog Food)

- I. Inorganic and organic forms
 - A. Inorganic absorbed through gastrointestinal tract, lungs
 - B. Organic: also through skin
 - C. Aryl and methoxyethyl forms produce signs similar to inorganic
 - D. Alkyl = typical signs + neurologic signs
- II. "Typical" signs
 - A. Gastrointestinal, abdominal pain, weakness, anorexia, central nervous system depression, renal signs
 - B. Proteinuria = common
- III. Alkyl mercurial signs
 - A. Sudden onset, ataxia, stumbling, hyperesthesia, convulsions, prostration
 - B. Young born with neurologic deficits
 - C. Focal central malacia, cord not affected.
- IV. Treatment:
 - A. Acute, "typical"-bronchoalveolar lavage
 - B. Chronic-penicillamine
 - C. No treatment for alkyl mercurial intoxications

Arsenical Intoxication

- I. Inorganic and organic forms
- II. Extremely important in some areas of United States, equal to lead in some cases
- III. Many sources: herbicides (old and new), insecticides, tonics, heartworm treatment, growth promotants
- IV. Clinical signs: gastrointestinal, abdominal pain, depression, diarrhea; chronic: rough hair coat, unthrifty, cattle may have enlarged joints
- V. Clinical signs (phenylarsonic): central nervous system, paresis, incoordination (drunk pig syndrome), alert and will continue to eat, blindness (not constant); signs are reversible unless nerve damage has developed; just remove from source
- VI. Treatment: "typical"
 - A. Early = general treatment, sodium thiosulfate, orally
 - B. Late = bronchoalveolar lavage 2.5 to 5 mg/kg, 2 to 4 times per day for 10 days or until recovery
 - C. No treatment for phenylarsonic compounds.

Copper and Molybdenum

- I. A "toxicity" of one means a deficiency of the other.
- II. Copper toxicoses occurs primarily in sheep, although Bedlington Terriers have a congenital problem with copper accumulation.
- III. Molybdenum toxicoses (molybdenosis) occurs primarily in cattle but may cause a problem in young lambs.
- IV. Ideal ratio is Cu:Mo = 6:1 in the diet, total intake if the ratio is outside 2:1 to 10:1, problems can be expected.

V. Copper toxicoses

- A. An acute disease can occur; typical heavy metal along with intravascular hemolysis
- B. Usual disease = chronic accumulation in liver with a subsequent massive release of copper, > 150 ppm Cu, wet weight = potential problems

- C. Usual sign = a sudden hemolytic crisis leading to anemia and jaundice (not always)
- D. Course of disease = 24 to 48 hours
- VI. Molybdenum toxicoses
 - A. Usually a chronic disease: "poor doers," chronic diarrhea, appear hypoproteinemic, achromotrichia, poor reproductive performance, anemia, joint problems
 - B. Sheep may develop wool problems, produce lambs with incoordination ("swayback")
- VII. Treatment:
 - A. Copper toxicoses = penicillamine –chelating agent, ammonium tetrathiomolybdate, change diet
 - B. Molybdenosis = copper glycinate, change diet

Table 1 Some Available Activated Charcoal Products			
Commercial Trade	Ingredients	Manufacturer or Distributor	Address
Activated charcoal gel	Activated charcoal, 100 mg/mL with electrolytes	Vets Plus, Inc 800-468-3877	102 3 rd Ave Knapp, WI 54749
D-TOX-BESC	Activated charcoal, 100 mg/mL	Agripharm 901-366-4442	4869 E. Raines Road Memphis, TN 38175
Toxiban	Granules 47% activated charcoal, 10% kaolin, 42% wetting and dispensing agents, 5 kg-pail, Suspension, 10.4% activated charcoal, 6.25% kaolin in an aqueous dose; 240-mL bottle	Vet-A-Mix 800-831-0004	604 W. Thomas Ave. Shenandoah, IA 51601
UAA Universal Animal (Antidote Gel)	Activated charcoal, 100 mg/mL	Vedco 888-708-3326	5503 Corporate Dr. St. Joseph, MO 64507

Toxicant	Antidote and Dose or Concentration
Acids, corrosives	Weak alkali-magnesium oxide solution (1:25 warm water) internally. <i>Never give sodium bicarbonate!</i> Milk of magnesia—1 to 15 mL. Flush externally with water. Apply paste of sodium bicarbonate.
Alkali, caustic	Weak acid—vinegar (diluted 1:4), 1% acetic acid, or lemon juice given orally. Dilute albumin (4 to 6 egg whites to 1 qt warm water) or give whole milk followed by activated charcoal and then a cathartic because some compounds are soluble in excess albumin. Local—flush with copious amounts of water and apply vinegar.
Alkaloids	Potassium permanganate (1:5000 to 1:10,000) for lavage or oral administration.
	Tannic acid or strong tea (200 to 500 mg in 30 to 60 mL of water) except in cases of poisoning by cocaine, nicotine, physostigmine, atropine, and morphine.
	Emetic or purgative should be used for prompt removal of tannates.
Arsenic	Sodium thiosulfate—10% solution given orally (0.5 to 3 g for small animals), followed by lavage or emesis.
	Protein—evaporated milk, egg whites.
	Tannic acid or strong tea (see specific antidote in Table 3).
Barium salts	Sodium sulfate and magnesium sulfate (20% solution given orally) Dosage: 2 to 25 gm.
Bismuth salts	Acacia or gum arabic as mucilage.
Carbon tetrachloride	Empty stomach, give high-protein and carbohydrate diet; maintain fluid and electrolyte balance.
	Hemodialysis is indicated in anuria. Epinephrine is contraindicated (ventricular fibrillation).
Copper	Albumin (see Alkali, above).
	Sodium ferrocyanide in water (0.3 to 3.5 g for small animals). (See specific antidote in Table 3.)
	Magnesium oxide (see Acids, above).
Detergents, anionic (Na, K, NH ₄ +salts)	Milk or water followed by demulcent (oils, acacia, gelatin, starch, egg white)
Detergents, cationic	Soap (castile) dissolved in 4 times its bulk of hot water.
(chlorides, iodides)	Albumin (see Alkali, above).
Fluoride	Calcium (milk, lime water, or powdered chalk mixed with water) given orally.

Toxicant	Antidote and Dose or Concentration
Formaldehyde	Ammonia water (0.2% orally) or ammonium acetate (1% for lavage).
	Starch—1 part to 15 parts hot water, added gradually.
	Gelatin soaked in water for 30 min.
	Albumin (see Alkali, above).
	Sodium thiosulfate (see Arsenic, above).
Iron	Sodium bicarbonate—1% for lavage. (See specific antidote in Table 3.)
Lead	Sodium or magnesium sulfate given orally.
	Sodium ferrocyanide (see Copper, above).
	See specific antidote.
	Albumin (see Alkali, above).
Mercury	Protein—milk, egg whites (see Alkali, above).
	Magnesium oxide (see Acids, above).
	Sodium formaldehyde sulfoxylate—5% solution for lavage.
	Starch (see Formaldehyde, above).
	Activated charcoal—5 to 50 g. (See specific antidote in Table 3.)
Oxalic acid	Calcium—calcium hydroxide as 0.15% solution.
	Other alkalis are contraindicated because their salts are more soluble.
	Chalk or other calcium salts.
	Magnesium sulfate as cathartic.
	Maintain diuresis to prevent calcium oxalate deposition in kidney.
Petroleum distillates	Olive oil, other vegetable oils, or mineral oil given orally. After 30 min, sodium sulfate as cathartic.
(aliphatic hydrocarbons)	Emesis and lavage are contraindicated for ingested volatile solvents, but petroleum distillates are used as
	carrier agents for more toxic agents.
Phenol and cresols	Soap and water or alcohol lavage of skin.
	Sodium bicarbonate (0.5%) dressings.
	Activated charcoal and/or mineral oil given orally.
Phosphorous	Copper sulfate (0.2 to 0.4% solution) or potassium permanganate (1:5000 solution) for lavage.
	Turpentine (preferably old oxidized) in gelatin capsules or floated on hot water. Give 2 mL 4 times at
	15-minute intervals.
	Activated charcoal.
	Do not give vegetable oil cathartic. Remove all fat from diet.
Silver nitrate	Normal saline for lavage.
	Albumin (see Alkali, above).
Unknown (e.g., toxic plants	Activated charcoal (replaces universal antidote). For small animals: through stomach tube, as a slurry in wate
or other materials)	Follow with emetic or cathartic and repeat procedure.

Table 3 Specific S	Systemic Antidotes and Dosag	es
Toxic Agent	Systemic Antidote	Dosage and Method for Treatment
Acetaminophen	B-acetylcysteine (Mucomyst, Mead Johnson)	150 mg/kg loading dose, PO or IV, then 50 mg/kg every 4 hours for 17-20 additional doses.
	Cimetidine	5 mg/kg, orally, every 6-8 hours for 2-3 days. To prevent biotransfor- mation of acetaminophen.
Amphetamines	Chlorpromazine	1 mg/kg IM, IP, IV; administer only half dose if barbiturates have been given: blocks excitation. Higher doses (10-18 mg/kg IV) may be beneficial if large volumes are consumed. Treatment of increased intracranial pressure may be indicated (mannitol, furosemide)
	Urinary alkalinization: Ammonium chloride	100 to 200 mg/kg per day divided every 8 to 12 hours (contraindi- cated with myoglobinuria, renal failure of acidosis).
Amitraz	Atipamezole	50 g/kg IM. Signs should reverse in 10 minutes. Repeat every 3-4 hours as needed. Can follow with 0.1 mg/kg yohimbine IM every 6 hours.
	Yohimbine	Dogs 0.11 mg/kg IV slowly Cats 0.5 mg/kg IV slowly

Toxic Agent	Systemic Antidote	Dosage and Method for Treatment
Antitussives	Naloxone	If narcotic (e.g., hydrocodone, codeine)
Arsenic, mercury and other heavy metals except cadmium, lead silver, selenium, and thallium	Dimercaprol (BAL, Hynson, Wescott & Dunning)	10% solution in oil; give small animals 2.5 to 5 mg/kg IM every 4 hours for 2 days, bid for the next 10 days or until recovery. NOTE: In severe acute poisoning, 5 mg/kg dosage should be given only for the first day.
	D-Penicillamine (Cuprimine, Merck & Co.)	Developed for chronic mercury poisoning, now seems most promis- ing drug; no reports on dosage in animals. Dosage for humans is 250 mg orally, every 6 hours for 10 days (3 to 4 mg/kg).
Aspirin	No specific antidote (see also, nonsteroidal antiinflammatory drugs)	Acute toxicosis: urinary alkalinization, other supportive therapy; doses of 50 mg/kg per day (dog) and 25 mg/kg/day (cat); 7 mL/kg per day of bismuth subsalicylate (dogs and cats) may be toxic.
Atropine,	Physostigmine salicylate	0.1 to 0.6 mg/kg (do not use neostigmine).
Belladonna alkaloids		
Barbiturates	Doxapram (Dopram)	2% solution: Give small animals 3 to 5 mg/kg IV only (0.14 to 0.25 mL/kg) repeated as necessary.
Barium, bismuth salts	Sodium sulfate/magnesium sulfate	20% solution given orally, 2 to 25 g.
Bleach	Treat as alkali	Use of emetics is controversial; treat as an alkali poisoning. Therapies have included milk or water (large volumes), milk of magnesia (2-3 mg/kg), egg whites, or powdered milk slurry. Sodium bicarbonate is <i>not</i> recommended.
Borates (roach killers, fleas products, fertilizers, herbicides, antiseptics, disinfectants, contact lens solutions)	No specific antidote	Supportive therapy includes emetics and gastric lavage, fluid therapy and diuresis, treatment of seizures and hyperthermia as indicated.
Botulism	Antitoxin	Use is controversial. Supportive care may be sufficient. Supportive therapy may include penicillin, physostigmine or neostigmine, and atropine.
Bromethalin	No specific antidote	Supportive care may include treatment of cerebral edema.
Bromides	Chlorides (sodium or ammonium salts)	0.5 to 1 g daily for several days; hasten excretion.
Caffeine/chocolate	No specific antidote	General treatment, diazepam (2 to 5 mg/kg) for tremors, treat arrhythmias as indicated.
Carbon monoxide	Oxygen	Pure oxygen at normal or high pressure; artificial respiration; blood transfusion.
Cholinergic agents	Atropine sulfate	0.02 to 0.04 mg/kg, as needed.
Cholinesterase inhibitors	Atropine sulfate	Dosage is 0.2 - 0.4 mg/kg, repeated as needed for atropinization. Treat cyanosis (if present) first. Blocks only muscarinic effects. Atropine in oil may be injected for prolonged effect during the night. <i>Avoid atropine intoxication!</i>
	Pralidoxime chloride (2-PAM) (organophosphates, some carbamates; but not carbaryl, dimethan, or carbam piloxime)	 5% solution; five 20 to 50 mg/kg IM or by slow IV (0.2 to 1.0 mg/kg) injection (maximum dose is 500 mg/min), repeat as needed. 2-PAM alleviates nicotinic effect and regenerates cholinesterase. Morphine, succinylcholine, and phenothiazine tranquilizers are contraindicated.
	Diphenhydramine	1-4 mg/kg IM, PO every 8 hours to block nicotinic effects.
Cocaine	No specific antidote	Chlorpromazine (up to 15 mg/kg; may lower seizure threshold, use cautiously); butylcholinesterase may convert cocaine to inactive metabolites (currently under investigation); fluids metoprolol or isopropanolol to treat cardiac arrhythmias (see methylxanthines); phentolamine or sodium nitroprusside if beta blockers cause hypertension; lidocaine (instead of beta blockers) to control cardiac arrhythmias; see methylxanthines.

 Table 3
 Specific Systemic Antidotes and Dosages—cont'd

Toxic Agent	Systemic Antidote	Dosage and Method for Treatment
	Methylene blue (if ascorbic acid fails)	Dogs: 3-4 mg/kg IV Cats: 1.5 mg/kg.(Methylene blue may cause Heinz body formation in the absence of methemoglobinemia, and sometimes in the pres- ence of methemoglobinemia.)
Copper	D-Penicillamine (Cuprimine)	52 mg/kg for 6 days (also see Arsenic)
	Ammonium molybdate Sodium thiosulfate	50 to 500 mg, PO, once a day 300 to 1000 mg, PO, once a day
	Ammonium tetrathiomolybdate	100 to 500 mg, PO on alternate days for 3 treatments
Coumarin-derivative anticoagulants	Vitamin K ₁ (Aqua- MEPHYTON, 5 mg caps, Merck & Co.) (Vita K ₁ , Eschar, 25 mg caps) Whole blood or plasma	Give 3-5 mg/kg/day with canned food. Treat 7 days for warfarin-type treat 21 to 30 days for second-generation anticoagulant rodenti- cides. Oral therapy is more efficacious than IV. Blood transfusion, 25 mL/kg.
Curare	Neostigmine methylsulfate	Solution: 1:5000 for 1:2000. (1 mL = 0.2 or 0.5 mg/mL). Dose is 0.005 mg/5 kg, SC. Follow with IV injection of atropine (0.04 mg/kg).
	Edrophonium chloride (Tensilon, Roche) Artificial respiration	1% solution; give 0.05 to 1.0 mg/kg IV.
Cyanide	Methemoglobin (sodium nitrite is used to form methemoglobin) Sodium thiosulfate	1% solution of sodium nitrite, dosage is 16 mg/kg IV (1.6 mL/kg). Follow with sodium thiosulfate 20% solution at dosage of 30 to 40 mg/kg (0.15 to 0.2 mL/kg) IV. If treatment is repeated, use only sodium thiosulfate. NOTE: The above may be given simultaneously as follows: 0.5 mL/ kg of combination consisting of 10 g sodium nitrite, 15 g sodium thiosulfate, distilled water quantity sufficient 250 mL. Dosage may be repeated once. If further treatment is required, give only 20% solution of sodium thiosulfate at level of 0.2 mL/kg.
Decongestants	No specific antidote	Treat symptomatically.
Detergents: anionic (Na, K, NH ₄ ⁺)	*	Milk or water followed by demulcent (oils, acacia, gelatin, starch, egg white.)
Detergents: cationic (chlorides, iodides		Castile soap dissolved in 4 times bulk of hot water. Albumin, see Alkali above.
Diatomaceous earth		No treatment indicated unless pulmonary, then supportive.
Digitalis glycosides, oleander, and <i>Bufo</i> toads	Potassium chloride	Dog: 0.5 to 2.0 g, orally in divided doses, or in serious cases as diluted solution given IV by slow drip (ECG control is essential).
	Diphenylhydantoin Propranolol (ß -blocker)	25 mg/minute IV control is established.0.5-1.0 mg/kg IV or IM as needed to control cardiac arrhythmias (ECG control is essential).
	Atropine sulfate	0.02 to 0.04 mg/kg as needed for cholinergic control.
		2 to 5 mg/kg, control convulsions
Ethylene glycol	Diazepam (Valium, Roche) Ethanol	(2 to 5 mg/kg) in the case of <i>Bufo</i> toads, must treat convulsions first. See methanol and ethylene glycol. Minimal lethal dose of ethylene glycol is 4.2 to 6.6 mL/kg (4.5 ounces in 20-lb dog) and 1.5 mL for cats. Give IV, 1.1 g/kg (4.4 mL/kg) of 25% solution. Give 0.5 gm/kg (2.0 mL/kg) every 4 hours for 4 days. To prevent or correct acido- sis, use sodium bicarbonate IV, 0.4 g/kg. Activated charcoal: 5 g/kg orally if within 4 hours of ingestion.
	4-Methylpyrazole	20 mg/kg, 15 mg/kg at 12 and 24 hours, 5 mg/kg at 36 hours
	Sodium bicarbonate 5%	8 mL/kg (dog) or 6 mg/kg (cat) IP every 4 hours for five treatments, then every 6 hours for four more treatments.
Fertilizer	No specific antidote	Supportive therapy may include treatment for electrolyte disorders, vomiting, H ₂ receptor blockers for gastritis, (sucralfate and analge-
		sics as needed)

Toxic Agent	Systemic Antidote	Dosage and Method for Treatment
Fluoracetate (Compound 1080®, Sigma)	Glyceryl monoacetin	0.1 to 0.5 mg/kg IM hourly for several hours (total 2 to 4 mg/kg); or diluted (0.5 to 1%) IV (danger of hemolysis). Monoacetin is avail- able only from chemical supply houses.
	Acetamide	Animal may be protected if acetamide is given before or simultane- ously with Compound 1080 (experimental).
	Pentobarbital Note: All treatments are generally unrewarding.	May protect against lethal dose (experimental).
Formaldehyde		 Ammonia water (0.2% orally) or ammonium acetate (1% for lavage). Starch—1 part to 15 parts hot water, added gradually. Gelatin soaked in water for 30 minutes. Albumin (see Alkali, above). Sodium thiosulfate (see Arsenic, above).
Garbage	No specific therapy.	Supportive therapy may include antiemetics (metoclopramide or phenothiazines) and treatment of endotoxemia.
Hallucinogens (LSD, phencyclidine[PCP])	Diazepam (Valium, Roche)	As needed—avoid respiratory depression (2 to 5 mg/kg).
Heparin	Protamine sulfate	1% solution; give 1 to 1.5 mg to antagonize each 1 mg of heparin; slow IV injection. Reduce dose as time increases between heparin injec- tion and start of treatment (after 30 minutes give only 0.5 mg).
Iron salts	Deferoxamine (Desferal, Ciba)	Dose for animals not yet established. Dose for humans is 5 g of 5% solution given orally, then 20 mg/kg IM every 4 to 6 hours. In case of shock, dose is 40 mg/kg by IV drip over 4-hour period; may be repeated in 6 hours, then 15 mg/kg by drip every 8 hours.
Ivermectin	Physostigmine	0.06 mg/kg IV very slowly; actions should last 30 to 90 minutes.
	Picrotoxin (GABA antagonist)	Use is controversial. May cause severe seizures. Other treatment may include epinephrine and, if the product causing toxicosis is Eqvalan, an antihistamine to counteract polysorbate 80 (releases histamine in dogs), and atropine.
Lead	Calcium disodium edetate (CaNa ₂ EDTA)	Dosage: Maximum safe dose is 75 mg/kg/24 hours (only for severe case). EDTA is available in 20% solution; for IV drip, dilute in 5% glucose to 0.5%; for IM, add procaine to 20% solution to give 0.5% concentration of procaine.
Lead (cont.)	EDTA and BAL	 BAL is given as 10% solution in oil. Treatment: 1. In severe case (CNS involvement w/> 100 ug Pb/100 gm whole blood) give 4 mg/kg. BAL only as initial dose; follow after 4 hours, and every 4 hours for 3 to 4 days, with BAL and EDTA (12.5 mg/kg) at separate IM sites; skip 2 or 3 days, and then treat again for 3 to 4 days. 2. In subacute case w/< 100 ug Pb/100 g whole blood, give only 50 mg EDTA/kg/24 hours for 3 to 5 days.
	Penicillamine (Cuprimine, Merck & Co.)	3. May use after treatments either 1 or 2 with 100 mg/kg/day orally for 1 to 4 weeks.
	Thiamine HCl	Experimental for nervous signs; 5 mg/kg, IV, bid, for 1 to 2 weeks; give slowly and watch for untoward reactions
	Succimer (Chemet)	Oral human dose = 10 mg/kg every 8 hours for 5 days, then 10 mg/kg bid for 2 weeks (total of 19 days of therapy) Animal dosages have not been established. (Used if blood lead levels > 45 ppm.)
Local anesthetics	See treatment for methemo- globinemia	Particularly cats.
Marijuana	No effective antidotes	Protein—milk, egg whites (see alkali, above). Magnesium oxide (see acids, above). Sodium formaldehyde sulfoxylate—5% solution for lavage. Starch (see Formaldehyde, table 2) Activated charcoal—5-50 g.
Metaldehyde	Diazepam (Valium, Roche)	2 to 5 mg/kg IV to control tremors.

Toxic Agent	Systemic Antidote	Dosage and Method for Treatment	
	Triflupromazine	0.2 to 2 mg/kg IV.	
	Pentobarbital	To effect.	
	Note: Should monitor liver function and treat accordingly		
Methanol and ethylene glycol	Ethanol	Give IV, 1.1 g/kg (4.4 mL/kg) of 25% solution. Give 0.5 g/kg (2 mL/kg) every 4 hours for 4 days. To prevent or correct acidosis, use sodium bicarbonate IV, 0.4 g/kg. Activated charcoal: 5 g/kg orally if within 4 hours of ingestion.	
	4 - Methyl Pyrazole	20 mg/kg, 15 mg/kg at 12 and 24 hours, 5 mg/kg at 36 hours	
Methemoglobinemia-producing agents (nitrites, chlorates)	Methylene blue	 1% solution (maximum concentration), give by <i>slow</i> IV injection, 8.8 mg/kg; (0.9 mL/kg); repeat if needed. To prevent fall in blood pressure in case of nitrite poisoning, use a sympathomimetic drug (ephedrine or epinephrine). (Not recommended for cats.) 	
	Ascorbic acid	20 to 30 mg/kg PO or 20 mg/kg IV slowly; methylene blue; dog 3-4 mg/kg IV slowly if ascorbic acid not effective; cats 1.5 mg/kg.	
Morphine and related drugs	Naloxone chloride (Narcan, Endo)	0.1 mg/kg IV. Do not repeat if respiration is not satisfactory.	
	Levallorphan tartrate (Lorfan, Roche)	Give IV, 0.1 to 0.5 mL of solution containing 1 mg/mL. Note: Use either of the above antidotes only in acute poisoning. Artificial respiration may be indicated. Activated charcoal is also indicated.	
Mothballs (naphthalene, paradichlorobenzene)	No specific antidote	Supportive care includes fluid therapy and maintenance of renal and hepatic function.	
Narcotics	Naloxone	Emesis—indicated only if patient is sufficiently alert. Dog: 0.02 to 0.04 mg/kg IV; repeat as needed. Cat: 0.05 to 0.1 mg/kg IV; repeat as needed. Supportive therapy may include anticonvulsants (especially for meperidine), fluid therapy.	
Nicotine	No specific antidote	Emesis—indicated only within 60 minutes and in absence of clinical signs. Atropine indicated to control parasympathetic signs.	
Nonsteroidal antiinflammatory drugs	Sucralfate	500-100 mg PO every 8 hours.	
	Misoprostol	3 to 5 µg/kg every 8 to 12 hours	
	Omeprazole	0.7 mg/kg every 24 hours (dog); alternative, ranitidine or famotidine (dog and cat)	
Oxalates	Calcium	Treatment: 23% solution of calcium gluconate IV. Give 3 to 20 mL (to control hypocalcemia). Or Ca hydroxide as 0.15% solution or chalk or other calcium salts. Magnesium sulfate as cathartic. Other alkalines are contraindicated because their salts are more soluble. Maintain diuresis to prevent calcium oxalate deposition in kidney.	
Onion/garlic	No specific antidote	Supportive therapy should address methemoglobinemia and hemo- globinuria. Avoid acidic urine.	
Organic solvents: acetone, benzene, benzol, methanol, methylene chloride, naphtha, trichloroethane, acetonitrile, chloroform, trichloroethylene, tuolulene, xylene, xylol	No specific antidote	Emesis contraindicated. Supportive therapy includes treatment of cardiac arrhythmias, methemoglobinemia, renal failure, chemical pneumonia.	
Petroleum distillates (aliphatic hydrocarbons)		Olive oil, other vegetable oils, or mineral oil given orally. After 30 minutes, sodium sulfate as cathartic. Emesis and lavage are contraindicated for ingested volatile solvents, but petroleum distillates are used as carrier agents for more toxic agents.	
Phenols and cresols		Soap and water or alcohol lavage of skin. Sodium bicarbonate (0.5%) dressings. Activated charcoal and/or mineral oil given orally.	
Phenothiazine	Methylamphetamine (Desoxyn, Abbott)	0.1 to 0.2 mg/kg IV; also transfusion. Only available in tablet form.	

Toxic Agent	Systemic Antidote	Dosage and Method for Treatment	
	Diphenhydramine HCl	For CNS depression, 2 to 5 mg/kg IV for extrapyramidal signs.	
Phytotoxins and botulin	Antitoxins not available commer- cially except with botulism.	 As indicated for specific antitoxins. Examples of phytotoxins: rici abrin, robin, crotin. 	
Plants		Treat signs as necessary.	
Red squill	Atropine sulfate, propranolol, potassium chloride	As for digitalis and oleander	
Scorpion sting	Ativenin (may not be recom- mended)	Supportive therapy includes analgesia to control pain (morphine and meperidine but not butorphanol are contraindicated because of potential synergy with scorpion venom); methocarbamol (if muscle spasms evident) and fluid therapy.	
Smoke inhalation	Supportive therapy	Supportive therapy should target the respiratory system and treat- ment of carbon monoxide intoxication. Oxygen therapy; intermit- tent positive pressure ventilation with positive end-expiratory pressure with positive inotropic support, bronchodilators, treat- ment for cyanide poisoning if indicated, and treatment for cerebral edema.	
Snake bite Rattlesnake Copperhead Water moccasin	Antivenin (Wyeth) (Trivalent Crotalidae)(Fort Dodge)	Caution: equine origin. Administer 1 to 2 vials, IV, slowly, diluted in 250 to 500 mL of saline or lactated Ringer's. Also administer antihistamines. <i>Corticosteroids are contraindicated.</i>	
Coral snake	(Wyeth)	Caution: equine origin. May be used as with pit viper antivenin.	
Spider bite Black widow	Antivenin (Merck & Co.)	Caution: equine origin. Administer IV undiluted. Supportive therapy should include muscle relaxants (dantrolene or methocarbamol) analgesics, calcium gluconate for severe muscle cramping.	
	Dantrolene sodium (Dantrium, Norwich-Eaton)	1 mg/kg IV. Followed by 1 mg/kg PO every 4 hours.	
Brown Recluse	Dapsone	1 mg/kg, bid for 10 days	
Strontium	Calcium salts	Usual dose of calcium borogluconate.	
	Ammonium chloride	0.2 to 0.5 g orally 3 to 4 times daily.	
	Potassium chloride	Give simultaneously with thiocarbazone or Prussian blue, 2 to 6 g orally daily in divided doses.	
Strychnine and brucine	Pentobarbital	Give IV to effect; higher dose is usually required than that required for anesthesia. Place animal in warm, quiet room.	
	Amobarbital	Give by slow IV infusion; inject to effect. Duration of sedation is usu- ally 4 to 6 hours.	
	Methocarbamol (Robaxin, Robins)	10% solution; average first dose is 149 mg/kg IV (range: 40 to 300 mg). Repeat half dose as needed.	
	Glyceryl guaiacolate (Guaiafenison, Summit Hill Labs)	110 mg/kg IV, 5% solution. Repeat as necessary.	
	Diazepam (Valium, Roche)	2 to 5 mg/kg, control convulsions, induce emesis, then use other agents.	
Thallium	Prussian blue	0.2 gm/kg orally in 3 divided doses daily.	
	Potassium chloride	Give simultaneously with Prussian blue, 2 to 6 gm orally daily in divided doses.	
Theobromine	See caffeine/chocolate poisoning		
Toad poisoning (Bufo alvarius, Bufo marinus)	Propranolol (<i>Bufo</i> poisoning only)	1.5-5 mg/kg IV; repeat in 20 minutes if ECG does not normalize; sup- portive therapy includes fluid therapy.	
	Atropine	0.04 mg/kg IV to control hypersalivation or asystole.	
	Lidocaine	Dogs: 1-2 mg/kg IV followed by continuous infusion of 25 to 75 µg/kg/min; cats: 0.25 to 1 mg/kg IV bolus followed by 5 to 40 µg/kg/min continuous IV infusion.	

Table 3	Specific Systemic Antidotes and Dosages-cont'd
---------	--

Continued

Toxic Agent	Systemic Antidote	Dosage and Method for Treatment
	Diazepam (Valium, Roche)	(2 to 5 mg/kg) in the case of <i>Bufo</i> toads, must treat convulsions first.
Tricyclic antidepressants	No specific antidote	Supportive therapy should target seizures (diazepam, phenobarbital, or general anesthesia with pentobarbital or short-acting thio- barbiturates; or, if unsuccessful, neuromuscular blockade with pancuronium (0.03 to 0.06 mg/kg IV) or vercuronium (10 to 20 µg, kg IV in dogs or 20 to 40 µg/kg in cats]); cardiotoxicity (see toad poisoning): propanolol, lidocaine (quinidine, procainamide and disopyramide are contraindicated); sodium bicarbonate (1-3 meq/kg).
Unknown (e.g., toxic plants or other materials)	No specific antidote	Activated charcoal 2-5 gm/kg (replaces universal antidote). For small animals: through stomach tube, as a slurry in water. Follow with emetic or cathartic, and repeat procedure.
Vitamin D ₃ rodenticides	Treatment of hypercalcemia	Supportive therapy should target treatment of hypercalcemia (0.9% saline solution); control of seizures and treatment of hyperthermia. Calciuria can be promoted with furosemide (1 to 5 mg/kg every 6 to 12 hours for 2 to 4 weeks); prednisolone; calcitonin (4 to 6 IU/kg every 6 to 12 hours if calcium > 18 mg/dl; sodium bicarbonate if severe metabolic acidosis.
	Amphogel, Basagel	As phosphate binders (aluminum hydroxide 30 to 90 mg/kg PO every 8 to 24 hours for 2 weeks).
Xylitol		Hypoglycemia: 1-2 mL of 25% dextrose followed by 2.5%-5% dextrose infusion as needed to maintain normoglycemia. Add potassium to fluids to maintain serum potassium (treat for 12 to 24 hours). Hepatic necrosis: 140 to 280 mg/kg <i>N</i> -acetylcysteine IV followed by 70 mg/kg qid IV or PO; S-adenosylmethionine 17-20 mg/kg/day PO, silymarin 20 to 50 mg/kg/day PO.
Zinc	Chelation therapy (see lead)	CaEDTA, Succimer. Other supportive therapy includes fluid therapy and antisecretory drugs such as ranitidine, famotidine, or omepra- zole to decrease oral absorption of zinc.

Toblo 2	Creatine C	votamia Antidataa	and Dosages-cont'd
I able 3	Specific S	ystemic Antidotes	and Dosages-cont d

PO, By mouth; IV, intravenous; IM, intramuscular; IP, intraperitoneal; SC, subcutaneous; ECG, electrocardiogram; CNS, central nervous system.

Generic and Trade Names*

Provision of proprietary names is not intended to be comprehensive. Generics are generally human unless noted otherwise. The absence of a proprietary name for a particular product generally indicates that only a generic form of the drug exists in the United States. Note that oral bioavailability of human generics should not be assumed to be equally bioavailable in dogs or cats. Whenever possible, a drug approved for dogs or cats should be used in preference to a human generic, in part because of the risk that bioavailability will differ among human generics in animals. The absence of the word *generic* does not rule out the availability of a generic version of a particular product. The absence of a number in general indicates the drug is approved for use in humans; most of the drugs are approved in the United States, although occasionally a drug (and its trade or brand name) reflects approval in a different country. For both generic and trade names of human drug products, and for approved drugs (but not biologics), the FDA Orange Book can be consulted at http://www.accessdata.fda.gov/scripts/ cder/ob/docs/queryai.cfm; for veterinary-approved products. For information regarding animal-approved drugs (but not biologics), the FDA Green Book can be consulted at http://www.fda.gov/AnimalVeterinary/Products/ ApprovedAnimalDrugProducts/UCM042847.

Etretinate (acitretin)	Soriatane	Flavoxate (HCl)	Urispas

1, Approved in dogs; 2, approved in cats; 3, approved in other animal; 4, no longer available: if need is appropriate, may be available through a compounding pharmacist; 5, OTC (human or animal); 6, dietary supplement (human or animal), also indicates an OTC designation; 7, human cosmetic product, also indicates an OTC designation; 8, EPA-approved product; 9, biological (if animal, may not be approved; if animal approved, approval is likely through US Department of Agriculture and generally is based only safety, not efficacy); 10, distribution controlled by the Drug Enforcement Agency, Schedule status (I-V) indicated; 11, obtain through chemical or other company, compounding pharmacist may assist; 12, product may not be available from manufacturer; 13, animal generic available; 14, special restrictions.

Generic	Proprietary
Florfenicol	Nuflor (3)
Fluconazole	Diflucan in Dextrose 5% in
51 1	plastic container
Fluconazole	Diflucan in Sodium Chloride 0.9%
Fluconazole	Diflucan in NaCl 0.9% in plastic container
Fluconazole	Diflucan
Flucytosine	Ancobon
Fludrocortisone	Florinef
Flumazenil	Romazicon
Flumethasone	Flucort Solution (1, 2)
Flunixin meglumine	Banamine (3)
Flunixin meglumine	Banamine Paste (3)
Flunixin meglumine	Banamine Granules (3)
Flunixin meglumine	Banamine Granules (3)
Fluorouracil	5-fluorouracil
Fluoxetine HCl	Prozac Pulvules
Fluoxetine HCl	Prozac
Fluoxymesterone	Generic (10-III)
Flurazepam	Dalmane (10-IV)
Flurbiprofen	Ocufen
Flurbiprofen	Ansaid
Fluticosone proprionate	Flovent
Fluvoxamine maleate	Luvox
Folic acid	Folicet (6)
Folinic acid	See Leucovorin
Follicle-stimulating hormone Formoterol	Super-OV Foradil
	Perforomist
Formoterol	Foscavir
Foscarnet sodium	
Furazolidone	Furoxone
Furosemide	Lasix, generic
Furosemide	Lasix Injection 5%, generic
Gabapentin	Neurontin
Gamma globulin	Generic (9)
Gemfibrozil	Lopid, generic
Gentamicin SO4 0.1%	Gentocin
Gentamicin sulfate	Gentocin Otic
Gentamicin sulfate	Garamycin
Glargine	
Glimeperide	Amaryl
Glipizide	Glucotrol XL
Glipizide	Glucotrol
Glucagon	GlucaGen
Glucosamine	Generic (6)
Glucosamine with chondroitin sulfate	Cosequin
Glucose 40% ophthalmic	Glucose-40
Glutamine	Generic (6)
Glyburide-metformin HCl	Glucovance

Generic	Proprietary
Glycerin	Osmoglyn, others
Glyceryl guaiacolate	Gecolate (3)
Glycerol monoacetate	Generic
Glycopyrrolate	Robinul-V (1, 2)
Glycopyrrolate	Robinul
Gold sodium thiomalate	Myochrysine
Gonadotropin-releasing hormone	Gonadorelin (3)
(synthetic)	
Gonadotropin, chorionic (See	
Chorionic gonadotropin)	
Granisetron HCl	Kytril
Granulocyte colony-stimulating factor (Filgrastim)	Neupogen
Griseofulvin	Fulvicin (1)
Griseofulvin	Fulvicin-U/F Tablets (3)
Griseofulvin	Ultramicrosize Gris-PEG
Growth hormone	See Somatotropin
Guaifenesin	Guailaxin (3)
Guaifenesin	Robitussin (5)
Guaifenesin	Guaifenesin Injection
Haloperidol	Generic
Haloperidol (Decanoate)	Generic
Haloperidol (Lactate)	Generic
Haloperidol (Lactate)	Haldol
Halothane (Inhalant anesthetic)	Fluothane
Halothane	Generic
Hemoglobin (see Oxyglobin)	Polymerized bovine,
	Oxyglobin (1, 3)
Heparin sodium	Heparin Sodium
Heparin sodium (w/ 0.9% sodium chloride)	Generic
Heparin sodium (w/ 0.45% sodium chloride)	Generic
Heparin sodium (Lock Flush Solution)	Hep-Lock
Hetacillin	Hetacin-K (1, 2)
Hetastarch (see Hydroxyethyl starch)	Hextend, generic
Human gamma globulin (see	
Gamma globulin)	Hvalovet
Hyaluronate = Hyaluronan Hyaluronate (sodium)	Hyalovet Legend (3)
Hyaluronate (sodium)	Hyvisc (3)
Hyaluronate (sodium)	Hylartin (3)
	•
Hyaluronate (sodium) Hydralazine	HyCoat (3)
	Apresoline, generic
Hydrochlorothiazide: metoprolol	HydroDiuril, generic
Hydrochlorothiazide; metoprolol tartrate	Lopressor
Hydrochlorothiazide; spironolactone	e Aldactazide
Hydrochlorothiazide; triamterene	Dyazide
Hydrocodone bitartrate	Hycodan (10-III)
	Continued

Generic	Proprietary	Generic	Proprietary
Hydrocodone bitartrate	Hycodan Syrup (10-II)	Insulin Aspart recombinant	Novolog
Hydrocortisone acetate	Generic	Insulin detemir recombinant	Levemir
Hydrocortisone Na succinate	Solu-Cortef	Insulin glargine recombinant	Largine
Hydrocortisone	Acticort 100, generic	Interferon, α2	Roferon-A
Hydrocortisone	Cortef, generic	Iodine	Lugol's Solution (3)
Hydrocortisone (acetate)	Hydrocortone Acetate	Iodine sodium, potassium	Generic
Hydrocortisone (cypionate)	Cortef	Iohexol	Omnipaque 140
Hydrocortisone (sodium	Hydrocortone Phosphate	Iohexol	Omnipaque 180
phosphate)		Iohexol	Omnipaque 240
Hydrogen peroxide 3%	Hydrogen peroxide 3%,	Iohexol	Omnipaque 300
	generic (5)	Iohexol	Omnipaque 350
Hydromorphone	Dilaudid, generic (10-II)	– Iopamidol	Isovue-200
Hydromorphone	Dilaudid-HP (10-II)	– Iopamidol	Isovue-250
Hydromorphone	Dilaudid-5 (10-II)	– Iopamidol	Isovue-300
Hydroxyethyl starch (Hetastarch)	Hetastarch	– Iopamidol	Isovue-370
Hydroxyurea	Droxia	– Iopamidol	Isovue-M 200
Hydroxyurea	Mylocel	– Iopamidol	Isovue-M 300
Hydroxyzine	Atarax	– Ipecac syrup	Generic (5)
Hydroxyzine	Vistaril	- Ipodate	Oragratin
Hydroxyzine (pamoate)	Vistaril	– Ipronidazole	Ipropran (3)
Hypertonic saline	Generic	- Iron dextran	Dexferrum
Ibuprofen	Motrin, Advil	– Isoflupredone	Predef (3)
Ibuprofen	Ibuprofen, generic	- Isoflurane (inhalant anesthetic)	IsoFlo
Idarubicin	Idamycin PFS	- Isometheptene	Generic
Idarubicin hydrochloride	Idomycin, generic	- Isoniazid	Generic
Idoxuridine	Dendrid, Herplex	- Isoniazid	Laniazid
Ifosfamide; Mesna	IFEX/Mesnex Kit	– Isopropamide, iodide	Darbid (4)
Imidocarb dipropionate	Imizol (1)	- Isopropamide/prochlorperazine	Darbazine (1, 2)
Imidacloprid	Advantage (1, 2)	- Isopropamide, prochlorperazine,	Neodarbazine (1)
Imipenem-cilastatin (beta-lactam antibiotics)	Primaxin IV	neomycin	
Imipenem-cilastatin (beta-lactam	Primaxin IM	Isoproterenol	Isuprel
antibiotics)		Isosorbide dinitrate	Isordil
Imipramine	Tofranil	Isosorbide dinitrate	Dilatrate-SR
Imipramine	Tofranil-PM	Isosorbide mononitrate	Generic
Inamrinone lactate	Amrinone	Isosorbide mononitrate	Monoket
Indomethacin	Generic	Isotretinoin	Accutane
Indomethacin	Indomethegan	Isoxsuprine	Vasodilan
Indomethacin	Indocin	Itraconazole	Sporanox
Indomethacin	Indocin IV	Ivermectin	Heartgard (1, 2, 13)
Pork insulin regular,	Vetsulin (1, 2)	Ivermectin-pyrantel	Heartgard-Plus (1, 2, 13)
Insulin, lente	Humulin L	Ivermectin	Heartgard (1)
Insulin, NPH	Humulin N	Ivermectin	Ivomec (1)
Insulin, PZI	PZI Insulin (2)	Kanamycin	Kantrex
Insulin, Ultralente	Humulin U	Kaolin-pectin	Kaopectate (5)
Insulin Lispro recombinant	Humalog	Kaolin-pectin	Kaolin Pectin Plus (5)
Insulin glusiline recombinant	Apidra	Ketamine HCl	Ketaset (1, 10-III)
Insulin Regular Humunin R		Ketamine HCl	Ketalar (1, 10-III)

Loperamide HCl	Imodium (5)
Loperamide HCl simethicone	Imodium Advanced (5)
Loratadine	Claritin, others
Lorazepam	Ativan (10-IV)
Lufenuron	Program (1, 2)
Lufenuron	Program Suspension (2)
Lufenuron-milbemycin	Sentinel (1)
Luteinizing hormone	LH
Lysine	Generic (6)
Lysine-8-vasopressin	Diapid
Mafenide acetate	Sulfamylon cream
Magnesium chloride	Generic (5)
Magnesium citrate	Evac-Q-Mag (5)
Magnesium hydroxide	Milk of Magnesia, Mylanta (5)
Magnesium oxide	Generic
Magnesium salts	Generic (5)
Magnesium sulfate	Generic
Mannitol 20%	Osmitrol
Marbofloxacin	Zeniquin (1, 2)
Maropitant	Cerenia (1, 2)
Mebendazole	Telmintic (1)
Meclizine	Dramamine Less Drowsy Formula (5)
Meclizine	Antivert (5)
Meclofenamic acid	Meclofen, Arquel (1)
Mechlorethamine HCl	Mustine
Medetomidine hydrochloride	Domitor (1)
Medium-chain triglycerides	MCT in oil (5)
Medroxyprogesterone acetate (Progestins)	Depo-Provera
Medroxyprogesterone acetate	Provera, generic
Megestrol acetate	Megace
Megestrol acetate	Ovaban (1)
Meglumine antimonate	Glucantime
Melarsomine HCl	Immiticide
Melatonin	Circadin, generic (6)
Meloxicam	Mobic
Meloxicam	Metacam (1, 2)
Melphalan	Alkeran
Menadiol	Adaprin
Meperidine HCl	Demerol (10-II)
Mephenytoin	Mesantoin
Mepivacaine	Carbocaine

Plicamycin	Mithracine	Prostaglandin $F_{2-alpha}$	Lutalyse, Dinoprost (3)
Polyethylene glycol electrolyte	Miralax, generic	Protamine sulfate	Generic
solution		Protopam chloride	Pralidoxime
Polymyxin B	Aerosporin	Protriptyline	Vivactil
Polysulfated glycosaminoglycans	Adequan I.A.	Prucalopride	Resolor (4)

1, Approved in dogs; 2, approved in cats; 3, approved in other animal; 4, no longer available: if need is appropriate, may be available through a compounding pharmacist; 5, OTC (human or animal); 6, dietary supplement (human or animal), also indicates an OTC designation; 7, human cosmetic product, also indicates an OTC designation; 8, EPA-approved product; 9, biological (if animal, may not be approved; if animal approved, approved is likely through US Department of Agriculture and generally is based only safety, not efficacy); 10, distribution controlled by the Drug Enforcement Agency, Schedule status (I-V) indicated; 11, obtain through chemical or other company, compounding pharmacist may assist; 12, product may not be available from manufacturer; 13, animal generic available; 14, special restrictions.

Generic	Proprietary
Pseudoephedrine	Sudafed, generic (5, 14)
Psyllium	Fiberall (6)
Psyllium	Metamucil (6)
Pyrantel pamoate	Nemex (1)
Pyridostigmine bromide	Mestinon
Pyrilamine maleate	Nisaval
Pyrimethamine	Daraprim
Pyrimethamine / sulfadoxine	Fansidar
Quinacrine	Atabrine
Quinidine gluconate	Generic
Quinidine polygalacturonate	Cardioquin
Quinidine sulfate	Generic
Racemethionine	
(see DL-Methionine)	
Ranitidine HCl	Zantac
Retinol (vitamin A)	Retin A
Ribavirin	Virazole, Rebetol
Riboflavin (vitamin B ₂)	Vitamin B ₂
Rifampin	Rifadin
Ringer's solution (see Lactated	
Ringer's solution)	
Roxithromycin	Azuril (4)
Rutin	Rutin (6)
S-adenosyl methionine	Denosyl (6)
Scopalamine	Donnatal (5)
Scopalamine	Generic (5)
Scopolamine	Transderm Scop
Selamectin	Revolution (1, 2)
Selegiline	Anipryl (1)
Selenium	Generic (6)
Selenium Sulfide	Selenium sulfide (6)
Senna	Senokot (6)
Sertraline hydrochloride	Zoloft
Sevelamer	Renagel
Sevoflurane	SevoFlo
Sevoflurane	Ultane
Silver nitrate solution 0.5%	Silvadene
Silver sulfadiazine	Silvadene
Silymarin (see Milk thistle)	
Simethicone	Flatulex
Skin So Soft (SSS)	(7)
Sodium aurothiomalate	Generic, Myochrysine
Sodium bicarbonate	Baking Soda, others
Sodium chloride	Adsorbonac
Sodium chloride	Ayr
Sodium chloride 5%	Muro 128
Sodium chloride 7.5%	Generic
Sodium iodide, 20% solution	Iodopen, generic
Sodium phosphate p-32	Phospho-Soda
Sodium polystyrene sulfonate	Generic
Sodium stibogluconate; antimony	Pentostam

Osmania	Ducaviatora
Generic	Proprietary
Sodium sulfate	Glauber's salts (5)
Sodium thiopental	Pentothal (10)
Sodium thiosulfate 10%	Sodium thiosulfate
Somatotropin	Nutropin
Sorbitol	Sorbitol
Sotalol	Betapace
Spectinomycin	Spectinomycin
Spiramycin	Foromacidin, Rovamycin (4)
Spironolactone	Aldactone (4)
Spironolactone/	Aldactazide
hydrochlorothiazide Stanozolol	Winstrol (1, 10, III)
	Winstrol (1, 10-III) SPL-Serologic Types I and
Staphage lysate	III (9)
Staphylococcal A	Generic (9)
Streptokinase	Streptase
Streptomycin, dihydro	Streptomycin, dihydro
Streptozocin	Zanosar
Styrylpyridium/DEC	Styrid Caracide
Succimer	Chemet
Succinylcholine	Anectine
Sucralfate	Carafate
Sufentanil	Sufenta (10-II)
Sulfadiazine	Sulfadiazine
Sulfadiazine-trimethoprim	Tribrissen (1)
Sulfadimethoxine	Albon (1, 2)
Sulfadimethoxine	Bactrovet (1, 2)
Sulfadimethozine-ormetoprim	Primor (1)
Sulfamethoxazole	Gantanol
Sulfamethoxazole; trimethoprim (Sulfonamides)	Bactrim
Sulfasalazine	Azulfidine
Sulfisoxazole	Pediazole
Sulfobromophthalein sodium	(BSP)
Suprofen 1% ophthalmic solution	Profenal
Tamoxifen	Nolvadex
Taurine	Taurine (6)
Tegaserod	Zelnorm (14)
Teicoplanin	Tarsocid investigational drug
Telazol (See Teletamine +	
Zolazepam)	
Teletamine HCl (w/zolazapam)	Telazol (1, 2, 10-III)
Tepoxalin	Zubrin
Terbinafine HCl	Lamisil
Terbutaline	Brethine
Testosterone cypionate	Depo-Testosterone (10-III)
Testosterone ethanate	Delatestryl (10-III)
Testosterone propionate	Test Pro (10-III)
Testosterone, methyl (see Methyltestosterone)	Android (10-III)
Tetanus toxoid	Tetanus Toxiod (9)
	Continued

Generic	Proprietary
Tetracycline HCl	Achromycin
Tetracycline HCl	Achromycin V, generic
Tetracycline HCl	Panmycin, generic (1, 2)
Tetracycline hydrochloride,	Delta-Albaplex (1)
novobiocin sodium and	
prednisolone	
Tetramine	Syprine
Tetramisole	Anthelvet
Thenium closylate	Canopar
Theophylline	Theophylline
Theophylline	Slo-Phyllin
Theophylline sustained-release	Slo-Bid Gyrocaps
Theophylline sustained-release	Theo-Dur
Thiabendazole	Tresaderm (1, 2)
Thiacetarsamide	Caparsolate (4)
Thiacetarsamide	Filaramide (4)
Thiamine	Vitamin $B_1(6)$
Thiamylal sodium	Biotal (1, 2, 10-III)
Thiamylal sodium	Surital (1, 2, 10-III)
Thiethylperazine	Torecan
Thioguanine	Thioguanine Tabloid
Thiopental sodium	Pentothal (10-III)
Thioridazine	Mellaril
Thiotepa	Thiotepa, generic
Thyroid Stimulating Hormone/	Thyrogen
Thyrotropin (Thyroid Hormones)	Dermathycin (1)
L-Thyroxine, T[₄]	
(see Levothyroxine)	
Ticarcillin	Ticar
Ticarcillian-clavulanate	Timentin
Tiletamine HCl/Zolazepam (see Telazol)	Telazol (1, 2, 10-III)
Tilmicosin	Micotil
Tinidazole	Tindamax
Tiopronin	Thiola
Tobramycin	Nebcin
Tobramycin	Tobrex
Tocainide	Tonocard
Tolazoline	Priscoline hydrochloride
Tolfenamic acid	Generic (4)
Toltrazuril	Baycox
Topiramate	Topamax
Tramadol	Ultram, others
Tramadol, acetaminophen	Ultracet
Tretinoin	Retin-A
Triamcinolone	Vetalog
Triamcinolone acetonide	Generic (1, 2)
Triamcinolone, ophthalmic	Generic

Generic	Proprietary
Triamterene	Dyrenium
Trientine HCl	Syprine
Trifluoperazine	Stelazine, others
Triflupromazine	Vetame
Trifluridine ophthalmic solution	Viroptic
Triiodothyronine, T ₃ liothyronine	Cytobin
(Thyroid hormones)	
Trilostane	Vetoryl (1)
Trimeprazine	Temaril-P (1)
Trimethobenzamide	Tigan, generic
Trimethoprim	Trimethoprim
Trimetrexate glucuronate	Neutrexin
Tripelennamine	Recovr, generic (1)
Trypan blue	VisionBlue
Tylosin	Tylan (3)
Tylosin tartrate	Tylan (3)
Tylosin with vitamins	Tylan Plus (3)
Urea	Generic (6)
Urofollitropin	Fertinex
Ursodiol (ursodeoxycholic acid)	Actigall
Valproic acid (valproate)	Depakene
Vanadium	trace element (supplement)
	(6)
Vancomycin	Vancocin
Vasopressin, aqueous	Pitressin
Vasopressin, tannate in oil	Pitressin tannate
Vecuronium bromide	Norcuron
Verapamil HCl	Calan
Verapamil HCl	Calan SR
Verapamil HCl	Isoptin SR
Verapamil HCl	Isoptin
Vidarabine	Vira-A
Vinblastine	Velban
Vincristine sulfate	Oncovin, generic
Vitamin A	Aquasol A (6)
Vitamin B complex	Becotin (6)
Vitamin B complex	Betalin complex (6)
Vitamin B ₁ (Thiamine)	Thiamine HCl (6)
Vitamin B ₁₂	Vitamin $B_{12}(6)$
Vitamin B ₂ (Riboflavin)	Vitamin B_2 (riboflavin) (6)
Vitamin C (Ascorbic Acid)	Ascorbic acid (6)
Vitamin D (Dihydrotachysterol)	Dihydral, Hytakerol
Vitamin D_2 (see Vitamin D)	Calciferol
Vitamin D ₃	Calcitriol
Vitamin E	Aquasol E (6)
Vitamin E	Eprolin (6)
Vitamin E	Natopherol (6)

1, Approved in dogs; 2, approved in cats; 3, approved in other animal; 4, no longer available: if need is appropriate, may be available through a compounding pharmacist; 5, OTC (human or animal); 6, dietary supplement (human or animal), also indicates an OTC designation; 7, human cosmetic product, also indicates an OTC designation; 8, EPA-approved product; 9, biological (if animal, may not be approved; if animal approved, approval is likely through US Department of Agriculture and generally is based only safety, not efficacy); 10, distribution controlled by the Drug Enforcement Agency, Schedule status (I-V) indicated; 11, obtain through chemical or other company, compounding pharmacist may assist; 12, product may not be available from manufacturer; 13, animal generic available; 14, special restrictions.

Generic	Proprietary		
Vitamin K ₁ (phytonadione)	AquaMEPHYTON		
Voriconazole	Vferd, generic		
Warfarin	Coumadin		
Xylazine	Rompun (1, 2)		
Yohimbine	Yobine		
Zafirlukast	Accolate		

Generic	Proprietary
Zidovudine	AZT, Retrovir, generic
Zinc acetate (Zinc)	Generic (5)
Zinc methionine (Zinc)	Zinpro (5)
Zinc sulfate (Zinc)	Vi-Zac, others (5)
Zolazepam HCl (see Tiletamine)	Telazol (1, 2, 10)
Zonisamide	Zonegran

*A formula for more precise values follows: BSA in m^2 (K x W [2])/100 where BSA, body surface area; m^2 , square meters; and W, weight in kilograms. The constant K varies with the body shapes: smaller values apply to small compact animals. The most common K value used for cats tends to be 10.1 (up to 10.4), and the most common value for dogs is 10.1 (ranging from 9.9 to 12.3).

From Ettinger, SJ: Textbook of veterinary internal medicine, vol 1, Philadelphia, Saunders, 1975, p.146.

INDEX 1295

Amoxicillin-clavulanic acid (Continued) for pyoderma, 292, 293t, 295t-296t, 297-298 for pyothorax, 330 for urinary tract infections, 316, 317t-318t, 319 Amphocil, 376 Amphotec, 376 Amphotericin B, 368-380 adverse effects of, 377-378 anaphylactoid reaction to, 377-378 minimization of, 378 for aspergillosis, 393 for blastomycosis, 391 for coccidioidomycosis, 392-393 in combination therapy, 379 for cryptococcosis, 392 for digestive decontamination, 545 dilution of, 379 dosing regimens for, 371t–374t, 379–380 drug interactions with, 57t–59t, 378 azole derivatives in, 383 for histoplasmosis, 392 for leishmaniasis, 446 liposomal, 375t, 376–377, 379 mechanism of action of, 366f, 370-374 minimum inhibitory concentration of, 369t, 374-375 nephrotoxicity of, 370-374, 374f, 377-378 drug interactions and, 378 minimization of, 378-380 pharmacodynamics of, 374-375 pharmacokinetics of, 375t, 376-377 preparations of, 375-376, 378-379 pretreatment for, 378-379 for protozoal infections, 435t-436t rate of administration of, 379 resistance to, 375 with rifampin, 389 routes of administration for, 371t-374t, 379 for shock prophylaxis, 545 spectrum of activity of, 374-375 structure-activity relationship of, 368, 370f therapeutic use of, 378-380 topical, 855 Ampicillin bronchial concentration of, 322 chemical characteristics of, 198t dosage for, 199t-201t drug interactions with, 57t-59t for hepatic encephalopathy, 733–734 for leptospirosis, 350 for pediatric animals, 38 pharmacokinetics of, 190t-194t for pyothorax, 330 serum concentration of, 197t skin lesions due to, 98, 98t spectrum of activity of, 195t susceptibility to, 196t, 210t for urinary tract infections, 307t, 315t Amprolium for coccidioidomycosis, 727 for coccidiosis, 439 dosage for, 199t-201t for protozoal infections, 435t-436t Amrinone dosage for, 484t-491t for heart failure, 525 in dilated cardiomyopathy, 535 Amvlin, 814 Amyloid deposits, in diabetes mellitus, 814 Amyloidosis, 1187 renal, 654-656 Anabolic steroids, 577-580 adverse effects of, 579 for anemia of renal disease, 654 with anticancer agents, 579 chemistry of, 577 for chronic renal disease, 579 efficacy of, 578-579 indications for, 579-580 mechanism of action of, 577-578 pharmacokinetics of, 579 pharmacologic effects of, 578-579 preparations of, 579 for racing dogs, 580 structure of, 577, 578f thyroid effects of, 100t-101t

Anaerobes, 129-131, 130b-131b facultative, 342 in normal flora, 342 obligate, 342 oxygen-tolerant, 342 pathogenicity of, 342 Anaerobic infections, 342-346 anaerobe types in, 342 antimicrobial resistance in, 343-344 culture and sensitivity in, 343 diagnosis of, 342 mixed, 343 oxidation-reduction potential in, 343 pathogenesis of, 342 treatment of antimicrobial selection for, 343-344 beta-lactams in, 344-346 resistance in, 343-344 susceptibility to, 345t Analgesia, definition of, 999 Analgesics for acute pancreatitis, 737 epidural administration of, 1013t, 1038 contraindications to, 1038 for feline lower urinary tract disease, 665 for head trauma, 980 opioid, 1026-1027. See also Opioid(s) for pediatric animals, 41 proconvulsant, 976t for urinary tract infections, 320 Anaphylactic shock, 543 Anaphylactoid reaction, 86, 174–175, 1156 to amphotericin B, 377-378 treatment of, 1183 Anaphylaxis, 85–86 glucocorticoid-induced, 1145-1146 treatment of, 1183 Anaplasmid diseases, 354-356 Androgens. See also specific drugs synthetic, 880 thyroid effects of, 100t-101t Androstenedione, structure of, 578f Anemia aplastic anabolic steroids for, 579 cyclosporine for, 1173 sulfonamide-induced, 250-251 cancer-related, erythropoietin for, 576 of chronic renal disease, 575 drug-induced, 102t, 113-116, 250-251 erythropoietin for, 575-576 feline infectious, 348-349 hemolytic anabolic steroids and, 579–580 aspirin vs. heparin for, 595 glucocorticoids for, 1143 immune-mediated, 1183-1184 in renal failure, 653-654 Anesthesia, definition of, 999 Anesthetics, 887. See also specific drugs gastroesophageal reflux and, 699 gastrointestinal motility and, 704-705 general definition of, 999 for head trauma, 980 ocular tissues targeted by, 984–985 redistribution of, 12–13 inhalant, 892-893 hepatotoxicity of, 89 for pediatric patients, 41 injectable, 890-892 local, 1031-1034 for critical ill patient, 1036 malignant hyperthermia due to, 542 metabolism of, breed differences in, 45 overdose of, naloxone reversal for, 547t, 548 for pediatric animals, 41 premedication for, 887-890 route of administration for, for pediatric patients, 41 vomiting due to, 699, 724 Angioedema, drug-induced, 98 Angiotensin, in renin-angiotensin-aldosterone system, 477–479, 478f Angiotensin escape, 496 Angiotensin II receptor antagonists, 502-503

Angiotensin receptors, 478-479 Angiotensin-converting enzyme, 477, 479 in heart failure, 480 Angiotensin-converting enzyme inhibitors. See ACE inhibitors Angiotensin-receptor blockers, ACE inhibitors and, 499 Anidulafungin, 386 Animal Poison Control Center, 105 Anorexia appetite stimulants for, 675-684, 686 glucocorticoid, 1144 for renal failure, 647t-648t, 651 chemotherapy-induced, 1217 in chronic renal failure, 647t-648t, 650-651 Anorexigenic peptides, 672–673 Antacids, 697–699 for vomiting, 691 Antagonists, 3–4. See also specific drugs mixed, 1023–1025 narcotic, 1025-1026 pharmacodynamics of, 1006-1007 Anthelmintics, 452-463. See also specific drugs arsenicals, 462 benzimidazoles, 458-459 combination, 453t, 463-464 cyclic depsipeptides, 460 development of, 452 discontinued, 452 isoquinolones, 461-462 macrolide, 452-458 piperazines, 460-461 tetrahydropyrimidines, 459 therapeutic use of, 452-463, 453t Antiarrhythmics, 504–519. See also specific drugs for bradyarrhythmias, 542 Class I, 506–511 Class IA, 507 Class IB, 509-511 Class IC, 511 Class II, 511–516 Class III, 516-517 Class IV, 517-518. See also Calcium channel blockers classification of, 506 for dilated cardiomyopathy, 532, 533-534 mechanism of action of, 504-506 proarrhythmic effects of, 505-506 proconvulsant, 976t structure of, 507f for supraventricular premature contractions, 540 for supraventricular tachycardia, 540-541 target receptors for, 506 for ventricular arrhythmias, 541-542 Antibacterial shampoos, 865 Antibiograms, 144f, 147, 148f, 270-271, 272f-273f Antibiotic-responsive diarrhea, 728-729 Antibiotics. See also Antimicrobial(s) antitumor, 1220t-1221t Antibodies, 1154-1155. See also Immunoglobulin(s) monoclonal, 1179 for cancer, 1232 for septic shock, 341 polyclonal, 1179 Anticancer agents, 1210. See also specific drugs in adjuvant therapy, 1215–1218, 1220t–1221t adverse effects of, 1215–1218, 1220t–1221t alopecia as, 1218 gastrointestinal, 1217 myelosuppression as, 1216-1217 necrosis as, 1217-1218 palmar-plantar erythrodysesthesia as, 1218 phlebitis as, 1217-1218 reproductive, 1218 alkylating, 1219-1223, 1220t-1221t anabolic steroids with, 579 antimetabolites, 1227-1228 antitumor antibiotics, 1220t-1221t, 1224-1225 bacillus Calmette Guérin, 1177-1178 bacillus Calmette-Guérin, 666-667 biological response modifiers, 1160–1182 cell cycle and, 1210, 1211f cell turnover and, 1216, 1216 classification of, 1210, 1211f in combination therapy, 1214 in curative therapy, 1212-1213 development of, 691, 1211b

Anticancer agents (Continued) dosage for, 1214, 1220t-1221t calculation of, 1214 dose escalation and, 1214 dose-schedule relationship and, 1215b maximum tolerated dose and, 1215 doxorubicin analogues, 1220t-1221t, 1225-1226 efficacy of, 1212 erythropoietin with, 576 extravasation of, 1217–1218 fractional kill hypothesis and, 1211-1212, 1212t glucocorticoids, 1231-1232 guidelines for, 1215 hematologic disorders due to, 102t, 102-104 immunomodulators, 1232 immunostimulants, 1177 immunosuppressants, 1176 indications for, 1220t-1221t in induction phase, 1213–1214 in intensification protocols, 1213–1214 interferons, 1197 interleukins, 1199 intravesicular administration of, 666-667 in maintenance phase, 1213-1214 mechanism of action of, 1210 in metronomic chemotherapy, 1215 mitotic inhibitors, 1220t-1221t, 1223-1224 mixed bacterial vaccines, 1179 monoclonal antibodies, 1232 myelosuppression due to, 1214 in neoadjuvant therapy, 1213 neurotoxicity of, 93t neutropenia due to, granulopoietin for, 577 nitrogen mustards, 1219–1223, 1220t–1221t NSAIDs with, 1062 ototoxicity of, 96, 96t in palliative therapy, 1213 platinum agents, 1229–1230 prednisolone as, 1136 receptor tyrosine kinases, 1230 in remission phase, 1213-1214 resistance to, 1213 safe handling of, 1218 sensitivity to, 1212-1213 sites of action of, 691, 1211b skin lesions due to, 98, 98t taxanes, 1220t-1221t, 1224 vinca alkaloids, 1220t-1221t, 1223-1224 vomiting due to, 691, 723-724. See also Vomiting Anticholinergics. See also specific drugs adverse effects of, 660 for bladder hypercontractility, 658t–659t, 659–660 as bronchodilators, 757t–758t, 760 for diarrhea, 705 for feline lower urinary tract disease, 664 pharmacologic effects of, 760 pharmacology of, 887 preanesthetic, 887-888 for vomiting, 691–692 Anticoagulants, 585-592. See also specific drugs coumarin derivatives, 592-593 for heartworm disease, in pretreatment therapy, 553 heparins, 585–593. See also Heparin indandione, 592–593 international normalized ratio for, 593 oral (vitamin K antagonists), 592–593 for pulmonary embolism, in heartworm disease, 556-557 for septic shock, 340–341 Anticonvulsants, 950–973, 1030–1031. See also specific drugs for behavior modification, 920 drug interactions with, 947-948 impact of dosing interval and half-life of, 946-947, 947b pharmacokinetics of, 940-947, 941t-945t, 946f, 947b prophylactic, for head trauma, 980 safety of, 947 for seizures, 939-940, 939t, 940f, 950-973 for tetanus, 347 therapeutic monitoring of, 948-950, 948t, 949b Antidepressants, 910-911. See also specific drugs or drug classes atypical, 918 for feline lower urinary tract disease, 665

Antidepressants (Continued) neurotoxicity of, 93t, 94 tricyclic, 906t-908t, 911-915 clinical pharmacology of, 912–914 clinical use of, 914-915 contraindications to, 914 drug interactions with, 914, 914t indications for, 914 mechanism of action of, 911 pharmacologic effects of, 911-912 side effects of, 913 structure-activity relationships of, 911 Antidiabetic agents, 796f, 812–815. See also specific drugs Antidiarrheals, 705–707. See also specific drugs Antiemetics, 331, 688–692. See also specific drugs for chemotherapy, 723-724, 1217 for motion sickness, 689-690 receptors for, 689t for renal failure, 647t-648t, 650-651 structure of, 690f Antiepileptic drugs, 939–940. See also Anticonvulsants Antiflatulence drugs, 710 Antifreeze poisoning metabolic acidosis in, 607 sodium bicarbonate for, 614-615 Antifungal agents. See also specific drugs and drug classes for aspergillosis, 393 for blastomycosis, 391 for candidiasis, 391 for coccidioidomycosis, 392-393 in combination therapy, 386, 389 for cryptococcosis, 392 for dermatophytosis, 389–390 development of, 368 dosing regimens for, 371t–374t efficacy of, 367–368 for histoplasmosis, 391–392 intravesicular, 666–667 for *Malassezia* dermatitis, 390–391 mechanism of action of, 366f, 370–374, 374f minimum inhibitory concentration of, 368, 369t for paracoccidioidomycosis, 393 post-antifungal effect and, 374-375 for pythiosis, 394 resistance to, 367, 367, 375, 381 for rhinosporidiosis, 393-394 for sporotrichosis, 393 structure of, 370f structure-activity relationships of, 368, 370f for subcutaneous infections, 393-394 for systemic disease, 391-393 therapeutic use of, 389–394 toxicity of, 367–368, 370–374, 374f types and classes of, 368 Antigens, 1151, 1154 Antigestagens, 874 Antihemostatic drugs, 585 Antiherpes agents, 405-408. See also Antiviral agents Antihistamines, 1089-1091. See also specific drugs adverse effects of, 1091 antisecretory. See H2-receptor antagonists for behavior modification, 921 drug interactions with, 1090 for feline respiratory infections, 418–419 for motion sickness, 689-690 neurotoxicity of, 93t pharmacokinetics of, 1090, 1091t pharmacologic effects of, 1090 for pruritus, 865–866 for pyoderma, 299 for respiratory disease, 757t-758t, 764, 765f for skin disease, 858t, 860 structure of, 1087f structure-activity relationships of, 1087f, 1089-1090 therapeutic use of, 1091 Antihypertensives. See also specific drugs for renal failure, 647t-648t for renal hypertension, in renal disease, 500-501 for systemic hypertension, 538-539 Anti-inflammatory drugs, 1045. See also specific drugs or drug classes glucocorticoids as, 1125-1126, 1126f for inflammatory bowel disease, 731 nonsteroidal. See Nonsteroidal anti-inflammatory drugs (NSAIDs)

Anti-inflammatory drugs (Continued) for ocular disease, 985-986 for respiratory disease, 753 for skin disease, 857–862, 858t for thoracolumbar disk extrusion, 982-983 Anti-insulin antibodies (AIAs), 811-812 Antileukemic activity, 1180 Antimetabolites, 1220t-1221t, 1227-1228 in chemotherapy, 1176 Antimicrobial(s), 128. See also specific drugs and drug classes absorption of, 172 adverse reactions to, 174-176 aerosolization of, 772b antifungal effects of, 389 bactericidal vs. bacteriostatic, 157-158, 157t cardiotoxicity of, 242-243 chemical characteristics of, 198t in combination, 178–179, 180f with antifungals, 389 synergism and antagonism in, 178–179, 178f, 178t concentration-dependent use of, 158–161, 159f culture and sensitivity testing for, 138-141. See also Culture and sensitivity testing de-escalation for, 166-167, 270-271 diarrhea due to, 332 probiotics for, 713 distribution of, 172-173, 173b dosage for, 190t-194t dosing regimens for, 176-177, 199t-201t drug interactions with, 175 duration of use of, 177-178 elimination of, 173 empirical use of, 128–129, 134–138, 167 endotoxin release and, 161-162, 175-176, 176f for feline respiratory infections, 418–419 gastrointestinal toxicity of, 90–92, 114t–115t half-life of, 190t–194t hepatotoxicity of, 87-89 host factors affecting negative, 168-171 positive, 170-171 immunomodulatory effects of, 174 indications for, 131-134, 132f-133f inflammatory response and, 168, 168t, 169f intravesicular, 666-667 judicious use of, 128-129 decision-making in, 131-134, 132f-133f information sources for, 270–271, 272f–273f macrolide, 862-863 mechanism of action of, 171-172, 171f, 190t-194t, 194-196 microbial factors affecting, 161-167 biofilm, 162, 162f inoculum size, 161 virulence, 161-162 minimum bacterial concentration of, 157-158 minimum inhibitory concentration of, 142-147, 189-194. See also Minimum inhibitory concentration musculoskeletal toxicity of, 242-243, 306 nephrotoxicity of, 89-90, 90b neurotoxicity of, 92-94, 93t nonantimicrobial effects of, 174 ocular toxicity of, 94-97, 95t ototoxicity of, 96-97, 96t for pediatric animals, 40 pharmacokinetic data for, 189-194, 190t-194t postantibiotic exposure and, 158, 159t proconvulsant, 976t prophylactic, 181 for dental procedures, 331 surgical, 181-183 for pruritus, 865 resistance to. See Antimicrobial resistance routes of administration for, 172, 176-178 selection of, 134-156, 270-271 for shock, 545 for skin disease, 857, 858t spectrum of activity of, 195t surface. See Antiseptics; Disinfectants susceptibility to, 148–154, 196t, 272f–273f antibiograms for, 144f, 147, 148f, 270–271, 272f–273f systemic, 857, 858t target concentration of, 177

Antimicrobial(s) (Continued) target organism identification in, 134-156 terminology for, 129–131 therapeutic goals for, 131, 166b therapeutic goals for, 151, 1660 therapeutic monitoring of, 127 three D's approach to, 166–167, 270–271 time-dependent, 158–161, 159f topical, 261–262, 854–855 for ocular disease, 986 urine glucose testing and, 109 volume of distribution of, 190t-194t Antimicrobial effects, of nonantimicrobial drugs, 174 Antimicrobial peptides, 1156 Antimicrobial resistance, 128-129, 148-154, 162-163 adaptive, 158-159 by anaerobes, 343-344 antibiograms and, 144f, 147, 148f to antifungals, 367, 367–368 biochemical mechanisms of, 165–166 biofilms and, 430 clinical, 367 to disinfectants, 430 drug selection and, 167 efflux pumps in, 165-166 emergence of contributory factors in, 163-164 timeline for, 162 inherent vs. acquired, 163 MDR genes in. See MDR genes molecular tests for, 167 multidrug, 163 mutant prevention concentration and, 164-165, 165f porins in, 165-166 prevention/reduction of, 166–167, 166b, 273b primary (intrinsic), 367 risk factors for, 167 secondary (acquired), 367 urinary catheterization and, 312 virulence and, 161 Antimicrobial-impregnated beads, 303, 304 Antimony, for leishmaniasis, 445-446 Antimuscarinic agents. See also specific drugs for diarrhea, 705 Anti-obesity drugs, 684-686 Antioxidants. See also specific drugs for acute pancreatitis, 737 Antiparasitics active ingredients in, 855–857 delivery of, 855 in shampoos, 855 for skin disease, 858t, 862–863 topical, 855-857 Antiprogestins, commercial availability of, 875 Antiprotease drugs, for ocular disease, 986 Antipruritics. See also specific drugs for pyoderma, 299 systemic, 857-862, 858t topical, 854 Antipsychotic drugs, 904-910, 909f. See also specific drugs or drug classes adverse effects of, 910 clinical indications for, 910 disposition of, 910 drug interactions with, 910 pharmacologic effects of, 905–910 structure-activity relationships of, 905 Antipyretics, 542. See also specific drugs Antiretroviral agents, 402t, 408-409. See also specific drugs for feline immunodeficiency virus infection, 421 Antiseborrheics, topical, 852 Antisecretory drugs. See also specific drugs for diarrhea, 707 for gastric acid, 693-695 H₂-receptor antagonists, 693-694 prostaglandin analogues, 697 proton pump inhibitors, 695-697 for immune-mediated hemolytic anemia, 1184 Antiseizure drugs. See Anticonvulsants Antisepsis factors affecting, 429–430 surgical, 430-431 wound, 431

Antiseptics, 425, 426t. See also specific drugs characteristics of, 425-429 definition of, 425, 426b dilution of, 430 efficacy of, 429-430 for home care dentistry, 331 microbial targets of, 426f oral, 431 ototoxicity of, 96t resistance to, 430 types of, 425-429 urinary, for feline lower urinary tract disease, 664 vs. disinfectants, 425 for wounds, 300 Antispasmodics. See also specific drugs for bladder hypercontractility, 658t-659t, 659-660 for diarrhea, 705 for feline lower urinary tract disease, 664-666 Antithrombin, for septic shock, 340–341 Antithrombotics, 594–595. See also specific drugs for heartworm disease, in pretreatment therapy, 553 Antitoxin botulinum, 348 tetanus, 347 Antitubululin agents, 1220t–1221t Antitumor antibiotics, 1220t-1221t, 1224-1226 Antitussives, 757t–758t, 764–767, 765f. See also specific drugs for heart failure, 531 for kennel cough, 413 non-narcotic, 766 opioid, 766 Antiviral agents, 398, 400-411. See also specific drugs adjuncts to, 410-411 alternatives to, 410-411 antiherpes, 405–408 antiretroviral, 408–409 classification of, 401 development of, 398 dosing regimens for, 401, 403t limitations of, 398-399 mechanism of action of, 402t nephrotoxicity of, 405 pharmacokinetics of, 401 purine nucleosides, 402t, 404f, 406-408 pyrimidine nucleosides, 402t, 404f, 405-406 targets of, 401-405, 402t therapeutic uses of, 402t in vitro testing of, 398 Antiviral chemicals, 401 Anuria, 616 Anxieties, in dogs, 925–926 Anxiolytics, 906t–908t, 918–920. See also specific drugs clinical indications for, 919-920 for feline lower urinary tract disease, 665 pharmacology of, 918-919 side effects of, 919 Anxioselective drugs, 920. causative organisms in, 135t-137t, 275-276, 276t

anti-inflammatory and immunomodulatory, 985-986

Ocular tissues, drugs targeting (Continued) autonomic nervous system, 985 lubricants, 986 prostaglandins, 985 protectants, 986 Ocular toxicity, 94–97, 95t of azoles, 384-385 of fluoroquinolones, 243 of sulfonamides, 250 Ofloxacin, 231-232 adverse effects of, 242-243 dosage for, 199t-201t pharmacokinetics of, 190t-194t serum concentration of, 197t Ointments antipruritic, 864 eye, 984 as vehicles for topical drugs, 850–851 Older animals. *See* Geriatric animals Oliguria, 616 Olive oil, 709 Olmesartan, 502-503 Olsalazine for diarrhea, 707 dosage for, 676t-684t for inflammatory bowel disease, 731-732 Olstamavir, for viral enteritis, 725-726 Omega-3 fatty acids as appetite stimulants, 686 for glomerulonephritis, 655 in renal failure, 647t-648t, 648 for skin disease, 860-862, 861f, 861t Omega-6 fatty acids, for skin disease, 860–862, 861f, 861t Omeprazole adverse effects of, 696 as antisecretory drug, 695–697, 722 dosage for, 676t–684t drug interactions with, 696 for gastrointestinal ulceration, NSAID-induced, 1067-1068 mechanism of action of, 695-696 for nausea and vomiting, in renal failure, 650-651 pharmacokinetics of, 696 structure of, 690f Ondansetron dosage for, 676t-684t structure of, 690f for vomiting, 689, 691 chemotherapy-induced, 1217 in renal failure, 650–651 Ophthalmic disorders. *See under* Eye; Ocular Opiates, 1005–1012, 1006f. *See also* Opioid(s) definition of, 1005 Opioid(s) addiction to, 1011 adrenocortical effects of, 100t-101t adverse effects of, 1009-1012 agonist for behavior modification, 920-921 mild to moderate, 1022-1023 mixed, 1005-1006, 1023-1025 partial, 1005-1006 powerful, 1012–1022, 1013t–1016t analgesic, 1026-1027 antagonist for behavior modification, 920–921 mixed, 1023–1025 for stereotypic behaviors, 924-925 as antitussives, 766 cardiovascular effects of, 1011-1012 central nervous system depression and, 93t central nervous system depression with, 1009-1011, 1037 constipation due to, 706 for cranial trauma, 1037 in critically ill patients, 1036-1038 for diarrhea, 706 dosage for, 1013t-1016t drug interactions with, 1012 endogenous, 999–1000, 1000f epidural administration of, 1013t, 1038 gastrointestinal effects of, 1011–1012 in geriatric animal, 1035 immunomodulatory effects of, 1159

Opioid(s) (Continued) indications for, 1026-1027 mechanism of action of, 1005-1006 neonatal effects of, 1012 overdose of, naloxone reversal for, 547t, 548 in pediatric animal, 1035 for pediatric animals, 41 pharmacodynamics of, 1006-1008, 1007t pharmacokinetics of, 1008-1009, 1014t-1016t physical dependence on, 1011 postoperative, 1035-1036 postoperative ileus due to, 724-725 preanesthetic, 888-889, 889t in pregnant animal, 1034-1035 rotation of, 1027 for surgical pain, 1035-1036 tolerance to, 1011 transdermal preparations of, 1008–1009 ureteral effects of, 1012 uterine effects of, 1012 Opioid antagonists, 1025–1026 Opioid receptors, 1005–1006 intestinal, 706 pharmacodynamic effects of, 1007, 1007t Opiopeptins, 999-1000, 1000f Opium, dosage for, 676t-684t Opportunistic organisms, 132-134 OPPPD, adrenocortical effects of, 100t-101t Oral administration, 31 absorption and, 8-9, 9f compounding and, 108 distribution and, 13 dose extrapolation and, 48 drug interactions in, 59 esophageal motility and, 688–692 first-pass metabolism and, 9 Oral antiseptics, 431 Oral dryness, drug-induced, 91t, 92 Oral infections, bacterial, 330-333 causative organisms in, 135t-137t Oral mucosal tolerance, 1155 Oral toxicity, of calcium channel blockers, 493 Oral ulcers drug-induced, 90, 91t, 92 glucocorticoids for, 1141 in renal failure, 650-651 Orbifloxacin, 231-232, 234 chemical characteristics of, 198t ocular toxicity of, 95t for otitis externa, 282t pharmacokinetics of, 190t-194t, 235t, 238-242 for pyoderma, 293–294, 293t structure of, 232f for urinary tract infections, 317t-318t Organic nitrates, 503-504 Organisms, definition of, 131 Organophosphates, as antiparasitics, 856 Orgotein (superoxide dismutase), 1102 in inflammatory response, 1046t-1047t Orlistat, 685 Ormetoprim, 437-438 mechanism of action of, 248-249, 437-438 with sulfonamides, 247-251. See also Sulfonamides Orthopedic prostheses, osteomyelitis and, 305 Oseltamivir, 402t, 409 for canine parvoviral enteritis, 411 dosing regimens for, 403t structure of, 404f OSHA regulations, for chemotherapy, 1218 Osmolality effective, 599-600 measurement of, 599 plasma, 599-600 Osmotic cathartics, 709 Osmotic diuretics, 629-630. See also Diuretics Osteoarthritis, 1091-1094 cartilage in, 1091-1093, 1092f-1093f definition of, 1091 glucocorticoids for, 1139-1140 pathophysiology of, 1091 treatment of, 1093–1094 chondroprotectants in, 1094–1102 Osteomalacia, phenobarbital-induced, 954 Osteomyelitis, 301-305 causative organisms in, 135t-137t

Osteoporosis glucocorticoid-induced, 1127, 1143-1146 heparin-induced, 590 Osteosarcoma interferons for, 1197 interleukin-2 for, 1198 Otic infections, 278-286 Otitis externa, 278 causative organisms in, 135t-137t ceruminous, 285 ear mites and, 285 glucocorticoids for, 1139 Malassezia, 285, 385, 390-391 microbial targets in, 279, 280t pathophysiology of, 278 seborrheic, 285 treatment of, 279-286, 282t for acute disease, 284 for chronic disease, 284 Otitis interna, 286–299 vomiting in, 689–690 Otitis media, 279f, 285–286 pseudomonal, 284-285 swimmer's ear and, 285 Otodectes, 285 Ototoxicity of amikacin, 96 of aminoglycosides, 96, 174-175, 222, 229 of antimicrobials, 96-97, 96t of chlorhexidine, 281 of furosemide, 634-635 of topical agents for otitis externa, 281 for otitis media, 284 Ovarian activity, androgen suppression of, 880 Ovarian cysts, follicular and luteal, 879 Ovulation failure of in cats, 879 in dogs, 878–879 induction of, 878-879 Ovulation timing, 874 Oxacillin dosage for, 199t-201t pharmacokinetics of, 190t-194t Oxalate calculi, 638 probiotics for, 715 Oxandrolone, 577t Oxazepam as anxiolytic, 918–920 as appetite stimulant, 675 dosage for, 676t–684t, 906t–908t pharmacokinetics of, 944t–945t structure of, 946f Oxazolidinones, 260-261 Oxfendazole, teratogenicity of, 458 Oxibendazole, hepatotoxicity of, 89 Oxidation, 14, 14f Oxidation-reduction potential, in anaerobic infections, 343 Oxidized cellulose, 583, 583f Oxpentoxifylline, for inflammatory bowel disease, 731 Oxtriphylline, dosage for, 757t-758t Oxybutynin for bladder hypercontractility, 658t–659t, 659 for feline lower urinary tract disease, 664 Oxycarbazepine, pharmacokinetics of, 944t-945t Oxycarbazepine, pharmacenaria Oxycodone, 1022–1023 Oxygen free radicals, in shock, 543, 545 Oxygen radicals. See also Lipid peroxidation glucocorticoids as scavengers of, 1106 in inflammatory response, 1046t-1047t Oxygen therapy hyperbaric, for osteomyelitis, 305 for smoke inhalation, 778 Oxygen-carrying solutions, 580-582, 610, 612 drug interactions with, 57t-59t Oxyglobin, 580-582, 610 drug interactions with, 57t-59t Oxymetholone, 577t dosage for, 570t Oxymorphone, 1018 dosage for, 1001t–1005t, 1013t for gastric dilation-volvulus, 723 pharmacokinetic data for, 1014t-1016t structure of, 1006f

Oxytetracycline dosage for, 199t-201t pharmacokinetics of, 190t-194t, 252 Oxytocin, 872 drug interactions with, 57t-59t for dystocia, 881-882 р P2X receptor channels, in transmission of pain, 996 Pacemaker cells, 469-470, 473 automaticity and, 473 conduction velocity and, 473 Paclitaxel, 1220t-1221t, 1224 Pain acute, 994-995 chronic, 994-995 classification of, 994-995 control of, 998-1000. See also specific drug and class of drug agonists in mild to moderate, 1014t-1016t, 1022-1023 powerful, 1012–1022, 1013t–1016t analgesics in, 1026–1027 in animals, 1034–1038 anticonvulsants in, 1030–1031, 1030f behavior-modifying drugs in, 1030-1031 in cancer patients, 1034 in critically ill patients, 1036-1038 endogenous and exogenous, 999-1000, 1000f, 1001t-1005t in geriatric patients, 1034 levels of consciousness and, 999 local anesthetics in, 1031-1034, 1031f miscellaneous drugs in, 1034 mixed agonists/antagonists in, 1023-1025 narcotic antagonists in, 1025–1026 opiates in, 1005–1012, 1006f, 1007t other centrally acting drugs in, 1027–1030 pharmacologic, 998 in pregnant, neonate, and pediatric patients, 1034-1035 in surgical patients, 1035-1036 heightened sensitivity to, 997 IASP definition of, 994 increased perception of, prostaglandins causing, 1052 neuropathic, 994-995 pathophysiology of, 996-997 preemptive control of, 997–998 nociceptive, 994-995 physiologic, 994–995 response to, 998–999, 999b transmission of, 995-998, 995f Pain pathways, 995, 995f Palmar-plantar erythrodysesthesia, chemotherapyinduced, 1218 Pamidronate dosage for, 784t-786t for hypercalcemia, 784t-786t, 801 ocular toxicity of, 95t Pancreas diseases of, 801-818. See also specific disease physiology of, 801-802 Pancreatic disorders, 736-737 drug-related, 736 Pancreatic enzymes, 710, 737-738 dosage for, 676t-684t Pancreatic insufficiency, 710, 737-738 Pancreatin, 710 Pancreatitis acute, 736–737 fluid therapy for, 619 heparin for, 587t cholangitis and, 735-736 chronic, 737 glucocorticoid-induced, 1144, 1146 Pancuronium, 896 dosage for, 896t Pancytopenia drug-induced, 102-104 parvovirus-related, erythropoietin for, 576 Panleukopenia, feline, 413-414, 416t-417t Pantoprazole, 695–697 Pantothenic acid, dosage for, 676t-684t Papillomavirus infection, canine, 413 Paracoccidioidomyosis, 393 Parainfluenza virus, canine, 413

Paralytics, for head trauma, 980 Paramycin, 368 for cryptosporidiosis, 447 for protozoal infections, 435t–436t Paraoxetine, dosage for, 906t–908t Parasympatholytic agents, 985 for diarrhea, 705 Parasympathomimetic drugs, 985 Parathyroid glands in calcium homeostasis, 795-796, 796f diseases of, 795-801. See also specific disease Parathyroid hormone in calcium balance, 795, 796f calcium metabolism and, 652-653 Paregoric, 676t-684t Parenteral administration, 31-32 Paroxetine, for feline lower urinary tract disease, 665 Partial agonists, 3-4 Partition coefficients, 5, 6f Parvoviral enteritis, canine, 411-413, 619, 725-726, 1196-1197 erythropoietin for, 576 recombinant feline interferon-omega for, 1196-1197 Passive diffusion, 5-8, 5b Pasteurella multocida, antimicrobial susceptibility of, 317t-318t Pathogen(s), 132-134, 135t-137t infection site and, 132-134, 135t-137t Pathogen-associated molecular patterns, 711-712 Peak concentration, 4 in therapeutic drug monitoring, 114t-115t, 116-119 Pectin, 708 Pediatric animals age range of, 37 classification of, 37 drug disposition in, 36t, 37–39 fluid therapy for, 40 pain control in, 1034–1035 Pegaspargase, 1230–1231 Pemoline, for behavior modification, 921 Pemphigus, 1185 Pemphigus foliaceus, 1185 cyclosporine for, 1173 Penciclovir, 402t, 407 for feline respiratory infections, 402t, 415-419 D-Penicillamine for cysteine urolithiasis, 637 dosage for, 676t-684t Penicillin(s), 198–202. See also Beta-lactam antibiotics and specific drugs for actinomycosis, 352 for anaerobic infections, 344 bronchial concentration of, 322 chemical characteristics of, 198t dosage for, 199t-201t drug interactions with, 56, 57t-59t aminoglycosides, 230 international units of, 198-202 for leptospirosis, 350 for nocardiosis, 352 pharmacokinetics of, 216 for pyothorax, 330 resistance to, 211-214 serum concentration of, 197t spectrum of activity of, 195t, 205, 206t-209t structure of, 203f for tetanus, 347 thyroid effects of, 100t-101t for urinary tract infections, 315t, 316 Penicillin G dosage for, 199t-201t drug interactions with, 57t-59t for leptospirosis, 350 pharmacokinetics of, 190t-194t for urinary tract infections, 315t Penicillin V, dosage for, 199t-201t Penicillinase, 211, 212t Penicillin-binding proteins, 202–205, 204f in antimicrobial resistance, 213–214 Pennyroyal oil, as antiparasitic, 857 Pentamidine for babesiosis, 448 for leishmaniasis, 446 for protozoal infections, 435t-436t, 445 for trypanosomiasis, 446-447

Pentatrichomoniasis, 727 Pentazocine, 1025 dosage for, 1001t–1005t Pentobarbital, 956 for acute brain injury, 979–980 cytochrome P450 induction and, 64 drug interactions with, 57t-59t for seizures, 941t-943t structure of, 940f Pentosan polysulfate dosage for, 1055t-1056t for feline lower urinary tract disease, 665-666 for osteoarthritis, 1095-1096 Pentoxifylline, 1088-1089 for dermatomyositis, 1185 for dilated cardiomyopathy, 535 dose for, 1161t for inflammatory bowel disease, 731 structure of, 1087f Peptic ulcers, 721-723 antacids for, 698-699 antisecretory drugs for, 693-695 H2-receptor antagonists, 693-694 prostaglandin analogs, 697 proton pump inhibitors, 695-697 in chronic liver disease, 735 cytoprotectants for, 697-699 glucocorticoid-induced, 1127, 1144, 1146 H. pylori and, 722–723 mucosal defenses against, 693, 694f NSAID-induced, 722 stress, 722 sucralfate for, 699, 699f Peptostreptococci, antimicrobial susceptibility of, 345t Percutaneous administration, in pediatric animals, 38 Perianal fistula, 869 cyclosporine for, 1170, 1172 ketoconazole for, 1172 Pericardial effusion, 499 Periodontal disease, 330–331. See also Gingival hyperplasia; Gingivitis probiotics for, 713 Peripheral nerve stimulation, in neuromuscular blockade monitoring, 897, 898f Peripheral neuropathy, drug-induced, 93t, 94 Peristalsis, 701, 701f Peritoneal dialysis, 336, 656-657 Peritoneal irrigation, 336 Peritonitis, 334–336 feline infectious, 414–415, 416t–417t, 1196 interleukin-12 for, 1199 promodulin for, 1181–1182 Peroxygen compounds, 429 Perphenazine, for vomiting, 690-691 Petrolatum, 676t-684t PF1022A, 460 P-glycoprotein transporter, 5 blood-brain barrier and, 73 breed differences in, 44 in distribution, 73 drug interactions and, 61, 63 in herding breeds, 44 neurotoxicity and, 93 polymorphisms in, 44, 45t in absorption, 72 adverse drug reactions and, 84 in distribution, 73 in excretion, 75 species differences in, 44 substrates, inducers, and inhibitors for, 45t PH acid-base balance and, 601 antimicrobial efficacy and, 168 of intravenous solutions, 55-56 measurement of, 606 urine, drugs affecting, 65, 65b, 637-638 PH partition theory, 5, 6f, 7b Phagocytes antimicrobial accumulation in, 170 antimicrobial effects on, 170, 174 Pharmacodynamic indices, 152t, 158, 160-161 Pharmacodynamics agonist, 3–4 antagonist, 3–4 dose-response relationship and, 1-4, 2f

Pharmacodynamics (Continued) drug interactions and, 65-66 drug-receptor interactions and, 1-4, 2f-3f genetic factors in, 75–76 population data for, 147, 147-156, 149f-151f, 152t, 153f for antimicrobials, 189-194, 270-271 Pharmacogenetics, 71-78 of absorption, 71-73 adverse drug reactions and, 84 in clinical practice, 71, 76 of distribution, 73 drug-receptor interactions and, 75-76 of excretion, 75 future directions for, 76 hypersensitivity reactions and, 76 of metabolism, 73-75 overview of, 71 Pharmacokinetics, 25-30. See also Disposition, drug alternative, 29-30 compartmental analysis in, 25-28, 26b area under the curve and, 26b, 27 clearance and, 26b, 28 compartments in, 25 half-life in, 27 limitations of, 29 mathematical description in, 25-27 parameters for, 26b rate constants in, 27 volume of distribution in, 26b, 27-28, 28f definition of, 25 drug interactions and, 60-61 equations in for compartmental analysis, 26b for constant-rate infusion, 24b for half-life, 20b genetic factors in. See Pharmacogenetics noncompartmental analysis in, 29, 29f, 29b population, 29-30 population data for, 147, 147-156, 149f-151f, 152t, 153f for antimicrobials, 189-194, 190t-194t, 270-271 sources of, 189-194, 270-271 Phenamidine for babesiosis, 448 for protozoal infections, 435t-436t Phenicols, 253-255. See also Chloramphenicol; Florfenicol Phenobarbital, 950-955 acute toxicosis due to, 955 bone marrow dyscrasias due to, 954 disposition of, 950–951 dosage for, 676t-684t, 906t-908t dose modification with, 951, 952f-953f drug interactions with, 951-954 hematologic toxicity of, 102, 102t hepatotoxicity of, 954-955 hypertriglyceridemia due to, 955 mechanism of action of, 950 neurotoxicity of, 93t osteomalacia due to, 954 pharmacokinetics of, 944t-945t preparations of, 951 for seizures, 941t-943t, 951 side effects of, 954-955 structure of, 940f for tetanus, 347 therapeutic monitoring of, 114t-115t, 119b, 125, 126b, 948t thyroid effects of, 99, 100t-101t, 954 for vomiting, 691 Phenols, 429 Phenothiazines antimicrobial effects of, 174 for hyperthermia, 542 neurotoxicity of, 93t pharmacologic effects of, 905-909 for seizures, 976 side effects of, 909 skin lesions due to, 98, 98t for tetanus, 347 for vomiting, 690-691 Phenoxybenzamine dosage for, 484t-491t for feline lower urinary tract disease, 664-665 for urethral hypertonicity, 658t-659t, 662

Phentolamine, dosage for, 484t-491t Phenylbutazone, 1075-1076 dosage for, 1055t-1056t myelosuppression due to, 102 pharmacokinetic data for, 1060t-1061t structure of, 1050f thyroid effects of, 100t-101t Phenylephrine drug interactions with, 57t-59t ocular toxicity of, 95t Phenylethylmalonic acid (PEMA), 955-956 pharmacokinetics of, 944t-945t Phenylpropanolamine for heart failure, 529 for retrograde ejaculation, 883 for urethral hypotonicity, 658t-659t, 661-662 Phenytoin, 968-970 for arrhythmias, 511 blood concentrations and, 969 disposition of, 968-969 dosage for, 484t-491t drug interactions with, 969 hepatotoxicity of, 969–970 pharmacokinetics of, 944t-945t pharmacologic activity of, 968 for seizures, 941t-943t, 969 side effects of, 970 skin lesions due to, 98, 98t structure of, 940f therapeutic monitoring of, 114t-115t thyroid effects of, 99, 100t-101t Pheromones for behavior modification, 921 for feline lower urinary tract disease, 665 for noise phobias, 926 Phlebitis, chemotherapy-induced, 1217-1218 Phobias, noise, 925–926 Phosphate. *See also* Phosphorus for diabetic ketoacidosis, 816 dosage for, 784t-786t for hypophosphatemia, 613 Phosphate enemas dosage for, 676t-684t neurotoxicity of, 93-94 Phosphodiesterase inhibitors, 503-504, 525-527 for cardiovascular disorders, 525-527 ocular toxicity of, 95t structure of, 492f Phosphomethoxyethyladenine (PMEA) for feline immunodeficiency virus infection, 420-422 for feline leukemia, 419-420 Phosphorus. See also Phosphate dietary in hyperparathyroidism, 653 in renal failure, 648 for hypophosphatemia, 613 Phosphorus balance, 606 Phosphorus binders in hyperparathyroidism, 653 for renal failure, 647t-648t, 649-650 Photoallergy, 98-99 Photosensitization, 98-99, 99b drug-induced, 94, 99b Phycocyanin, 1102 Phycomycosis, 394 Physical dependence, on opioids, 1011 Physiologic pain, 994–995. *See also* Pain Physiologic saline solution, 609-610 for hyponatremia, 612 Physostigmine for avermectin neurotoxicity, 93, 455 for seizures, 941t-943t Phytonadione dosage for, 676t-684t drug interactions with, 57t-59t Picrotoxin for avermectin-induced neurotoxicity, 93 for seizures, 941t-943t Pilocarpine, 985 for seizures, 941t-943t Pimaricin, 368 Pimobendan, 524–525 as calcium sensitizer, 525-527 dosage for, 484t-491t as inodilator, 527-529

Pimobendan (Continued) as positive inotrope, 525-527 for pulmonary hypertension, 540 structure of, 520f toxicity of, 527 Pimozide, dosage for, 906t-908t Pinocytosis, 5 Piperacillin dosage for, 199t-201t pharmacokinetics of, 190t-194t serum concentration of, 197t susceptibility to, 210t Piperacillin/tazobactam antimicrobial susceptibility of, 317t-318t for urinary tract infections, 317t-318t Piperazines, for helminthic infections, 453t, 460-461 Piramicin, 380 Pirbuterol, dosage for, 757t-758t Piroxicam, 1076 for cancer, 1231 dosage for, 1055t–1056t intravesicular, 667 for lower urinary tract disease, 667 ocular toxicity of, 95t pharmacokinetic data for, 1060t-1061t structure of, 1050f Pituitary gland, disorders of, 835-839. See also specific disorder Pituitary macroadenoma, 824 Placenta, drug disposition and, 41-43, 73 Plantago seed, 676t-684t, 709 Plasma clearance. See Clearance, drug Plasma drug concentration.
